Specific carriers in the microvilli for the transport of glucose and galactose, as well as fructose, mediate the uptake of monosaccharides released by the mucosal glycosidases—and absorption occurs rapidly. Active transport by the sodium-dependent glucose–galactose carrier is accompanied by the passive flux of water from the lumen. Maldigestion of osmotically active sugars thus leads to retention of fluid in the gut. For most carbohydrates, hydrolysis in the lumen and at the mucosal surface is sufficiently rapid to saturate the pathways for glucose and fructose transport. For lactose, however, the rate of hydrolysis, rather than glucose and galactose uptake by the mucosa, may become limiting. Hence the functional reserve of lactase in the human intestine is restricted and assimilation of lactose is often impaired in the early stages of mucosal disease.

Although the biosynthesis of surface disaccharidases continues throughout the life of the epithelium, the enzymes are only active in mature cells on the upper reaches of small-intestinal villi. Complete turnover of the enzyme molecules occurs several times during the lifespan of the mature enterocyte. Brush-border disaccharidases are complex glycoproteins that undergo proteolytic processing; extensive glycan modification in the Golgi apparatus occurs before insertion into the membrane. The mature enzymes are derived from large, single-chain polypeptides. The genetically determined mechanism by which lactase expression is normally reduced after infancy is not fully understood but in most individuals it appears to regulate transcriptional activity of the lactase gene. Unabsorbed carbohydrate resulting from the maldigestion of disaccharides is fermented by bacteria in the colon to short-chain organic acids, hydrogen, and methane. In these circumstances, ingestion of carbohydrate may cause pain by distension of the bowel with fluid and gas, accompanied by an irritant and watery diarrhoea.

Carbohydrate intolerance syndrome Table 1)

Abdominal symptoms are usually noticed within an hour of the ingestion of foods containing the offending sugars. There is nausea, bloating, and distension of the abdomen accompanied by borborygmi and flatulence. Colicky pain precedes a watery diarrhoea, usually associated with flatus, and it may be explosive. Diarrhoea due to the maldigestion of carbohydrate can occur several hours after ingestion of the noxious food or drink. These symptoms may result from consumption of only a few grams of the offending sugar. Intestinal hurry aggravates fat malabsorption in disaccharidase deficiency and may obscure the underlying cause of the diarrhoea. Deficiency of particular disaccharidases is responsible for the dietary intolerance of specific foods and drinks: milk-containing products in the case of lactase deficiency; table sugar and starch in asucrasia; mushrooms (and probably shellfish) in the rare trehalase deficiency. Identification of a cause-and-effect relationship between particular items and the intolerance syndrome is often impossible, given the ubiquity of sucrose and lactose in commercial foods.

Lactose intolerance

Most patients suffering from intolerance of lactose in the diet suffer either from lactase deficiency acquired as a result of intestinal disease, especially postinfective gastroenteritis in children, or as a result of genetically determined restriction of lactase expression.

Congenital lactase deficiency

A few infants have been reported in whom diarrhoea occurred after the first feed with breast milk and who responded completely to a lactose-free formula feed. This disorder is distinct from congenital glucose–galactose malabsorption, in which lactose exclusion alone is ineffective. Congenital lactose intolerance is associated with a severe inherited deficiency of mucosal lactase activity and, unlike the intolerance of lactose associated with prematurity or secondary to diffuse intestinal disease, remains lifelong. This syndrome leads to lactosuria due to the abnormal absorption of intact lactose, principally in the stomach; renal tubular acidosis and aminoaciduria have been recorded in this autosomal recessive disease that leads to vomiting, failure to thrive, and dehydration.

Lactase deficiency of prematurity

Unlike the other mucosal glycosidases, which appear early during fetal development, intestinal lactase activity is not fully expressed until after the 28th week of gestation and transient intolerance of milk feeds is common before this age. Abdominal distress due to gaseous distension and diarrhoea requires careful attention to the diet and fluid balance in premature infants.

Lactase restriction in children and adults

The capacity of the infant's intestine to digest lactose is retained into adult life by only a minority of individuals. Persistence of high intestinal lactase activity is an unusual state in adult mammals, and in humans is believed to have become prevalent in populations in which dairy culture was introduced about 10 000 years ago. Thus, tolerance of lactose in milk, dairy products, and many processed and ready-to-eat foods (Table 2) is found mainly in peoples of Northern European descent and those with a tradition of dairy farming. In about 5 per cent of Northern European adults, compared with more than 90 per cent in parts of Africa and Asia, there is a genetically determined and physiological decline in mucosal lactase activity after weaning. In most instances, reduction of mucosal lactose activity is associated with reduced synthesis of the precursor protein in the epithelial cells with apparently normal processing to the mature enzyme. The physiological decline in activity occurs between 3 and 5 years of age.

The element that determines lactase activity in adults acts in *cis* with the human lactase gene on chromosome 2q21. Recent studies of multiple polymorphic sites at this locus have identified a C/T polymorphism approximately 14 kb upstream of the gene that is tightly linked to the deficient/persistent lactase phenotype in several distinct populations. Homozygosity for the *C* allele at nucleotide –13910 is associated with adult lactase 'deficiency'—a finding consistent with the ancestral origin of lactase persistence. Although only low levels of lactase activity remain, this need be of no consequence when the consumption of dairy products is insignificant. Symptoms develop on exposure to excessive milk-and lactose-containing foods or medicines in late childhood or early adult life. The selective pressures that maintain this physiological reduction in mucosal lactase deficiency in childhood are unknown but the concept of 'lactase deficiency' in adults is difficult to justify, since lactase persistence is the least frequent variant. Nonetheless, with the increasing migration of peoples and their adoption of Western-style diets, this physiological loss of lactase activity is a prevalent cause of abdominal distress. A significant proportion of patients considered to have spastic colon, irritable bowel disease, or other 'functional' disturbances may prove to have lactase deficiency.

The speculative possibility arises that lactase-deficient subjects are at risk from osteoporosis in countries of the Northern hemisphere because of a dietary deficiency of calcium or vitamin D. A modest positive selection for the lactase persistence allele in Northern Europe would explain its present frequency if it arose at the time dairy farming was introduced. The relative lack of functional reserve of mucosal lactase activity also explains the frequency with which lactose malabsorption becomes manifest after partial gastrectomy and related procedures that enhance delivery of carbohydrate to the jejunum.

Diagnosis of lactose malabsorption

Intolerance of dietary carbohydrate caused by the maldigestion of lactose may be suspected from the dietary history of a patient typically complaining of abdominal pain, flatulence, and diarrhoea. Symptoms are often related to changes in social circumstances; they are frequently reported by Oriental immigrants to Western countries. The stool has an acidic pH (<6) and the osmolality of stool water is generally greater than 350 mosmol/kg due to the presence of lactate and other organic anions. Breath-hydrogen analysis is a useful confirmatory test. Hydrogen excretion determined by rebreathing 2 h after the ingestion of 50 g of lactose identifies patients with lactase deficiency diagnosed by enzymatic assay of jejunal mucosa. Other investigations, such as the lactose barium-meal examination and determination of blood glucose profile after oral challenge with lactose, are cumbersome and, because they give false-positive results, are now obsolete.

Secondary lactase deficiency

Lactase activity may be depressed by mucosal disease of the small intestine. This may occur transiently after infective gastroenteritis. It is particularly frequent in infants suffering from viral gastroenteritis, and continuing symptoms provoked by milk feeds can persist for days or some weeks. In infants, dehydration may develop rapidly, accompanied by prominent bloating; disaccharidu ria is found and acid, sour-smelling stools may be obvious. The symptoms resolve rapidly when dairy products are excluded from the diet. Decreased lactase activity also accompanies extensive and long-standing mucosal disease—the milk intolerance syndrome due to maldigestion may complicate coeliac disease, intestinal giardiasis, and Crohn's disease.

In secondary deficiencies of disaccharidases, because of the critical relationship between lactase activity and the rate of hydrolysis, intolerance of lactose predominates. However, the use of high-calorie supplements containing disaccharides other than lactose (especially maltose and sucrose) in patients with nutritional disturbances caused by intestinal disease may also cause the syndrome of carbohydrate maldigestion.

Sucrase–isomaltase (a-dextrinase) deficiency

This recessively inherited enzyme deficiency of the mucosal brush border is rare in all populations except the Inuit of Greenland, in whom the frequency of homozygotes is up to 10 per cent. Cetacean mammals also lack sucrase–isomaltase. Several defects of the human gene on chromosome 3q appear to be responsible; in some, there is aberrant glycosylation and the enzyme is inefficiently transported to the brush border. Substantial degradation of the abnormal polypeptide occurs within the epithelial cell.

Intolerance of sucrose is responsible for most of the symptoms, which develop as table sugar and sugar-containing foods are introduced during weaning. Intolerance of starch is less prominent because the osmotic contribution of the larger a-dextrin molecules that remain unsplit in the gut lumen is less. However, ingestion of large, starchy meals may induce cramping discomfort, flatulence, and diarrhoea. Whilst taking a normal diet, patients with deficiency of sucrase–isomaltase have persistent diarrhoea with the passage of acid and frothy stools containing increased concentrations of lactate.

The diagnosis may be suspected on the basis of the history of diarrhoea at weaning and on the character of the stools. Differentiation from coeliac disease, cow's milk allergy, infective or postinfective gastroenteritis, pancreatic failure, and disaccharide intolerance syndromes in relation to other inflammatory disease of the bowel is important, and biopsy of the jejunal mucosa for enzymatic assay and histological examination should be considered. In inherited sucrase–isomaltase deficiency, these activities are selectively reduced to less than 10 per cent of control values in histologically normal mucosa. Hydrogen breath tests after ingestion of sucrose and isomaltose may also prove to be useful in diagnosis, but experience is limited.

Trehalase deficiency

A few patients have been reported with mushroom intolerance due to the absence of mucosal trehalase. Trehalase is a brush-border a-glycosidase that cleaves the unusual 1a–1a bond of trehalase into its component glucose moieties. Trehalose is found in the haemolymph of arthropods and in fungi, so that intolerance of crustacean shellfish as well as mushrooms in the diet might be expected. Given that intolerance of edible fungi is not uncommon, trehalase deficiency may prove to be more frequent than previously supposed. Trehalase deficiency has also been reported to occur in 10 to 15 per cent of Greenland Inuit but the functional significance of this is unknown.

Treatment

Dietary exclusion of the offending sugar is the best method of preventing symptoms in individuals with primary or acquired disaccharidase deficiency. Symptoms recur as soon as excessive lactose or sucrose is reintroduced and advice from a professional dietitian may be needed to avoid indiscretions. In hypolactasia, complete elimination is not usually required, as lactase deficiency is rarely absolute; nevertheless, if symptoms persist there are many potential sources of lactose that warrant investigation (see Table 2).

An early, alternative method for preventing symptoms in lactose malabsorbers was the use of b-galactosidases obtained from yeast or other micro-organisms. These enzymes were added to dairy products before consumption and often changed the taste. In the United States, b-galactosidase has been produced commercially from yeast ('LactAid') and has been shown to reduce symptoms as well as breath-hydrogen excretion in subjects with maldigestion of lactose. Similar studies have demonstrated the efficacy of b-galactosidase derived from *Aspergillus oryzae* ('Lactrase'), in children with late-onset intolerance of lactose. The enzymes are taken in

tablet form immediately before challenge with lactose, but their cost, compared with dietary exclusion, may not be justified. In the future, microbial b-galactosidases might be used for food supplementation programmes in countries where lactose intolerance and nutritional deprivation in the adult population are widespread.

Complete absence of sucrase–isomaltase activity in most patients with sucrose intolerance together with the ubiquity of sucrose in modern diets complicates symptom management. Modest reduction of amylopectin-rich foods usually suffices to improve symptoms of starch intolerance but complete avoidance of sucrose-containing foods can be difficult especially in infants and young children. It has been reported that ingestion of dried brewer's yeast (containing invertase or sucrase but little lactase activity) after food is effective in patients with sucrase–isomaltase deficiency. However, dried yeast is rather unpalatable and not usually accepted by children. Recently, a high-potency liquid preparation of invertase used for the industrial manufacture of fructose from unrefined sugar cane juice ('Sacrosidase'; Universal Foods Corporation), which is approved by the Food and Drug Administration of the United States, has been used in a double-blind, randomized, controlled trial in patients with sucrase–isomaltase deficiency. The agent was found to be safe, acceptable, and effective for the treatment of all the associated symptoms and signs of this disease in patients receiving a low-starch diet.

14.9.6 Whipple's disease

H. J. F. Hodgson

Whipple's disease is an uncommon infection caused by the recently characterized actinomycete *Tropheryma whippelii.* The organism is widely distributed in tissues in affected individuals, and may cause disease in many systems. The condition is most commonly diagnosed when overt small intestinal disease occurs, leading to malabsorption, but systemic features such as arthralgia and fever may have been present for many years. The disease may also present with involvement of many other systems, including the brain and heart. Molecular techniques for identifying the organism are increasing the frequency with which individuals with minimal or absent gastrointestinal disease are diagnosed, thus expanding the spectrum of manifestations of Whipple's disease. The condition responds well to antibiotics but may relapse. The organism is probably acquired as an enteric infection, because it has been identified in effluent samples from sewage plants.

Pathology and aetiology

Advanced or fatal cases of Whipple's disease predominantly show severe intestinal and intra-abdominal pathology. The presence of fatty deposits in the small intestine and mesenteric lymph nodes prompted Whipple to call the disease intestinal lipodystrophy. The small intestine is thick and oedematous, with stubby or absent villi and dilated lacteals (secondary lymphangiectasia reflecting obstructed lymph flow). The absorptive enterocyte layer is virtually normal, but the lamina propria is stuffed with macrophages containing foamy material which stains brilliant magenta with periodic acid-Schiff reagent (diastase resistant) (Fig. 1). There is little inflammation otherwise. There are fatty deposits, and occasionally granulomas, in the mesenteric nodes as well as the characteristic macrophages. Other organs are involved to a varying degree, with foamy macrophages in spleen, lymph nodes, central nervous system, liver, lung, heart, and joints. Valvular endocarditis and localized brain deposits account for two of the most severe forms of the disease.

Fig. 1 Jejunal biopsy specimen from a 50-year-old man with Whipple's disease showing stunted villi and infiltration of the lamina propria with densely staining macrophages (periodic acid-Schiff stained, ×150).

Rod-shaped micro-organisms, the source of the periodic acid-Schiff-positive material, are identifiable at light and electron microscope level in affected tissues. After many decades of failure to identify these by conventional microbial culture methods, molecular characterization of the bacterial 16S ribosomal RNA gene in the tissues assigned the organism to a previously unrecognized class of actinomycetes. More recently human macrophages deactivated with anti-inflammatory cytokines and dexamethasone have allowed culture and passage of *Tropheryma whippelii*. The use of the polymerase chain reaction technique to identify sequences encoding the specific bacterial ribosomal RNA provides an invaluable diagnostic tool. The condition is an example of the value of molecular techniques in demonstrating that a disease process is infective in origin. The presence of the organism in sewage-exposed water suggests that infection occurs by invasion of the alimentary tract, and may explain the preponderance of small intestinal disease, with subsequent haematogenous or lymphatic dissemination. It remains unclear whether those who become infected have an underlying immunodeficiency, but host factors are probably relevant as there is evidence of diminished monocyte function persisting after successful treatment. A weak HLA B27 association has also been reported.

Demonstration of bacterial RNA-encoding sequences by means of the polymerase chain reaction now offers an alternative to the classical diagnostic techniques of biopsy and histology. However, some reports on saliva suggest the organism may reside as a commensal, emphasizing the need for clinical interpretation. Most patients continue to be diagnosed by the examination of the histology of the small intestine, reflecting the ease with which tissues can be obtained at routine upper gastrointestinal endoscopy. However, polymerase chain reaction positivity has been reported on peripheral blood, lymph nodes, synovial tissue, bone marrow, and even in faeces, and may yield positive results on small intestinal and other tissues in which characteristic histology cannot be identified. Application of diagnostic techniques based on the polymerase chain reaction to patients with arthritis, pyrexia of unknown origin, and other chronic undiagnosed conditions can identify cases in which small intestinal disease is not apparent, and this technique is likely to become widely used as it become more available. The use of the polymerase chain reaction has suggested that intractable idiopathic thrombocytopenia, quadriparesis, isolated muscle weakness, and juvenile chronic arthritis may form part of the clinical spectrum of Whipple's disease.

Differential diagnosis

Histological appearances suggestive of Whipple's disease have been reported in AIDS patients affected with other organisms—atypical mycobacteria and rhodococci.

Clinical features and diagnosis

The condition is most frequently diagnosed in middle aged or elderly men but women and children may be affected. The typical patient is diagnosed with relatively advanced disease with malaise, weight loss, diarrhoea, and arthralgias, and on examination may show marked pigmentation, lymphadenopathy, anaemia, finger clubbing, hypotension, and oedema. Rarely gastrointestinal bleeding may also occur. In such cases, investigation of an obvious gastrointestinal complaint should quickly establish the diagnosis. Recognition is far more difficult if symptoms are limited to fever or arthritis, or another systemic manifestation, which may be present transiently or intermittently for many years before the disease is diagnosed. The arthritis is migratory, non-deforming, and seronegative, predominantly affecting peripheral joints and in some series affects up to 90 per cent of patients. Other early features include respiratory symptoms with pleurisy and pulmonary infiltrates, and pericarditis. Chylous or serous ascites, endocarditis, cardiac conduction defects, coronary arteritis, and neurological abnormalities may occur with progression of the condition. In a recent survey over 80 per cent of patients had gut disease at diagnosis but 15 per cent had no gastrointestinal disorder at any time. Joint symptoms were present at some time in 83 per cent of patients, 20 per cent had neurological disease, 17 per cent cardiovascular disease, and 15 per cent mucocutaneous manifestations (pigmentation or sarcoid-like plaques). The central nervous system manifestations are diverse and include depression, apathy, fits, and mycoclonus, and a variety of ocular manifestations including ophthalmoplegia, papilloedema, scotomata, pseudotumour, and uveitis. Meningitis and a hypothalamic syndrome with insomnia, hyperphagia, and polydipsia also occur. Oculomastatory myorhythmia is said to be diagnostic.

Supplementary investigations are of value in confirming the involvement of different organs, but are not diagnostic of the disease. Radiographs of the small intestine characteristically show dilatation. Ultrasonography and computed tomography of the abdomen may show lymphatic masses, and computed tomography or magnetic resonance imaging of the brain may show multiple lesions in the white matter and grey–white junction with characteristic appearances. The sedimentation rate is generally but not inevitably elevated and an anaemia due to folate or iron deficiency may be present. Eosinophilia and thrombocytosis may be apparent on blood

films. Steatorrhoea, hypocalcaemia, vitamin deficiencies, and an elevated alkaline phosphatase occur with advanced gut disease, which may also give rise to hypoproteinaemia and a protein-losing enteropathy.

Treatment and prognosis

Whipple's disease progresses slowly, but unrecognized disease is eventually fatal. Antibiotic therapy is effective, although short-term corticosteroid therapy may occasionally be required in malnourished individuals to correct the metabolic and nutritional state. Administration of many different oral and parenteral antibiotics has been successful, including penicillin alone, penicillin plus streptomycin, tetracycline, and cotrimoxazole. A comparison of tetracycline versus cotrimoxazole (trimethoprine-sulphamethiazole) indicated superiority of the latter. Clinical improvement occurs within a few weeks, but prolonged treatment for at least a year is recommended. In particular it appears that the risk of a relapse with central nervous system manifestations is reduced if the initial regime involves drugs that pass the blood–brain barrier. The third-generation cephalosporin cefiximine has been reported to be effective in relapsing central nervous system Whipple's disease. A Herxheimer-like syndrome with fever and vasculitic manifestations has been reported at the start of treatment. The histological appearance of the gut mucosa returns to normal within a few months, although scattered periodic acid-Schiff-positive macrophages may persist for longer. Serial studies show that analysis of affected tissues by the polymerase chain reaction becomes negative in advance of histological improvement, and patients with clearance of tissues, documented by the polymerase chain reaction, appear to have a low risk of subsequent relapse. However, it is important to be aware of the possibility of relapse even after many years, especially when progressive central nervous system disease occurs in the absence of other systemic manifestations.

14.9.7 Effects of massive small bowel resection

R. J. Playford

Introduction

Large resections of the small bowel may cause multiple nutritional and other medical abnormalities, now commonly termed the 'short bowel syndrome'. More patients with this condition are surviving, due in part to improvements in anaesthetic and surgical techniques which have enabled patients previously considered to be inoperable to undergo radical procedures. The survivors present formidable medical problems, but scrupulous attention to their nutrition and general care, with the application of physiological principles, has improved their quality of life and independence.

Aetiology and prevention

The two main reasons why adults require massive intestinal resection are major vascular events involving the superior mesenteric artery, usually thrombosis or embolus, or multiple surgical resections of the small bowel in patients with Crohn's disease (regional ileitis). To reduce the number of those patients with Crohn's disease who will develop life-threatening consequences of recurrent disease in the residual intestine, it is imperative that the minimum amount of bowel is resected. Stricturoplasty, rather than resection, may be possible and multiple small segments of relatively normal intestine should be retained *in situ* and joined in series, rather than removed. Preservation of only a few additional centimetres of gut may be enough to allow the patient to be maintained on oral rather than parenteral nutrition.

The principal conditions requiring massive resection in children include segmental volvulus in the prenatal period and necrotizing enterocolitis postnatally. Rarer causes affecting all ages include trauma, retroperitoneal tumours, radiation enteritis, and strangulation, mainly resulting from adhesions.

Physiology

Although digestion and absorption of water, electrolytes, and nutrients occurs throughout the small intestine, there are regional differences. Regional functions of the jejunum include iron and folate absorption and disaccharide digestion and, in combination with the duodenum, the production of cholecystokinin and secretin.

The ileum is the principal site for absorption of vitamin B_{12} and bile salts and, in contrast to the jejunum, is capable of absorbing sodium against a steep gradient. It also plays a key role, in combination with the proximal colon, in mediating the 'ileal brake', in which intestinal transit and secretions are reduced when nutrients reach the terminal small bowel. Hormones, particularly peptide YY, probably mediate this phenomenon.

Factors, including adaptation, that influence the metabolic consequences of massive resection

The ability of the residual bowel to adapt after resection varies greatly between patients; it influences the development of symptoms and may determine the long-term requirement for parenteral nutrition. Four main factors influence the patient's ability to absorb nutrients:

1. Extent and site resected. The length of the small intestine varies between individuals. As a general rule, patients who have an intact duodenum but less than 50 cm of additional small bowel if the colon is *in situ*, or less than 100 cm if the colon has been removed, will require long-term total parenteral nutrition. Conversely, a requirement for parenteral nutrition is unlikely if more than 25 per cent of the small bowel remains.
2. Condition of the remaining intestine. The capacity of the residual bowel to adapt postoperatively is influenced by any underlying condition. Patients in which the residual bowel is damaged or abnormal due to conditions such as Crohn's disease or radiation enterocolitis are more likely to have metabolic disturbances.
3. Presence of the ileocaecal valve. It is not unusual for part or all of the colon to be removed along with segments of small intestine. Removal of the ileocaecal valve has a major impact on subsequent clinical progress and troublesome watery diarrhoea that compounds malabsorption is frequent. Factors contributing to this include faster intestinal transit, possibly related to loss of the 'ileal brake' mechanism, and a much higher likelihood of bacterial overgrowth.
4. Function of other digestive organs. Pancreatic hypofunction, resulting from malnutrition and reduced hormonal stimulation, may exacerbate fat malabsorption; this is sometimes compounded by gastric hypersecretion that inactivates pancreatic enzymes in the lumen.

Pathophysiology

Because regional differences in the function of the small intestine exist, the clinical sequelae of resection vary according to the site removed. Resection of most of the jejunum can usually be compensated for by the distal bowel, and the consequences of proximal resections are usually slight. Patients may experience iron and folic acid deficiency as well as lactose intolerance, resulting in abdominal bloating and watery diarrhoea.

Clinical problems are more likely to occur following large resections that include most of the ileum. Intractable (cholerheic) diarrhoea, often with steatorrhoea, and consequential metabolic abnormalities including vitamin B_{12} deficiency occur.

Diarrhoea

This is probably the most troubling symptom. Multiple factors are involved in its aetiology (Table 1):

- Transit time is decreased due to the reduced length of bowel and alteration in the control of its motility.
- Luminal osmolality is increased, partly due to reduced absorption of lactose and other carbohydrates, which are then metabolized by colonic bacteria. Severe metabolic (lactic) acidosis may develop—the increased 'anion gap' being due to the microbial generation of D-lactate.
- Disruption of the enterohepatic circulation of bile salts reduces the total body pool of bile salts. This is initially compensated for by a homeostatic upregulation of bile salt production by the liver. Increased delivery of bile salts into the colon, however, stimulates colonic adenylate cyclase activity, increasing colonic secretion of water and electrolytes, resulting in watery diarrhoea sometimes termed cholerheic diarrhoea.
- If most of the ileum has been removed, the compensatory upregulation of bile salt production may be insufficient to balance losses. This leads to decreased micelle formation in the lumen of the small bowel with a resultant reduction in absorption of water-insoluble fatty acids, causing the patient to have steatorrheic diarrhoea. Resection of the terminal 100 cm of ileum is typically associated with clinically significant malabsorption of bile salts. The presence of excess a-hydroxy fatty acids derived from bacterial metabolism in the colonic lumen stimulates adenylate cyclase, further increasing secretion of fluids and electrolytes.
- In massive intestinal resections, the reduced micellar solubilization of fat and consequential impairment of lipolysis is compounded by the loss of absorptive

mucosa, thus aggravating the effects of maldigestion and fluid loss.

Stones

Gallstone formation is two to three times more common after ileal resection and may be of the cholesterol rich or pigment type. Reduced concentrations of bile salts within the bile due to depletion of the body pool of bile salts, in combination with gall bladder hypomotility, facilitate the formation of cholesterol crystals.

Renal stones (usually calcium oxalate) commonly result from increased absorption of oxalate and hyperoxaluria. The availability of free oxalate within the colon is increased by excessive complexation of calcium by fatty acids which normally promote formation of insoluble (non-absorbable) calcium oxalate. Although concentrations of bile salts in the small intestine may be reduced, the failure to reabsorb bile salts in the ileum increases luminal bile salts in the colon; this increases colonic permeability and further promotes oxalate absorption.

Gastric hypersecretion

This phenomenon occurs in some patients, although its severity tends to lessen over time. Hyperacidity may inactivate pancreatic enzymes by precipitating bile salts and lowering intraduodenal pH as in Zollinger–Ellison syndrome.

Nutritional status

Many patients undergoing resections will be malnourished preoperatively and energy consumption increases in the immediate postoperative period. If not appropriately managed, long-term protein-energy malnutrition, as well as life-threatening mineral and vitamin deficiencies develop.

Adaptation

Morphological and functional adaptive changes follow resection of the small intestine. The residual bowel undergoes mucosal hyperplasia and its capacity to absorb fluids and nutrients increases over a period of weeks or months. The molecular events that underly these changes are unclear but may include circulating trophic factors and growth factors present in pancreatic juice or secreted into the intestinal lumen. Early intervention is required to achieve maximal adaptation, and maintenance of a supply of luminal nutrients is a prerequisite for the adaptive changes. It is therefore important that luminal feeding is started as early as possible after surgery even if the patient also requires parenteral nutrition.

Management

Initial therapy

In the initial postoperative period, vigorous intravenous fluid and electrolyte replacement is required to prevent dehydration and to compensate for intestinal losses. Many patients will also require parenteral nutritional supplements while the residual bowel adapts. Ingestion of water may exacerbate diarrhoea and be counterproductive. The use of an oral iso-osmolar saline–glucose solution containing bicarbonate, similar to that used for the treatment of cholera, may often assist in reducing intravenous requirements without increasing intestinal fluid loss.

Nutrition

Oral nutrition, initially consisting of elemental or polymeric diets administered by nasogastric or enteral tube feeding, should ideally be started within the first few days of surgery. The introduction of luminal nutrition tends, however, to exacerbate the diarrhoea. Many high-calorie enteral supplements for use in malnourished patients who have little or no impairment of small intestinal function have a very high osmolality, thereby inducing catastrophic egress of luminal fluid and diarrhoea in patients with large resections. These preparations are to be used with great caution or avoided altogether in patients suffering the effects of massive bowel resections.

Subsequently, small-volume, frequent, solid or semisolid meals with low fat and oxalate content should be introduced. Low-fat meals and supplements containing large quantities of medium-chain fatty acids tend to be unpalatable. Compliance of patients with dietary advice is therefore best if symptoms are used as a guide to the amount of fat that is included in the diet. Since much of the energy content of the ingested diet may well be lost in the stool, the daily intake of calories often has to be greater than expected. This is best provided in a complex form including glucose polymers and starch which have little osmotic effect in the lumen and are hydrolysed rapidly by brush-border hydrolases at the site of absorption. Lactose intolerance, seen particularly in patients following significant jejunal resections, may induce bloating and exacerbation of diarrhoea but usually responds to reduction in lactose-containing dairy products. Low-fibre diets are helpful in some patients although they may aggravate symptoms in others; treatment must be tailored to the individual. Patients should be encouraged to take multivitamin and mineral supplementation at levels two to five times the normal recommended daily requirements; vitamin B_{12} injections are required following terminal ileum resection. In all patients, regular long-term monitoring of fat-soluble vitamins (A, K, and D), vitamin B_{12}, folate, magnesium, zinc, and bone status is required.

In some patients, adequate fluid and nutritional balance cannot be maintained by the oral route alone and long-term total parenteral nutrition is needed. These patients should be encouraged to continue oral nutrition, for social and psychological reasons as well as to minimize the amount of parental nutrition required.

Drugs

Most patients will require antiperistaltic drugs to increase the time of contact between luminal contents and residual bowel. A step-wise approach should be used, starting with agents such as loperamide or codeine phosphate. Long-term administration of the more potent constipating, but potentially addictive, opiates should only be used in intractable cases. Since diarrhoea may be particularly troublesome in the initial postoperative period, liquid or occasionally intravenous formulations may be needed.

Administration of H_2-receptor antagonists or proton pump inhibitors may reduce diarrhoea and promote digestion, as well as prevent peptic ulceration, by decreasing gastric secretions and preventing inactivation of pancreatic enzymes. Cholerheic diarrhoeas may respond well to bile acid sequestrants such as cholestyramine but its use can worsen the fatty component of diarrhoea by exacerbating the deficiency of bile salts. Similarly, the use of long-acting somatostatin analogues can reduce gastrointestinal secretions and fluid loss but may exacerbate steatorrhea and formation of gallstones. In patients with marked steatorrhea who do not respond to restriction of fat intake, the addition of oral pancreatic enzyme supplements to food may assist lipolysis and improve digestion.

Bacterial overgrowth

Colonization of the small bowel by colonic or pathogenic bacteria results in exacerbation of diarrhoea, malabsorption, and nutritional deficiencies. Culture and analysis of small bowel aspirates is required for definitive diagnosis but is a moderately invasive procedure. Because results from many of the usual non-invasive tests, for example glucose or lactulose hydrogen breath tests, are abnormal in all patients after significant resection, empirical trials of antibiotics may be justified.

Surgical options

In patients with severe intractable diarrhoea further surgery should be considered, although it is usually of limited benefit. Although not in general clinical use, reversal of a small segment of small bowel can delay gut transit; however, if too long a segment is used, obstruction may occur. Longitudinal lengthening may also be of value, particularly in paediatric patients.

Small bowel transplantation is now available in a limited number of centres. Because of the high morbidity and mortality associated with transplantation, it is usually only offered to those patients who cannot be maintained on total parenteral nutrition. Patients who have undergone intestinal transplantation are particularly prone to infections and lymphoma. Problems with acute and chronic rejection are also common. Patients therefore require detailed counselling about the risks of any such procedure.

Future directions

Administration of gut trophic factors, such as glucagon-like peptide 2, hepatocyte growth factor, epidermal growth factor, and growth hormone (possibly in combination with glutamine supplements), during the early postoperative period may increase the rate and extent of mucosal adaptation that occurs in the intestine. In patients who prove not to adapt adequately, continuing advances in techniques for small bowel transplantation and in antirejection therapy offers future hope. In the longer term, advances in tissue engineering technology may allow intestinal mucosa to be obtained from humanized animal gut or to be reconstituted in culture from the patient's own residual bowel, thereby removing the problems of rejection and immunosuppression.

14.9.8 Malabsorption syndromes in the tropics

V. I. Mathan

Introduction

Patients, in whom the 'digestive fire is weakened and food is expelled from the body without contributing to growth' were described in *Charaka-Samhita*, an ancient Indian treatise on medicine, compiled some time between the sixth and twelfth centuries BC. The clinical description in the section on '*Grahani Vyadhi*' or diseases of the organ of assimilation, clearly describes patients gradually wasting with chronic diarrhoea and loud borborygmi. Malabsorption of nutrients with its sequelae has therefore long been recognized as a clinical entity in some tropical regions.

Malabsorption is the result of the failure of intestinal function. It is multifactorial and may be due to failure in the luminal and mucosal phases of digestion and absorption, as well as of transport from the intestine. Detailed investigation of the individual patient is essential for diagnosing the causes of malabsorption.

In the context of the 'global village' of the third millennium, are there defined 'tropical' malabsorption syndromes? All the causes of nutrient malabsorption prevalent in temperate climates also occur in the tropics, but there are certain conditions: the majority being chronic enteric infections or infestations that are geographically limited to the tropics. Expatriates from other parts of the world to the tropics may have a higher susceptibility to some of these conditions.

Causes of malabsorption primarily prevalent in the tropics

The small intestinal and colonic mucosa of apparently healthy residents of many tropical countries, in comparison to residents of temperate-zone industrialized countries, show minor morphological and functional abnormalities. These changes, designated 'tropical enteropathy' and 'tropical colonopathy', are the normal background on which clinically significant malabsorption occurs.

Malabsorption in the tropics, as elsewhere, may have an identifiable underlying aetiology, when it is classified as secondary malabsorption. When no primary cause has yet been identified it is considered primary or idiopathic malabsorption (Table 1).

The importance of a variety of protozoal infections, especially intracellular protozoans, was recognized in temperate-zone countries at the beginning of the AIDS epidemic, these organisms having been identified as opportunistic infections. In tropical countries these protozoa have been identified in symptomatic and asymptomatic immunocompetent subjects.

Capillaria philippinensis infestation has been reported in epidemics from The Philippines and as sporadic cases from other tropical countries including India. Hyperinfection with *Strongyloides stercoralis* can occur rarely. Both these helminths burrow into the mucosa and form tunnels.

Abdominal tuberculosis occurs much less frequently than pulmonary tuberculosis and is often secondary. Malabsorption in abdominal tuberculosis is the result of bacterial colonization of the small intestinal lumen secondary to strictures and extensive ulceration, or due to obstruction of the lymphatic outflow (*Tabes mesenterica*).

Progressive wasting in African people infected with the human immune deficiency virus (**HIV**) is known as 'slim disease', and is a consequence of malabsorption secondary to enteric opportunistic infections. There is some evidence to suggest that a primary HIV enteropathy can also contribute to malabsorption.

Calcific pancreatitis affecting young adults, particularly in economically disadvantaged sections of society, is another cause of malabsorption unique to the tropics.

Immunoproliferative small intestinal disease (**IPSID**) is due to the clonal expansion of immunocytes producing altered alpha heavy-chain immunoglobulin. This is also known as Mediterranean lymphoma and has been reported from several tropical countries. The characteristic histology in the premalignant stage is diagnostic and can be reversed by prolonged antibiotic therapy at this stage. Once malignant transformation has occurred the treatment is as for other lymphomas, but the prognosis is guarded.

In many tropical regions, particularly south and south-east Asia, the high lactase activity in the intestinal epithelium in the neonates declines rapidly after weaning. Since most adults in such countries do not regularly consume milk or lactose in their diets, this abnormality is of relatively small significance. The use of fermented milk and milk products (for example, yoghurt) can ensure that milk-based nutritional supplementation is still possible in such populations.

Malabsorption, or increased secretion, is an invariable part of all acute diarrhoeal infections. These episodes, most frequent in children, are of short duration, usually a few days. A small proportion of infants and young children have diarrhoea that persists for longer than 2 weeks following an acute episode. This persistent diarrhoea syndrome, seldom if ever seen in adolescents and adults, is also not considered as one of the malabsorption syndromes.

The concept of a 'postinfective malabsorption state' associated with the presence of a mixed bacterial flora in the small intestine has been postulated to explain, in particular, the persistent diarrhoea and malabsorption reported in many European travellers to the Indian subcontinent. By extension, it has been suggested that the syndrome of primary malabsorption in the tropics, tropical sprue, is only another form of postinfective malabsorption. Several factors contradict this assumption. Significant bacterial colonization of the small intestine has been found in apparently healthy asymptomatic adults resident in the tropics. Detailed investigation of many overland travellers from Europe to the Indian subcontinent identified several of the infections described earlier as the cause of persistent malabsorption, along with an altered luminal bacterial flora. The epidemiology of tropical sprue is distinctly different from that of acute infectious diarrhoea. Detailed clinical and laboratory investigations of adults and children in over 20 epidemics of acute diarrhoea, studied in south India, identified no single case of persistent malabsorption, other than the background prevalence of tropical enteropathy. There are also well-documented instances of expatriates from Europe who developed a primary malabsorption syndrome many years after their return to temperate climes. A careful analysis of the available literature therefore suggests that significant persistent and symptomatic malabsorption following acute enteric infectious diarrhoea is a rare event in the tropics.

When patients with conditions that can give rise to secondary malabsorption unique to the tropics or elsewhere are excluded, a group remain who have chronic diarrhoea, malabsorption, and its nutritional sequelae. Such patients are relatively rare in temperate climates, but they are frequently encountered in areas such as southern India and the Caribbean islands. This primary or idiopathic malabsorption syndrome has been called 'tropical sprue'. Tropical sprue occurs on the background of tropical enteropathy in the indigenous population of these regions.

Tropical enteropathy

The intestinal mucosal morphology of germfree and conventionally reared, litter-mate, rats is different; the latter having shorter villi, higher crypts, and increased mononuclear cells infiltrating the lamina propria and epithelium. These differences are attributed to the modulating effect of the microbial flora in the intestinal lumen of the conventionally reared litter-mates.

Similar morphological differences are found between the jejunal mucosa of apparently healthy asymptomatic individuals living in temperate-zone industrialized countries and those in tropical preindustrialized countries. The morphological features of this tropical enteropathy are characterized by the replacement of finger- and tongue-shaped villi by broader structures in the upper small intestine, reduction in the height of villi with an increase in crypt thickness, and an increased infiltration by mononuclear cells in the lamina propria and the epithelium. Similar mucosal morphological changes have also been shown to occur in the large intestine.

The morphology of fetal intestinal mucosa is identical in both geographical regions, the earliest differences appearing shortly after birth. The morphological changes are not apparent in biopsies from residents of Singapore—although this is a tropical country, it has standards of environmental hygiene and nutrition that equal those in temperate-zone industrialized countries. People expatriated from temperate countries to tropical countries develop these mucosal morphological changes over time. Even if expatriates from tropical countries living in a temperate zone continue to ingest a diet similar to that in their original home, they eventually revert to having a temperate-zone morphology. The evidence therefore suggests that the morphological alteration in the small intestine of residents of tropical countries is not a result of climatic differences, but is probably a reflection of an adaptation to environmental factors. *In vitro* organ culture studies have shown a slightly accelerated cell turnover in the jejunal mucosa of people living in the tropics, further supporting an adaptive response as the basis for the change.

Extensive bacterial colonization of the upper small intestinal lumen and mucosa, in apparently healthy adults, by aerobic and anaerobic bacteria, has been documented in studies from southern India. There is also circulation of enteric pathogens in asymptomatic individuals. It is also known that the first dose of oral immunization agents to enteric pathogens usually results in a secondary response, even in children as young as 2-years old living in the tropics. There is no evidence that the macronutrient deficiency widely prevalent in many tropical countries influences intestinal structure or function. No such information is available regarding micronutrient deficiencies. Conceptually, it may be useful to categorize 'specific pathogen-free' populations (temperate zone) and 'conventional' populations (tropical)!

Minor abnormalities in absorption can also be demonstrated in these healthy subjects, with xylose malabsorption in 40 per cent, mild steatorrhoea in 10 per cent, and vitamin B_{12} malabsorption in 3 per cent. The overall absorption of calories is reduced by about 5 per cent, while the colonic bacterial mass is increased. Colonic salvage of unabsorbed calories is thereby reduced. There is no evidence that these changes in the lining epithelium of the intestinal tract, a primary barrier between the internal and external environment of the body, significantly affects the health of these 'conventional' populations. However, the reduction in overall caloric absorption can raise the question as to whether the absence of tropical enteropathy can increase the effective availability of food without an increase in supply.

Tropical sprue

Definition

This primary (idiopathic) malabsorption syndrome affecting residents of, or visitors to, certain tropical regions, with characteristic enterocyte damage, is usually associated with chronic diarrhoea and the nutritional sequelae of persisting malabsorption. The aetiology(ies) underlying this syndrome is not yet understood. There are differences in the presentation, epidemiology, and clinical course in different geographical regions and between expatriates to endemic regions and indigenous residents affected by the syndrome.

History

William Hillary described a chronic wasting diarrhoea in European expatriates in Barbados in 1759, probably the first description of the syndrome in the English literature. The disease apparently attained epidemic proportions 3 years after he arrived in Barbados. The syndrome in expatriates was well recognized by British and Dutch physicians in south and south-east Asia with expanding colonization. However, no cases were described from tropical Africa. Tropical sprue assumed epidemic proportions during the Second World War and was a major factor for repatriation from the Assam and Burma theatres of war. Indian troops were also affected. It was only in the postcolonial era, with the work of Baker and colleagues in southern India and of Klipstein in Puerto Rico and Haiti, that the extent of the problem of tropical sprue was defined in indigenous populations.

Epidemiology

Endemic cases in indigenous and expatriate residents and epidemics in troops and indigenous populations have both been described. Endemic tropical sprue is apparently geographically restricted to south and south-east Asia and the Caribbean islands other than Jamaica, with a few case reports from Central and South America and Sub-Saharan Africa. In fact, much of the literature up to the 1960s is limited to expatriate populations. In India, only two large medical institutions, with well-developed laboratory facilities, have reported detailed studies, suggesting that in marginally nourished indigenous populations many cases may be missed due to the poor availability of diagnostic facilities.

Apart from the reports during the Second World War, large epidemics have only been described from southern India. The first such reported epidemic in 1960–61 affected approximately 100 000 patients, with a 40 per cent case fatality. This was reflected in the unusual death rates in the North and South Arcot Districts of Madras state in the 1961 census of India. The last epidemic was detected in 1978. In all the epidemics, patients initially developed an apparent episode of acute diarrhoea accompanied by vomiting in about 30 per cent and fever in 25 per cent of cases. Significant malabsorption of fat, carbohydrate, and vitamin B_{12} was present even during the first week of illness and 50 per cent of those affected had diarrhoea for longer than 1 month. The epidemics evolved over a period of months to years: adults had a significantly higher attack rate and were affected earlier during the course of the epidemic. The epidemiological data suggested an infective aetiology, but no causal viral, bacterial, or parasitic agent could be found.

Clinical features

The patient with tropical sprue is usually an adult with a history of loose or watery stools lasting for several weeks or months and with symptoms and signs of nutritional deficiency. There is usually anorexia, a feeling of abdominal distension, and loud abnormal borborygmi. The signs of nutritional deficiency include pallor due to anaemia, angular stomatitis, glossitis, oedema, and the skin and hair changes of severe hypoproteinaemia. The prevalence of nutritional deficiency, measured by clinical or laboratory parameters, is higher in those patients with a longer duration of symptoms. In the epidemic situation the prevalence of nutritional deficiency in patients during the first month of illness was no different from that in the unaffected people in the same village. However, in patients affected in the epidemics persistent malabsorption begins during the first few days of illness. The diarrhoea can be severe enough to produce life-threatening dehydration: in the epidemics the early deaths were mainly due to fluid and electrolyte imbalance. These could be prevented by maintenance of hydration. As the disease progresses the sequelae of severe malnutrition and consequential acute infections, especially of the respiratory tract, contribute to mortality. The natural history of the illness shows periods of remission, relapses, and spontaneous recovery, which make an evaluation of specific therapy difficult. Although patients have been followed for up to 25 years in southern India, intestinal neoplasms have not developed.

Investigation

Investigation of these patients should confirm the presence of intestinal malabsorption, exclude conditions that can give rise to secondary malabsorption, and evaluate the nutritional sequelae of malabsorption (Table 2).

A simple faecal smear stained with a fat stain such as Sudan 3 can often detect fat globules and fatty acid crystals associated with steatorrhoea. The extent of tests for confirming the presence of malabsorption is determined by the availability of facilities, which in many tropical areas is still limited. Tests of xylose absorption should be interpreted in the light of xylose malabsorption as a part of tropical enteropathy in the particular community.

The exclusion of conditions that can give rise to secondary malabsorption is of importance since many of these conditions are amenable to therapy. The diagnosis of the syndrome of primary malabsorption is one of exclusion.

Evaluation of the nutritional sequelae of malabsorption, especially the presence of megaloblastic anaemia, provides useful benchmarks for appropriate nutritional

rehabilitation.

Pathology and pathogenesis

The wide availability of peroral mucosal biopsies confirmed the report, as early as 1924, that the primary lesson in tropical sprue was in the small intestinal mucosa. Electron microscopic examination of jejunal mucosal biopsies confirmed the presence of damage to enterocytes in the crypt (regenerative) and villous (functional) compartments. This damage can be demonstrated in the first weeks of illness in patients affected during epidemics. Accelerated cell turnover in the regenerative compartment and increased loss of enterocytes from the functional compartment was demonstrated by *in vitro* culture of jejunal mucosal biopsies labelled with tritiated thymidine. In fact these changes in the enterocyte lifecycle explain the observed mucosal architecture, which has often been called partial villous atrophy. In contrast to the situation in coeliac disease, where the initial damage to enterocytes occurs in the functional compartment and the crypts are hypertrophied with normal enterocytes, in tropical sprue the primary lesion appears to affect the regenerative compartment. These findings have only been confirmed in patients studied in southern India.

The mucosal lesion in tropical sprue is not confined to the small intestine, since functional and structural abnormalities have also been demonstrated in the stomach and the colon. Significant water malabsorption in the colon may contribute to the severity of diarrhoea.

An appreciation of regional differences in the patient profile is essential for understanding the pathology and pathogenesis. All patients have malabsorption, but vitamin B_{12} malabsorption is only found in about 70 per cent of patients in southern Indian, while it is almost invariable in expatriates from the temperate zones and in the Caribbean. In Haiti and Puerto Rico the observed seasonal incidence is ascribed to small intestinal colonization by toxin-producing coliforms, probably secondary to the consumption of rancid pork fat. In southern India, the extent and severity of small bowel colonization by enterotoxin-producing coliforms is no higher than in matched controls. Identification of one or more 'agents' that can damage the mucosal epithelial cells will enable a clearer understanding of these differences.

Treatment

Provision of symptomatic relief from diarrhoea, correction of fluid and electrolyte abnormalities and nutritional deficiencies, and attempts at specific curative measures are the cornerstone of treatment. Diarrhoea and abdominal distension can be helped by the judicious use of loperamide and dimethyl polysiloxane. Increasing the nutrient intake and providing therapeutic supplements such as vitamin B_{12} and folic acid, as indicated, is beneficial. However, specific therapy to cure the condition awaits understanding of its aetiology.

Empirical evidence from patients in the Caribbean and European expatriate community, indicates that folic acid can alleviate symptoms in cases of less than 2 months' duration. In patients with a longer duration of symptoms, the addition of oral tetracycline for up to 6 months leads to the restoration of normal intestinal absorption. In southern India, the results of therapy with vitamin B_{12}, folic acid, and tetracyclines were not so clear-cut and a few patients were resistant to all therapy. Nevertheless, the recommended management includes the use of all three of these therapeutic agents for up to 6 months.

Areas needing further research

Malabsorption syndromes occur in tropical regions and there are conditions that are unique to this geographical region. While the advent of HIV infection has created an added dimension, it is important to continue the search for agents that can directly damage the endoderm-derived epithelial cells. The public health significance of tropical sprue is probably declining, with the last reported epidemic occurring over 20 years ago and the improving nutritional status of many tropical populations enhancing their ability to compensate for mild to moderate degrees of intestinal malabsorption.

Nevertheless, understanding tropical sprue, a primary or idiopathic malabsorption syndrome of the tropics, continues to be an intriguing challenge.

14.10 Crohn's disease

D. P. Jewell

Crohn's disease is a chronic inflammatory disease of the gastrointestinal tract, the cause of which remains unknown. It is characterized by a granulomatous inflammation affecting any part of the tract, frequently in discontinuity, and by the tendency to form fistulas.

History

The first clear description of the disease affecting the terminal ileum (regional ileitis) was given by Crohn, Ginzburg, and Oppenheimer in 1932. However, the disease certainly existed long before then and many of the early descriptions of ulcerative colitis would now be regarded as Crohn's disease. Dalziel, in 1913, described an inflammatory process of the ileum and colon consisting of ulceration, submucosal oedema, fibrosis, and mesenteric lymphadenopathy. He reported the presence of granulomas on microscopy but could find no evidence of tuberculosis. Similar cases were described in the 1920s by oschowitz and Willensky.

After the description by Crohn and his colleagues, it was clearly recognized that the colon could also be involved and, on occasions, it could be the sole site of the disease. The disease therefore became known as regional enteritis or, preferably, Crohn's disease. Colonic disease is often referred to as Crohn's disease of the colon, Crohn's colitis, or granulomatous colitis.

Epidemiology

Crohn's disease is well recognized in Europe, Scandinavia, North America, and Australia but is rarely seen in India, tropical Africa, and South America. This may be largely due to the difficulty of diagnosing Crohn's disease in areas where intestinal tuberculosis is common and to the problems of long-term follow-up. However, it is now being recognized in India in specialist gastrointestinal units. The disease is about 10 times less common in Japan than in the West, but its prevalence in Japan appears to be increasing.

There has been a striking increase in the incidence and prevalence of Crohn's disease in Europe and Scandinavia since 1950 (Table 1). This is also shown by examining the annual discharge rates in England and Wales. For Crohn's disease, the rate rose from 2.8 per 100 000 in 1958 to 7.2 per 100 000 of the population in 1971, whereas the rate for ulcerative colitis during the same period was unchanged at 10 to 12 per 100 000. Recent studies in Scotland and in Stockholm have suggested that the incidence has begun to decline in adults, but there is a widespread belief that Crohn's disease is increasing in children, supported by studies in Scotland.

The reasons for the changing patterns of incidence are not clear. Much of the increased incidence is due to an increased frequency of colonic disease and it might be argued that this represents diagnostic transfer from ulcerative colitis to Crohn's disease. The annual discharge rates for England and Wales, quoted above, make this explanation unlikely. Whether similar changes in frequency have occurred in North America is uncertain, although the data available suggest that the incidence has probably not altered. It is possible that the changing incidence may result from an infective or environmental factor.

Crohn's disease occurs in all age groups but it is rare in early childhood and most commonly affects young adults. There is no marked sex difference, and no association with social class or occupation. There may be an increased incidence amongst Ashkenazi Jews, especially in the United States.

Genetics

Evidence for a genetic susceptibility to developing Crohn's disease is suggested by a much higher concordance in monozygotic twins (approximately 45 per cent) compared with dizygotic twins (approximately 15 per cent), and by the finding that 10 to 15 per cent of patients will have at least one other family member affected. The highest risk is between siblings (ls 20 to 25—this is a measure of relative risk), but there is still an increased risk of affected offspring (ls 15) if a parent is affected. However, given the low incidence of Crohn's disease, the absolute risk to family members if one individual develops the disease is still low. Within a multiply-affected family, there is a remarkable concordance with respect to disease type (most will also have Crohn's disease, although Crohn's disease and ulcerative colitis can occur in the same family) and disease behaviour. However, there is no clear mode of inheritance and recent linkage studies utilizing microsatellite markers to link disease to areas of the genome have suggested that multiple genes are involved. It seems likely that there are a variety of genes which render individuals susceptible to 'inflammatory bowel disease' but that other genes determine the type and behaviour of disease. Crohn's disease has been linked to a pericentromeric region of chromosome 16 in many different populations, thus providing strong evidence that there is a relevant gene in this region. In 2001 this gene was identified as *NOD2*, encoding a protein which is an intracellular receptor for bacterial lipopolysaccharide. A number of point mutations and a frameshift mutation are found in up to 40 per cent of patients with ileal disease but are not associated with colonic Crohn's disease. Linkages to chromosomes 6 and 14 have also been replicated.

Aetiology

The cause of Crohn's disease is unknown but clearly involves an interplay between genetic and environmental factors. The latter include smoking and intestinal luminal factors. There is a relative risk of 4 to 6 for Crohn's disease in smokers compared with non-smokers, which is in striking contrast to the reverse association seen in ulcerative colitis. Whether smoking predisposes to Crohn's disease by altering mucosal blood flow, synthesis of mucus, or by an effect on endothelial cells is unknown. The role of luminal factors is suggested by the tendency of Crohn's colitis to heal if the colon is rendered non-functional by an ileostomy and by the effectiveness of an elemental diet for the treatment of active disease. Other mechanisms may contribute to the pathogenesis and include diet, infective agents, ischaemia, and immune mechanisms. Recent claims that the measles virus or the **MMR** (measles, mumps, rubella) vaccine might predispose to Crohn's disease later in life have not been confirmed by subsequent data. Likewise there are no confirmatory data that *Mycobacterium paratuberculosis* is involved in disease pathogenesis.

Diet

Several investigators have reported that patients with Crohn's disease have a higher intake of refined sugar than a control population or a matched group of patients with ulcerative colitis. In addition, patients with Crohn's disease may also have a reduced intake of fibre, especially that derived from fruit and vegetables. However, the significance of these changes is unclear, especially as a controlled trial was unable to show that a low-sugar, high-fibre diet had any effect on the cause of the disease over a 2-year period. Claims have been made that many patients will benefit from dietary exclusion determined by a period on an elimination diet followed by challenge with individual foods. This might suggest a role for dietary factors, but the long-term benefit of dietary exclusion is by no means proven. Elemental diets consisting of glucose and amino acids have been shown to have equal efficacy to prednisolone for treating active Crohn's disease, but whether this effect is mediated by influencing bacterial populations, by removing dietary antigens, or by some other mechanism is unknown.

Infective agents

Viruses, cell-wall deficient bacteria, and atypical mycobacteria have been claimed to be the cause of Crohn's disease. Most of these claims have been discredited but there is current interest in the role of *M. paratuberculosis* and measles virus.

M. paratuberculosis is the organism that causes Johne's disease in cattle and other farm animals. This resembles Crohn's disease in so far as it is a granulomatous inflammatory disorder of the intestine. Over the last 20 years, an atypical mycobacterium has been isolated from intestinal tissue of a few patients with Crohn's disease and most of the isolated organisms have been shown to be identical to *M. paratuberculosis* using DNA analysis. The organism is very slow growing and it has taken 1 to 2 years of culture in order to demonstrate it. The possibility that such an organism might be involved in the aetiology of the disease was strengthened by the detection of *M. paratuberculosis* DNA in intestinal tissue in about two-thirds of patients using a specific probe and amplification by the polymerase chain reaction. However, specific DNA for the organism was also detected in 10 per cent of control tissue and other investigators have been unable to detect specific DNA in any patient with Crohn's disease. Antituberculous therapy has not proved effective so far. Thus, it is still very uncertain whether *M. paratuberculosis* is an aetiological agent, whether it is responsible for causing disease in all or just a subgroup of patients, whether some of the findings are laboratory artefacts, or whether it is a secondary invader of inflamed tissue.

The initial reports linking measles virus or the MMR vaccine to the risk of developing Crohn's disease later in life have not been substantiated by other investigators. At best, the case for measles virus remains unproven.

Ischaemia

Marked abnormalities of mucosal arterioles have been detected in resected specimens of intestine affected by Crohn's disease by making resin casts of the arterial tree. Many of the small vessels have been shown to be thrombosed, but in a rather patchy distribution, suggesting that much of the inflammation may arise from multifocal infarction. However, as many cytokines and inflammatory mediators released during an immunological or inflammatory response damage endothelium, it is not possible to be sure whether these vascular changes represent a primary abnormality or are merely secondary to the inflammation. It seems more likely that they occur as a consequence of the inflammation but, nevertheless, they may still contribute to the pathogenesis of chronic inflammation.

Immune mechanisms

Patients with Crohn's disease usually have normal serum concentrations of immunoglobulins and complement components, although raised concentrations may occur in association with active disease. Neutrophil and monocyte functions, *in vitro*, show no defect, although inhibitors of cell motility are often present in the serum of patients with active disease. The absolute number of peripheral blood T lymphocytes may be reduced but the proportion of phenotypic subsets (CD4, CD8) remains unchanged.

Within the inflamed tissue, there is a marked increase of plasma cells, lymphocytes, macrophages, and neutrophils. As with ulcerative colitis, the increased immunoglobulin production is predominantly of the IgG isotype, but in Crohn's disease, there is a greater proportional increase in the IgG2 subclass compared with the IgG1 or IgG3 subclasses. Antibodies to bacterial antigens and autoantibodies to epithelial and neutrophil antigens are much less common than they are in patients with ulcerative colitis, but antibodies to *Saccharomyces cerevisiae* (baker's yeast) have been frequently reported, especially with small intestinal Crohn's disease.

T cells and macrophages in the lamina propria are activated, as shown by the increased expression of activation markers and also, in the case of macrophages, by functional assays. The possibility that chronic inflammation results because of a defect in immunoregulation has been explored in a variety of assays but no consistent defect has been described. However, some evidence suggests that there may be an impaired facility to induce antigen-specific suppressor cells; if this is confirmed, it might explain some of the immunological overactivity that is characteristic of the disease. Cellular activation results in the release of cytokines and inflammatory mediators, which will influence the nature of the inflammatory response. Crohn's disease may reflect a predominant T_{H1} response. The possibility that the course of the disease, whether fibrosing or fistulating, may be determined by the cytokine profile is an attractive but unproven hypothesis.

Pathology

Crohn's disease may occur anywhere in the gastrointestinal tract, although the most common pattern is an ileocolitis. The disease is often discontinuous, giving rise to the so-called skip lesions. Isolated involvement of the mouth, oesophagus, stomach, and anus is recognized but such cases are extremely rare. Macroscopically the bowel is thickened and frequently stenosed. The serosal surface may be inflamed and the mesentery becomes oedematous. The regional mesenteric nodes are usually enlarged. The earliest macroscopic lesion on the mucosal surface is an aphthoid ulcer—a small, superficial lesion often surrounded by hyperaemia. In areas of more severe disease, deep, fissuring ulcers occur in the oedematous and inflamed mucosa, giving rise to a cobblestone pattern. Long, serpiginous ulcers are a further characteristic feature. Strictures occur as a result of submucosal fibrosis and, because of serosal inflammation, the affected intestine may become adherent to adjacent loops of intestine or other structures (such as the bladder or vaginal vault) with the subsequent formation of fistulas.

Histologically, the inflammation is transmural and consists principally of lymphocytes, histiocytes (tissue macrophages), and plasma cells. Granulomas are found in only 65 per cent of patients and they occur more commonly the more distal the disease; that is, they are present in most cases with rectal disease but are much less common in ileal disease. The granulomas appear to be in the walls of either blood vessels or lymphatics. The mucosal architecture is well preserved despite heavy inflammation and, in the colon, goblet cells are usually present even though the glands are being infiltrated with inflammatory cells. Fissures, penetrating into the submucosa and lined with histiocytic cells, are frequently present.

Quantitative histological and enzyme studies have suggested that the whole of the gastrointestinal tract is abnormal in patients with Crohn's disease even though only one segment may be overtly involved at any one time.

Immunofluorescent and immunoperoxidase studies have shown a large increase in IgG- and IgM-containing cells with a smaller rise in IgA-containing cells. Even in quiescent disease, the IgG- and IgM-containing cells appear to be increased compared with the normal intestine.

Clinical features

The manifestations of Crohn's disease are protean and are partly determined by the anatomical location of the disease. The majority of patients complain of diarrhoea (70 to 90 per cent), abdominal pain (45 to 66 per cent), and weight loss (65 to 75 per cent). Fever is also common (30 to 49 per cent). Obstructive symptoms (colic, vomiting) are much more commonly associated with ileal disease than colonic Crohn's disease. Colonic disease causes rectal bleeding more commonly than ileal disease, but even so, it is present in only about 50 per cent of patients with Crohn's colitis. Colonic disease is also associated with perianal disease (in about one-third of patients) and with extraintestinal manifestations, which are not commonly seen when the disease is confined to the ileum. Symptoms of anaemia are common and usually occur as a result of iron deficiency from intestinal blood loss or, less frequently, from vitamin B_{12} or folate deficiency. Other features of malabsorption are infrequent, but in patients with extensive small-bowel disease, symptoms and signs of osteomalacia may occur and there may be a bleeding tendency secondary to vitamin K malabsorption. Nutritional deficiencies may also be present, for example deficiencies of magnesium, zinc, selenium, ascorbic acid,

and the B vitamins, but these are uncommon and are usually only seen in patients with diffuse small-intestinal disease.

A few patients present with the clinical features of acute appendicitis but at operation they are found to have an acute terminal ileitis. Only a minority of these prove to be due to Crohn's disease. Diagnostic difficulties may also occur when the disease presents without gastrointestinal symptoms. These include patients presenting with fever, weight loss, and anaemia without diarrhoea or abdominal pain, and those with ileocaecal disease presenting with urinary frequency and dysuria due to ureteric involvement.

Physical examination may be normal but many patients will show evidence of anaemia. Glossitis and aphthous ulcers in the mouth, beaking or frank clubbing of the nails, evidence of weight loss, and a tachycardia are common features. Abdominal examination usually reveals tenderness over the affected bowel, which can often be felt to be thickened. An abdominal mass is frequently palpable when small- intestinal disease is present. Anal examination often shows the presence of fleshy skin tags, which have a characteristic violaceous hue. Anal fissures, perianal fistulas, and abscesses are particularly associated with colonic disease.

The extraintestinal manifestations of Crohn's disease are similar to those of ulcerative colitis. Table 2 lists those that are most frequently seen.

Complications

Patients with Crohn's disease can develop an acute dilatation of the bowel (defined as a colonic diameter of 5.5 cm or more on a plain radiograph), perforation, or massive haemorrhage, especially when the disease involves the colon. However, these complications occur less frequently than they do in ulcerative colitis. The more usual complications are intestinal obstruction due to strictures in the small or large intestine and fistulas. The latter may occur between other parts of the gastrointestinal tract (such as gastrocolic, enterocolic) or between the affected loop of intestine and the bladder or vagina. Pneumaturia, the passage of faeces in the urine, or a faecal vaginal discharge are cardinal features of the latter forms of fistula formation. The gross malabsorption that occurs with a gastrocolic or ileocolic fistula is largely due to bacterial overgrowth of the small intestine. External fistulas to the skin also occur, but this is usually secondary to surgical intervention. Crohn's disease affecting the terminal ileum or the right side of the colon may involve the right ureter, giving rise to frequency with a sterile pyuria, a frank urinary tract infection, or a ureteric stricture with subsequent hydronephrosis. Left-sided disease may occasionally involve the left ureter, but this is very uncommon. Hyperoxaluria and oxalate stones may be complications of ileal disease associated with steatorrhoea. The mechanism is currently thought to be due to binding of calcium to unabsorbed fat, leaving the oxalate free to be absorbed from the colon.

Carcinoma of the colon may complicate Crohn's colitis. The incidence is about 3 to 5 per cent, a frequency similar to that of colonic carcinoma associated with ulcerative colitis. The risk factors are not yet established, however, although histological dysplasia has been noted in some cases of Crohn's disease. Small-bowel carcinomas have been reported in association with ileal Crohn's disease.

Amyloid is another complication of Crohn's disease; it may occur within the bowel or systemically, for example in liver, spleen, and kidney. It usually occurs in patients with poorly controlled Crohn's disease complicated by complex fistulas and abscesses. If renal function is deteriorating, the affected bowel should be resected as the amyloid may then regress with concomitant improvement in renal function.

Radiological appearances

A plain radiograph of the abdomen should always be obtained in patients with severe disease, together with decubitus films. These are often normal but may show evidence of intestinal obstruction or suggest an inflammatory mass in the right iliac fossa. In acute Crohn's colitis, evidence of mucosal oedema and ulceration may be clearly seen on the plain films. This appearance could obviate the need for barium studies, which should, if possible, be avoided in the presence of severe, active disease. The plain film can also provide evidence of sacroiliitis or ankylosing spondylitis.

Examination of the oesophagus, stomach, and duodenum is best done endoscopically because the radiological appearances are often non-specific and biopsies are required for histological confirmation. The small intestine may be examined with a standard barium meal and follow through, but more information is obtained with the barium infusion technique (small-bowel enema, enteroclysis). After colonic preparation, a tube is passed until the tip lies just beyond the ligament of Treitz and a dilute barium suspension is infused (800 to 1200 ml). The earliest lesions are thickening of valvulae conniventes and small, discrete aphthoid ulcers. In more severe disease, cobblestoning, fissure ulcers, and thickening of the wall occur (Fig. 1). Longitudinal ulcers may also occur but these are uncommon. Areas of stenosis and dilatation may be present, and sinus tracts and fistulas may be demonstrated. Asymmetry of the bowel is often present, although this may be an unreliable sign. The abnormal segment of the intestine is usually well demarcated from the normal bowel.

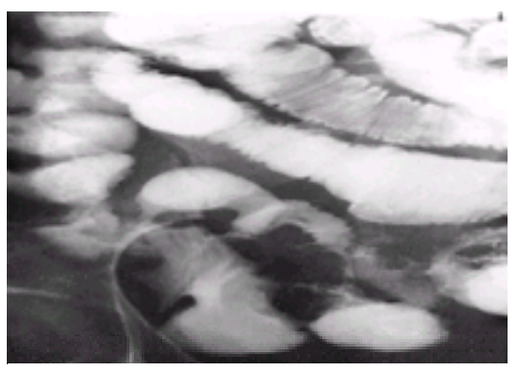

Fig. 1 Small-bowel enema demonstrating Crohn's disease of the terminal ileum with fissure ulcers, ileocaecal fistulas, and partial obstruction. (By courtesy of Dr D.J. Nolan.)

Radiological examination of the colon is made with a double-contrast barium enema after a thorough but gentle preparation. Characteristically there is rectal sparing but the appearances of Crohn's colitis are otherwise similar to those described for the small intestine (Fig. 2). Table 3 lists the main features that differentiate the radiological appearances of Crohn's colitis from ulcerative colitis. The barium enema is a good means of showing internal fistulas and fistulas to other organs.

Fig. 2 Barium enema showing Crohn's disease of the colon and terminal ileum. Distal sigmoid, rectum, and a segment of ascending colon are normal. The diseased segments show loss of haustration, shortening, and fissure ulcers. (By courtesy of Dr D.J. Nolan.)

If fistulas to the surface are present, sinograms should be taken to delineate the anatomy.

CT scans may be helpful in detecting intra-abdominal abscesses and also thickened loops of intestine. Magnetic resonance scans are particularly useful for visualizing peranal and perirectal fistulas, which often migrate between and through the sphincters and arbonize through the levator muscles.

Endoscopy

Sigmoidoscopy and rectal biopsy should be done in all patients. The rectal mucosa is frequently normal but may show a granular proctitis and occasionally the typical appearances of Crohn's disease. Nevertheless, histological examination of a rectal biopsy specimen from a macroscopically normal rectum often shows an inflammatory infiltrate, which is often focal and may contain granulomas. The indications for colonoscopy are: (i) to examine the colon and obtain biopsies in suspected cases where the barium enema is normal or equivocal; (ii) to obtain biopsies from strictures; (iii) to obtain biopsies when the differential diagnosis is in doubt; and (iv) to assess activity and extent of disease in symptomatic patients when there is little clinical evidence of activity. A further advantage of colonoscopy is that biopsies can often be obtained from the terminal ileum.

Endoscopically the earliest lesion of Crohn's disease is a small aphthoid ulcer surrounded by normal mucosa with a normal vascular pattern. This contrasts with the erythema and loss of vascular pattern seen in ulcerative colitis. In more severe disease the mucosa becomes oedematous and is penetrated by fissuring ulcers to give a cobblestone appearance. The ulcers are often linear and may eventually become confluent. A diffusely inflamed, granular, friable, and dark-red mucosa is more typical of ulcerative colitis, although discrete ulceration may occur in severe cases. Pseudopolyps and mucosal bridges occur in both diseases.

Multiple biopsies should be taken, even from apparently normal areas of mucosa, because granulomas may be present, which allows a precise diagnosis to be made.

Upper gastrointestinal endoscopy is not routinely required in these patients and is only indicated in the presence of appropriate symptoms or if abnormalities are noted on a barium meal. Although Crohn's disease of the stomach or duodenum may occur as an isolated phenomenon, most cases are associated with disease elsewhere in the gastrointestinal tract. Deep, longitudinal ulcers may occur in the stomach together with rugal hypertrophy and a cobblestone appearance. In the duodenum the major differential diagnosis is duodenal ulcer, but there is usually a 'cobblestone' mucosa surrounding the frank ulceration. Biopsies are usually helpful, although granulomas are found infrequently.

Examination of the small intestine is now possible using a push-type or sonde-type enteroscope (see Chapter 14.3.1). This is an expensive, lengthy procedure and, for these reasons, it is unlikely to become widely available. Nevertheless, it may be helpful for patients in whom the diagnosis is suspected but in whom the small-bowel enema is not diagnostic.

Laboratory data

Anaemia is common and is often due to mixed deficiencies. Iron deficiency from intestinal blood loss is the most common cause but serum folate and vitamin B_{12} concentrations may also be low. The blood film and mean corpuscular volume may therefore show microcytosis or macrocytosis. Serum ferritin is the best indicator of iron stores in those patients with chronic disease. A neutrophil leucocytosis is usually, but not invariably, associated with active disease and there may also be a thrombocytosis. The total lymphocyte count and the absolute number of circulating T lymphocytes may be reduced.

Hypokalaemia is associated with severe diarrhoea and the plasma urea concentration is often low, reflecting a poor dietary intake of nitrogen. Serum albumin is reduced in the presence of active disease, largely due to down-regulation of albumin synthesis by cytokines such as interleukin 1 (**IL-1**), tumour necrosis factor, and IL-6, but studies using albumin labelled with chromium-51 often demonstrate a protein-losing enteropathy. Serum immunoglobulins are normal or mildly elevated and there may be a rise in the a_2-globulins. A low serum calcium, when corrected for albumin, is unusual unless there is extensive small-bowel disease, and a low urinary calcium is more likely to reflect a poor diet rather than osteomalacia. Liver function tests are frequently abnormal, usually consisting of mild elevations of the aspartate transaminase and alkaline phosphatase. Persistence of abnormal liver tests suggests associated liver disease and should be investigated by liver biopsy and visualization of the biliary tree. Patients with extensive ileal disease or with ileal stricture may have increased faecal fat excretion. This is usually secondary to bacterial overgrowth rather than loss of absorptive surface, and is compounded by the low circulating pool and increased excretion of bile salts, which is often present in patients with long-standing ileal disease. It is important not to miss magnesium, zinc, and selenium deficiencies, which are occasionally present.

Diagnosis

This may be delayed for several years. Intermittent abdominal symptoms and diarrhoea without systemic symptoms are often labelled as an irritable bowel syndrome. Weight loss, fever, and anaemia without gastrointestinal symptoms are another source of misdiagnosis. The diagnosis of Crohn's disease in children may be considerably delayed when it presents as failure to thrive or delayed puberty but without gastrointestinal symptoms.

Even when the clinical diagnosis seems sound, all patients must have: (i) stool examination to exclude pathogens; (ii) sigmoidoscopy and rectal biopsy—characteristic features (such as granuloma) may often be present in the biopsy specimen even when the mucosa is macroscopically normal; (iii) radiographs of the small and large intestine to confirm the diagnosis and establish the extent of the disease; and (iv) colonoscopy with multiple biopsies is indicated where the above investigations are equivocal or normal and there are strong clinical reasons for suspecting Crohn's disease. Colonoscopy should also be done if the differential diagnosis is in doubt or if strictures are present.

Differential diagnosis

Few patients with an acute ileitis and a clinical picture of acute appendicitis subsequently develop Crohn's disease. Serological examination helps to diagnose those cases caused by yersinia; the aetiology of the remainder is unknown. The main differential diagnosis of ileal Crohn's disease is tuberculosis, especially when the disease occurs in patients from areas where intestinal tuberculosis is common. Laparoscopy may be helpful if serosal tubercles are present, as biopsies can be taken from them and cultured. Stool culture and circulating antibodies to mycobacteria are unhelpful. Colonoscopy with multiple biopsy specimens may be helpful. If genuine doubt exists, corticosteroid therapy for Crohn's disease must be covered with antituberculous therapy. Other differential diagnoses include abdominal lymphoma, a-chain disease, actinomycosis, amyloid, Behçet's disease, and carcinoma of the small bowel.

The major differential diagnosis of Crohn's colitis is ulcerative colitis (Table 3). Crohn's disease should also be considered in patients presenting with proctitis, as 30 per cent of patients with ileal Crohn's disease may have a proctitis and may present in this way. When a segmental colitis occurs, ischaemia, tuberculosis, and lymphoma have to be excluded. Young adults may present with an acute segmental colitis, which is self-limiting. The cause is unknown, although in women, oral contraceptives have been implicated. Crohn's disease can be overlooked on the barium enema when it occurs in association with severe diverticular disease.

As indicated above, Crohn's disease may have to be considered in the differential diagnosis of a fever with weight loss, malabsorption, and delayed development.

Assessment of activity

There is no satisfactory method of assessing activity of the disease and this poses a major clinical problem. Symptoms such as fever or continuing weight loss are obvious indicators, but severe disease can be present in the absence of any major symptom. Laboratory evidence of activity includes a reduced serum albumin, and a rise in acute-phase reactants (C-reactive protein, orosomucoid) and in the erythrocyte sedimentation rate. Recently, a number of activity indices have been developed in order to standardize assessment for the purpose of multicentre studies, two examples being the American Crohn's disease activity index and the Dutch activity index. However, they are mostly too complex for normal clinical use. Furthermore, they tend to measure different aspects of disease activity. At present it is worth remembering that disease activity can be assessed by the clinical picture (symptoms and signs), morphologically (for example by radiography or endoscopy), and by laboratory indices. Another technique for the assessment of activity is the use of indium-labelled neutrophils. The labelled cells preferentially migrate to inflamed mucosa and the increased uptake of isotope can be detected using a g-camera (Fig. 3). Faecal excretion of the labelled cells can also be quantified and this has shown good correlation with the Crohn's disease activity index and albumin loss.

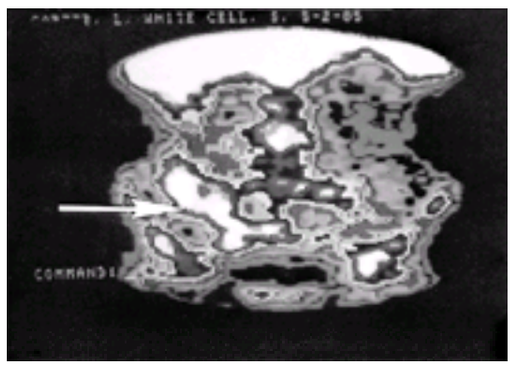

Fig. 3 A neutrophil scan labelled with indium-111 in a patient with active Crohn's disease. Active inflammation in distal ileal loops is well shown (arrow).

Labelling neutrophils with technetium-99 using hexamethyl propylene amine oxime (HMPAO) as a chelator is gradually replacing indium because it is easier, quicker, and less expensive. It appears to provide similar sensitivity and specificity but it cannot be used to assess faecal excretion of neutrophils.

Management

The management of Crohn's disease involves a team approach between physician and surgeon and includes nutritional support, medical therapy, and surgical treatment.

Nutritional support

For most patients, a well-balanced diet should be advised. A low-residue diet should be used for patients with strictures and a low-fat diet may be helpful for those with a steatorrhoea. Some centres claim good long-term results with elimination diets, but the value of this approach for all patients is far from proven. A lactose-free diet is obviously indicated for those with hypolactasia.

Iron and vitamin B_{12} deficiencies are common and need to be excluded. In patients with chronic active disease, the serum iron, binding capacity, and ferritin may all be low, making it difficult to know whether the anaemia is due to iron deficiency or to chronic inflammation. However, if the serum iron is less than 10 per cent of the iron-binding capacity it is reasonable to diagnose iron deficiency and treat accordingly. Many patients are intolerant of oral iron and for these a total-dose intravenous infusion is the best form of treatment. Patients with extensive small-intestinal disease may develop deficiencies of the fat-soluble vitamins (A, D, E, K). Deficiencies of folic acid and B vitamins may also occur because of poor dietary intake. Parenteral nutrition is often indicated for seriously ill patients who are being prepared for surgery or who have a short bowel syndrome.

Drug therapy

Active disease

In general, Crohn's disease is only treated if it is causing symptoms; there is no indication for treatment in asymptomatic patients. Active disease can usually be controlled with corticosteroids, the dose and route depending on the severity of the disease. Severe disease requires admission to hospital and treatment with intravenous prednisolone (60 to 80 mg daily) or hydrocortisone (400 mg daily), together with fluids and electrolytes. Most patients settle within 5 to 7 days and can then be given prednisolone orally (for example 40 mg daily). Patients with less severe disease can be treated with 20 to 40 mg of prednisolone daily. There is no defined duration of corticosteroid therapy but most patients will have made a good symptomatic response by 4 to 6 weeks; the dose can then be reduced over the next 3 to 6 weeks and finally stopped.

Active disease can also be treated with liquid diets. Elemental diets have been repeatedly shown to be as effective as prednisolone in controlling active Crohn's disease, but the major problem is one of compliance. Some patients intubate themselves at night with a fine-bore nasogastric tube and feed themselves during sleep. Polymeric diets may be as effective as elemental diets and are certainly more palatable. If an individual patient responds well and is willing to carry on with the diet, it should be continued until symptoms have settled and the laboratory indicators of inflammation have returned to normal. Experience then differs as to the course of the disease once normal food is introduced. Some data suggest that relapse occurs more rapidly than if remission has been achieved by the use of corticosteroids.

There is some evidence that antibiotics can be useful in treating active disease (for example metronidazole, ciprofloxacin, or clarithromycin), but the controlled trials are small and many are only published in abstract. However, they are often indicated to treat bacterial overgrowth, perianal sepsis, or abscesses associated with fistulas. Randomized controlled trials of antimycobacterial regimens have failed to confirm the optimism of anecdotal series.

The role of 5-aminosalicylic acid drugs for treating active disease is unclear. Using high doses of mesalazine (4 g daily), the initial trial showed benefit after 12 to 16 weeks but this has not been confirmed in subsequent trials. Meta-analysis of all trials shows no overall benefit compared with placebo.

Chronic active disease

There is good evidence from several trials, supported by meta-analysis, that azathoprine (2.0 to 2.5 mg/kg) or 6-mercaptopurine are effective treatment for steroid-dependent or steroid-resistant disease, although they act slowly and it may take up to 16 weeks before an effect is seen. Furthermore, both drugs are effective maintenance therapy in those patients who respond well. Retrospective studies suggest they maintain their effect over 4 to 5 years without inducing long-term side-effects. About 15 per cent of patients are unable to tolerate the drug (mostly because of gastrointestinal symptoms, myalgia, and occasionally hepatitis). Acute pancreatitis is rare. Bone marrow suppression is also rare and is confined to those who are homozygous for a deletion in the gene encoding the thiopurine methyl transferase enzyme (approximately 1 in 300 of the population). Interestingly, patients who develop nausea, diarrhoea, or myalgias on azathioprine are frequently able to tolerate 6-mercaptopurine. For patients failing to respond, or who are intolerant of these drugs, methotrexate may induce a response in two-thirds as shown by a clinical trial and by open series. In the trial, 25 mg of methotrexate by weekly intramuscular injection was used, but open series suggest a similar response when it is given orally. Recently, monoclonal antibodies to tumour necrosis factor have been developed. Infliximab is now licensed as a single infusion for chronic active disease unresponsive to steroids and immunosuppressants. It is an IgG1 chimeric antibody containing 75 per cent human immunoglobulin. A dose of 5 mg/kg by slow intravenous infusion over 2 h appears to give maximal response and this occurs in about 70 per cent of cases. Endoscopic healing can be shown but the response is usually temporary and, after a few months, patients begin to relapse. Side-effects are few (nausea, headaches, and rarely, infusion reactions can occur) but about 12 per cent of patients develop antibodies to double-stranded DNA, probably secondary to apoptosis induced by the antibody.

Maintenance of remission

There is no good maintenance therapy for Crohn's disease. The 5-aminosalicylic acid drugs have very little effect if remission has been induced by medical therapy, although high doses (3 g daily) can delay recurrence following surgical resection. However, eight such patients need to be treated to prevent one recurrence over a 5-year period. As described above, azathioprine and 6-mercaptopurine are effective long-term in steroid-dependent patients who make a good initial response to immunosuppression. Undoubtedly the best maintenance therapy is to stop patients smoking—that is associated with a more benign course and lower recurrence rates following surgical resection.

Osteoporosis

Many patients at the time of diagnosis have reduced bone density (chronic inflammation, poor nutrition) and this can be exacerbated subsequently if frequent courses of corticosteroids are required to control active disease. Dual energy X-ray absorptiometry (DEXA) scans should be obtained in patients with long-standing

troublesome disease, and appropriate treatment begun (see Chapter 19.4).

Surgery

The majority of patients (70 to 80 per cent) will require at least one operation during the course of their disease. Indications for surgery include failure to respond to medical therapy, strictures causing mechanical obstruction, fistulas, and other complications such as abscess and perforation.

If surgery is required, the following principles apply. Resection should be limited to removing the most severely affected segment and an end-to-end anastomosis should be made, even if there is some inflammation in the tissue being anastomosed. Wide resections have not been shown to diminish the subsequent recurrence rate. Bypass procedures (such as ileotransverse colostomy) should not be done. If surgery is for internal fistulas, nutrition must be corrected, infection controlled, and active disease controlled with steroids before the operation. The anatomy of the fistulas must also be determined by sinograms or by CT scans or MRI. The fistula is excised together with the segment of affected intestine and the subsequent anastomosis is usually best protected with a temporary ileostomy. For colonic disease, the choice is a conservative operation of a split ileostomy or a proctocolectomy with terminal ileostomy. Colectomy with ileorectal anastomosis is associated with a high recurrence rate. Defunctioning the colonic disease with an ileostomy often allows the disease to settle and the patient's nutritional state to be restored. In Oxford, our practice is to reconnect after 12 to 18 months and the majority of patients then remain well. However, other clinicians claim a rapid relapse following restoration of continuity and will only use a split ileostomy as a means of getting patients fit for more radical surgery.

Perianal disease is common, both in ileal and colonic Crohn's disease. It may consist of simple fissures but, more frequently, consists of complex fistulas with abscess formation. Management has to include demonstration of the anatomy (e.g. a pelvic MRI scan), drainage of abscesses, control of infection and suppression of disease activity. The use of setons has been a major advance in allowing fistulas to heal by providing effective drainage and they can be kept in for months. Immunosuppression with thiopurines may allow some degree of healing but, recently, infliximab has been highly effective. In a randomized clinical trial, two-thirds of patients assigned to infliximab closed their fistulas, significantly more frequently than a placebo infusion. However, MRI scans have shown persistent fistula tracks even though the cutaneous orifice heals. Thus, it is not surprising that the apparent 'healing' is usually only temporary. Nevertheless, infliximab (usually an infusion of 5 mg/kg) at 0, 2, and 6 weeks) has been a major advance in the overall management of fistulas.

Some patients with small-intestinal disease present with multiple short strictures. Once active disease is controlled with corticosteroids, the strictures should be dealt with by stricturoplasty rather than by multiple resections. This gives good symptomatic relief and it is unusual for further stricturing to occur at sites of previous stricturoplasties. This conservative approach has greatly reduced the need for repeated resections and has therefore minimized the chances of a short bowel syndrome.

Management during pregnancy

Crohn's disease should be treated in the pregnant woman along the lines outlined above. Overall, the outcome of the pregnancy is not influenced by the disease except in very severe cases where there may be an increased risk of abortion. Corticosteroids and sulphasalazine are safe to use and have not been associated with fetal abnormalities. Likewise, azathioprine has not been clearly demonstrated to be teratogenic and can be used if there is sufficient clinical indication. Methotrexate is known to be teratogenic and is therefore completely contraindicated for women who are trying to conceive or who are pregnant.

Management in children

There is no essential difference in the principles of management from those described for adults, although dosages may need to be reduced. Alternate-day steroids should be employed, especially if long-term treatment seems likely. Excellent but uncontrolled results have been reported in adolescents using maintenance corticosteroids, as an alternate-day regimen, which allowed puberty and growth to develop normally. One of the major effects of the disease in children is growth retardation. Corticosteroid therapy often promotes a growth spurt but great emphasis should be paid to the child's nutrition. Dietary intake should be assessed and supplemented to provide a high-calorie, high-nitrogen intake. Many paediatric gastroenterologists use elemental or polymeric diets as first-line therapy for active disease, often administered via a percutaneous gastrostomy.

Course and prognosis

Patients are never cured of Crohn's disease and they are subject to relapses of their disease and to recurrence following surgical resection. Most patients (70 to 80 per cent) will receive surgical treatment at some point during the course of their illness. After a resection, the disease recurs in about 30 per cent of patients during the subsequent 5 years and in 50 per cent of patients during the subsequent 10 years; of these, half will require further surgery. Although there is still some controversy, the balance of evidence suggests that the risk of requiring second or third operations is no greater than the risk of requiring the initial operation. Patients with Crohn's colitis who have a proctocolectomy appear to have a lower risk of recurrence than those who have an ileal or ileocolic resection.

Recent endoscopic visualization of the neoterminal ileum has shown that the recurrence rates, when assessed by endoscopic appearance, are even higher than the rates quoted above, which are based on symptoms. For patients who have had an ileal or ileocolic resection, 70 to 80 per cent of them will show endoscopic lesions just proximal to the anastomosis within the first postoperative year. The more severe lesions, such as aphthoid ulcers, predict a high chance of symptomatic recurrence. Mesalazine has been shown to have no influence on the endoscopic recurrence rate and it remains to be seen whether steroid compounds with low systemic bioavailability (such as budesonide) will be effective in this context without inducing systemic side-effects.

The overall mortality of Crohn's disease varies from 10 to 15 per cent in different studies. Some of these reports have suggested a worse prognosis for women than for men, and for patients over the age of 50 years, although this was mainly associated with higher operative mortality. Overall, age and gender probably have little influence on the outcome of the disease. The Oxford experience has suggested that mortality is not appreciably increased during the first 15 years of the disease but then becomes progressively greater during subsequent follow-up. In contrast, however, data from Birmingham suggest that the highest mortality occurs in young people during the early stages of the disease.

In general, most patients with Crohn's disease will have a good prognosis with a mortality of only about twice that expected. Considerable morbidity can be expected but this will be intermittent and the overall quality of life should be good.

14.11 Ulcerative colitis

D. P. Jewell

Ulcerative colitis is a chronic inflammatory disease of the colon of unknown cause. It always affects the rectum and extends proximally to involve a variable extent of the colon. It is characterized by a relapsing and remitting course.

The disease was first described in 1859 by Samual Wilks, a physician at Guy's Hospital, who recognized that 'simple, idiopathic colitis' could be distinguished from other forms of colitis, mainly bacterial dysentery. It took many years for the concept to be accepted, but finally, in 1931, Sir Arthur Hurst was able to give a complete description of the disease including the sigmoidoscopic appearances. Nevertheless, he still considered the disease to be primarily infective, even though its chronic nature might be induced secondarily by other factors.

Epidemiology

Ulcerative colitis is a worldwide disease, although it may be difficult to diagnose in areas where infective colitis is prevalent. Accurate figures for incidence and prevalence are not universally available but the disease is now recognized in most countries. Table 1 lists data for the high-incidence areas and also shows that there have been no trends to suggest the disease is becoming more common, which is in contrast to Crohn's disease. The low-incidence areas include Eastern Europe, Asia, Japan, and South America where the incidence rates are at least tenfold less.

The age of onset peaks between 20 and 40 years but the disease may present at all ages from the first few months of life to the 80s. Some series show a secondary peak of onset in the 60- to 70-year-old age group, but this has not been a universal finding. Earlier series suggested a predominance of the disease in women, but more recently, there has been little difference between the sexes.

Both in the United States and Cape Town, Jews are more prone to ulcerative colitis than non-Jews by a factor of 3 or 4. Within Israel, Ashkenazi Jews have a higher incidence than Sephardim but it is still less than the incidence in Jews in the United States or, indeed, than the European incidence. This suggests that environmental factors may be involved in addition to genetic factors. However, the differences in incidence between urban as opposed to rural communities or between different socio-economic groups have been slight and inconstant.

Genetics

The familial incidence of ulcerative colitis has long been recognized, with 10 to 20 per cent of patients likely to have at least one other family member affected either with ulcerative colitis or with Crohn's disease. Most of the familial association is within first-degree relatives, but there is controversy about the precise relation, with a preponderance of parent–sibling combinations being found in the United States, whereas in the United Kingdom the disease is more commonly shared by siblings. Within a multiply-affected family there is a high degree of concordance for disease characteristics (for example extent, severity, presence of extraintestinal manifestations).

A study of twin pairs in Sweden showed that of 16 pairs of monozygotic twins in whom one member had ulcerative colitis, only one pair was concordant for the disease whereas all 20 dizygotic twins were discordant. This gave a proband concordance rate of 6.3 per cent, which is very much lower than 45 per cent for Crohn's disease.

This low concordance rate might suggest that familial clustering reflects environmental influence rather than inherited genetic susceptibility. However, the incidence of ulcerative colitis in spouses of probands is extremely low, although, of course, that does not exclude environmental factors operating early in life.

The mode of inheritance is unknown, but as with Crohn's disease, multiple genes are probably involved in determining disease susceptibility and its behaviour. Studies of multiply-affected families, using microsatellite technology, have demonstrated linkage to chromosome 12 and, less strongly, to chromosomes 3 and 7. These susceptibility loci are shared by patients with Crohn's disease although some evidence suggests that the locus on chromosome 12 contains two separate genes, one for ulcerative colitis and a second for Crohn's disease. In most studies, ulcerative colitis is more strongly linked to chromosome 6p (the HLA region) than Crohn's disease. Study of individual HLA alleles has shown that possession of HLA DR103 is likely to be associated with severe disease. In Japan and in the Jewish population of California, the disease is associated with HLA DR1502 (an allele of DR2 common in these populations but very uncommon in Europeans). The occurrence of extraintestinal manifestations also appears to be related to genetic make-up. For example, patients who develop a reactive, large joint arthropathy in association with active disease are likely to possess the HLA DR103 allele (35 per cent) compared with patients who do not (8 per cent) or healthy controls (3 per cent). In contrast, the small joint, seronegative arthropathy is associated with HLA B44 (77 per cent) and MICA-8 (98 per cent). Nevertheless, it is not possible to be

sure on the basis of present knowledge whether these associations are biologically meaningful or whether they represent linkage disequilibrium with a nearby gene.

Aetiology

The cause of the disease remains unknown. The main hypotheses that have been proposed include infection, allergy to dietary components, immune responses to bacterial or self-antigens, an abnormality in epithelial cell integrity, and the psychosomatic theory. There are virtually no data to support a primary role for psychosomatic factors in the aetiology of the disease, although they may play a secondary role in determining the pattern of symptoms and must always be considered when managing individual patients.

Infection

No specific infective organism has been consistently isolated from patients with ulcerative colitis. However, the recognition that the strains of *Escherichia coli* in the normal colon are continually changing has led to the concept that patients may carry strains which, by releasing enzymes or other toxic products, might damage the mucosa. The demonstration that, even in remission, patients with ulcerative colitis are more likely to harbour *E. coli* expressing adhesins than control subjects is a particularly interesting observation, as these may allow the bacteria to adhere readily to the epithelium. The role of sulphate-reducing bacteria is also of interest as these organisms are found more commonly in those with colitis. They reduce sulphate to sulphide which, in turn, inhibits butyrate oxidation in epithelial cells. Several investigators have demonstrated reduced activity of butyrate dehydrogenase within colitic epithelium, even in remission, raising the possibility that luminal bacteria may have a deleterious effect on epithelial cell metabolism and, hence, integrity.

Food allergy

The early suggestions of allergic responses to milk proteins, eggs, and other dietary proteins have not been substantiated as an aetiological factor. Milk-free diets may be beneficial in a minority of patients but it is not clear whether this results from an associated hypolactasia, an immunological response, or some other mechanism. The failure of ulcerative colitis to respond either to intravenous nutrition avoiding oral food or to colonic isolation by means of a split ileostomy are further pointers that dietary factors play little part.

Environmental factors

As well as infection and diet, smoking and the use of oral contraceptives may influence disease. Many studies have now shown that ulcerative colitis is more common in non-smokers than smokers, with a relative risk of 2 to 6. Ex-smokers have a particularly high incidence and this is highest for former heavy compared with light smokers. Women taking oral contraceptives may have a slightly increased risk of the disease but this association is weak and loses significance when the data are corrected for smoking habits and social class.

Immunopathogenesis

The intense infiltration of the inflamed mucosa with plasma cells, B and T lymphocytes, and macrophages suggests immunological activity. Whether activation of both humoral and cellular immune mechanisms merely reflects increased antigenic absorption through an abnormal epithelium, a response to a specific aetiological agent, or an underlying defect in mucosal immunoregulation is unknown.

There is an increase in plasma cells synthesizing all three of the major immunoglobulin isotypes—IgA, IgG, and IgM. However, the largest proportional increase is in IgG-producing cells and this is predominantly of the IgG1 and IgG3 subclasses, which is in contrast to Crohn's disease where an IgG2 response is predominant. IgG1 and IgG3 are synthesized in response to protein antigen and are effective in fixing complement. Complement activation is known to occur in active colitis, probably as a result of the formation of antigen–antibody complexes, and is likely to be one of the principal effector mechanisms in establishing the inflammatory lesion. Some of the increased mucosal IgG synthesized is known to have antibody specificity for bacterial and epithelial antigens. As antibody to epithelial antigens, especially a 40-kDa protein, is a feature of ulcerative colitis, rather than Crohn's disease, it is possible that autoimmunity plays a part in ulcerative colitis. This concept is strengthened by the association with other autoimmune disorders and with circulating antibodies to neutrophils (pANCA), neither of which is associated with Crohn's disease. Nevertheless, whether anticolon antibodies or pANCA have a pathogenetic role is still very uncertain.

The main subsets of T cells (CD4+, CD8+) are present in increased numbers in the inflamed mucosa but their proportions do not change significantly. Several lines of evidence suggest that the T cells are activated and release a variety of cytokines. Whether there is a failure of T cells to either upregulate or downregulate the mucosal immune response has not been clearly shown. However, data suggest that there may indeed be a failure to induce suppression to specific antigens, which could lead to some of the immunological overactivity that is observed in this disease. Intraepithelial T lymphocytes isolated from colons resected for severe ulcerative colitis also fail to suppress T-cell proliferative responses to specific antigens, a property that is not due to the increased numbers of intraepithelial T lymphocytes using g† T-cell receptors.

As well as T-cell activation, there is also a marked increase in the population of activated macrophages, which not only release inflammatory mediators (reactive oxygen metabolites, leukotrienes, platelet-activating factor) but serine proteases, metalloproteinases, and cytokines. The release of interleukin 1 (**IL-1**), IL-6, and tumour necrosis factor will not only lead to tissue damage but will initiate an acute-phase response, downregulate albumin synthesis, and induce fever. Release of interferon-g from activated T cells induces HLA class II molecules on colonic epithelial cells, which, in turn, are then able to present antigen to the adjacent CD4+ lymphocytes and to activate the CD8+ intraepithelial T lymphocytes. Changes in epithelial permeability induced by interferon-g and inflammatory mediators, endothelial damage by a wide variety of cytokines and mediators leading to local ischaemia, and stimulation of collagen synthesis by transforming growth factor-b, IL-1, and IL-6 may all contribute to the inflammatory process.

Pathology

Macroscopic

Ulcerative colitis always involves the rectum but in about 40 per cent of patients the disease is limited to the rectum and sigmoid. In adults, only about 20 per cent will have the whole colon involved, although this proportion rises to about 50 per cent in children. In mild disease, the mucosa is hyperaemic and granular, but as the disease becomes more severe, small punctate ulcers appear, which may then enlarge and extend deeply into the lamina propria. The ulceration may be linear along the line of the taeniae coli. The mucosa can become intensely haemorrhagic. In patients with long-standing disease, inflammatory polyps (pseudopolyps) may develop. They are usually found in the colon and rarely in the rectum. Inflammatory polyps are of no significance and have no malignant potential. In occasional patients, they may regress.

When the disease goes into remission, the colonic appearances may return to normal, but, especially in patients who have had recurrent attacks, the mucosa becomes atrophic and featureless. There is often narrowing and shortening of the bowel. Fibrous strictures complicating long-standing chronic disease are extremely rare.

If an acute dilatation occurs in a patient with severe disease, the bowel becomes thin and congested. There is usually severe ulceration, with only small islands of mucosa remaining. An acute dilatation may be accompanied by a perforation.

Microscopic

The inflammation of ulcerative colitis is largely confined to the mucosa. The lamina propria becomes oedematous, with dilated and congested capillaries, and extravasation of red blood cells. There is a cellular infiltrate of acute and chronic inflammatory cells: neutrophils, lymphocytes, plasma cells, macrophages, mast cells, and eosinophils.

The neutrophils invade the epithelium, usually in the crypts, giving rise to a cryptitis and eventually to a crypt abscess. The triggers for this migration of neutrophils are unknown, but chemotactic peptides of colonic bacteria (for example formyl methionyl leucyl phenylalanine) as well as IL-8, leukotriene B4, platelet-activating factor, and activated complement are potential candidates. Damage to the crypts leads to increased epithelial cell turnover and a discharge of mucus from goblet

cells. With increasing inflammation, the surface epithelial cells become flattened, irregular, and eventually ulcerate. Deep ulcers may extend into the lamina propria, leading to inflammatory changes in the submucosa—this may be accompanied by an acute dilatation or perforation.

Many of the acute changes of ulcerative colitis are non-specific and may also be seen in infective colitides. However, the diagnosis of ulcerative colitis can be made with some accuracy (more than 80 per cent probability) if features of a chronic inflammatory process are present. These include distorted crypt architecture, crypt atrophy, basal lymphoid aggregates, and a chronic inflammatory infiltrate.

Once the disease has gone into remission, the histological appearances may return to normal. However, there is frequent evidence of bifid or shortened crypts, hyperplasia of the muscularis mucosae, neuronal hypertrophy, and Paneth-cell metaplasia at the base of the crypts.

Clinical features

Patients usually present with a gradual onset of symptoms, often intermittent, but which become progressively more severe. Occasionally, ulcerative colitis can present much more rapidly and may mimic an infective colitis. Indeed, some patients begin with a documented infection (such as a campylobacter or salmonella colitis) but continue to have symptoms that ultimately lead to the correct diagnosis.

The principal symptoms include diarrhoea, rectal bleeding, the passage of mucus, and less frequently, abdominal pain. When the inflammation is confined to the rectum (proctitis), patients often pass fresh blood, which is usually mixed with the stool but can be streaked on the surface. These patients often complain of constipation rather than diarrhoea and, on clinical symptoms alone, may be mistakenly diagnosed as suffering from haemorrhoids. When the inflammation extends beyond the rectum, there is usually diarrhoea with the passage of partly altered blood. The diarrhoea is often accompanied by urgency and tenesmus, and patients can be incontinent. Nocturnal diarrhoea is a common symptom in the presence of severe inflammation. With a severe ulcerative colitis affecting most or all of the colon, patients are usually anorexic, nauseated, and have lost weight. They usually have severe diarrhoea (in excess of six motions daily) that becomes a slurry of faecal material, pus, and blood—it may resemble anchovy sauce and, indeed, some patients may fail to recognize that they are passing blood.

Patients may also complain of malaise, lassitude, and symptoms referable to chronic iron deficiency or to some of the extraintestinal manifestations, especially recurrent aphthous ulcers of the mouth.

On examination, patients with mild or moderate attacks usually look well and exhibit few abnormal physical signs. Weight should always be recorded and, for children and adolescents, both height and weight should be recorded on growth charts. Abdominal examination may reveal a tender colon but is often normal. Bowel sounds are normal and rectal examination is also normal apart from blood.

Patients with a severe attack may also look deceptively well and a tachycardia or a tender colon may be the only abnormal signs. However, many of these patients are obviously ill, with fever, salt and water depletion, anaemia, and evidence of weight loss. There may be oral candidiasis, aphthous ulceration, signs of iron deficiency, and finger clubbing. The skin changes of hypoalbuminaemia and dependent oedema may occur. The abdomen is often distended and tympanitic, with reduced bowel sounds and marked colonic tenderness.

Minor perianal disease, such as a fissure, may occur in patients with an active ulcerative colitis but it is never as severe as is seen in patients with Crohn's disease.

Assessment of disease severity

This can be done clinically, by grading the degree of inflammation seen endoscopically or histologically, and by using laboratory tests of inflammatory activity.

Clinical grading

1. Mild—there are less than four stools daily, with or without blood, with no systemic disturbance and a normal erythrocyte sedimentation rate.
2. Moderate—this is between mild and severe.
3. Severe—there are at least six stools daily, with bleeding, and evidence of systemic illness as shown by fever, tachycardia, a falling haemoglobin, hypoalbuminaemia, and raised erythrocyte sedimentation rate and C-reactive protein.

Laboratory markers of inflammation

Active disease is often accompanied by a neutrophil leucocytosis, thrombocytosis, and a rise in acute-phase proteins (C-reactive protein, oroso-mucoid) and in erythrocyte sedimentation rate. There may also be a fall in haemoglobin and albumin levels. These inflammatory markers are useful when measured serially during the course of treatment as an indicator of disease activity. However, if corticosteroids are used, the white cell count can no longer be used as a marker of disease activity because it will often rise in response to the steroids. Patients with a proctitis rarely have a rise in C-reactive protein unless the inflammation is particularly severe.

Diagnosis

The diagnosis is made on the basis of the history, the absence of faecal pathogens, and the endoscopic and histological appearances of the colon.

Stool cultures should be set up for all patients presenting for the first time and, ideally, for all those presenting with a relapse of established disease. Special culture conditions are required for campylobacter, yersinia, gonococci, and *Clostridium difficile*. The possibility of an infection with *E. coli* 0157 must also be considered, especially in patients in whom bleeding and abdominal pain are predominant symptoms. An infective colitis with opportunistic organisms in patients with immunodeficiency syndromes has become much more common and has to be remembered in differential diagnosis.

Sigmoidoscopy is safe, even in patients with a severe attack, and not only confirms rectal inflammation but also allows a biopsy specimen to be taken and an assessment of severity to be obtained. Although some centres use colonoscopy in severe attacks, this is rarely necessary for diagnosis, for assessment of severity, or for determining management. It is best avoided in the acute stage. The earliest signs of colitis on sigmoidoscopy are blurring of the vascular pattern associated with hyperaemia and oedema, leading to blunting of the valves of Houston. With increasing severity, the mucosa becomes granular and then friable. With severe inflammation, the mucosa shows spontaneous bleeding and ulceration. These changes begin in the rectum, they are diffuse, and extend proximally to affect a variable length of the colon. Pseudopolyps (inflammatory polyps) often occur in patients with long-standing disease but tend to be in the colon rather than the rectum.

Colonoscopy with multiple biopsies is useful for assessing the extent of disease and is mandatory for patients with a colonic stricture. It is also required for cancer surveillance (see later). Preparation of the colon should follow the normal methods and osmotic purgation is the most satisfactory. However, a more gentle approach is needed if colonoscopy is done in the presence of severe inflammation, but this is rarely indicated.

All patients with a severe attack must have a plain abdominal radiograph. Not only does this exclude a dilated colon but it may provide prognostic information (mucosal islands, distended small bowel loops) and demonstrate the extent of the disease. An abnormal haustral pattern, thickening of the bowel wall, and mucosal oedema can be detected on a plain film (Fig. 1). As an inflamed colon does not hold faecal material, the presence of faecal matter in the ascending or transverse colon will indicate that the inflammation is distal. In a severe attack, barium radiography is virtually never indicated, but if it is done, a single-contrast study in an unprepared colon with barium entering the colon at low pressure should be used. In less severe disease, a double-contrast barium enema can be safely given (Fig. 2), but the colon must not be overdistended and the procedure must be stopped if the patient complains of pain.

Fig. 1 Plain abdominal radiograph of a 24-year-old man with severe ulcerative colitis. The ascending and transverse colon are grossly oedematous and diseased with loss of the normal haustral pattern. In addition, there are multiple loops of distended small intestine.

Fig. 2 A double-contrast barium enema in a patient with active ulcerative colitis. The figure is a close-up view of the splenic flexure to show extensive mucosal ulceration, loss of haustration, and narrowing of the colon. The patient also has diverticula in the descending colon.

Biopsy specimens must be taken at sigmoidoscopy or colonoscopy, preferably with small, cupped forceps. Histological assessment contributes to grading severity as well as the differential diagnosis.

Laboratory data

These are required for assessing severity, as discussed above, and to document haematological or biochemical complications.

Iron deficiency is common as a result of chronic iron loss; this can be exacerbated by a severe attack, in which 0.5 g of elemental iron can be lost. Thus, a hypochromic, microcytic anaemia is frequently present. A neutrophil leucocytosis, thrombocytosis, eosinophilia, or monocytosis may also be present and are indicators of active inflammation.

Biochemical abnormalities are rare in mild or moderate attacks, but hypokalaemia, hypoalbuminaemia, and a rise in a $_2$-globulin frequently accompany a severe attack. Minor elevations of the aspartate transaminase or alkaline phosphatase are also frequently seen in patients with a severe attack, but they return to normal when the disease goes into remission. They probably reflect a fatty liver, together with the effects of toxaemia or poor nutrition. Persistent elevation, especially of alkaline phosphatase, may indicate underlying chronic liver disease and needs further investigation (see below).

Serum immunoglobulins rarely exceed the upper limit of normal during a relapse, but usually fall as remission occurs.

Differential diagnosis

If the patient has a history of slow onset of symptoms, including blood and mucus, and has diffuse inflammation on sigmoidoscopy, the diagnosis of ulcerative colitis is highly probable. The major differential diagnosis is Crohn's disease (see Chapter 14.10). If clinical, radiological, endoscopic, and histological information is considered together, less than 10 per cent of patients fall into the category of indeterminate colitis. The recently recognized collagenous colitis usually has only a mild inflammation on colonoscopy and is diagnosed on the basis of a thickened subepithelial collagen band (wider than 15 µm) seen in a rectal biopsy specimen. Microscopic or lymphocytic colitis has a normal endoscopic appearance but shows a diffuse infiltration of the lamina propria with lymphocytes and eosinophils on histological examination. Although ischaemic colitis classically occurs around the splenic flexure, it may occur in the rectum, especially in the elderly, and can be diagnosed histologically. Radiation damage to the rectum may occur, especially in men who have had radiotherapy to the prostate.

Rarely, a drug-induced colitis may occur. The drugs that have been implicated include non-steroidal anti-inflammatory drugs, gold, penicillamine, and 5-aminosalicylic acid. The last drug may cause considerable diagnostic confusion in patients who already have ulcerative colitis. An antibiotic history must be taken but a pseudomembranous colitis secondary to *Cl. difficile* can occur in the absence of antibiotic usage, especially in the elderly.

For those patients presenting with a much more acute history, infective forms of colitis must be excluded by stool culture. A sudden onset of symptoms, the predominance of abdominal pain, the ingestion of potentially infected food (chicken, shellfish), and evidence of diarrhoeal disease in contacts are obvious pointers to an infection. Sigmoidoscopic appearances are usually very similar to ulcerative colitis but a rectal biopsy can be very useful in distinguishing an infective from a more chronic ulcerative colitis. The presence of a chronic inflammatory infiltrate, architectural disturbances of the glands, and basal lymphoid aggregates favour ulcerative colitis. The common organisms causing an infective colitis are salmonella, shigella, and campylobacter. Yersinial infections may also cause a colitis and can pursue a chronic course over many months before resolving. Special culture conditions may isolate the organism from stool, but a rising titre of serum antibody is often the more reliable method of identifying the infection. *E. coli* 0157 is a recognized cause of an acute colitis, especially in institutions, and massive bleeding is often a characteristic feature. Children may develop a haemolytic uraemic syndrome. Diagnosis is difficult because most laboratories are not equipped either to detect this strain of *E. coli* or to measure specific antibody. For patients who have travelled in endemic areas, amoebic and schistosomal colitis must be considered—stool examination and histological demonstration of amoebas or schistosomal ova in rectal biopsy specimens make the diagnosis.

Other causes of infective colitis can occur in immunosuppressed patients and include cytomegalovirus, herpes simplex, and *Mycobacterium avium intracellulare*. Although these organisms are usually associated with fairly characteristic sigmoidoscopic appearances, they can be associated with a more diffuse pattern of inflammation. Other sexually transmitted causes of proctitis (gonorrhoea, chlamydia, lymphogranuloma) do not usually cause diarrhoea and, especially with gonorrhoea, are associated with the passage of watery pus.

Ulcerative colitis also has to be differentiated from irritable bowel syndrome, colonic polyps or carcinoma, diverticular disease, solitary rectal ulcer syndrome, and factitious diarrhoea. Sigmoidoscopy usually clarifies the diagnosis, but if the ulceration of the solitary rectal ulcer syndrome becomes circumferential, this can be mistaken for ulcerative colitis. A biopsy specimen showing strands of smooth muscle radiating up into the lamina propria between the glands is characteristic of the solitary ulcer syndrome.

Extraintestinal manifestations

Table 2 lists the extraintestinal manifestations.

Skin

The most common skin rash seen in patients with ulcerative colitis is a hypersensitivity rash to sulphasalazine (related to the sulphapyridine moiety), which may be photosensitive. Erythema nodosum occurs in about 2 per cent of patients and is mostly associated with active disease. The lesions occur most commonly on the anterior aspect of the lower legs. Pyoderma gangrenosum is rare (1 to 2 per cent) and is usually seen in patients with active disease, but occasionally persists despite inactive colitis. The lesions usually begin as sterile pustules, usually on the limbs, which break down as they enlarge and finally coalesce. Ulceration leads to necrosis and the lesions become surrounded by black, necrotic tissue. Treatment of the colitis is usually followed by regression of the skin lesions.

Mouth

Crops of aphthous ulcers are common in patients with active disease. A sore tongue and angular stomatitis often accompany chronic iron deficiency.

Eyes

Episcleritis or an anterior uveitis occur in 5 to 8 per cent of patients. Local corticosteroids and treatment of active colitis usually lead to resolution.

Joints

An acute arthropathy occurs in 10 to 15 per cent of patients with active disease. It affects the larger joints (knees, hips, ankles, wrists, elbows) and is usually asymmetrical. It is a non-erosive condition and settles as the colitis goes into remission. A less common joint complication is a symmetrical small-joint polyarthropathy which is seronegative and is unrelated to the activity of the colitis.

Low back pain is a common symptom and is usually due to a sacroiliitis, which can be seen radiologically in 12 to 15 per cent of patients. It is unrelated to disease activity, is not strongly associated with HLA B27, and rarely progresses to ankylosing spondylitis. The latter disease occurs in only 1 to 2 per cent of patients and 60 per cent of these have the HLA B27 phenotype. There is a 2:1 ratio in favour of males with this complication. The spondylitis may present before the colitis becomes apparent or may follow the intestinal symptoms. Its natural history is independent to that of the colitis and should be treated with physiotherapy, hydrotherapy, and if necessary, non-steroidal anti-inflammatory drugs. However, these drugs can occasionally worsen the colitis and should therefore be used cautiously.

Liver disease

Patients with severe attacks of ulcerative colitis often have minor elevations of alkaline phosphatase or transaminases. The cause of these enzyme rises is probably multifactorial, including malnutrition, sepsis, and a fatty liver, which occurs in up to 60 per cent of patients coming to urgent colectomy. The liver enzymes return to normal activities when remission is achieved.

However, there may be persistent abnormalities in liver enzymes in about 3 per cent of patients, usually a rise in alkaline phosphatase. The overwhelming majority of these patients will have primary sclerosing cholangitis when the bile duct is visualized by endoscopic cholangiography. Histologically, liver biopsy specimens show evidence of chronic liver disease, but the spectrum of appearances ranges from those of an autoimmune hepatitis to the classic picture of concentric periductular fibrosis with obliteration of bile ducts.

Many patients with ulcerative colitis and sclerosing cholangitis remain well for many years. The colitis is often very mild, though frequently affecting the whole colon, but the liver disease is progressive and ultimately leads to portal hypertension and liver failure. Sclerosing cholangitis is a premalignant condition and explains the well-recognized association between ulcerative colitis and cholangiocarcinoma. Pathogenesis and treatment of the liver disease are discussed in Chapter 14.20.2.3.

Rare associations

Pericarditis with or without an effusion has been described in association with an acute attack of colitis but a true association is not yet proven. Autoimmune haemolytic anaemia has been reported in ulcerative colitis and may recur when the colonic disease becomes active. Amyloid rarely occurs in ulcerative colitis—it is much more likely to be associated with Crohn's disease. A rapidly progressing bronchiectasis has also been described in some patients with ulcerative colitis.

Medical management

The main principles of therapy for the treatment of ulcerative colitis are: to control active disease rapidly, to maintain remission, to select patients for whom surgery is appropriate, and to ensure as good a quality of life as possible.

Treatment of active disease

The most effective drugs for controlling active disease are the corticosteroids, which may be given systemically, topically, or in combination. Drugs containing 5-aminosalicylic acid (sulphasalazine, olsalazine, balsalaizide, mesalazine) are often used to treat a mild colitis but prednisolone has been shown to be more effective and to control symptoms more rapidly, which make it the drug of choice. The dosage and route of administration are largely governed by disease severity. Once active inflammation has been controlled and remission obtained, the corticosteroids should be tailed off because they are ineffective as maintenance therapy and prolonged use puts the patient at risk of long-term side-effects such as osteoporosis.

Proctitis

Proctitis refers to disease limited to the rectum—in practice, it refers to inflammation that does not extend beyond the limits of a rigid sigmoidoscope. It can be remarkably difficult to treat. Initial therapy is usually a 5-aminosalicylic acid drug by mouth in combination with topical therapy. The latter can be a corticosteroid or 5-aminosalicylic acid in the form of a suppository. For patients who do not respond, oral prednisolone may be given. Some have sufficiently severe proctitis to warrant intravenous steroids, and occasionally colectomy may be necessary. Many patients with a refractory proctitis develop a severe proximal constipation, which can cause considerable abdominal discomfort, bloating, and nausea. Relief of the constipation, usually by gentle osmotic purgation, will often give considerable symptomatic benefit but may also be associated with a marked improvement in the inflammation. Some patients appear to be refractory because foam or enema preparations are used: changing to a suppository allows a much higher concentration of drug in the rectum and is frequently associated with improvement in symptoms.

Mildly active disease

Patients who have no more than four motions daily on average, with inflammation extending beyond the limits of the rigid sigmoidoscope, should be given 20 mg of oral prednisolone daily, together with topical steroids or 5-aminosalicylic acid. Treatment should be given for at least 4 weeks before being tailed off over the subsequent 3 to 4 weeks. Clinical trials have shown that 5-aminosalicylic acid formulations are more effective than placebo in treating active disease, especially in high doses. However, corticosteroids achieve remission more quickly and in a higher proportion than 5-aminosalicylic acid drugs.

Moderately active disease

Patients who have, on average, more than four bowel motions daily but who are not systemically ill should be given 40 mg of prednisolone by mouth daily. Giving larger doses (such as 60 mg daily) provides only a marginally better effect but increases the frequency of side-effects quite considerably. The dose is reduced to 20 mg daily over 2 to 3 weeks and the regimen then follows that described for mild disease.

Severe disease

This is defined as an attack in which the patient has more than six bowel motions daily, with blood, and who is systemically ill as shown by tachycardia, fever, and anaemia. The colon is usually tender on palpation. These patients should be admitted to hospital and assessed by both physician and surgeon. Fluid and electrolyte losses are replaced intravenously; a blood transfusion should be given if the haemoglobin is less than 10 g/dl. Patients are given intravenous corticosteroids (such as 100 mg of hydrocortisone, 6-hourly) together with a twice daily rectal drip of hydrocortisone (100 mg in 100 ml water). Parenteral nutrition is indicated for patients who are malnourished, but for the majority, intravenous saline and dextrose–saline are sufficient, together with potassium supplements. Most patients with a severe attack prefer to have only clear fluids by mouth during the first 24 h. Thereafter, there is no evidence that a light diet has any adverse effect on the disease, but many clinicians will leave the patient on only clear fluids for the first few days.

Provided the patient is improving, treatment is continued for 5 to 7 days. At this time, a good response is one in which the patient feels well, there is no fever or tachycardia, the colon is not tender on abdominal palpation, and the diarrhoea has largely settled, usually to less than four motions daily. At this stage, the stools are rarely formed but macroscopic bleeding has stopped. These patients can then go on to oral prednisolone (for instance 40 mg daily), a retention enema, an oral 5-aminosalicylic acid drug, and a light diet. Patients who deteriorate during the first few days of intravenous treatment or those who have not made a substantial improvement by the end of the first week should be advised to have urgent surgery. The more difficult decision is when patients have made some improvement but are still not well—they may still be anorexic, have an intermittent low-grade fever, tachycardia, and continuing diarrhoea. Continuing intravenous therapy for more than 7 to 10 days is rarely beneficial and surgery is usually required. It is in this group of patients that the introduction of a light diet towards the end of the first week of treatment often provides a guide to future management. If the pulse rises or a fever develops in response to feeding, urgent colectomy is required. For the group of patients who do not make a rapid response to intravenous steroids, the addition of cyclosporin will induce remission in 60 to 80 per cent. The drug is usually given by continuous intravenous infusion (4 mg/kg), although the new oral formulation (Ne-oral) may be as effective. Intravenous cyclosporin should not be given in patients with a low cholesterol level (less than 3.00 mmol/l) as it can be complicated by fits. In these patients oral cyclosporin should be used as it is the cremaphor that is used to suspend the intravenous form that causes the fits. If cyclosporin is to be used, it should be added after 3 to 5 days of steroid therapy. Most patients respond very quickly (3 to 4 days) and thus, for those in whom surgery becomes necessary, a decision about colectomy can be made after a week or so of treatment. Those who do respond to drug therapy can be converted to oral treatment with decreasing doses of prednisolone. Practice varies between continuing oral cyclosporin for some months, changing to azathioprine, or using the two in combination. No controlled trial data are yet available to provide evidence-based guidelines.

So far, the use of cyclosporin has not been associated with major side-effects when used in the way described above, although prolonged use of high-dose steroids and cyclosporin can be associated with *Pneumocystis carinii* pneumonia. Minor, reversible side-effects are frequent with long-term use of oral cyclosporin.

Approximately 25 per cent of patients with a severe attack will require an urgent colectomy. These patients can often be identified early on using clinical and radiological features, which have been shown to have prognostic significance. These are the passage of more than nine stools daily, a pulse rate greater than 100/min, or a temperature greater than 38°C during the first 24 h of treatment. A serum albumin level of less than 30 g/l during the first few days or the failure of acute-phase proteins such as the serum C-reactive protein to fall are also poor prognostic signs. Seventy-five per cent of patients showing mucosal islands in the colon or having more than three loops of distended small bowel on a plain abdominal radiograph will come to urgent surgery. These findings, based on retrospective studies, have been confirmed by a prospective series which showed, in addition, that if, on day 3 of steroid therapy, patients were still having more than eight motions daily or four to six daily with a C-reactive protein greater than 45 mg/l there was an 85 per cent chance that urgent colectomy would be required. Thus, for patients falling into this category, cyclosporin should be added at this stage unless there are other reasons for proceeding directly to surgery.

Chronic active disease

Some patients repeatedly relapse when they come off corticosteroids or receive a daily dose of less than 10 to 15 mg of prednisolone. Immunosuppression therapy with azathioprine or 6-mercaptopurine is often beneficial in this group. In the United Kingdom, azathioprine is the drug that is most used, in doses of 2.0 or 2.5 mg/kg, and may allow the prednisolone to be withdrawn. It usually takes 4 to 6 weeks before an effect is seen and the drug is then continued for several months. Although few long-term sequelae have been encountered, most clinicians do not usually continue therapy for more than 18 to 24 months. Oral cyclosporin (5 mg/kg) has also been used for chronic active disease but no formal clinical trials have been made. High-dose prednisolone (40 mg) given on alternate days is another approach that may be useful. However, if the patient's lifestyle is impaired by chronic disabling symptoms or by the side-effects of treatment, surgical management should be considered.

Maintenance of remission

Sulphasalazine and its active moiety, 5-aminosalicylic acid, are able to maintain the disease in remission when given over many years and reduce the relapse rate by about fourfold. Thus, provided they are well tolerated, they should be given indefinitely.

For sulphasalazine, the optimal dose to obtain good therapeutic efficacy with the least side-effects is 2 g daily. Common side-effects are nausea, anorexia, and headache, which are dose related and are caused by the sulphapyridine component. Other side-effects, which are also usually due to the sulphonamide but are not dose related, include hypersensitivity skin rashes, male infertility, agranulocytosis, and Heinz-body haemolytic anaemia. Overall, 10 to 15 per cent of patients are unable to take the drug, although the nausea and headache can often be overcome by starting at a low dose and gradually increasing it.

Sulphasalazine is an unusual drug in that it is poorly absorbed in the stomach and small intestine. When it reaches the colon, the azo-bond linking the 5-aminosalicylic acid and sulphapyridine moieties is split by bacterial azoreductases. The sulphapyridine is absorbed, metabolized in the liver, and excreted in the urine. The majority of the 5-aminosalicylic acid (about 70 per cent) is poorly absorbed and excreted in the faeces. As it is the 5-aminosalicylic acid that is the active compound, several drugs are now available that present 5-aminosalicylic acid to the colon without the sulphapyridine which causes the majority of the side-effects of sulphasalazine. The 5-aminosalicylic acid cannot simply be given by mouth as it is rapidly absorbed. Thus, it is either given as a delayed-release formulation (the mesalazine group) or as a prodrug (olsalazine, balsalazide). Table 3 lists these and details their characteristics.

Which drug containing 5-aminosalicylic acid should be prescribed as maintenance therapy for ulcerative colitis? Sulphasalazine is well tolerated by 85 per cent or so of patients, it is cheap, and serious side-effects (such as Stevens–Johnson syndrome, agranulocytosis, and pancreatitis) are very rare. The newer drugs are much more expensive than sulphasalazine but they have equal therapeutic efficacy. In general they are associated with fewer side-effects. However, occasional patients develop typical salicylate reactions (rhinitis, urticaria, and a colitis). About 10 to 12 per cent of patients will develop loose stools when given olsalazine. This gradually settles if treatment is continued, but about 5 per cent will develop a severe watery diarrhoea, which usually necessitates stopping the drug. The risk of diarrhoea can be minimized by taking the drug with food. There have been reports of renal failure, mainly due to an intestinal nephritis, and have been mostly associated with the delayed-release forms of mesalazine. It is a rare complication and the mechanism is unknown although 5-aminosalicylic acid has structural similarity to phenacetin. Both Asacol and, especially, Salofalk give higher plasma concentrations of 5-aminosalicylic acid than either Pentasa or the prodrugs (olsalazine, balsalazide, and sulphasalazine).

Diet

Patients with recurrent, severe disease have a slightly higher prevalence of hypolactasia and a lactose-free diet may be beneficial. Individual patients may be intolerant of dairy products, wheat, eggs, and other dietary constituents but the majority of patients should have a normal, well-balanced diet.

Local complications

Perianal lesions

Minor lesions such as fissures, perianal abscesses, or haemorrhoids may occur in patients with ulcerative colitis, but extensive lesions such as fistulas are exceptional and, if they occur, suggest Crohn's disease. Treatment of fissures involves treatment of active inflammation. Surgical treatment should be avoided wherever possible and, if necessary, should be conservative.

Massive haemorrhage

This occurs in association with severe attacks but is rarely seen. Intravenous corticosteroids and blood transfusion usually allow the bleeding to stop. However, if patients have already received six or more units of blood and are still bleeding, urgent colectomy must be considered.

Perforation

This is the most dangerous of the local complications and carries appreciable mortality. In patients receiving corticosteroids, the physical signs of peritonitis may not be obvious, and malaise, tachycardia, and reduced or absent bowel sounds may be the only clinical features. Plain abdominal films usually show free intra-abdominal gas. It may complicate an acute dilatation but can occur in its absence. Management consists of immediate intravenous fluid, electrolytes, antibiotics, and hydrocortisone. As soon as the patient's condition improves, urgent colectomy is performed immediately. The mortality of a perforation is as high as 16 per cent, even in specialist centres.

Acute dilatation

This is defined as a transverse colon with a diameter of greater than 5.0 to 6.0 cm with loss of haustration seen on a plain radiograph in a patient with a severe attack of ulcerative colitis. It occurs in about 5 per cent of patients with a severe attack and can be precipitated by hypokalaemia or the administration of opiates. Physical signs are often minimal but the patient is usually obtunded, the bowel sounds are reduced, and the abdomen may become distended. If the colon is already dilated on presentation of the severe attack, medical therapy with intravenous steroids should be given. Approximately 50 per cent of patients will settle on medical therapy alone, but urgent surgery is required for those who continue to deteriorate or do not improve within 24 h. If the colon dilates during the course of treating a severe attack, colectomy should be performed.

Strictures

These occur very rarely in patients with long-standing ulcerative colitis with a shortened, narrow colon. Colonoscopy with multiple biopsies must be carried out as there should be a high index of suspicion for carcinoma.

Pseudopolyps

These are common and may be filiform, sessile, or may form bridges. They can occur throughout the colon but often spare the rectum. They are not premalignant and may occasionally regress.

Colonic carcinoma

The risk of cancer is mainly in patients who have had extensive disease for more than 10 years, especially if they have had recurrent attacks. The most recent series studying primary cohorts suggest that the cumulative risk for patients with extensive disease is about 7 to 15 per cent at 20 years, with very little risk up to 15 years of disease.

Carcinoma is usually, but not always, preceded by dysplasia. This can be detected histologically and has led to the use of colonoscopic surveillance programmes for patients with long-standing ulcerative colitis affecting most or all of the colon. Provided no dysplasia is found, the examination is repeated every 1 to 3 years. If high-grade dysplasia is present, prophylactic colectomy is usually considered. For low-grade dysplasia, repeat colonoscopy within a few months is usually advised, but there are increasing reports of cancers occurring in association with low-grade dysplasia. Thus colectomy is increasingly being recommended whenever dysplasia is recognized regardless of grade. As large numbers of colonoscopies are involved in a surveillance programme the question of cost–benefit has been raised. However, two recent studies have shown that patients have a worse outcome with respect to cancer if they are not in a surveillance programme. The possibility of using flow cytometry to detect DNA aneuploidy in biopsy specimens as a means of increasing the sensitivity of surveillance has been explored, but is probably no better than a histological assessment given by an experienced intestinal pathologist.

Surgery

The indications for surgery have already been mentioned and are:

1. severe inflammation unresponsive to medical therapy;
2. acute complications—perforation, dilatation;
3. for chronic active disease; and
4. to prevent cancer.

The choice of operation is partly determined by the expertise available and the activity of the disease. When surgery is done for a severe attack, a one-stage proctocolectomy with a Brooke ileostomy has been shown to be a safe and effective procedure. The major problems with the operation are poor healing of the perineal wound, adhesion obstruction, and ileostomy dysfunction. Sexual dysfunction in males rarely occurs if a perimuscular excision of the rectum is made. However, with the advent of restorative proctocolectomy with the formation of an ileoanal reservoir or pouch, many surgeons will do only a colectomy in the acute stage. The rectal stump is either oversewn (which is not recommended as it often leaks with abscess formation), or brought out as a mucous fistula either in the lower end of the wound or in the left iliac fossa. This allows histological examination of the whole colon to exclude Crohn's disease. The rectum is excised and the pouch formed some months later when nutrition has been restored and patients are not taking corticosteroids or immunosuppressive drugs.

Restorative proctocolectomy has become the procedure of choice for specialist centres provided the anal sphincter is intact. For this reason, this operation is not advised over the age of 65 years. Either the two-limb (J) or four-limb (W) pouch is now the favoured design and most surgeons preserve the anal transitional zone by anastomosing the pouch 1 to 2 cm above the dentate line. This allows for a stapled anastomosis which shortens the operation and is associated with better continence than a mucosectomy which inevitably requires anal dilatation by retractors. If the operation is being carried out for high-grade dysplasia or cancer, most surgeons will perform a mucosectomy and hand-sew the pouch to the dentate line.

The majority of patients who undergo a pouch operation have excellent function, with less than 10 per cent having any leakage, which is usually limited to night-time soiling. Nevertheless, all patients should be advised to wear a pad at first after a pouch procedure. The pouch usually requires emptying 6 to 12 times daily within the first few weeks of functioning and loperamide is usually needed. Adaptation occurs during the first few months, and by the end of a year the emptying frequency is around four to six times daily but without urgency. Complications of the pouch, once the immediate surgery is over, include anal stenosis, adhesion obstruction, and pouchitis. Pouchitis occurs in 10 to 20 per cent of patients and consists of diarrhoea with blood and evidence of inflammation on endoscopy. It usually responds to antibiotics such as metronidazole or ciprofloxacin but occasionally requires topical treatment with corticosteroids or 5-aminosalicylic acid.

The causes of pouchitis are heterogeneous and include ischaemia, infection with a recognized pathogen (such as campylobacter), and poor emptying, but most pouchitis attacks are unexplained.

Poor emptying can be recognized by isotopic scanning using a radiolabelled artificial stool and usually responds to regular catheterization of the pouch. The idiopathic pouchitis is particularly interesting in so far as it is only seen in patients who have previously had ulcerative colitis and is rarely, if ever, seen in patients who have a pouch for other reasons. After the formation of a pouch, for whatever indication, the ileal mucosa undergoes colonic metaplasia. The triggers for this are unknown but almost certainly involve luminal stasis. Thus, whatever factors first render an individual susceptible to developing ulcerative colitis also seem to render him/her susceptible to developing acute inflammation in ileal mucosa that has undergone colonic metaplasia.

Course and prognosis

Most patients with ulcerative colitis have intermittent attacks of the disease, but the duration of remission between attacks can vary from a few weeks to many years. About 10 to 15 per cent of patients will have a chronic continuous course and rarely achieve a full remission for any appreciable time. A few (5 to 10 per cent) will

have a severe first attack requiring urgent surgery, but fewer, if any, have one attack only and never relapse.

Patients with extensive or total disease are much more likely to have a severe attack within 1 year of diagnosis than patients with distal disease and are therefore at greater risk of colectomy. However, a year from diagnosis the risk of colectomy is similar in all groups with a cumulative rate of about 1 per cent per year. Patients with disease limited to the rectum are a special group in so far as most of them continue to have very limited involvement. Only about 30 per cent will develop more extensive disease in the 20 years after diagnosis.

Despite having a chronic relapsing disease, 90 per cent or so of patients are able to work with very few days of sick leave each year. Nevertheless, quality of life can be impaired in many patients. During active inflammation, lassitude, discomfort, and urgency of defaecation are the major symptoms that limit everyday activities. Sexual and marital problems are not uncommon but may be no more frequent than that seen in other populations of patients with acute-on-chronic illnesses. Most of these problems disappear during remission, although fear of relapse and the need for continuing treatment and medical supervision can cause considerable anxiety. Many patients will alter their lifestyle with respect to daily activity, travel, and diet, but with prompt treatment of active disease and supportive medical care, most are able to have a normal life for most of the time. The development of patient self-help groups (such as The National Association for Colitis and Crohn's Disease in the United Kingdom) has been of tremendous value in providing education and an environment in which patients can regain their confidence and overcome the problem of isolation, an important and common factor in patients with an uncommon and socially unpleasant disease.

There has been a dramatic fall in the mortality rates for ulcerative colitis since the introduction of corticosteroids in the 1950s and the improvement in the management of severe attacks. The mortality rate for a severe attack, including urgent surgery, should now be less than 2 per cent. In the longer term, mortality differs hardly at all from that expected in a matched healthy population, a fact which the majority of life assurance companies fail to recognize.

Ulcerative colitis in pregnancy

Women with ulcerative colitis have normal fertility, are not at increased risk of having a spontaneous abortion, and there is no evidence that pregnancy is a risk factor for relapse. If they do become pregnant, the chance of having a normal baby is the same as for healthy women. Furthermore, there is no good evidence that corticosteroids, drugs containing 5-aminosalicylic acid, or even azathioprine are harmful. Therefore, maintenance treatment should be continued throughout the pregnancy and, if a relapse does occur, it should be treated aggressively with corticosteroids to obtain a rapid remission.

Ulcerative colitis in childhood

Ulcerative colitis is less common in children than in adults and, for the United Kingdom, the prevalence is about 6 to 7 per 100 000. Nevertheless it can present within the first few weeks of life, although the mean age of presentation is about 10 years. The symptoms are those of diarrhoea, rectal bleeding, abdominal pain, and failure to thrive. There may be evidence of delayed growth but this is more commonly a feature of childhood Crohn's disease. The proportion of children with a total colitis is about 50 per cent, which is higher than in adults, and probably accounts for the higher rate of colectomy reported in most series.

Treatment follows the same principles as for adults, although dosages are adjusted for the child's weight. In addition, great attention must be made to nutrition to allow for adequate growth. For children requiring repeated courses of corticosteroids, an alternate-day regimen usually controls the disease activity but prevents growth retardation. If colectomy becomes necessary, a restorative proctocolectomy should be done.

14.12 Functional bowel disorders and irritable bowel syndrome

D. G. Thompson

Introduction

Functional bowel disorders

Symptoms suggestive of disturbed lower gastrointestinal function without adequate explanation are very common in the adult population of the Western world. Surveys from the United Kingdom and United States indicate that up to 15 per cent of the adult population experience such symptoms at any one time, although most do not seek medical advice. The chief questions that remain largely unresolved are whether the symptoms of those individuals who do seek medical help have a different pathophysiological basis from those who do not, and whether the seeking of medical advice is an indication of a worried individual rather than of disturbed gut function.

Given these difficulties, it has to be accepted that most of the currently used terms are best viewed as an attempt by clinicians to provide some clinically useful categorization of such patients and their symptoms. Since knowledge of the physiology and the psychology of the problem remains incomplete, therapy remains largely empirical. Current observations about functional bowel disorders should therefore be regarded as the latest (but by no means the last) attempt at rationalizing a complex interrelationship between brain and gut function.

Definition of terms used

Over the last century many attempts were made to categorize functional bowel disorders. It is not surprising that most have failed to stand the test of time, as the symptoms suffered (whilst being genuine and troublesome to the patient) are often difficult to define, variable in their expression, and defy pathophysiological explanation. The latest and perhaps most comprehensive attempt has been made by a working group whose recommendations, known as the 'Rome criteria', are now accepted as useful research tools. Whether these criteria will stand the test of time as clinical diagnostic tools will, however, depend upon whether they turn out to provide a better understanding of the pathogenic mechanisms of the disease or to aid its therapy. The Rome Working Group has suggested the division of functional bowel disease into a number of symptom-based categories (Table 1). Because they do seem to have some practical value in guiding approaches to management, this chapter is based on some of the Rome categories, with emphasis on those previously encompassed by the term 'irritable bowel syndrome'. However, it must be recognized that the Rome criteria do not necessarily include all symptoms presented by patients with abnormal bowel function. Failure to allocate a patient into one or other category should therefore not be taken to mean that the patient does not have a functional bowel disorder.

Irritable bowel syndrome

Definition

This syndrome is characterized by the presence of abdominal pain associated with defaecation, or a change in bowel habit, together with disordered defecation and the sensation of abdominal distension. For practical purposes, its recognition relies upon the presence of abdominal pain that is relieved by defaecation and of an associated change in frequency in defaecation and/or stool consistency, together with two or more of the following symptoms:

1. altered stool frequency;
2. altered stool consistency;
3. altered ease of defaecation;
4. passage of mucus;
5. sensation of abdominal distension.

These criteria are themselves based on the studies of Manning and of Kruis, which identified that the above features were reported most frequently in patients with functional bowel problems but were very unusual in patients with structural disease of the colon.

Diagnosis

The diagnosis of irritable bowel syndrome is clinically based, and relies on a carefully taken history and examination, there being no specific endoscopic, radiological, or laboratory investigation that is yet capable of providing a positive diagnosis. Despite the absence of a specific pathological indicator, the identification of irritable bowel syndrome is usually not difficult, and in most cases it is unnecessary to investigate the patient extensively in an attempt to exclude other, more serious disease.

Clinical features

The history

In addition to the careful elicitation of the above specific symptoms, other features may be found that serve to increase clinical confidence. For example, many patients have upper-gut symptoms, for example food-related abdominal distension. Women may also complain of menstrual and bladder symptoms, and there is also an increased prevalence of psychosexual problems.

Examination

Clinical examination is important. Whilst there is no physical abnormality that is diagnostic of irritable bowel syndrome, a number of features occur commonly. Palpation over the site of the lower colon, particularly in the left iliac fossa, may produce discomfort, and a sigmoid colon containing faeces is often palpable. Similar tenderness may be present under the rib margins and in the right iliac fossa.

Rectal examination and sigmoidoscopy should be conducted as part of the initial clinical assessment. Characteristic findings are the presence of pellety stools in the rectum and a mucosa of normal appearance, evidence of mucosal inflammation is incompatible with the diagnosis. A further helpful pointer is the response to air insufflation during the sigmoidoscopy; abdominal discomfort is often reproduced and relieved by air expulsion. Evidence of a pigmented rectal mucosa (melanosis coli) may be found in patients who have been taking stimulant laxatives and is a useful indicator of the chronicity of the problem.

Further laboratory investigations remain at the discretion of the clinician, depending upon the confidence with which a clinical diagnosis is made. Routine haematological and biochemical screening is usually done on the assumption that they will be normal, and thus to provide reassurance both to the patient and the doctor. Radiological and endoscopic examination of the colon is not mandatory unless a clinical suspicion of a structural colonic disorder, particularly neoplasia, remains after the history and examination have been completed.

Features that raise the suspicion of organic disease and indicate a need for further investigation include the onset of symptoms in the middle-aged or elderly, weight loss, or blood in the stool. The development of new colonic symptoms in a patient with a long history of irritable bowel syndrome should also be taken seriously, as there is no evidence that the syndrome protects against the development of other disease and the incidence of colonic neoplasia increases with age.

Pathophysiology

Despite much interest and many painstaking clinical studies, our understanding of the pathophysiology of irritable bowel syndrome remains limited and the following hypotheses are discussed solely as a guide to current thinking.

Neuromuscular dysfunction

The most popular hypothesis is that these patients have a disorder of neuromuscular function of the gastrointestinal tract. However, whilst this seems eminently plausible, evidence is lacking. Manometric studies of the colon do show an increased contractile activity in patients with this syndrome, particularly after food, but the neurophysiological basis of this finding and its relationship to symptoms remains to be determined.

Visceral hypersensitivity

Another currently popular hypothesis is that visceral sensation from the gastrointestinal tract is somehow enhanced in these patients. This idea is based on the observation that distension of the rectum and colon produces greater discomfort than in people with normal bowel function. This increased sensory awareness appears to be viscerally specific, as cutaneous responsiveness is normal. However, it remains to be determined whether the mechanism for this hypersensitivity is peripheral (abnormal mechanoreceptor responsiveness in the gut) or central (abnormal sensory processing by the brain and spinal cord).

Psychiatric disease

There is convincing evidence that psychiatric disease and abnormal illness behaviour are more prevalent in patients with irritable bowel syndrome. The relationship between the psychological problem and any neuromuscular abnormality remains uncertain, although it is recognized that a heightened awareness of visceral sensation is a feature of affective disorders, particularly depression.

Diet

It is customary to regard diet as being a pathogenic factor and to attribute constipation symptoms to fibre deficiency, on the basis that irritable bowel syndrome is uncommon in those parts of the world where a high-fibre diet is consumed. While it is true that faecal bulk can be increased by ingesting more fibre and that constipation is improved, careful studies of fibre intake and symptom development do not show a clear causal relationship. Food 'allergy' or sensitivity is occasionally confused with irritable bowel syndrome because abdominal pain and diarrhoea can accompany both problems. Classic food allergy with measurable immunological alterations in response to a particular food (for example, eggs, shellfish) is readily distinguishable from irritable bowel syndrome by a clear relationship between ingestion of the implicated food and symptom development. More subtle forms of food intolerance (for example, lactose intolerance, fructose intolerance) that produce gut symptoms without an accompanying immune response are much more difficult to recognize because the nutrient in question is often present throughout the diet. Recognition requires a painstaking dietary history and the clear demonstration of a relationship between symptoms and food intake. In most patients such a relationship is not found.

Functional abdominal bloating

Definition

This is characterized by symptoms of abdominal fullness or distension, awareness of audible bowel sounds, and excessive flatus with no evidence of either maldigestion and malabsorption or excessive consumption of poorly absorbed fermentable carbohydrate.

Pathophysiology

Distension of the colon at sigmoidoscopy characteristically produces greater discomfort than normal, suggesting increased gut sensitivity. However, there is no evidence that intestinal gas production is increased. As in irritable bowel syndrome, the prevalence of psychological disorders is high.

Clinical features

The clinical assessment of such patients is identical to that for irritable bowel syndrome and features will be identical.

Functional constipation

Definition

This is arbitrarily defined as either persistently difficult, infrequent defaecation or the sensation of incomplete defaecation. Usually, two or more of the following are present: straining at defaecation; lumpy or hard stools; the sensation of incomplete evacuation; and two or fewer bowel movements per week.

Clinical evaluation

As with the other categories of functional bowel disorders, the diagnosis is based on a carefully conducted history and examination designed to exclude the possibility of more serious colonic disease, particularly cancer. When considering the diagnosis, it is important to enquire about immobility, concomitant drug therapy (particularly opiate analgesia), and a low roughage diet, which are well recognized as contributing to constipation, particularly in the infirm.

An abnormality of pelvic-floor function on attempted defaecation is an unusual cause of constipation that should be suspected in individuals who feel the need to defecate but cannot expel faeces despite severe straining. Such a problem should be considered when symptoms develop following pelvic trauma or difficult childbirth. Clinical evidence of diabetes, hypothyroidism, and hypercalcaemia must also be sought, as these may also lead to altered colonic function and

constipation.

Physical examination should include a rectal and vaginal examination. The absence of perineal descent on straining is a simple indicator of impaired pelvic-floor relaxation, while descent below the level of the ischial tuberosities indicates pelvic-floor weakness. Sigmoidoscopy is required to identify the presence of formed faeces, and to exclude faecal impaction and organic obstruction of the lower colon and rectum.

Laboratory examination

Extensive laboratory investigation is usually unnecessary in the absence of clinical indicators of systemic disease and in the presence of the above criteria. A plain abdominal radiograph is often helpful to confirm the presence of faecal material throughout the colon and to allow estimation of the diameter of the small intestine and colon, which helps to exclude the rare cases of intestinal pseudo-obstruction and megacolon caused by intestinal myopathies and neuropathies.

Transit studies using radio-opaque markers are commonly performed as part of the investigation of constipated patients to determine the severity of transit delay, and to distinguish those with a pancolonic abnormality from a more localized problem of pelvic relaxation. However, measurement of whole-gut transit should not be regarded as necessary for the diagnosis—documented infrequent defaecation is usually sufficient. The electrophysiological and radiological assessment of anorectal function is only indicated if there is evidence of abnormal perineal descent or rectal prolapse, as the accurate recognition of pelvic-floor dysfunction can influence the choice of therapy. Such investigations are indicated when Hirschsprung's disease is suspected.

Pathophysiology

The cause of functional constipation is uncertain. Factors likely to be of relevance are similar to those proposed for irritable bowel syndrome, in particular, enteric neural dysfunction.

In the mildest cases, dietary-fibre deficiency may be relevant; however, in the more severely affected patients, fibre supplementation does not abolish the problem and may even worsen symptoms, making, in such individuals, a causal role for fibre untenable. By contrast, a histological abnormality of the enteric nerves of the colon or muscle of the colon may be found in the most severe cases; for the great majority of constipated patients, however, no structural abnormality has been identified.

In a proportion of patients, almost invariably female, defecatory dysfunction appears to be the major factor. A failure of the pelvic-floor muscles to relax on attempted stool expulsion is identifiable in these patients; this appears to be a 'learned' phenomenon with a psychophysiological aetiology rather than peripheral nerve dysfunction. In other patients, low tone in the pelvic floor and rectal prolapse appear to be the result of damage to the pudendal nerve from straining at stool or parturition and thus may be a consequence of the constipation rather than its cause.

In some severely affected women, there is a relationship between symptom severity and the luteal phase of the menstrual cycle, which has led to the suggestion of a sex-hormonal aetiology. In support of this hypothesis is the fact that colonic muscle tone is reduced by progesterone and that constipation is a frequent accompaniment of normal pregnancies. Against the hypothesis, however, is the failure to demonstrate abnormal colonic sensitivity to progesterone in constipated women, leaving the possibility that the menstrual cycle-related events are merely the expression of a normal cyclical progesterone effect on a malfunctioning colon.

Functional diarrhoea

Definition

This is defined as the frequent passage of unformed stool without the presence of other features of irritable bowel syndrome. Neither abdominal pain nor the frequent passage of formed stools are included in the symptoms.

The diagnosis of functional diarrhoea depends on the presence of two or more of the following: unformed stool; three or more bowel movements per day; and increased stool weight, greater than 200 g/day.

Clinical features

This disorder is recognized only after excluding other, more medically serious conditions, in particular, inflammatory bowel disease and secretory diarrhoeas. The possibility of surreptitious laxative use should always be borne in mind. Some patients identify the time of onset of the problem to a specific life-event, particularly a bout of severe gastroenteritis. The possibility of a chronic intestinal infection needs to be considered carefully in such patients, although evidence of an infective agent will be lacking in most and the label 'postinfective diarrhoea' is usually applied.

Physical examination should determine the extent of nutritional deficiency, exclude metabolic disorders such as hyperthyroidism, and rule out intra-abdominal structural abnormalities. Careful examination of stool samples for pathogens and laxatives is required.

Laboratory investigations

Unlike the other functional diseases, it is important to make a careful search for a structural mucosal disease in such patients. Key diagnoses that must be excluded are: chronic malabsorption due to pancreatic insufficiency or gluten sensitivity, inflammatory bowel disease, infections, and infestations of the gastrointestinal tract.

Pathophysiology

In the absence of any definable structural abnormality, functional diarrhoea is generally assumed to be a disorder of neuroenteric control of intestinal epithelial transport.

In some patients, there is a clear relationship between psychological state and symptoms, with diarrhoea worsening whenever anxiety occurs. However, whether the relationship is truly causal is unknown.

Functional abdominal pain

Definition

While this symptom category is commonly included amongst the functional bowel disorders, the relationship between the abdominal pain and a disturbance of gastrointestinal-tract function is difficult to ascertain. Abdominal pain is frequent, recurrent, or continuous, and characteristically persists for many months. The relationship between pain and recognizable physiological events such as eating, defaecation, or menstruation is lacking, and evidence of organic disease in the abdomen is absent. Most of these patients show a major loss of daily functioning capacity and exhibit chronic illness behaviour.

Management of functional bowel diseases

The management of patients with functional bowel disorders remains empirical. Perhaps it should not be surprising that in an area of human suffering with such symptom diversity and in which the pathophysiological mechanisms remain obscure, no single pharmacological agent or group of agents have ever been found to be consistently effective.

A review of randomized, double-blind, placebo-controlled trials for the treatment of irritable bowel syndrome examined 43 trials and concluded that none offered convincing evidence that any therapy was effective, a conclusion which is perhaps as much an indictment of trial design as the efficacy of the drug therapy. Furthermore, in a condition in which the patient's mental state plays such an important part in defining symptom severity, it is not surprising that in most clinical trials placebo responses have been very high, usually up to 50 per cent. Also, short-term trials of therapeutic agents in diseases where symptoms are intermittent may be

unable to distinguish a true drug effect from a placebo response.

So what can the clinician do to help patients with functional bowel disease? As in all chronic problems without a cure, a principal task is to give an explanation and reassurance. Therapy must be patient-centred and designed to provide a solution for the patient's personal needs and expectations. The clinician should give a full explanation of the likely nature of the problem and firm reassurance that organic disease is not likely to be present. Attention to the patient's psychological state is very important, as it is clear that mood is a powerful modulator of symptoms.

In more severe cases of irritable bowel syndrome, psychological treatment using a variety of techniques has been found to provide greater improvement in a patient's sense of well being than drug therapy alone. Good prognostic factors for improvement seem to be overt psychiatric symptoms, particularly anxiety or depression, together with intermittent pain exacerbated by stress. In contrast, patients in whom the abdominal pain is constant, and who exhibit evidence of chronic illness behaviour, do not seem to be helped by a psychotherapeutic approach but they may respond to antidepressants.

In mild cases, attention to the individual and his/her symptoms is usually the approach taken. In patients with predominant constipation, supplementary dietary fibre and poorly absorbed fermentable carbohydrates increase faecal bulk, soften the stool, and may ease defaecation. On occasion, however, this approach can exacerbate symptoms of abdominal distension, probably as a result of increased colonic gas produced by the fermentation of the unabsorbed carbohydrate. Wherever possible, long-term use of stimulant laxatives is best avoided because of the concern that such drugs may themselves damage the colonic enteric-neural function and eventually make the problem worse. Osmotic laxatives and enemas are the mainstay of therapy of the severely constipated patient with slow transit.

For the patient who appears unable to relax the pelvic floor musculature on attempted defaecation, a variety of biofeedback techniques are now available that help the individual to 'relearn' the process. Success is high in those able to engage closely with the therapist in the process.

For patients with diarrhoea-predominant symptoms, attention to diet is also often helpful, as the size of and timing of meals is likely to influence the frequency and social inconvenience of the diarrhoea. Fermentable carbohydrates are best taken in moderation because they can exacerbate symptoms. In the more persistent cases of diarrhoea, symptoms can be improved by simple antidiarrhoeal agents, the dose being adjusted according to the symptoms and administered before a meal.

In the management of patients with unexplained abdominal pain it is tempting to prescribe opiate-derivative analgesics. These are unlikely to be of benefit in the long term, however, and may even exacerbate symptoms because of their constipating effect. Antidepressants are often prescribed empirically in low doses, with evidence of benefit at least in mood elevation. Antispasmodics (for example, hyoscine butyl bromide) are frequently employed. Whilst there are undoubtedly a number of patients and doctors who are convinced of their value, a beneficial effect has yet to be proven beyond doubt by clinical trial.

Relaxation therapy, in particular hypnosis, seems to benefit those individuals who are prepared to participate. In the right conditions, programmes of self-delivered 'autohypnosis' may offer a satisfactory approach for some sufferers.

Surgical intervention for symptoms of functional bowel disorders is usually best avoided, as benefit is unlikely. On occasions, however, subtotal colectomy and ileorectal anastomosis will provide symptomatic benefit in carefully selected patients with severe constipation.

The management of patients with functional bowel disease therefore remains a major challenge that cannot be shirked by clinicians, with whom responsibility exists to provide a careful, individually oriented explanation, and support. The careful conduct of clinical trials of current and new therapies remains a priority for these disorders.

14.13 Colonic diverticular disease

N. J. McC. Mortensen and M. G. W. Kettlewell

Diverticula can be found throughout the gastrointestinal tract, but are seen most commonly in the sigmoid and descending colon.

Epidemiology

Asymptomatic diverticular disease is much more common than clinical diverticulitis. Autopsy studies in the United Kingdom and Australia have shown that the prevalence of colonic diverticula increases with age. It is rare in those under 30 years of age but occurs in more than 50 per cent of those over 70 years. On the other hand, colonic diverticulosis is very rare in African and Asian countries and right-sided disease predominates in Japan. This geographical distribution is not due to race, as West Indians and Asians living in Britain, American Blacks, and Japanese who have moved to Hawaii or the mainland United States are just as prone to the disease as Caucasians. Patients presenting with complicated diverticular disease have a low intake of dietary fibre, whilst vegetarians have a low incidence of the disease.

In Edinburgh, 23 per cent of all barium enemas demonstrated diverticula. The annual incidence increased from 0.17/1000 in those under 45 years to 5.7/1000 in those over 75 years of age. Women were affected more than men. In spite of the introduction of high-fibre diets, there is no evidence that the incidence of acute diverticulitis is declining.

Aetiology

Diverticular disease is said to be a disease of the twentieth century. It was rarely described in the nineteenth century literature, and in Britain there is a correlation between the rising incidence at the beginning of the twentieth century and an increased consumption of refined flour and sugar. Sugar consumption has trebled since 1860, and in the late 1870s the stone grinding of flour was replaced by roller milling, which removes more fibre. Modern white and some brown breads contain little fibre compared with the amount in wholemeal bread, which was previously a staple part of the diet.

The development of diverticula therefore can be ascribed to a lifelong diet deficient in dietary fibre. An unrefined, high-fibre diet produces swiftly passed, soft stools that subject the colon to little strain. Modern, fibre-deficient diets on the other hand give rise to stiff, viscous stools that need high intracolonic pressures to propel them. High luminal pressures cause a protrusion of the mucosa through vulnerable points in the sigmoid and descending colon. They usually occur at the site where colonic blood vessels penetrate the wall. This hypothesis is supported by the observation that, although basal intracolonic pressures are similar in health and diverticular disease, when the diseased colon is activated by emotion, eating, mechanical stimuli, or drugs such as morphine or prostigmine, high pressures are generated in those segments that have diverticula. This is due to hypersegmentation by the colonic smooth muscle, and the difference has been recorded in the earliest stage of disease and may explain its progressive nature. In symptomatic patients an increase in dietary fibre causes a relief of symptoms in many cases.

Changes in the colon wall also play a part. With age, and following episodes of diverticulitis, the colonic wall becomes stiff and less distensible, aggravating the effects of raised intracolonic pressure. An increase in elastin and changes in collagen have been reported. Diabetic patients are prone to diverticular disease at an earlier stage, suggesting a defect in glycolysation of colonic collagen with advancing age. In those with connective tissue disorders such as Ehlers–Danlos syndrome or Marfan's disease, diverticula are also seen at an unusually early age.

The distinction between symptomatic and asymptomatic diverticular disease is important, for whilst something is known about the formation of diverticula it is not known why some diverticula become symptomatic.

Pathology

A diverticulum consists of a herniation of mucosa through the colonic musculature, and as it enlarges its muscle covering atrophies, so that the fully developed diverticulum consists of mucosa, connective tissue, and peritoneum. The striking abnormality is in the thickening of the circular and longitudinal muscle, which both narrows the colonic lumen and shortens the sigmoid like a concertina to give a saw-tooth appearance on barium enema. The diverticula occur as slit-like apertures between the muscle clefts.

Inflammation in diverticular disease is the result of infection around diverticula, which spreads within the pericolic fat to form a dissecting abscess. Usually a single diverticulum is the cause of a pericolic abscess, perhaps initiated by the presence of a faecolith. Involvement of the peritoneum results in local peritonitis, which may become generalized in the event of a perforation. This may also give rise to intra-abdominal abscesses or fistulae to the bladder, small bowel, vagina, or uterus. Repeated episodes of diverticulitis lead to a contracted, narrowed sigmoid colon surrounded by fibrous tissue. Bleeding in diverticular disease can often be traced to an infected diverticulum. This may cause either the erosion of a vessel in its wall or the formation of granulation tissue inside the diverticulum, which then bleeds.

Clinical features

As diverticulosis is so common, most diverticula are asymptomatic. They are usually discovered incidentally and only some 10 per cent produce symptoms, and around 1 per cent require surgery. The symptoms usually result from disordered motility rather than secondary complications of the disease.

Uncomplicated diverticular disease

Pain can be felt along the course of the colon, particularly over the sigmoid, and is often accompanied by a change in bowel habit with the passage of broken, pellety stools after considerable straining. These symptoms may be indistinguishable from those of the irritable bowel syndrome. The passage of blood with an unformed stool is unusual and should alert one to the possibility of other pathology.

Management

All patients should have a rigid or flexible sigmoidoscopy in addition to a barium enema to exclude a rectal or sigmoid carcinoma (Fig. 1). They should be reassured that there is no serious underlying disease and a high-fibre diet should be recommended. This must include wholemeal bread, wholewheat breakfast cereals, rough porridge or muesli, and fresh fruit and vegetables daily. Fibre increases stool bulk in three ways—by holding water, by proliferation of bacteria, and from the byproducts of bacterial fermentation. The coarser the fibre the greater is the faecal bulk, and unpalatability, and although cooking bran improves its taste, it reduces its water-holding capacity. A good clinical response is usually achieved by including two tablespoons of bran with the morning cereal, but about half the patients will experience gaseous distension or cramps on starting the high-fibre diet. It is worth warning them that this is likely to happen and that it will resolve within a month or so if they persist with the diet.

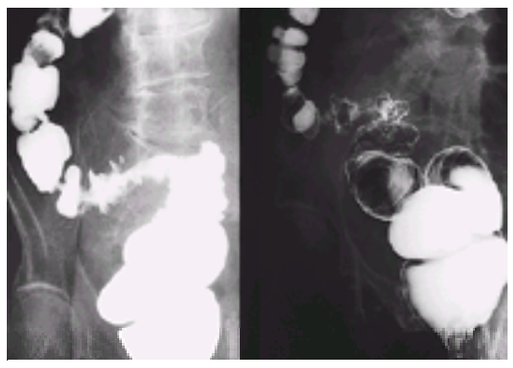

Fig. 1 Barium enema showing a narrowed sigmoid colon with a few diverticula. This appearance can be confused with those of a carcinoma and colonoscopy would be indicated to clarify the diagnosis.

In patients with pain, antispasmodics such as mebeverine may be useful, and in a minority with repeated severe attacks an elective resection is then indicated (Table 1). This is probably more effective than sigmoid myotomy, an operation popularized in the mid-1960s. In this procedure the circular muscle is divided with a longitudinal incision to widen the colonic lumen. The incision is made through the taenia so as to avoid opening diverticula, and is deepened until the mucosa is just seen. The operation lowers the sigmoid intraluminal pressures and improves symptoms but, after 3 years, pressures return to their former levels. The need for myotomy has declined but it may still be useful in some elderly or obese patients.

Complicated diverticular disease

It is important to distinguish the minority of patients who suffer from a febrile attack with left iliac-fossa peritonism, sometimes called left-sided appendicitis, from those with chronic pain and diarrhoea. The inflammation may settle with minimal symptoms or develop into a pericolic abscess or peritonitis.

Acute diverticulitis

Pain is felt over the left lower abdomen, and the patient may have pyrexia, malaise, anorexia, and nausea. The white blood count is raised.

Treatment is with rest, antibiotics, usually cefuroxime 750 mg and metronidazole 500 mg 8-hourly, and analgesia. Most cases settle and the diagnosis can be confirmed after 2 to 3 weeks by barium enema. A narrow segment can sometimes be difficult to distinguish from a carcinoma and any doubtful cases can be clarified by subsequent colonoscopy (Fig. 2).

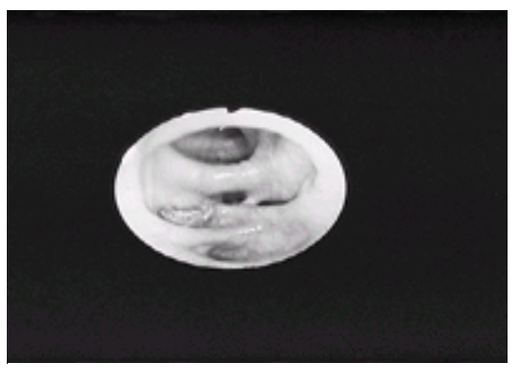

Fig. 2 The typical appearance of diverticula seen at colonoscopy. Note the muscular haustra and the mouths of diverticula—one with a faecolith. (Reproduced from the *Slide atlas of gastroenterology*, Gower Medical Publishing, London, with permission.)

If symptoms fail to resolve, or recur, resection of the sigmoid colon may be necessary. When it is necessary to resect an acutely inflamed and unprepared colon, a Hartmann's operation may be safer than a primary anastomosis.

For recurrent diverticulitis operated electively, a primary anastomosis would be ideal.

Diverticular abscess

Acute diverticulitis can lead to a local peritonitis with abscess formation, either in the paracolic or pelvic area. There may be a palpable mass and a swinging fever. When in doubt the diagnosis can be confirmed by ultrasound or computed tomography (**CT**) with rectal contrast (Fig. 3).

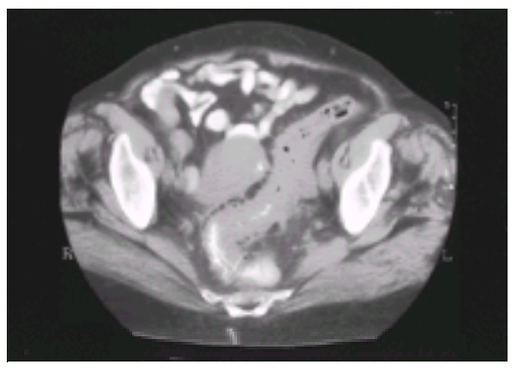

Fig. 3 Computed tomography of the pelvis in a patient with acute diverticulitis. The sigmoid colon is grossly thickened, the lumen narrowed, and pockets of air are seen in the diverticular disease.

It is wise to let an abscess localize whilst treating the patient with rest, antibiotics, and analgesia. Some abscesses will be amenable to drainage by direct incision, over them or via the rectum or vagina. More complicated collections are best drained by CT-guided aspiration or drain placement. There is rarely any need to do a proximal transverse colostomy. If drainage persists, an elective sigmoid colectomy with primary anastomosis can be done at a later time. Even when an abscess is localized, however, the condition remains potentially dangerous as it may rupture into the peritoneal cavity giving rise to peritonitis.

Perforated diverticulitis

Acute diverticulitis can be complicated by generalized purulent peritonitis, either by direct spread from the inflamed colon or by rupture of a peridiverticular abscess.

The clinical picture is of severe intraperitoneal sepsis with toxaemia, ileus, and abdominal pain, and septicaemia will often follow. Emergency laparotomy is almost always required, although time must be allowed for adequate rehydration, correction of electrolytes, and starting antibiotic therapy—again cefuroxime and metronidazole.

Other causes of the acute abdomen that may not require surgery should be excluded, including pelvic inflammatory disease, ureteric calculus, and even pulmonary embolus. In these circumstances a CT scan is invaluable.

There has been a shift away from the more conservative procedures in this situation. At one time, peritoneal toilet, pelvic drainage, and a defunctioning transverse colostomy was the favoured procedure, but this has the disadvantage that the 'septic colon' is left in place and that there is a column of faecal material below the stoma and above the perforation. There is the further problem of the unsuspected carcinoma within the inflammatory mass.

For these reasons more radical measures are favoured by experienced surgeons. A Hartmann's procedure—removing the diseased sigmoid, oversewing the distal rectum, and bringing out an end colostomy—is the most frequently used procedure (Fig. 4). In favourable cases it may be possible to do an on-table colonic lavage via the appendix stump and make an immediate anastomosis but this carries the risk of leakage.

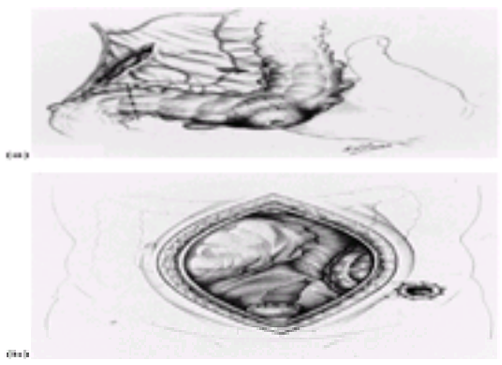

Fig. 4 (a) The area of sigmoid colon resected for perforated diverticular disease. (b) Hartmann's operation—the sigmoid colon has been resected, the rectum oversewn, and a left iliac fossa colostomy fashioned.

Hartmann's procedure is safe and effective, although subsequent reconnection may involve a major operation in elderly patients. Purulent peritonitis carries a mortality of around 15 per cent.

Faecal peritonitis

This is a catastrophic complication with a mortality of around 50 per cent particularly in the elderly. A diverticulum ruptures, often with little or no inflammation, liberating quantities of faeces into the peritoneal cavity. Rapid and severe shock with septicaemia ensues. Energetic resuscitation is necessary, followed promptly by surgery and a Hartmann's operation. These patients often need to be stabilized in an intensive care unit postoperatively.

Intestinal obstruction

Recurrent inflammation with fibrosis and muscular hypertrophy can lead to progressive stenosis and colonic obstruction, which is usually chronic but may present acutely. Conservative treatment is worth trying at first, provided a carcinoma has been excluded. With the aid of a stool softener the symptoms may resolve and the stricture gradually dilate. If these measures fail, the bowel should be prepared for a resection, with care taken not to aggravate the obstruction.

Small-bowel obstruction is sometimes a complication of acute diverticulitis, as the bowel may adhere to the inflammatory mass. It usually resolves as the inflammation subsides but on occasion a laparotomy and division of adhesions or even a small-bowel resection may be necessary.

Colonic fistulae

A colovesical fistula usually presents with recurrent urinary tract infections together with pneumaturia or faecuria. The fistula arises in the sigmoid, which has often folded over into the pouch of Douglas, and adheres to the apex of the bladder. This is the most frequent cause of colovesical fistula but carcinoma and Crohn's disease should be excluded.

Fistulae may also occur between the sigmoid and vagina, uterus, ureter, and ileum. They seldom heal spontaneously but do not always give rise to disabling symptoms and so represent a relative indication for surgery. Sigmoid colectomy as a one-stage procedure is the best option, and colostomy is rarely required. A fistula into the bladder is simply closed and urethral catheter drainage continued for a week.

Haemorrhage

Major haemorrhage is an uncommon but well-recognized complication. It is usually self-limiting, only requiring transfusion and supportive measures. The precise reason for the bleeding is not known but angiographic and colonoscopic studies suggest that many bleeds attributed to diverticula are caused by other lesions such as polyps and angiodysplasia.

Repeated or minor haemorrhage is seldom caused by diverticula and is more likely to be due to carcinoma or polyps. It is therefore vital to exclude other sources of bleeding by barium enema or colonoscopy. The source of a persistent major bleed must be sought urgently, and selective angiography whilst the patient is bleeding is essential. As the haemorrhage can be from any part of the colon, good localization is an essential prelude to any operation. Blind colonic resections have a particularly poor record and if the site of bleeding has still not been located, on-table colonic lavage via the appendix stump and intraoperative colonoscopy will usually target the bleeding segment.

A recent study reported the results of urgent colonoscopy in bleeding diverticular disease. Instead of the tradititional conservative measures patients were given a bowel prep and colonoscoped within 12 h. Bleeding sites thus identified were treated by colonoscopic diathermy and the number of major bleeds, blood transfusions, and operations was reduced together with length of hospital stay. It remains to be seen whether this will result in a major shift of emphasis in management.

14.14 Congenital abnormalities of the gastrointestinal tract

V. M. Wright and J. A. Walker-Smith

Although present at birth, congenital abnormalities of the gastrointestinal tract usually manifest shortly after birth, but on occasion symptoms may be delayed for months or even years. For example duodenal atresia presents in the first few days of life whereas duodenal stenosis may not present until adult life.

The widespread use of ultrasound to assess the fetus allows many of these abnormalities to be recognized prenatally; in particular, abdominal wall defects, fluid-filled stomach in duodenal atresia, dilated bowel in the more distal atresias, and cystic masses. In addition, associated anomalies may indicate a major chromosome abnormality or cardiac lesion. This allows parental choice to continue with or terminate the pregnancy.

Embryology of the congenital abnormalities of the gastrointestinal tract

The primitive gut is initially a simple tube of endoderm, the muscle and connective tissue developing from the splanchnopleuric mesoderm. Cranially, the gut terminates at the buccopharyngeal membrane and caudally at the cloacal membrane. Both membranes disappear; failure of the cloacal membrane to do so results in one of the rarer forms of imperforate anus. The primitive foregut diverticulum gives rise to the respiratory system, oesophagus, stomach, duodenum to the level of the ampulla of Vater, liver, and pancreas. The primitive oesophagus lengthens rapidly, becomes narrow, and frequently the lumen is transiently obliterated. A longitudinal, ventral diverticulum of the foregut forms the trachea with ridges on either side that fuse, initially caudally with progression cranially, until the primitive respiratory system is separated from the oesophagus. Failure of this complex process results in the various forms of oesophageal atresia and tracheo-oesophageal fistula. Dilatation of the foregut distal to the oesophagus produces the stomach, initially slung from the dorsal body wall by the dorsal mesentery and from the septum transversum by the ventral mesentery. Rapid differential growth results in the stomach rotating through 90° on its long axis, the dorsal border becoming the greater curvature and the ventral border the lesser curvature. The dorsal mesentery forms the greater omentum. The ventral mesentery, into which the liver bud grows, forms the falciform ligament and coronary ligaments attaching the liver to the diaphragm, and the lesser omentum. Congenital abnormalities of the stomach are excessively rare. The liver arises as a shallow groove on the ventral aspect of the duodenum. The groove becomes tubular and invades the septum transversum and the ventral mesentery. Bile is secreted from the fifth month, and gives meconium its characteristic dark-green appearance. The mesoderm of the septum transversum forms the fibrous tissue of the liver.

The pancreas develops as two outgrowths of the duodenum. One comes from the dorsal aspect, the other from the ventral. The dorsal bud grows into the dorsal mesentery and the ventral bud is swept around dorsally into the mesentery when the duodenum rotates to the right. These two primordia fuse, the ducts fuse, and the main pancreatic duct joins the bile duct to enter the duodenum at the ampulla of Vater. If the ducts do not fuse, an accessory pancreatic duct persists. Annular pancreas is a congenital anomaly where the pancreas surrounds the duodenum, which may be atretic or intrinsically stenosed. Annular pancreas is not the primary cause of the duodenal obstruction in these cases.

The duodenum is derived partly from foregut and partly from the midgut. The loop of primitive duodenum is fixed at the pyloric end, and by the ligament of Treitz at the duodenojejunal flexure to the left of the first lumbar vertebra. By rotating to the right, the entire duodenum comes to lie retroperitoneally in a curve around the head of the pancreas. Failure of the duodenum to fix in this position is a fundamental reason for the gut failing to rotate correctly. During rapid growth the duodenal lumen is obliterated and partial or total failure of recanalization will result in the anomalies of duodenal atresia or stenosis. The small intestine and colon, suspended on the dorsal mesentery, rapidly lengthen and outgrow the primitive peritoneal cavity, and herniation occurs into the umbilical sac during the fifth week of development. Growth in length continues, the loop of bowel rotating through 90° anticlockwise, the cranial limb lengthening more than the caudal limb. About the tenth week the loops of bowel return to the peritoneal cavity, undergoing a further 180° anticlockwise rotation. The small intestine goes first, the large intestine subsequently. Thus the large intestine lies in front of the small. The caecum is initially subhepatic, the large liver occupying the right side of the abdomen, eventually retreating to the right upper quadrant and allowing growth in the length of the ascending colon. The caecum, ascending colon, and descending colon become fixed to the posterior abdominal wall; thus the small bowel is suspended from a mesentery that runs from the left side of the first lumbar vertebra to the right iliac fossa. Failure of the duodenum to rotate and fix, coupled with a failure of normal rotation of the bowel with consequent lack of normal fixation, gives rise to malrotation of the intestine. Abnormal bands run from the caecum, which lies to the left of the midline, to the region of the gallbladder and may compress the duodenum. The narrow mesentery of the small intestine predisposes to a volvulus of the entire midgut.

At the apex of the midgut loop, the primitive gut is in continuity with the extraembryonic yolk sac via the vitellointestinal duct, which runs in the umbilical cord. Obliteration and disappearance of this duct occurs, allowing the bowel to return from the umbilical sac to the enlarged peritoneal cavity. Failure of the duct to disappear may result in a Meckel's diverticulum, a band connecting the ileum to the umbilicus, a communication between the lumen of the ileum and the umbilicus, or failure of the gut to return completely to the peritoneal cavity, resulting in a small umbilical hernia.

Persistence of the umbilical sac will result in an exomphalos, with the sac containing a variable amount of gut and much of the liver. The embryology of gastroschisis is disputed. It may be due to early rupture of the umbilical sac allowing the primitive gut to extrude into the extraembryonic coelom, or failure of fusion of the lateral body folds producing a defect in the anterior abdominal wall adjacent to the umbilicus.

The midgut comprises the duodenum distal to the ampulla of Vater, jejunum, ileum, caecum, and colon as far as the left transverse colon. Atresia affecting the midgut may occur at single or multiple sites. The cause is probably intrauterine interference with the blood supply to that part of the gut which is affected, with consequent resorption of the ischaemic bowel.

The hindgut gives origin to the left third of the transverse colon, the descending colon, sigmoid, rectum, and upper part of the anal canal, and a considerable part of the urogenital system. The hindgut terminates in the primitive cloaca, which is separated from the proctodaeum (a shallow ectodermal depression) by the cloacal membrane. The primitive cloaca communicates with the hindgut and the allantois. Early in development the cloaca is joined by the pronephric ducts. A coronal septum (the urorectal septum) arises in the angle between the allantois and hindgut, grows caudally, fuses with the cloacal membrane, and divides the cloaca into a dorsal primitive rectum and a ventral primitive urogenital sinus. The cloacal membrane breaks down, establishing continuity between the endodermal hindgut and the ectodermal part of the anal canal. There are many varieties of imperforate anus. Absence of a variable length of rectum and anal canal, known as the 'high' anomaly, is frequently associated with the bowel terminating via a rectourethral or rectovaginal fistula. Ten per cent of babies with an imperforate anus will have oesophageal atresia, with or without a fistula, suggesting that the division of trachea and oesophagus and urogenital system and rectum must be occurring at a similar time in gestation, with possibly a similar mechanism producing the division. Anomalies of the urogenital system occur in a very high proportion of affected infants. Abnormalities of the ectodermal component of the anal canal result in 'low' imperforate anus.

The ganglion cells of the gut lie in the submucosa and intermyenteric plane. Ectodermal in origin, they migrate caudally along the length of the gut. Failure of migration down to the internal sphincter of the anal canal results in an aganglionic segment extending for a variable distance proximally, and is the underlying abnormality in Hirschsprung's disease.

Mucosal differentiation occurs in the early months. The inner circular muscle differentiates earlier than the outer longitudinal. Thus the fetal intestinal tract is prepared for digestion, absorption, and propulsion at a comparatively early stage in development.

Oesophageal atresia and tracheo-oesophageal fistula

The incidence of this condition is approximately 1 in 3500 live births.

The upper oesophagus ends in a blind pouch. In the majority of cases, the lower oesophagus communicates at its upper end with the trachea, that is there is a tracheo-oesophageal fistula. Although much less common, there are a number of well-recognized anatomical variations illustrated in Fig. 1.

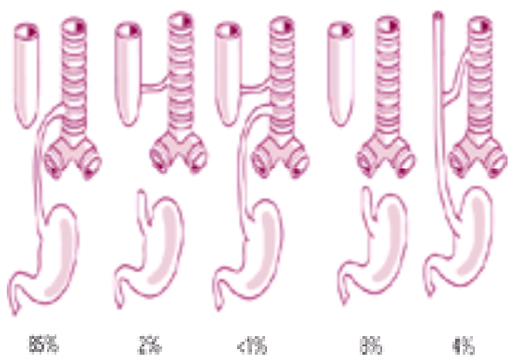

Fig. 1 Anatomical variations of oesophageal atresia and tracheo-oesophageal fistula, indicating the relative frequency.

Clinical features

Frequently the infant with oesophageal atresia is premature or small for gestational age. In 50 per cent there is a history of polyhydramnios. Shortly after birth, because swallowing is impossible, copious amounts of frothy saliva dribble from the mouth, associated with choking, dyspnoea, and cyanotic episodes. Frequent suction is required to keep the airway clear. The infant with a tracheo-oesophageal fistula without associated oesophageal atresia coughs, chokes, and becomes cyanosed during feeds. Because air escapes through the fistula into the oesophagus, gaseous distension of the abdomen is frequently present. Aspiration of feed into the airway results in pulmonary collapse/consolidation.

Over 50 per cent of infants with oesophageal atresia will have significant associated anomalies. Of particular importance are cardiac, anorectal, urogenital, and skeletal anomalies. The premature infant or the infant who is small for gestational age are more likely to have multiple anomalies than is the full-term infant.

Survival of infants with oesophageal atresia depends on birth weight and associated abnormalities. All infants with a birth weight greater than 1.8 kg and no associated abnormalities or pneumonia should survive; this is also true of the larger infant with a moderately severe associated abnormality or pneumonia. The mortality for the infant less than 1.5 kg, or one with multiple severe congenital abnormalities, remains in the region of 20 to 30 per cent.

Diagnosis

When oesophageal atresia is suspected a size 10 or 12 FG catheter is passed through the mouth and into the oesophagus. If the oesophagus is obstructed, the catheter meets a resistance 9 to 11 cm from the gum margin. A smaller catheter may curl up in the obstructed oesophagus. Contrast studies of the oesophagus are rarely necessary. A chest and abdominal radiograph will show the position of a radio-opaque tube in the upper oesophagus, and the presence of gas in the bowel if a tracheo-oesophageal fistula is present. Complete absence of gas in the abdomen is diagnostic of an oesophageal atresia without a distal tracheo-oesophageal fistula. The radiograph will also reveal any abnormalities of ribs or vertebrae, signs of pneumonia, and may provide evidence of an associated cardiac abnormality.

In isolated tracheo-oesophageal fistula, very careful contrast studies of the oesophagus are required to demonstrate the fistula. Endoscopic examination of trachea and oesophagus is usually diagnostic.

Management

Early division of the tracheo-oesophageal fistula and anastomosis of the oesophagus are possible in the majority of cases. Postoperatively, mechanical ventilation may be necessary, but usually the full-term infant with no preoperative complications only needs careful suction of the nasopharynx to maintain a clear airway. A gastrostomy or a transanastomotic nasogastric tube is usually used to enable the infant to be fed within 48 h of operation. A primary anastomosis may not be feasible in pure oesophageal atresia, extreme prematurity, or where the infant's general condition is poor. In such cases a tracheo-oesophageal fistula, if present, would be divided and a feeding gastrostomy established. Subsequently, an oesophageal anastomosis, after a delay of 4 to 6 weeks, having left the upper oesophageal pouch intact and kept empty of saliva by continuous suction, may be feasible. Alternatively, a cervical oesophagostomy is done with the intention, when the infant's condition

permits, of establishing continuity between mouth and stomach, using a length of colon, a tube of stomach, or the whole stomach. The choice depends on the surgeon's preference.

Anterior abdominal wall defects

The incidence of exomphalos and gastroschisis is approximately 1 in 3000 births. An exomphalos occurs because the intra-abdominal contents herniate through the umbilical ring into the base of the umbilical cord and are covered by a translucent membrane composed of peritoneum and amnion. Exomphalos major indicates that the diameter of the defect is greater than 5 cm, exomphalos minor that the defect is less than 5 cm. The contents of the exomphalos almost always include liver and a variable amount of bowel. On occasion, a very small amount of bowel alone herniates into the base of the cord. The diagnosis is frequently made on a prenatal ultrasonographic scan and prompts a search for associated major abnormalities, particularly anencephaly, chromosomal trisomies, major cardiac anomalies, and the Beckwith–Wiedemann syndrome. Associated abnormalities occur in 40 per cent.

The Beckwith–Wiedemann syndrome also termed the exomphalos macroglossia gigantism (EMG) syndrome, usually presents as a large-for-dates infant with a small exomphalos. The tongue is strikingly large, there are frequently ridges in the ear lobes, and a prominent naevus flammeus on the forehead. Hypoglycaemia as a result of hyperinsulinism produced by islet-cell hyperplasia is a common early problem, which may require steroids, glucagon, and rarely subtotal pancreatectomy to effect control. In the long term, children with this syndrome have an increased incidence of solid tumours, particularly nephroblastoma and hepatoblastoma.

In gastroschisis there is a full-thickness defect in the anterior abdominal wall, usually to the right of the umbilical cord. The defect is small but most of the gastrointestinal tract may be extruded through it. In contrast to exomphalos, other intra-abdominal organs are rarely eviscerated and abnormalities outside the gastrointestinal are unusual. Again, prenatal diagnosis on ultrasonographic scan is common.

Exomphalos

Clinical features

The lesion will be obvious at birth. Occasionally the membrane will rupture during, or shortly after, delivery. Careful examination for associated defects is essential.

Management

A nasogastric tube is passed to decompress the bowel. The sac can be very satisfactorily covered and supported by wrapping clingfilm around the exomphalos and the baby's trunk. Plain radiographs of chest and abdomen are taken preoperatively in order to study the cardiac contour, the intestinal gas pattern, and to look for evidence of an associated diaphragmatic hernia. If the contents of the sac can be reduced into the peritoneal cavity, the abdominal wall can be closed in layers. If closure of all layers of the abdominal wall is impossible, skin closure alone may be used, or a synthetic material such as Silastic sheeting or Prolene mesh is used to enclose the sac after suturing it to the margins of the defect. Gradual reduction of the contents into the peritoneal cavity is then possible, with delayed closure of the abdominal wall. An alternative is to paint the sac with an antiseptic solution such as 70 per cent alcohol or one of the iodine-based preparations. This results in the formation of a dry eschar that separates after some weeks, leaving a granulating surface, which gradually epithelializes. Any method that does not achieve muscle closure will leave a ventral hernia, which requires surgery at a later date.

Postoperatively, ventilatory support may be necessary. Antibiotics commenced preoperatively are continued postoperatively, particularly if an artificial material is used. Parenteral nutrition will be necessary if oral feeds cannot be given. Survival is related to the size of the lesion and the severity of any associated abnormalities.

Gastroschisis

Clinical features

Babies with this abnormality are frequently small for gestational age. After delivery, heat loss from the exposed bowel rapidly causes hypothermia. Hypoproteinaemia is very common. The small size of the defect in the anterior abdominal wall and the often narrow pedicle from which the bowel is suspended may impair the blood supply and result in infarction of much of the extruded intestine. Atresia may have occurred because of intrauterine impairment of the blood supply.

Management

A nasogastric tube is passed and the bowel decompressed. The bowel can be enclosed in clingfilm wrapped around the baby's trunk, or the baby can be placed in a large polythene bag taped around the chest. This keeps the bowel moist and prevents excessive heat loss. Antibiotics are commenced preoperatively and colloid is given to counteract the existing hypoproteinaemia and hypovolaemia. At operation the anterior abdominal wall is stretched and any meconium washed out *per rectum* to reduce bulk. Reduction of the extruded bowel is attempted and abdominal wall closure achieved where possible.

In about 10 per cent of cases, primary closure is not possible and a Silastic sheet or Prolene mesh is used to form an artificial sac to enclose the intestine. The material is sutured to the margins of the defect and the size of the sac gradually reduced over some days, squeezing the bowel back into the peritoneal cavity until closure of the abdominal wall becomes feasible—usually after 10 to 14 days. Ventilatory support postoperatively is often necessary. Parenteral nutrition is essential and may need to continue for many weeks until gastrointestinal motility and absorption are adequate. Sepsis is a considerable hazard. The mortality is now 5 to 10 per cent compared with 80 per cent 10 years ago. Improved postoperative management is largely responsible for this.

Congenital pyloric stenosis

Congenital hypertrophic pyloric stenosis is a disorder characterized by hypertrophy of the circular muscle of the pylorus and so obstruction to the gastric outlet. The incidence is 2 per 1000 live births. The aetiology is unknown. Theories include primary muscle hypertrophy, abnormalities of the maturation of ganglion cells, absence of a certain type of ganglion cell, or a response to abnormally high concentrations of circulating gastrin. Genetic and environmental factors play an important part. There is an increased incidence of pyloric stenosis in siblings of an affected child and in the offspring of a woman who has had the condition. Environmental factors include social class, type of feeding, and a seasonal variation with an increase in the winter months. In any large series the male:female ratio is 3 or 4:1 and half the cases will be first-born children.

Clinical features

The onset of symptoms is usually between 3 and 6 weeks of age, but may present shortly after birth. Vomiting of increasing severity is the cardinal symptom, eventually occurring after most feeds and becoming projectile. The vomitus is milk and mucus, and may contain altered blood suggesting an oesophagitis or gastritis; bile is never present. The baby stops gaining weight and becomes constipated. Characteristically the baby is alert, anxious, and hungry. If diagnosis is delayed, severe malnutrition may develop.

Examination reveals evidence of weight loss and in advanced cases signs of dehydration will be evident. When the stomach is full, waves of peristalsis travelling from left to right in the epigastrium will be seen (visible peristalsis). The thickened pylorus is felt as an olive-sized tumour lying deep to the edge of the right rectus and is often most easily felt when the stomach is empty. The diagnosis of pyloric stenosis is made on clinical grounds in the majority of cases. A plain radiograph of the abdomen may be very helpful in revealing a large stomach with a paucity of distal gas. A barium meal is diagnostic when the 'string' sign of the elongated pylorus is demonstrated. The barium study may also reveal gastro-oesophageal reflux, which is commonly associated with pyloric stenosis. Ultrasound is now widely used—pyloric length more than 1.2 cm and wall width more than 3 mm supporting the diagnosis.

Management

In the child presenting early, electrolyte disturbance and dehydration are minimal. In the later case, dehydration with hypochloraemic alkalosis and marked potassium depletion occurs. Preoperative correction of water and electrolyte deficits is essential. The operation of pyloromyotomy, described by Ramstedt in 1912, splits the hypertrophied muscle longitudinally allowing the mucosa to bulge through the defect, thus enlarging the pyloric canal. Postoperatively, various feeding regimens are

advocated; all aim to have the baby on a normal feeds by 48 to 72 h postoperatively. The prognosis is excellent.

Atresia and stenosis of the small intestine

An intrinsic obstruction may produce either complete or partial obliteration of the bowel lumen. Complete obliteration may be due to a gap between the two ends of the small intestine, with or without a connecting band between these ends, or a complete mucosal diaphragm. Such complete obstruction is known as atresia. When obstruction is incomplete it may be due to a narrowing of the lumen—a stenosis—or a mucosal diaphragm with a hole. Small-intestinal atresia is a more common finding than is stenosis. The duodenum is most often affected, followed by jejunum, and least often ileum.

Associated abnormalities of the gastrointestinal tract, including malrotation, oesophageal atresia, imperforate anus, biliary atresia, and annular pancreas are a feature of duodenal atresia/stenosis. Localized volvulus and meconium ileus are associated with jejunoileal atresias.

Intrinsic obstruction of the small intestine of congenital origin presents most often in the neonatal period but when the obstruction is partial it may first present much later, in infancy and childhood.

Congenital intrinsic duodenal obstruction

When duodenal obstruction is complete, vomiting usually occurs within a few hours of birth and is bile stained unless the obstruction is proximal to the ampulla of Vater, when the vomiting is persistent and copious but not bile stained. Meconium may be passed normally and there may be obvious epigastric distension. In view of the association with other abnormalities, these should be sought carefully. In particular the infant should be examined for evidence of Down's syndrome. Duodenal lesions are an association of this syndrome and occur in 10 per cent of cases.

When obstruction is incomplete the symptoms may be intermittent and the diagnosis delayed.

Congenital intrinsic duodenal obstruction may be accompanied by an annular pancreas; this is a sign of failure of duodenal development rather than an obstructive lesion *per se*. In infants with duodenal atresia, at operation, it often looks as if there is an annular pancreas because there is interposition of the pancreas between the two ends of the duodenal atresia.

Congenital intrinsic duodenal obstruction is not, in general, associated with multiple atresias in the remainder of the small intestine, but there may be obstruction at two levels in the duodenum.

Jejunoileal obstruction

Symptoms, typically bile-stained vomiting and abdominal distension, usually occur within the first 2 days of life. Meconium may or may not be passed. When obstruction is incomplete the diagnosis may again be long delayed and the child may present with intermittent vomiting, abdominal distension, and even with features of malabsorption—a clinical picture that may resemble coeliac disease.

Diagnosis

Plain radiographs of the abdomen are usually diagnostic in infants who present with a complete obstruction. In duodenal atresia there is the characteristic 'double bubble' (Fig. 2). When duodenal obstruction is incomplete there may be small amounts of air in the lower bowel. A barium meal may be necessary to demonstrate the obstruction and may suggest an associated malrotation. When there is complete jejunoileal obstruction there are usually multiple dilated loops of intestine. A barium enema may reveal an unused microcolon. When obstruction is incomplete a barium follow-through may be needed to establish the diagnosis. Rarely, laparotomy may be the final court of appeal.

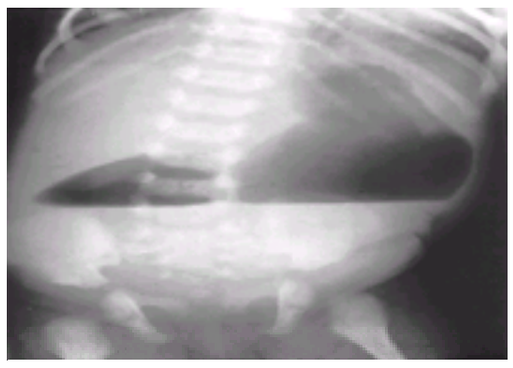

Fig. 2 Plain radiograph of the abdomen of an infant with duodenal atresia showing characteristic 'double bubble'.

Management

A nasogastric tube is passed to empty the stomach and allow accurate measurement of gastric losses. Correction of fluid and electrolyte disturbances, if present, should precede surgery, provided that gangrenous or ischaemic bowel is not suspected. At laparotomy, care should be taken to exclude any other gastrointestinal abnormality. In duodenal obstruction, the operation of choice is duodenoduodenostomy. In jejunoileal lesions, adequate resection of the proximal dilated gut reduces the great discrepancy in size between the two blind ends and so facilitates end-to-end anastomosis, although an oblique-to-end anastomosis is sometimes necessary. Leaving the dilated gut immediately proximal to the anastomosis results in ineffective peristalsis and delay in establishing enteral feeds.

Considerable loss of intestinal length may occur as a result of the intrauterine process producing the atresia; surgical correction, particularly of multiple atresias, will result in further loss. Every effort is made to preserve some ileum and the ileocaecal valve. Loss of considerable lengths of jejunum is well tolerated. Loss of ileum, particularly if the ileocaecal valve is also lost, presents management problems throughout childhood because malabsorption of a variety of important nutrients occurs. The enterohepatic circulation may be impaired. Early liver damage is a consequence of prolonged parenteral nutrition and episodes of sepsis.

Duplication of gastrointestinal tract

Definition

Duplications are cystic or tubular structures whose lumen is lined by a mucous membrane, usually supported by smooth muscle. They occur most often within the dorsal mesentery of the gut. They are also sometimes described as enteric cysts, neurenteric cysts, and reduplications. Duplications may occur anywhere along the alimentary tract but they are found most often in relation to the small intestine, particularly the ileum. They may not communicate with the lumen of the gastrointestinal tract. Duplications may be found in association with intestinal atresias. Sometimes those associated with the small intestine are lined by gastric mucosa and peptic ulceration of the adjacent small-intestinal mucosa, with bleeding, may occur. Those associated with the colon never contain ectopic gastric mucosa.

Clinical features

These are congenital malformations that present most often in early infancy. Later presentation, even into adult life, is well recognized. Duplications may present in infancy as a small-bowel obstruction, or a small cystic duplication may form the lead point of an intussusception. A palpable abdominal mass in infancy, as well as rectal bleeding and volvulus, may also be modes of presentation of this disorder. The clinical diagnosis is often difficult and the diagnosis may sometimes be made

only at laparotomy. A technetium scan may be helpful by demonstrating ectopic gastric mucosa. Initial presentation may be a posterior mediastinal cystic mass, possibly associated with cervical or upper thoracic vertebral abnormalities. The mass is likely to communicate through the diaphragm with an intestinal duplication.

Management

Excision of a cystic duplication with or without the adjacent intestine is usually straightforward. Any associated thoracic cyst will also need excision. Short tubular duplications can be excised with the adjacent intestine; very extensive tubular duplications can be opened longitudinally and the mucosa stripped out, leaving the common muscle wall.

Small-intestinal malrotation with or without volvulus

Malrotation of the small intestine is due to disordered movement of the intestine around the superior mesenteric artery during the course of development of the embryo.

Two main abnormalities that produce symptoms may occur. First, there is a gross narrowing of the base of the mesentery, which may allow the midgut to twist around and cause a volvulus. This may occur acutely, causing complete obstruction, or it may occur intermittently, producing bouts of partial or complete obstruction that release themselves spontaneously. Secondly, there may be partial duodenal obstruction from extrinsic compression of the small intestine by peritoneal bands (Ladd's bands) that extend from the caecum to the subhepatic region.

Malrotation may be associated with duodenal atresia or stenosis. It is also found in association with diaphragmatic hernia, omphalocele, and gastroschisis. However, malrotation may be asymptomatic and is sometimes discovered only as an incidental finding on a barium study. The majority of children who develop symptoms related to malrotation do so within the neonatal period, presenting with features of intestinal obstruction, complete or incomplete. When there is a volvulus there may also be obstruction to the blood supply to the bowel, which if complete will lead to extensive gangrene of the small bowel. The passage of bloody stools may be an early sign of this complication.

Those children with malrotation who present later in childhood may do so with features of intermittent obstruction such as episodes of vomiting, often bile stained, and abdominal pain, but sometimes they may manifest with features of malabsorption and many clinical features suggestive of coeliac disease. This is due to intestinal stasis with bacterial overgrowth in the lumen of the small intestine. Steatorrhoea may be accompanied at times by protein-losing enteropathy from obstruction of the mesenteric lymphatics, and chylous ascites may also occur.

Diagnosis

The diagnosis needs to be considered in the differential diagnosis of small-intestinal obstruction in infancy.

Plain radiographs of the abdomen may be very useful, typically revealing an air-filled stomach with some gas scattered through the lower part of the abdomen. However, a malrotation may not be accompanied by any abnormality on the plain radiograph of the abdomen and a barium meal will then be necessary to reveal the presence of malrotation by outlining the failure of the duodenum to cross to the left of the vertebral bodies with the fourth part lying adjacent to the first lumbar vertebra. A barium enema may be useful if it demonstrates the abnormal position of the caecum, but a barium meal is more reliable.

Management

Surgical intervention is indicated when a firm diagnosis is established. Ladd's operation is usually the procedure of choice. This involves, in general, the placement of the colon on the left and the small intestine on the right, having divided any bands and adhesions between the duodenum and large bowel, and, by dissection, broadened the base of the mesentery as much as possible. After a volvulus, total bowel necrosis is untreatable, but severe bowel ischaemia can be reversible and a 'second look' laparotomy may be necessary.

Small-intestinal lymphangiectasia

Small-intestinal lymphangiectasia has been described as a primary, that is a congenital, abnormality or as a secondary manifestation of some other disease process such as constrictive pericarditis. The primary abnormality may be accompanied by generalized lymphatic abnormalities including lymphoedema, chylous ascites, and hypoplasia of the peripheral lymphatic system, but the lymphatic abnormality may be confined to the small bowel and its mesentery. It is usually, but not invariably, accompanied by hypoproteinaemic oedema. Radioisotope studies have demonstrated that the hypoproteinaemia is due to abnormal protein loss into the gut. The pathogenesis of the hypoproteinaemia has been attributed to the rupture of dilated lymphatic channels or to protein exudation from intestinal capillaries via an intact epithelium, where there is obstruction of lymphatic flow.

Clinical features

It is a rare condition, which may present throughout life but most often in the first 2 years with diarrhoea and failure to thrive and, later, generalized oedema with hypoproteinaemia. The clinical picture may resemble coeliac disease. There is lymphopenia in the presence of a normal bone marrow and reduction of serum albumin, serum IgG, and carrier proteins such as protein-bound iodine. The severe protein loss may be accompanied by enteric calcium loss, leading to hypocalcaemia. Steatorrhoea is often found in this disorder.

Diagnosis

Diagnosis is made by showing the characteristic lymphatic abnormality on small intestinal biopsy, that is dilated lacteals, but the lesion is patchy. One negative biopsy does not exclude the diagnosis. Radioisotope demonstration of abnormal enteric protein loss using a technique such as intravenous $CrCl_3$ is helpful in diagnosis but is not specific. Barium studies in most cases show coarse mucosal folds.

Pathology

Autopsy studies reveal a considerable variation in the distribution of the lymphatic abnormality along the length of the small intestine. Dilated lacteals may occur irregularly along the small bowel and there may be gross dilatation of lymphatics projecting into the lumen. Lymphatic proliferation and dilation may also occur within the mesentery, as well as the serosal, muscular, and submucosal layers of the small-intestinal wall, and extend into the lymph nodes and occupy part of the nodal tissue.

Treatment

This is usually dietetic, as the lymphangiectasia is rarely localized enough to allow surgical excision to effect a permanent cure. The amount of long-chain fat in the diet, which is normally absorbed via the intestinal lymphatics, should be limited. This leads to a reduction in the volume of intestinal lymph and in the pressure in the dilated lymphatics. It is best done by placing the child on a low-fat diet (5–10 g/day) and adding medium-chain triglycerides, instead of the usual long-chain dietary fats, in unrestricted amounts. A milk containing medium-chain triglyceride such as Pregestimil ^{R} may be used with medium-chain triglyceride oil for cooking. Some children may be resistant to this therapy when the abnormality is very extensive and, on occasion, death may result despite therapy. Albumin infusions are of little value in management as their benefit is so transitory. Steroids have been advocated but there is little evidence to justify their use. In a follow-up study of children, although there was a continuing chyle leak, as shown by persistent lymphopenia and hypoalbuminaemia, there was a rapid and sustained improvement in dependent oedema following the use of the diet recommended above, although asymmetrical oedema from peripheral lymphatic abnormalities was unaffected. Their growth rate improved on the diet. Clinical relapse occurred quickly when the diet was relaxed. Continued adherence to a strict diet, at least through puberty, is therefore recommended. Indeed it seems probable that this is a life-long disorder and that some dietetic management may usually need to be permanent.

Meckel's diverticulum

This diverticulum is the vestigial remnant of the vitellointestinal duct. Although most people who have such a diverticulum are asymptomatic, complications may arise, which may present in a variety of ways. In children, these complications chiefly arise in association with the presence of ectopic gastric mucosa in the diverticulum. Other ectopic tissue, for example pancreatic tissue and colonic mucosa, may be found in some cases.

The diverticulum is located in the distal ileum within 100 cm of the ileocaecal valve. It is always antemesenteric.

Clinical features

Rectal bleeding is the main symptom. This is usually the passage of bright blood rather than tarry melaena stools. Typically the stool is at first dark in colour but later bright red. Bleeding may be acute, with shock requiring urgent blood transfusion, or it may be chronic. From a practical viewpoint any child who has a massive, painless, rectal bleed should be regarded as having a Meckel's diverticulum until proved otherwise. Most often bleeding from a Meckel's diverticulum is associated with ulceration of the small bowel adjacent to ectopic gastric or pancreatic mucosa but this is not always the case as bleeding may occur in the absence of ectopic mucosa.

Small-intestinal obstruction may also be a mode of presentation. This may be as a volvulus associated with a band, or an intussusception with the diverticulum as the lead point. Acute diverticulitis occurs and may produce a picture indistinguishable from acute appendicitis.

Diagnosis and management

This depends upon the mode of presentation. When rectal bleeding occurs, other causes need excluding. Investigation may include colonoscopy to exclude colonic causes and upper endoscopy to exclude peptic ulceration or oesophagitis.

Barium follow-through is usually an unrewarding investigation. a technetium scan is usually the most important investigation. The radionuclide technetium-99m concentrates in the gastric mucosa. When it is given intravenously, ectopic gastric mucosa appears as an abnormal localization on abdominal imaging with a gamma-camera. In this way a Meckel's diverticulum with ectopic gastric mucosa or indeed a duplication with such ectopic tissue may be diagnosed. A negative scan may prompt angiography. However, negative investigations in a child with severe bleeding should not deter a surgeon from proceeding with a diagnostic laparotomy, or laparoscopy if appropriately skilled. Indeed, when considering the other modes of presentation of Meckel's diverticulum it is often only at laparotomy that the role of a Meckel's diverticulum in the child's intestinal pathology is appreciated.

Meconium ileus

This is a manifestation of cystic fibrosis, the disorder sometimes known as fibrocystic disease of the pancreas. Meconium ileus is the earliest mode of presentation of this disorder during the neonatal period. A similar syndrome in older children and young adults who have cystic fibrosis may occur—the meconium ileus equivalent. The abnormally viscid consistency of the meconium produces an intraluminal obstruction. It may result from several factors including the lack of pancreatic enzymes during fetal life, which may account for the high protein content of the meconium. There is also evidence of reduced secretion of water and electrolytes in such infants, which may further render the meconium more viscid. The meconium, because of its high viscosity and tendency to adhere to the mucosa, cannot be propelled along the bowel and so small-intestinal obstruction results. This occurs most often in the distal ileum.

Clinical features

The neonate with this disorder usually develops signs of intestinal obstruction within the first 24 to 48 h of life, with the classical signs of bile-stained vomiting, progressive abdominal distension, and failure to pass meconium. In simple meconium ileus, the meconium is the sole source of the obstruction, but meconium ileus may be complicated by perforation of the gut and, when this occurs *in utero*, intraperitoneal calcification may be observed on a plain radiograph of the abdomen, providing evidence of meconium peritonitis. Perforation may also occur in the neonatal period. Volvulus and atresia may also complicate meconium ileus.

In simple meconium ileus, the plain radiograph of the abdomen may show dilated bowel but few fluid levels. Sometimes there is the appearance of bubbly meconium in the right lower quadrant. Bowel loops may be palpable. If a contrast enema is performed a microcolon, a consequence of disuse, will be demonstrated. Atresia associated with meconium ileus is frequently indistinguishable radiologically from an atresia of ischaemic origin.

Management

When meconium ileus is complicated by atresia or perforation, gangrene, peritonitis, or associated volvulus, surgical intervention is essential. Surgical options include the formation of a double-barrelled stoma with subsequent irrigation of the meconium from the distal bowel over a week or so, or intraoperative irrigation of the bowel with an immediate end-to-end anastomosis. In both options, an associated atresia or necrotic bowel are resected. The treatment of uncomplicated meconium ileus using enemas containing pancreatic enzymes, mucolytic agents such as acetylcysteine, and the detergent Tween 80 had been advocated for some time. Noblett in Melbourne, in 1969, used a Gastrografin enema to relieve intraluminal obstruction. Gastrografin is a radio-opaque, hyperosmolar solution that is effective because of its hypertonicity. This technique should not be used until a plain radiograph of the abdomen has excluded the possibility of complicated meconium ileus. An initial barium enema should exclude Hirschsprung's disease and demonstrate a microcolon extending to the proximal colon. The retrograde passage of contrast medium through the ileocaecal valve should demonstrate intraluminal meconium with passage into proximal dilated ileum, thus excluding an ileal atresia. After a successful Gastrografin enema, large amounts of meconium will be passed.

Although there may be no signs clinically or radiologically of pulmonary complications in the neonatal period, physiotherapy should be started and any chest infections treated with antibiotics when they occur (as for older children with cystic fibrosis). A pancreatic enzyme preparation should also be started, at first in small dosage when milk feedings have begun. The diagnosis should be confirmed by sweat electrolyte estimations; concentrations of sweat sodium above 60 mmol/l are abnormal. In the majority of infants with cystic fibrosis, the finding of the abnormal gene † *F508* or one of the other recognized mutations confirms the diagnosis. In a minority the abnormal gene is not identifiable.

Congenital short intestine

There is a syndrome of congenital short intestine in association with malrotation with clinical features similar to those that follow massive intestinal resection. There is also another syndrome of congenital short intestine in association with pyloric hypertrophy and malrotation. This latter syndrome is due to an absence or diminution of argyrophil ganglion cells in the small-intestinal wall. These cells normally organize peristalsis and ensure that the bolus moves forward at the correct speed. In the absence of such innervation, smooth muscle of the small-intestinal wall contracts spontaneously and rhythmically, but segmentation is not co-ordinated and the food bolus does not move forward, and there is work hypertrophy of smooth muscle. Both syndromes are rare and often only diagnosed at laparotomy.

Colonic atresia

Atresia of the large intestine is rare. In any series of cases of intestinal atresias, fewer than 10 per cent will have isolated colonic atresia.

Clinical features

The baby presents in the first 24 to 48 h with marked abdominal distension, vomiting, and failure to pass meconium.

Diagnosis

Abdominal radiographs reveal multiple dilated loops of bowel with fluid levels; the position of the loops may suggest a large bowel obstruction. Confirmation of the level of the atresia is obtained by barium enema.

Management

Nasogastric suction and intravenous fluids are commenced preoperatively. At laparotomy the lesion may be an isolated atresia or associated with multiple atresias of small and large bowel. If the atresia is solitary, it may be possible to perform an anastomosis after resection of the atresia and a length of the grossly dilated proximal bowel. Frequently a colostomy is fashioned to allow the dilated proximal bowel to contract before an end-to-end anastomosis some weeks later.

Hirschsprung's disease

In this condition, ganglion cells are absent in the bowel wall. The distal rectum is always aganglionic and the aganglionosis extends proximally for a variable distance. In 70 per cent the rectosigmoid is involved, in 20 per cent the aganglionosis extends proximal to the sigmoid for a variable distance up the colon, and in 10 per cent the aganglionosis extends into the small intestine. The aganglionic bowel is incapable of co-ordinated peristalsis and passively constricts, resulting in a mechanical obstruction. The incidence is approximately 1 in 5000 births.

Clinical features

Hirschsprung's disease is not associated with a high incidence of prematurity, and most of the babies have a birth weight appropriate for gestational age. This contrasts sharply with most of the other congenital obstructions of the alimentary tract. Associated abnormalities are rare. The most important association is with Down's syndrome.

Symptoms of Hirschsprung's disease are present in the first few days of life in almost all cases. Exceptionally, a baby will have no symptoms during the early neonatal period. The major symptoms are failure to pass meconium within 36 h of birth, abdominal distension, vomiting, and poor feeding. These may occur singly or in combination. Frequently, a rectal examination will relieve the obstruction by passively dilating the aganglionic segment. Twenty to 50 per cent of patients with Hirschsprung's disease are not diagnosed in the early weeks of life. Later presentation is with constipation that dates back to the neonatal period. It is not accompanied by soiling and is frequently associated with failure to thrive. Presentation may be delayed for months or years.

Hirschsprung's enterocolitis may be the mode of presentation in the infant of a few weeks of age. This condition, the precise cause of which is unknown, presents with abdominal distension, profuse diarrhoea, and circulatory collapse. The infant is gravely ill and the mortality is 20 per cent. The child with this complication, successfully treated initially, may have absorptive problems for some time, suffer recurrent episodes of enterocolitis despite successful surgery, and the surgery is attended by a higher rate of complications. The incidence of enterocolitis can be greatly reduced if the diagnosis of Hirschsprung's disease is made in the first week of life.

Diagnosis

In the neonatal period a plain abdominal radiograph will reveal distension of small and large bowel. A barium enema may show the narrow aganglionic bowel with dilated proximal bowel (Fig. 3) but a normal barium enema does not exclude Hirschsprung's disease. A 24-h film showing retained barium in the colon is often more helpful than the actual enema in confirming the clinical suspicion of Hirschsprung's disease. The definitive diagnostic procedure is a rectal biopsy. Suction biopsy enables the pathologist to look for ganglion cells in the submucosal plexus; full-thickness biopsy provides the intermyenteric plexus as well but this is usually unnecessary. In Hirschsprung's disease, ganglion cells are absent, hypertrophic nerve trunks are present, and if a histochemical stain for acetylcholinesterase is used, this reveals excessive amounts of this enzyme in the bowel wall. Anorectal manometry in Hirschsprung's disease typically shows failure of relaxation of the internal sphincter in response to rectal distension but this reflex is frequently absent in normal term babies until after the second week of life. This method of diagnosis is therefore unreliable in the neonatal period, requires considerable expertise to obtain reliable results, and cannot be regarded as suitable for the routine diagnosis of Hirschsprung's disease.

Fig. 3 Barium enema in Hirschsprung's disease illustrating a narrow aganglionic rectum with dilation proximally.

Management

Following diagnosis, either definitive surgery is carried out or a colostomy is fashioned in ganglionic bowel and definitive surgery deferred for a period of time. Definitive surgery consists of excision of aganglionic bowel with a 'pull through' procedure, enabling an anastomosis to be made between the anus and ganglionic colon. The three operations most often performed are those described by Swenson, Duhamel, and Soave. Provided that the surgery is uncomplicated, the long-term complications, which include faecal and urinary incontinence, and impotence, should be minimal. Bowel control is likely to be imperfect for a number of years, with soiling as a major problem, but good bowel control will be achieved in the majority of patients treated by experienced surgeons.

Imperforate anus

The exact incidence of this abnormality is not known but the usual incidence quoted is 1 in 5000 births. The basic classification differentiates between the high anomalies, where the bowel terminates above the pelvic floor, the bowel narrowing down to communicate with the urethra in the male (a rectourethral fistula) and the vagina or vestibule in the female (a rectovaginal/vestibular fistula) in the majority of cases. In the low anomalies, the bowel passes through the pelvic floor and either opens on to the perineum in an ectopic position, or lies just beneath the skin-covered anus. The high anomaly is more likely to occur in boys, the low in girls. Overall, more boys than girls present with an imperforate anus. Associated anomalies of the urogenital tract, oesophagus, heart, and skeletal system are common.

Clinical features

Early examination of the perineum will establish the presence of an anorectal anomaly. In the male, the presence of meconium on the perineum usually indicates a low anomaly. In the female, careful inspection is necessary to differentiate meconium being passed *per vaginum*, indicating a high anomaly, from meconium emerging from a perineal site, suggesting a low anomaly. Careful probing of any opening will enable the direction in which the bowel is running to be established. In the female, doubt about the precise anatomy of the anomaly may be resolved by contrast studies. In the male, differentiating a completely covered anus from a high anomaly may be difficult in the early hours after birth. Examination of the urine microscopically may reveal the presence of squamous cells or debris, suggesting a fistula between bowel and urethra. Occasionally, meconium is passed *per urethra*.

A lateral film of the pelvis taken after the infant has lain 'bottom up' over a foam wedge for some minutes will often reveal the level at which the rectum terminates, but this film cannot be reliably interpreted in the first few hours after birth because air may not have reached the distal bowel. In boys, a micturating cystourethrogram will demonstrate a rectourethral fistula in a high proportion of cases, but is rarely necessary as an initial diagnostic procedure. Having defined the nature of the anorectal

anomaly, evidence of any associated abnormality should be sought by careful clinical examination and radiographs of chest, abdomen, and the vertebral column.

Management

A low anomaly usually requires a perineal procedure to enlarge the opening. Dilatation alone may suffice, but in the majority of cases a simple anoplasty produces a more satisfactory result. In the long term, the functional results for the low anomalies should be very good. A high anomaly necessitates a defunctioning colostomy in the neonatal period. Definitive surgery involves division of any fistula and positioning the bowel accurately within the pelvic floor and sphincter muscles. Delay in achieving bowel control is common and a number of secondary operations designed to improve control have been advocated. However, if the initial surgery is meticulous, acceptable continence should be achieved in over 80 per cent of children within the first 10 years. A permanent colostomy should rarely be necessary. The high incidence of associated genitourinary abnormalities makes it mandatory to investigate carefully the urinary tract at an early stage. The mortality for anorectal anomalies is largely dictated by the presence of other serious abnormalities.

14.15 Tumours of the gastrointestinal tract

A. F. Markham, I. C. Talbot, and C. B. Williams

Introduction

Breakthroughs in our understanding of the basic molecular pathology of tumours of the gastrointestinal tract have provided a paradigm for explaining the development of malignancy. Insights into the mechanisms of carcinogenesis in specific tumours of the gut now inform aspects of their clinical management, but carcinomas of the digestive tract remain difficult to treat successfully. Indeed, only minor improvements in 5-year survival rates have been achieved over several decades. The realization that certain gene products are overexpressed early in the development of specific malignancies has led to the evaluation of known drugs in chemoprevention studies. The best example is the use of non-steroidal anti-inflammatory drugs (**NSAIDs**) to inhibit colorectal adenoma and cancer development in predisposed individuals. NSAIDs inhibit cyclooxygenase-2 (**COX-2**), which is upregulated in early colonic adenomas and may drive carcinogenesis. The ability to discriminate between genetic variants (phenocopies) of colorectal and other gastrointestinal cancers will allow more definitive clinical trials of specific treatments for particular forms of these conditions.

Screening strategies to detect surgically resectable gastrointestinal cancers at ever earlier stages are proving successful, particularly for gastric cancer in Japan and for colorectal malignancy in many countries. An appreciation of the natural history of colorectal cancer has informed the design of screening programmes, and also enables the diagnostic yields expected from faecal occult-blood testing, flexible sigmoidoscopy, or colonoscopic examination to be predicted. The complex health economic issues that such screening programmes raise are being subjected to examination.

As well as the gene encoding the adenomatous polyposis coli (**APC**) tumour suppressor protein, which is mutated in familial adenomatous polyposis (**FAP**) (OMIM175100; this refers to the number designation of the condition in McKusick's catalogue, *Online Mendelian inheritance in man*, available online at http://www.ncbi.nlm.nih.gov/, which provides detailed clinical information on inherited conditions), seven different variants of hereditary non-polyposis colon cancer (OMIM114500) (**HNPCC** 1–7) are now recognized. Most of these involve mutation in one of the genes encoding components of the protein complex that repairs DNA mismatches introduced erroneously at replication. These Mendelian diseases are responsible for 5 per cent of colorectal cancers.

Genetic loci responsible for at least a proportion of the disease burden in juvenile intestinal polyposis (OMIM174900), mixed hereditary polyposis (OMIM601228), hyperplastic polyposis, and Peutz–Jeghers syndrome (OMIM175200) have been mapped and in some cases the mutant genes identified. Mutations in the E-cadherin gene have been shown to lead to familial gastric carcinoma (OMIM192090). The gene mutated in 'tylosis with oesophageal cancer' (OMIM148500) has been mapped to chromosome 17q24. Thus, there have been significant recent developments in all these disease areas.

Vogelstein and colleagues have added to their familiar model of the adenoma-to-carcinoma sequence of genetic alterations in colorectal cancer, with the concept of 'gate-keeper', 'caretaker', and 'landscaper' tumour suppressor genes in gastrointestinal cancer. *APC* is the classic example of a gate-keeper gene. The protein plays a key role in preventing carcinogenesis, and loss of such a tumour suppressor gene (**TSG**) leads inevitably to malignancy, with very high penetrance. The mismatch repair genes represent examples of genetic 'caretakers'. Mutations do not lead inevitably to cancer, but loss of their function leads to widespread genetic damage (characterized in the cell by 'microsatellite instability') including secondary mutation in gate-keeper genes, which can eventually generate a malignant phenotype. Thus, for example, colorectal cancer will develop in some 80 per cent of male carriers of an HNPCC mutation by the age of 85 years.

The concept of genetic 'landscaping' emerged from study of the paradox that colorectal cancers with microsatellite instability (**MSI**, sometimes referred to as 'replication error-positive' or **RER**+ tumours) did not contain the MLH1 mismatch repair protein, even though at least one allele of the gene encoding this protein appeared normal on DNA sequencing. This was the result of an epigenetic cause of tumorigenesis, which has proved to be a widespread factor in malignancy. DNA hypermethylation of CpG residues in the promoter regions of this or other genes starts a complex process involving histone deacetylation and permanent promoter silencing. This leads to the loss of function at a TSG allele, equivalent to that caused by a point mutation in the gene, or gene deletion.

In many cases, the roles of mutations in the genes discussed above in human cancers have been confirmed by introducing the corresponding mutations into transgenic mice. Although the phenotypes are by no means always identical, these animal models of human malignancy do act as model systems in which to develop the next generation of therapeutic agents.

The consensus emerging from these progressively more comprehensive, evidence-based surveys of the optimum approaches to the clinical management of gastrointestinal tumours has been incorporated herein. The reader is encouraged to consult these accessible sources directly.

Oesophageal tumours

Benign

Submucosal leiomyomas are the least rare of benign oesophageal lesions. Rarely, fibrovascular polyps, lipomas, haemangiomas, or other mesenchymal tumours are detected on barium-swallow examination. Endoscopic ultrasound can confirm the intramural localization of these lesions to exclude tracheal compression. Tumours large enough to cause dysphagia are removed by enucleation. Mucosal papillomas, foci of leucoplakia, or acanthosis nigricans also occur.

Malignant: oesophageal carcinomas

These constitute only 1 per cent of all malignancies and 6 per cent of gastrointestinal cancer, but cause some 10 per cent of all cancer deaths given their 5-year survival of less than 10 per cent. Historically, the majority of malignant tumours of the oesophagus were squamous carcinomas. However, there appears to be a current epidemic of adenocarcinoma in the lower third of the oesophagus, so that over 50 per cent of the disease in the Western world is now of this histological type.

Other malignant tumours are rare. They include metastases (primarily from the stomach), malignant melanoma, plasmacytoma, stromal tumours, and spindle-cell

carcinoma. Some 50 per cent of patients dying with AIDS have gastrointestinal Kaposi's sarcoma. Although the incidence in the oesophagus is less than in the mouth or hypopharynx, oesophageal extension is associated with a poorer prognosis.

Epidemiology and aetiology

Squamous oesophageal carcinoma

Only half the 3000 cases of oesophageal cancer diagnosed annually in the United Kingdom are now squamous carcinoma. A threefold greater incidence in men may reflect an association with tobacco smoking and alcohol intake. The incidence is much higher in an area extending from the Caspian Sea to China. The high incidence in this 'oesophageal cancer belt' suggested that carcinogenic *N*-nitroso compounds in pickled foods in the diet might be responsible. The possibility that these may be population isolates with predisposing genotypes or even hereditary forms of the disease has only recently begun to be explored.

The incidence of squamous carcinoma is increased in patients with caustic oesophageal strictures due to the ingestion of corrosives, or after radiotherapy. Persistent achalasia predisposes to disease, possibly related to stasis above the narrowed segment. There is also an association with coeliac disease. The Patterson–Kelly (Plummer–Vinson) syndrome, characterized by iron deficiency anaemia, glossitis, postcricoid webs, and dysphagia, particularly in Scandinavian populations, has been associated with squamous carcinoma in up to 20 per cent of cases.

The autosomal dominant disease 'tylosis with oesophageal cancer' (OMIM148500) eventually causes carcinoma in 95 per cent of patients. Pedigrees segregating the characteristic hyperkeratosis of the palms and soles, have allowed the gene for this disease to be mapped to chromosome 17q24. Its identification can be anticipated. This may allow consideration of prophylactic oesophagectomy in carriers.

A number of loss-of-heterozygosity (**LOH**) studies have been performed with squamous carcinomas and several loci show consistent allelic losses compared with matched normal tissues, as would be expected at a tumour-suppressor gene locus. Pedigrees in northern China with consanguinity, and possibly segregating autosomal recessive forms of the disease, have recently been described.

Adenocarcinoma of the oesophagus

Barrett's oesophagus is attributed to chronic gastro-oesophageal reflux, resulting in replacement of the squamous epithelium by an abnormal columnar, metaplastic epithelium. This specialized intestinal metaplasia, with mucus-secreting goblet cells, is thought to increase the risk of developing adenocarcinoma 40-fold. Increasing epithelial atypia defines low to high grades of dysplasia. The frequent association of high-grade dysplasia with adenocarcinomas in surgical-resection specimens suggests that the former is a true precursor of the latter. The claimed annual incidence of adenocarcinoma in an established Barrett's oesophagus is approximately 1 per cent.

However, optimal surveillance of individuals with Barrett's oesophagus remains ill-defined. There is no correlation between the severity of symptoms nd the extent of Barrett's metaplasia. The cancer risk in Barrett's oesophagus may have been overestimated because of publication bias towards reporting positive studies. The incidence of adenocarcinomas appears to be higher in long-segment than in short-segment metaplasia. Aggressive antireflux therapy or endoscopic ablation of the metaplastic epithelium have not been proved to decrease the risk of oesophageal cancer. There is no difference between proton-pump inhibitors and H_2-antagonists in preventing the progression of Barrett's oesophagus. Our lack of understanding of the pathophysiology of Barrett's metaplasia means it is not clear what endpoint in treating reflux disease (symptom relief, epithelial healing, or elimination of reflux) is relevant in preventing progression to oesophageal cancer.

High-grade dysplasia may produce a much higher risk of disease progression. Given the cost implications of endoscopic surveillance programmes, which may not even measure progression effectively, there is an urgent need for reliable molecular markers of high risk. A few pedigrees have been described that apparently segregate an hereditary predisposition to Barrett's oesophagus and associated adenocarcinomas in an autosomal dominant, Mendelian fashion. These may provide the opportunity to identify predisposing mutant genes. Molecular markers associated with other malignancies in the gastrointestinal tract (TP53, RB1, E-cadherin, and cyclin D1) may be informative in that, for example, high levels of cyclin D1 expression in biopsy specimens appear to correlate with an increased risk of carcinoma.

Clinical features

Patients generally present with dysphagia, initially for solids but eventually also for liquids and even saliva. Unfortunately, dysphagia usually reflects circumferential disease. Impact pain from food, or pain in the front or back of the chest, are bad prognostic features. Loss of weight and appetite more often reflect the cachexia of advanced disease, rather than simply the difficulty in swallowing. Regional lymph node involvement is present in approximately 50 per cent of cases at diagnosis. Direct spread may involve the bronchi and aorta. Perforation may result in tracheo-oesophageal fistulas or mediastinitis. Hoarseness may be apparent on involvement of the recurrent laryngeal nerve. Obstruction with difficulty swallowing saliva may result in aspiration pneumonia. However, the physical signs may be limited to weight loss, anaemia, and/or cervical lymphadenopathy.

Diagnosis and staging

Barium swallow characteristically shows abrupt, irregular lumenal narrowing, in contrast to the smooth narrowing of a benign stricture. Endoscopy allows biopsy of the lesion, producing a diagnostic accuracy of over 95 per cent. Palliative dilatation or intubation may then be performed. **TNM** (primary tumour, regional nodes, and metastasis) staging is achieved using endoscopic ultrasound to image the tumour in the oesophageal wall and to assess regional lymph nodes. Computed tomography (**CT**) or magnetic resonance imaging (**MRI**) will highlight invasion of adjacent structures, more distal lymph node involvement, and metastatic disease.

Treatment

Patients with superficial carcinomas at stage T_1N0M0 may achieve 5-year survival rates of over 50 per cent. However, overall the results of treatment are dire, with a 5-year survival rate of less than 10 per cent. Unfortunately, perioperative mortality is rarely less than 10 per cent. Adjuvant chemo/radiotherapy has been advocated for otherwise inoperable disease that has spread beyond the oesophageal wall. Squamous-cell carcinomas are more sensitive to both these treatment modalities than adenocarcinomas. Chemotherapy and radiotherapy are the subjects of Cochrane Reviews, but there is no clear evidence of improved survival in patients with potentially resectable lesions. Palliative therapy is based on radiotherapy and therapeutic endoscopy for endoscopic dilatation or insertion of a stent to overcome dysphagia and bridge any fistulas which may have formed. Ablation of tumour growing into the lumen of the oesophagus may be attempted using laser photocoagulation or electrocautery. Ethanol injection induces tumour necrosis and is effective, particularly when combined with intubation.

Stomach tumours

Benign

Benign gastric tumours may be derived from the mesenchyme or epithelium. Gastrointestinal stromal tumours (GISTs) arising from the gastric wall are most frequent, though not common. These project into the gastric lumen and occasionally become superficially ulcerated leading to haemorrhage. When large, these tumours have low grade malignant potential (see section on small bowel tumours). Even rarer submucosal lesions include lipomas, haemangiomas, hamartomas, gastric carcinoids, and lymphoid hyperplasia. The latter may be difficult to discriminate from a mucosa-associated lymphoid tissue (**MALT**) lymphoma.

Gastric epithelial polyps are mainly hyperplastic or inflammatory and usually asymptomatic. The historical view that they are not susceptible to malignant change, may be questioned. Only 15 per cent of gastric polyps are adenomatous. Although the risk of gastric cancers in these adenomas is not as clear-cut as in the large bowel, their association with FAP in particular, the eventual development of gastric cancer in FAP, and their occurrence at the margins of gastric carcinomas indicate that they should be removed endoscopically. Villous adenomas and polyps larger than 2 cm have a particularly high malignant potential. Rarely, large pedunculated polyps may ulcerate and bleed, or obstruct the pyloric outflow. Gastric hamartomas occur in Peutz–Jeghers syndrome, Cronkhite–Canada syndrome, Cowden's disease, and juvenile intestinal polyposis and these polyps are associated with an increased incidence of malignancy, highest in Peutz–Jeghers syndrome. This is obscured by the higher risk of carcinomas elsewhere in the gastrointestinal tract in these conditions. Paradoxically the most numerous gastric polyps in FAP are cystic gland (mucus retention) polyps which have no malignant potential or clinical significance whatever.

Malignant: carcinoma of the stomach

Pathology

The antrum is the most frequent site of gastric adenocarcinoma. The incidence of proximal cancers (which are smoking-related) and gastro-oesophageal junction tumours is rising for reasons that are not fully understood. Pathological classification is not entirely clear-cut. The histological approach of Lauren defines two subtypes. The intestinal type (60 per cent) is glandular and polypoid, associated with metaplasia, chronic gastritis, and the presence of *Helicobacter pylori*. The diffuse type (30 per cent) consists of scattered clusters of cells and spreads submucosally to ultimately result in linitis plastica. It has a worse prognosis and occurs in younger individuals. Tumours of mixed type (10 per cent) are also recognized.

Morphological classifications have been attempted, including that of Borrmann for advanced gastric cancer: type 1, polypoid without ulceration; type 2, fungating with surface ulceration; type 3, ulcerated with a wall-like edge and surrounding infiltration; and type 4, diffusely infiltrative. This bears some resemblance to the Japanese classification of early gastric adenocarcinomas: type 1, protruded, polypoid; type 2, superficial (elevated, flat, or depressed); and type 3, excavated. An alternative histological classification defines early cancer as not penetrating the submucosa (T1 disease), with advanced disease involving extension through the submucosa to the muscularis propria or serosa (T2), breaching the peritoneum (T3), and into adjacent tissues (T4). The TNM classification defines lymph node status as N_1 when one to 6 nodes are involved, N_2 when 7 to 15 nodes are posistive and N3 when more than 15 nodes are involved. Differences in classification between Japanese and Western pathologists have resulted in attempts at International consensus statements: the Vienna and the Padova classifications—which, unfortunately, are not identical.

An autosomal dominant, familial form of gastric cancer of diffuse type occurs, with presentation at early ages (OMIM192090). This disease is caused by germline mutations in the E-cadherin gene. The finding is of significance because the intracellular domain of this protein interacts at the epithelial adherens junction with b-catenin, an important participant in colorectal carcinogenesis. Gastric cancers frequently demonstrate *P53* mutations and consistent LOH in a number of specific chromosome regions. HNPCC provides a fourfold increased risk of gastric cancer, presenting in 10 per cent of carriers. *APC* mutations also occur in early sporadic gastric cancers.

Epidemiology and aetiology

There are approximately 10 000 new cases in the United Kingdom annually, making gastric cancer the sixth commonest malignancy, and, like oesophageal cancer, accounting for about 10 per cent of cancer deaths. There has been a sustained slow decline in incidence in the United Kingdom, but an increase in the number of cases involving the cardia. There are marked geographic differences in incidence, the rate in Japan being eight times higher than amongst Whites in the United States. Gastric cancer rates in Japanese immigrants to the United States halve in one generation, suggesting an environmental factor in its aetiology. Mass radiographic screening for gastric cancer has been undertaken in Japan since 1960. Some 5 million barium studies conducted annually detect 6000 cases. Approximately half of these are early stage, offering the potential for curative resection. Screening in the United Kingdom cannot be justified given the lower incidence. The incidence in men still approaches twice that in women, worldwide.

H. pylori has emerged as a causative agent for distal gastric cancer and is now classified as a class 1 carcinogen. It causes gastritis, gastric and duodenal ulcers, and both adenocarcinoma and lymphoma in the stomach. Some 60 per cent of the world's population are infected. In the developing world most of the population is infected from early childhood. In contrast, the prevalence of infection is falling in the developed world. This probably reflects decreased childhood infection rates, rather than eradication of infection in adults. Bacterial isolates with the *Cag-A* genotype are particularly implicated in carcinoma of the middle and distal thirds of the stomach, of both intestinal and diffuse types.

The organism can be detected by urease breath-testing or immunologically by a serum enzyme-linked immunosorbent assay (**ELISA**). Initial infection induces pangastritis with achlorhydria. There is a brisk serum immune response and the appearance of IgA in gastric secretions. However, *H. pylori* is not eradicated and gastritis is maintained by a combination of *H. pylori*-induced cytokine release from gastric epithelium and a TH1-type T-cell response. A sustained period of antral gastritis ensues, associated with duodenal ulceration. Persistent reduction in acid secretion may lead to the reduced effectiveness of antioxidant mechanisms in the stomach. Eventually, multifocal atrophic gastritis develops with metaplasia, followed by dysplasia, leading on to malignancy. This pathway remains consistent with the model originally proposed by Correa in 1988 (Fig. 1).

Fig. 1 Flow chart of the pathogenesis of gastric cancer.

The increased frequency of gastric carcinoma in lower socioeconomic groups may reflect their increased prevalence of *H. pylori* infection. A decreased incidence of *H. pylori* infection in childhood may explain the reduced rate of gastric carcinoma in Japanese immigrants to the United States. Eradication of the organism leads to resolution of the gastritis and normalization of basal acid secretion over several months. Reinfection rates in adults appear to be low in the developed world. This offers the possibility of achieving a long-term reduction in cancer incidence.

There is no convincing evidence that the prolonged use of H_2-blockers or proton-pump inhibitors is associated with an increased incidence of gastric cancer, secondary to prolonged suppression of acid secretion. Dietary factors such as nitrites or a lack of free-radical scavengers in the diet (for example, vitamin C, selenium) have long been suspected of causation in gastric carcinoma. Conversion of nitrates to nitrosamines by bacteria at neutral pH has been suggested to be carcinogenic. Smoking and increased alcohol use are associated with gastric cancer. Whether these dietary agents exert their effects indirectly through their influence on *H. pylori* infection rates remains to be established. An increased incidence in blood group-A individuals has been recognized since 1955. There is no direct connection between peptic ulcers and gastric cancers. Malignant ulcers may heal on initial treatment for dyspepsia, which can confuse the diagnosis. Furthermore, because they are both associated with *H. pylori* infection, the two conditions do tend to coincide.

Pernicious anaemia also leads to gastric atrophy in the body and fundus of the stomach and, presumably as a consequence, is associated with a threefold increase in the incidence of gastric cancer. The incidence may approach 10 per cent in patients followed up for 20 years. Intestinal metaplasia is recognized as a predisposing feature secondary to gastritis as it is found associated with carcinoma in resected specimens. However, this is again likely to be secondary to *H. pylori* infection in the main. Intestinal metaplasia and chronic active gastritis occur in gastric stumps postgastrectomy. These show an increased incidence of cancer, particularly after gastrojejunostomy. A prolonged bile reflux may be a cause of this gastritis. As in gastric atrophy, 10 per cent of patients may develop cancer during a 20-year follow-up for chronic gastritis. This is consistent with the need for multiple genetic hits to generate a malignant phenotype.

Clinical features

Although early gastric cancer may be asymptomatic, clinical suspicion of dyspepsia in older patients may lead to its early diagnosis, with the possibility of successful surgical intervention in early-stage disease. Common presenting symptoms include epigastric pain, which may be relieved or made worse by food. This pain can be constant and severe. The clinical features of anaemia, anorexia, early satiety, and weight loss suggest advanced disease at presentation. Large proximal tumours of

the cardia may cause dysphagia. Tumours of the fundus are more likely to result in anaemia and nausea. Distal tumours of the antrum may cause outlet obstruction and result in vomiting.

Gross haematemesis from gastric cancers is unusual. Metastasis occurs to the peritoneum (with ascites and possibly ovarian involvement—Krukenberg's tumour), to the liver, and latterly to the lung and other sites. An epigastric mass may be palpable in 30 per cent of patients, and suggests advanced disease. Palpable lymphadenopathy (Virchow's node) in the left superclavicular fossa (Troisier's sign) may be present. Carcinoma of the stomach is the malignancy most frequently associated with dermatomyositis or acanthosis nigricans.

Diagnosis

Although double-contrast plain imaging of the stomach can provide up to 90 per cent diagnostic accuracy, flexible endoscopy and biopsy has become the definitive diagnostic procedure (Fig. 2). Sensitivity increases with the number of biopsy samples taken from the base of an ulcer and its margins—10 biopsies of adequate depth will give a reliability approaching 100 per cent and eliminate false-negative results.

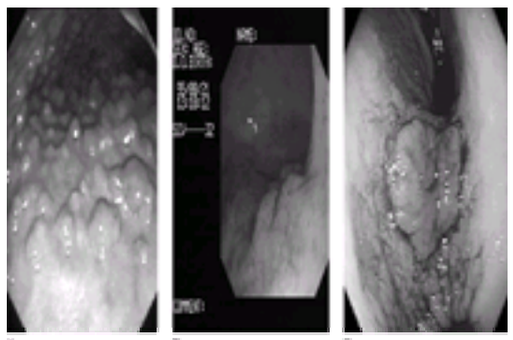

Fig. 2 Early gastric cancer – endoscopic appearance. (a) Initial view. Better view in retroversion (b) and (c) after dye-enhancement.

Staging of disease prior to attempted surgery relies on a number of imaging modalities. CT scanning defines the spread of the primary tumour and gross lymphatic and metastatic disease. CT is approximately 75 per cent accurate in detecting involved lymph nodes larger than 5 mm. However, it often fails to detect small involved lymph nodes and peritoneal deposits. Resolution may be improved with the use of intravenous contrast media. It is particularly important to detect distant involved lymph nodes because these would not normally be removed during surgery, and would therefore result in treatment failure. MRI scanning may help in this context.

Endoscopic ultrasound is useful in the local staging of gastric carcinoma. The normal stomach wall comprises five hyperechoic layers. Carcinomas present as hypoechoic lesions that disrupt the normal pattern. The depth of tumour invasion of the gastric wall can be assessed accurately, as can the presence of involved perigastric lymph nodes. T staging with 90 per cent accuracy and N staging with 70 per cent accuracy are achievable by correlation with pathological examination of specimen obtained during surgery. However, the technique is limited in its ability to detect distant enlarged lymph nodes. Classification of a tumour as stage T4 by endoscopic ultrasound renders surgical cure highly unlikely, so that palliative bypass or endoscopic techniques may be the preferred clinical option. Laparoscopy may be necessary to confirm the presence of peritoneal metastases. MRI or ultrasonography will identify hepatic metastases.

Treatment

Surgical resection of a tumour and involved lymph nodes is undertaken in the absence of metastases. The site of the tumour dictates the surgical approach. The goal is a tumour-free margin of 5 cm with lymphadenectomy to an uninvolved point along the arterial tree (defined as resection levels R1, R2, or R3, reflecting increasingly distal nodal involvement). This may require total gastrectomy, or some variant of a proximal or distal gastrectomy for tumours in these sites, ideally avoiding postoperative biliary reflux, which may itself predispose to disease recurrence. Endoscopic surgery for early gastric cancers may be possible, provided the tumours are small, confined to the mucosa, and non-ulcerated. This approach requires a high degree of certainty that local lymph nodes are not involved. Endoscopic ultrasound-guided needle biopsy may be useful in this context.

Palliative procedures in symptomatic patients with disseminated disease may also include gastrectomy, which can double survival time, or less radical interventions including stenting, feeding gastrostomies, or laser photoablation. Adjuvant chemotherapy regimens including 5-fluorouracil (combined with various other agents) have produced small survival advantages in randomized clinical trials. Radiotherapy alone has not been shown to be beneficial.

Predicting the prognosis for an individual patient is complex. The stage of the cancer at operation is crucial and 5-year survival rates approaching 90 per cent have been reported for early gastric cancer detected by screening in Japan. However, apparently superior stage-specific survival rates in Japan may reflect a lower incidence of diffuse or proximal tumours. This dependence of 5-year survival rates on stage at presentation is mirrored in the United Kingdom, where new cases present with roughly a third each at stage 1/2, stage 3, and stage 4. Whilst patients in the first category may achieve a 30 to 50 per cent 5-year survival, this falls to less than 15 per cent in those with stage 3 disease. Those at stage 4 have less than a 3 per cent 5-year survival rate.

The 5-year survival rate is marginally lower for patients with proximal tumours than distal tumours, with those with tumours in the middle third showing a slightly better prognosis. Unfortunately, the latter category of tumours (20 per cent) is less common than the others (one-third of cases each), with disseminated diffuse cancer making up the remainder. Cancers with a diffuse histology appear to have a worse 5-year survival rate than those of intestinal type.

In summary, the combination of tumour stage, lymph node involvement, position in the stomach, and histological subtype all exert subtle influences on outcome in the absence of metastases. These factors and more sensitive detection of metastatic disease leading to less operations with intent to cure, make interpretation of possible improvements in 5-year survival rates after supposedly curative resections difficult to interpret. The need for *H. pylori* prophylaxis and for improved chemotherapy approaches are pressing. The requirement for vitamin B_{12} supplementation after gastrectomy should not be overlooked.

Malignant: gastric lymphoma

Mucosa-associated lymphoid tissue (MALT) lymphomas are B-cell, non-Hodgkin's lymphomas, associated with *H. pylori* infection in over 90 per cent of cases. These represent 5 per cent of all gastric malignancies. The disease arises as a low-grade MALT lymphoma in areas of chronic gastritis, characterized by large centroblast-like cells. High-grade lesions have immunoblastic features. The clinical presentations of these patients are not readily distinguishable from gastric carcinoma. *H. pylori* eradication can result in lymphoma regression or complete remission, especially for low-grade disease, with an overall response rate of over 60 per cent. Surgery to debulk the disease, chemotherapy (using CHOP (cyclophosphamide, hydroxydaunomycin, Oncovin, prednisone) regimens), and radiotherapy are effective in high-grade disease. The disease stage and histological grade determine prognosis. In the absence of distal lymph node involvement and bulky disease, the 5-year survival rate is over 70 per cent.

Cochrane Reviews have been published on the eradication of *H. pylori* (in the context of non-ulcer dyspepsia) and Protocols have appeared for Cochrane Reviews of extended-versus-limited lymph node dissection techniques for adenocarcinoma of the stomach.

Small-bowel tumours

Given the length of the small intestine, the incidence of neoplasia (5 per cent of all gastrointestinal tumours) is remarkably low. Some two-thirds of small-bowel tumours are malignant. Attempts to explain the rarity of these tumours on the basis of the reduced carcinogenic effects of small-bowel contents, their bacterial flora, or levels of protective secretory IgA are not convincing. There are, however, clear-cut associations between specific genetic traits, including FAP and Peutz–Jeghers

syndrome, and small-bowel neoplasia.

The stem-cell compartment in the small bowel expresses low levels of the antiapoptotic protein, BCL-2, compared to the higher levels in the colonic crypt stem-cell compartment. It is possible that epithelial stem cells suffering genetic damage in the small intestine undergo apoptosis and are eliminated without the development of a neoplasm. In contrast, mutant colonic stem cells are resistant to apoptosis and persist to undergo further genetic hits, and a 50-fold increased rate of carcinoma compared to the small bowel. Paradoxically, the small bowel is the most common site in the gastrointestinal tract for metastatic melanoma.

Benign tumours

Adenomas and lipomas are the least rare, solitary benign tumours (with the exception of tumours arising in a variety of inherited forms of polyposis, discussed below). Adenomas predominate in the duodenum and are premalignant; haemangiomas and neurofibromas are more common in the jejunum; and fibromas and lipomas are more frequent in the ileum.

These tumours are frequently asymptomatic, incidental findings at operation. Symptoms where they do occur include obstruction, intussusception, pain or chronic haemorrhage with anaemia. Endoscopic examination and polypectomy in the duodenum, proximal jejunum and terminal ileum may be achievable. Barium follow-through is the appropriate diagnostic tool supplemented by angiography, for example where bleeding from an angioma or ectasia is suspected. Symptomatic benign small-bowel tumours are treated by surgical resection.

Gastrointestinal stromal tumours (GISTs) (formerly known as smooth muscle tumours) arise in the bowel wall, can grow to a large size and have low grade malignant potential, sometimes metastasizing to the liver many years after initial presentation and surgical resection. Evidence of malignancy is large size and more than 5 mitoses in 50 high power fields.

Malignant: carcinoma of the small bowel

Many adenocarcinomas of the small intestine occur in specific conditions. Management of FAP by total colectomy means that patients present with small-bowel adenomas, which have malignant potential. These occur commonly (50 per cent) in the duodenum (and rarely the stomach), particularly around the ampulla of Vater. Hamartomatous polyps are common in the jejunum in Peutz–Jeghers syndrome. These again undergo malignant change, imparting a 500-fold relative risk of small-bowel carcinoma. Coeliac disease is associated with an increased incidence of adenocarcinoma, as well as lymphoma, in the small bowel and an increased incidence of malignancies throughout the gastrointestinal tract (for example, the oesophagus) and elsewhere (for example, testes). Gluten-free diets do protect against the development of malignancy. Crohn's disease of prolonged duration slightly increases the incidence of small-bowel adenocarcinoma.

Clinical presentation usually involves abdominal pain, anorexia, cachexia, and/or anaemia. Patients may present with diarrhoea or, rarely, a palpable abdominal mass. Diagnosis involves radiological follow-through examination (Fig. 3) and CT or MRI scanning. Surgical treatment involves resection to uninvolved margins with any locally involved lymph nodes. The 5-year survival rates are dependent on tumour grade, lymph node involvement, and distant spread: with disease limited to the mucosa they approach 100 per cent, while the rate with lymph node involvement and distal metastases is essentially zero. The overall 5-year survival rate is around 25 per cent. There are very limited data on the value of adjuvant chemotherapy or radiotherapy. Combined preoperative radiotherapy and 5-fluorouracil have been claimed to be beneficial in duodenal adenocarcinoma. Where ampullary carcinomas are unresectable, palliation involves bile-duct stenting to avoid jaundice.

Fig. 3 Small bowel follow-through: compression view of mid-jejunum shows annular 'apple-core' appearance with pre-stenotic dilatation typical of an adenocarcinoma.

Carcinoid tumours are usually found in the ileum. Patients with these tumours have 5-year survival rates in excess of 75 per cent, in the absence of liver metastases. Multifocal small-bowel disease is present in approximately 30 per cent of cases. Carcinoids that are more than 2 cm in diameter have frequently metastasized when detected. Carcinoid syndrome due to excessive amounts of serotonin occurs with liver metastases. Treatment involves resection of the primary tumour and hepatic metastases, with the use of somatostatin analogues (octreotide) to control the effects of hormone excess (see Chapter 14.8).

Malignant: lymphoma of the small bowel

Primary small-bowel lymphoma occurs not infrequently in the ileum (Fig. 4) and represents 5 per cent of all lymphomas. It is also a feature of disseminated lymphoma. Lymphomas constitute one-third of primary small-bowel malignancies: distinct groups of B- and T-cell lymphomas are recognized.

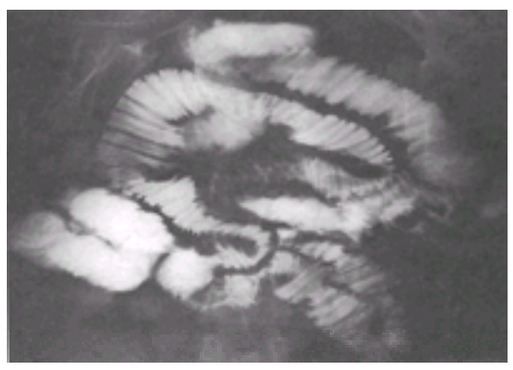

Fig. 4 Small bowel follow-through showing diffuse thickening of folds in ileum indicating submucosal infiltration (proved to be a lymphoma).

Immunoproliferative small-intestinal disease (IPSID)

These B-cell, non-Hodgkin's lymphomas occur mainly in the Middle East, Africa, and South America. This 'Mediterranean' lymphoma demonstrates an unusually strong association with low socioeconomic status. IPSID occurs in young adults as well as in the elderly. Initially the mucosa becomes infiltrated with plasma cells. It is sometimes associated with intestinal giardiasis, reminiscent of the association of gastric lymphoma with *H. pylori*. The clinical features resemble adenocarcinoma but with progressive diarrhoea, cachexia, and finger clubbing. Treatment of the infection, lymphoid infiltration, and secondary malabsorption is usually with tetracycline, or metronidazole and ampicillin. The progression to a large B-cell immunoblastic lymphoma histologically requires cytotoxic treatment with CHOP (cyclophosphamide, hydroxydaunomycin, Oncovin, prednisone) or one of its variants. IPSID frequently involves extensive areas of the small bowel so that surgical resection is often

impossible. It tends to occur proximally and is associated with the production of monoclonal immunoglobulin heavy chains, which may be detectable in the serum.

Enteropathy-associated T-cell lymphoma (EATCL)

EATCL is less common than B-cell small-bowel lymphomas. The condition develops in patients with long-standing coeliac disease or dermatitis herpetiformis. Consequently, their relative risk of a T-cell lymphoma is 50-fold higher than the general population. Clinical suspicion should be raised in patients with coeliac disease who experience increased malabsorption despite maintaining their gluten-free diet. The disease is usually high-grade and consequently of poor prognosis. The lesions tend to ulcerate with a risk of intestinal perforation. They are notoriously unresponsive to standard lymphoma chemotherapy. Again surgical resection is precluded by the large areas usually involved, particularly in the jejunum.

Other small-bowel lymphomas

Non-IPSID, non-EATCL primary small-bowel lymphomas are usually distal, and unifocal, so that surgical resection to debulk them prior to chemotherapy with CHOP, may be appropriate. Small intestinal lymphoma is frequent in patients with the acquired immunodeficiency syndrome (**AIDS**), and a form of Burkitt's lymphoma has been described in the terminal ileum in susceptible populations.

Gastrointestinal polyps and the polyposis syndromes

A tumour projecting into the lumen of the gut is termed a polyp, from the Greek *polypous* for squid, which pedunculated polyps resemble. The nomenclature used to describe the wide range of gastrointestinal tumours encompassed by this general definition can be confusing (Fig. 5). However, recent advances in elucidating the genetic basis of several inherited polyposis syndromes have clarified some of these classification difficulties. These are autosomal dominant diseases in which multiple polyps (from five or more, to many thousands in particular conditions) of a given histological type occur. All these familial forms of polyposis predispose, to some extent, to the development of carcinoma in individual polyps.

Fig. 5 Diagrammatic representation of the histology of adenomatous polyps.

In the subgroup of polyps which are adenomas, the progression from adenoma to carcinoma is well established. The molecular basis for this has been elucidated in the autosomal dominant disease familial adenomatous polyposis. The same mechanism has subsequently been shown to drive carcinogenesis in solitary adenomas occurring sporadically in individuals without the germline mutations present in the inherited condition.

Solitary hyperplastic (metaplastic), hamartomatous, or juvenile (retention) polyps have not been regarded as premalignant. However, the strong predisposition to malignancy in familial forms of polyposis of these histological types calls this into question. Identification of the different tumour-suppressor genes (TSGs) mutated in these familial diseases means that it is now possible to look for somatic mutations of the same TSGs in the corresponding histological types of sporadic polyps occurring in the general population. By analogy with adenomatous polyps, this may highlight other types of isolated polyp having a genotype suggestive of malignant potential.

Polyps can be classified simplistically on the basis of their gross shape and appearance as either sessile (villous), pedunculated, or flat. The latter type is of particular current interest as the significance of flat adenomas comes under greater scrutiny. However, these macroscopic descriptions offer little insight into the underlying histology. Polyps can range in size from almost invisible at less than 1 mm, to larger lesions several centimetres in diameter. They may occur singly or literally thousands of polyps may carpet the bowel in the polyposis syndromes. The system of classification of polyps as 'non-neoplastic' or 'neoplastic' requires revision. Many conditions historically included in the former category clearly predispose to the development of carcinoma. With this proviso, the traditional histological classification into non-neoplastic and neoplastic polyps is retained herein (Table 1). The majority of colorectal polyps are adenomas (neoplastic) in which a carcinoma may develop. Thus the detection and removal of these lesions are crucial. This can also be the case with many of the so-called non-neoplastic types of polyp.

Non-neoplastic polyps

Hyperplastic (metaplastic) polyps

These metaplastic lesions are a common finding on proctosigmoidoscopy, usually presenting as 2- to 4-mm pale shiny nodules. Metaplastic polyps are increasingly recognized to occur in association with so-called 'serrated adenomas' and mixed hyperplastic–adenomatous polyps, these latter demonstrating epithelial dysplasia. Large hyperplastic polyps are frequently found on the right side of the colon and are associated with the development of carcinoma. Multiple hyperplastic polyps (hyperplastic polyposis) are strongly associated with a family history of colorectal cancer. Hyperplastic polyposis appears to involve an early loss of chromosome 1p in about 25 per cent of patients. It seems increasingly likely that a metaplastic polyp–mixed hyperplastic/adenomatous polyp–carcinoma sequence occurs, reminiscent of the more familiar adenoma to carcinoma sequence.

Hamartomatous polyps

Polyps of this general histological type have usually been considered together as non-premalignant lesions. However, the natural history of familial diseases in which hamartomatous polyps are a feature casts doubt on this conclusion.

Peutz–Jeghers syndrome (OMIM175200) is an autosomal dominant disease characterized by hamartomatous polyps throughout the gastrointestinal tract, particularly in the jejunum, with mucocutaneous pigmentation of the buccal mucosa, perioral region (Fig. 6), and digits. Peutz–Jeghers hamartomatous polyps have a characteristic histopathological appearance distinct from other gastrointestinal polyps. They contain frond-like epithelium with cystic dilatation of glands overlying a network of characteristic fibromuscular bundles. Hypermucinous goblet cells are often prominent. Clinically there is a risk of intussusception or infarction of Peutz–Jeghers polyps that are more than 1 cm in diameter.

Fig. 6 Peutz-Jeghers patient showing characteristic lip pigmentation.

The disease has been mapped to chromosome 19p13.3 with possible genetic heterogeneity and a second locus on 19q. A putative tumour-suppressor gene, *STK11,* which encodes a serine/threonine kinase, harbours germline mutations in patients. Consistent with its function as a tumour suppressor, the normal allele of *STK11* is lost in hamartomas and in associated adenocarcinomas, suggesting that the former may be precursors of the latter.

Recent meta-analysis of the risk of a wide variety of malignancies in Peutz–Jeghers syndrome has confirmed the very high relative risks of developing cancer of the oesophagus (57 times higher than the general population), stomach (relative risk (**RR**) 213), small bowel (RR 520), colon (RR 84), and pancreas (RR 132), with increased risks also for lung, breast, uterine, and ovarian cancer. The cumulative risk for all cancer is over 90 per cent by the age of 65 years. Thus patients with the Peutz–Jeghers syndrome are at a very high relative and absolute risk for both gastrointestinal and non-gastrointestinal cancers. Endoscopic follow-up should be at 2-yearly intervals, barium follow-through series is needed at similar intervals. Periodic laparotomies may be needed to remove large (2 cm+) polyps and avoid the danger of intussusception and gangrene

Juvenile intestinal polyposis

Juvenile intestinal polyposis (OMIM174900) is another autosomal dominantly inherited hamartomatous polyposis syndrome that is genetically heterogeneous, with loci mapped to chromosomes 18q21.1 and 10q23.3. A further variant is the atypical juvenile polyposis syndrome called hereditary mixed polyposis syndrome (OMIM601228). These patients also have an increased incidence of inflammatory and metaplastic polyps. This autosomal dominant disease has been mapped to chromosome 6q, although identification of the actual gene involved has not yet been achieved.

Juvenile polyps are pedunculated hamartomas, prone to surface ulceration, which can cause bleeding and stalk torsion that can autoamputate the polyp with bleeding. The main distinction from Peutz–Jeghers syndrome is a lack of muscle fibres. Juvenile polyps are characteristically overlaid with a layer of normal epithelium in contrast to the dysplastic changes in adenomas. Single juvenile polyps are usually located in the distal colon and have a macroscopic cherry-red appearance. Up to 1 per cent of children may have a juvenile polyp, and in 70 per cent only a single polyp is present. Juvenile intestinal polyposis, defined by the presence of more than three to five polyps, is therefore relatively rare.

About one-quarter of juvenile intestinal polyposis pedigrees segregate mutations in the *SMAD4/DPC4* gene on chromosome 18q21.1. This gene was originally identified as a tumour suppressor deleted in pancreatic cancers. The protein functions in the signal transduction pathway of the inhibitory growth factor **TGF-b** (transforming growth factor-beta). Absence of this protein would be expected to lead to a loss of response to the growth inhibitory effects of TGF-b. Other pedigrees show genetic linkage to chromosome 10q23.3. The *PTEN* tumour-suppressor gene maps in this region. It encodes a phosphatase, which works through the PI3-kinase pathway to modulate the cell-cycle control protein p27. *PTEN* is mutated in pedigrees with the allelic conditions Cowden disease (OMIM158350) or Bannayan–Zonana syndrome (OMIM153480), in both of which hamartomas in multiple tissues and macrocephaly occur. Juvenile polyps are features of both these autosomal dominant diseases, but the number of polyps is not as high as in juvenile intestinal polyposis. The occurrence of *PTEN* mutations in juvenile intestinal polyposis remains unconfirmed and another gene at 10q23 may be involved.

Juvenile polyps also occur in patients with the Gorlin syndrome (OMIM 123456), an autosomal dominant disease primarily characterized by basal-cell carcinomas of the skin and odontogenic keratocysts in the mouth. The genes mutated in this condition encode the receptor for the sonic hedgehog (**SHH**) protein. Again, however, no mutations have been detected in pedigrees segregating juvenile intestinal polyposis. Interestingly, SHH signalling indirectly controls the expression of the *SMAD4/DPC4* gene, which is causative in some juvenile intestinal polyposis pedigrees. SHH signalling is also indirectly involved in wingless (**WNT**) expression. Loss of signalling control through the WNT pathway leads to FAP.

Juvenile intestinal polyposis predisposes to adenomatous transformation and an increased risk of colorectal cancer and cancers elsewhere in the gastrointestinal tract. The accepted view of solitary juvenile polyps has been that they do not predispose to malignancy in children, who do not therefore require follow-up. It will now be possible to confirm this if it can be shown that *DPC4* mutations (or mutations in the putative gene at 10q23) are not found in solitary retention hamartomas. The occurrence of mutations would suggest these tumours have malignant potential.

Cronkhite-Canada syndrome is a rare, non-Mendelian condition characterized by juvenile-type polyps throughout the gastrointestinal tract (with the exception of the oesophagus). Ectodermal abnormalities include nail dystrophy, alopecia, and brown hyperpigmentation of the skin. Patients present with severe diarrhoea, malabsorption, and weight loss. This condition is rapidly progressive with inflammation of the entire intestinal mucosa. In some cases the condition resolves spontaneously with corticosteroids, but up to one-third of patients die within months. Survivors have an increased incidence of adenomatous change and carcinoma warranting regular colonoscopic surveillance. Surgical resection is necessary for otherwise uncontrollable bleeding. The pathogenesisof this disease remains unknown.

Inflammatory polyps

These pseudopolyps arise during the healing phase after attacks of severe colitis (ulcerative colitis, Crohn's disease, and schistosomiasis).have led to extensive mucosal ulceration. Histologically the colonic epithelial-cell layer is often normal. Larger inflammatory polyps may be composed of granulation tissue in the healing mucosa. These polyps may be friable and bleed, and can be multiple (Cap polyposis). Biopsy may be necessary to distinguish between inflammatory polyps and adenocarcinoma but those over 1 cm diameter are usually removed endoscopically for surety.

Other types of non-neoplastic polyp

Lipomas are usually located in the right colon. With the exception of intussusception, they are asymptomatic and do not require removal. Other rare benign tumours arising from the colonic submucosa include leiomyomas, neurofibromas, and polypoid haemangiomas. Pneumocystic disease (also called pneumatosis cystoides or pneumatosis coli) leads to multiple submucosal cysts, which can be punctured and collapsed in patients when they cause abdominal pain. The cysts may resolve when treated with oxygen therapy.

Neoplastic (adenomatous) polyps and the adenoma to carcinoma progression

Adenomas are dysplastic epithelial growths with malignant potential. Most frequently they are tubular (Fig. 7), having glandular organization, with a peduncle of normal tissue. Adenomatous polyps with a tubulovillous mixed character occur as well as the less common villous adenomas, which are sessile lesions, frond-like histologically, often quite large, and with the highest tendency to malignant change. Our understanding of the molecular events during first adenoma then carcinoma development has mainly been gained from genetic studies of familial adenomatous polyposis.

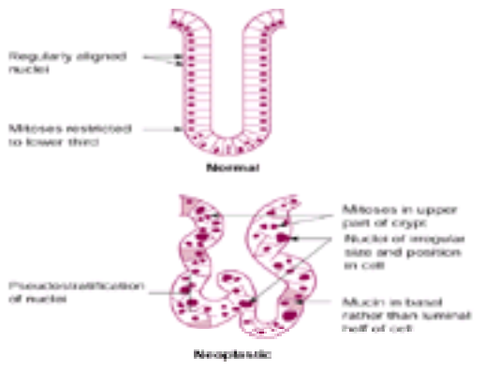

Fig. 7 Diagrammatic representation of the difference between the histology of a normal colonic crypt and the disorder of a neoplastic (dysplastic) crypt.

Aetiology, epidemiology, and pathology (Table 2)

'Sporadic' colonic adenomas are extremely common and are usually asymptomatic. Adenomas are found in around 20 per cent of individuals in their sixth decade and the incidence increases steadily with age. The distribution of adenomas in the colon reflects the site-specific incidence of colorectal carcinomas, with only minor differences. The majority of adenomas are found on the left side of the colon and in the rectum, although more right-sided lesions are found with increasing age. The role of environmental factors in adenoma development is suggested by their increased incidence in the developed countries. Furthermore, migrant communities such as the Japanese in the United States acquire an adenoma (and carcinoma) incidence comparable to the local population.

Around 60 per cent of adenomas can be accessed by flexible sigmoidoscopy. A distal adenoma is associated with the presence of a second more proximal adenoma in around 30 per cent of individuals. Like FAP adenomas, sporadic colorectal adenomas are thought to progress slowly over time. This means that only 5 per cent of 50-year-olds will eventually develop colorectal cancer, even though their incidence of adenomas is much higher than this. Because they are slow growing, only some 10 per cent of adenomas are greater than 1 cm in diameter when found. The incidence of malignant progression increases with tumour size.

Adenomas may arise in aberrant crypt foci, which are small areas of epithelium with irregular glandular organization, but without apparent dysplasia. These develop into single dysplastic crypts (unicryptal adenomas) so that the earliest recognizable adenomas have dysplastic epithelium. Dysplasia progresses through mild, moderate, to severe, which is reflected in the increasing malignant potential of the polyp. Adenomas may also be classified as early, intermediate, and late in histological appearance, and these histological changes have been correlated with the acquisition of a series of genetic alterations by Vogelstein and colleagues. Endoscopic excision is usually facilitated by the macroscopic difference in appearance between the normal mucosa and neoplastic epithelium, which appears hyperaemic and raised above the surrounding surface. In around 5 per cent of adenomas, carcinoma is detected (when neoplastic cells have breached the muscularis mucosae) (Fig. 8). Only at this stage is there access to the local lymphatics and blood vessels with the possibility of metastasis.

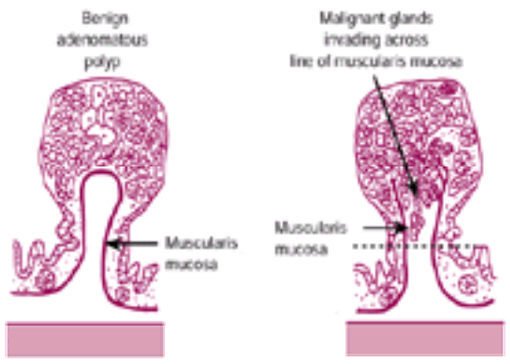

Fig. 8 Diagrammatic representation of the histology of a benign adenoma and a 'malignant polyp' showing adenoma and invasive adenocarcinoma (dotted line indicates transaction line to achieve complete removal).

There is increasing recognition of the existence of flat adenomas. These polyps are only very slightly raised and indeed may appear as depressed lesions. Flat adenomas are difficult to see endoscopically, but pioneering studies by Japanese gastroenterologists using non-absorbable mucosal dyes to provide contrast has led to a more widespread recognition of these lesions. Their clinical significance is that they can be more severely dysplastic than polypoid adenomas of comparable size, and therefore may represent a much-increased risk of carcinoma. The difficulties of studying the natural history of flat adenomas and their progression to so-called 'flat carcinomas' is complicated by the fact that they are more common on the right side of the colon. Some individuals with germline *APC* mutations appear to develop a flat adenoma phenotype.

The location of colonic carcinoma within about 5 per cent of adenomas suggests that the adenoma is a precursor of carcinoma. The time for progression to carcinoma is slow, usually 10 years or more. Patients with large or villous adenomas have an increased risk of coexisting synchronous carcinomas, or for the subsequent development of another carcinoma and so merit colonoscopy and follow-up. Later stage cancers contain less adenomatous material, presumably because this is overgrown by the malignant cells. Epidemiological data also support the adenoma to carcinoma sequence.

Additional mutations accumulate as the adenoma moves through intermediate to late stages (Fig. 9). These include activating mutations in the K-*ras* proto-oncogene and loss of tumour-suppressor function at chromosome 18q21. It appears unlikely that this is the so-called 'deleted in colorectal cancer' (*DCC* gene) and is more likely to involve the *DPC4/SMAD4* pancreatic TSG. It is the accumulation of these different genetic changes rather than their stepwise occurrence that drives carcinogenesis. K-*ras* mutations occur in 50 per cent of sporadic colorectal tumours. Loss of function of the *P53* tumour-suppressor gene occurs in 70 per cent of sporadic colorectal cancers. The resulting lack of apoptosis correlates with a metastatic phenotype, in that the incidence of *P53* mutations in carcinomas is much higher than in associated adenomas. Additional mutations occur in distant metastases.

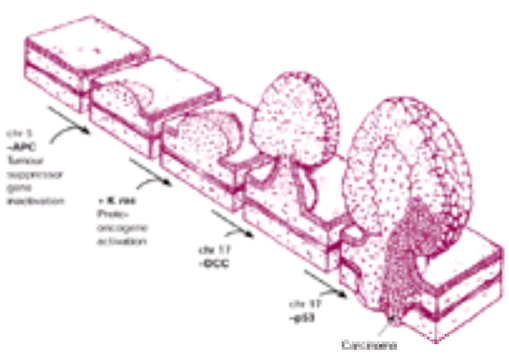

Fig. 9 The 'adenoma-carcinoma sequence' – a possible genetic model. Accumulated genetic changes to the stepwise progression from normal epithelium through increasing polyp size to eventual malignant change. Genetic alterations, which do not occur in a rigid sequence, include inactivation of tumour suppressor genes (adenomatous polyposis coli (APC), deleted in colorectal cancer (DCC) and p53, as well as the activation of proto-oncogenes such as K-ras. (Adapted from Fearon and Vogelstein (1990). *Cell* **61**, 759.)

Clinical features, management, and surveillance

Colonic adenomas do not usually cause symptoms. Abdominal pain, altered bowel habit, or intermittent bleeding are unusual. Large villous adenomas of the rectum may rarely present with mucoid diarrhoea and hypokalaemia. Polyps are usually discovered accidentally on barium enema or scanning examination or during endoscopic screening. Histological discrimination from other types of polyp is mandatory. The detection of a distal adenoma by proctoscopy or flexible sigmoidoscopy justifies colonoscopy to exclude the presence of proximal adenomas. The health economic implications of this are considerable given the high incidence of adenomas in the adult population.

Polyps are removed by endoscopic snare polypectomy or electrocoagulation. This is painless except for polyps within 2-5 cm of the anal margin. Around 90 per cent of patients with polyps have only two lesions, the majority of which are under 1 cm, stalked, and easy to snare. The tendency to bleed after polypectomy is greater with larger tumours. Very large, sessile polyps may need to be removed in multiple portions, but few are so large as to need surgical resection. Endoscopic removal of an adenomatous polyp that subsequently proves to contain a focus of carcinoma is a satisfactory outcome not requiring subsequent operation if there are clear histological margins.

Post-polypectomy surveillance is necessary in patients who have had an adenoma detected and removed. They are at higher risk of second adenomas, particularly when multiple (five or more) polyps are present at first examination. Villous adenomas are particularly liable to recur locally. Repeat colonoscopy is performed at 3 to 5 yearly intervals, depending on number and size of polyps found. The decision to cease surveillance at 75 years of age is justified after a negative examination because of the slow natural history of the disease, despite the increased incidence of both polyps and carcinoma with age.

Familial adenomatous polyposis (FAP)

The principal feature of FAP (OMIM175100) is the presence of hundreds to thousands of adenomatous polyps throughout the colon (Fig. 10). The condition is inherited as an autosomal dominant, although about one-quarter of cases arise without a family history, thus implying a high rate of new mutations. As well as the colonic polyps, adenomas are found in the duodenum in the majority of patients, and also in the stomach and elsewhere in the small intestine. Adenomas usually begin to develop during the second decade so that screening is performed between 12 and 14 years of age. The risk of colorectal cancer developing in one of the adenomas is essentially 100 per cent by the age of 40 years, so that this condition is fully penetrant. Screening by flexible sigmoidoscopy with biopsy of polyps for histological diagnosis confirms the condition and allows surgery before the age of 20. Screening family members by flexible sigmoidoscopy confirms or eliminates the diagnosis in relatives. The creation of Polyposis registers makes FAP an example of practical colorectal cancer prevention.

Fig. 10 Familial adenomatous polyposis (FAP) colectomy specimen, showing carpeting of the colon by hundreds of adenomas.

There is a 10- to 20-year period between the appearance of an adenoma and its progression to colorectal carcinoma. Clinically, therefore, colectomy with ileorectal or ileoanal anastomosis is usually performed on FAP subjects in their late teens, as there is low risk of carcinoma before this age. Careful long-term follow up is required. There is a 10 per cent risk of carcinoma in any rectal stump over a 30-year period, although rectal polyps may undergo regression, suggesting that adenoma progression to carcinoma is not inevitable. Total proctocolectomy with ileostomy is also an option with large numbers of rectal polyps if the increased operative risks of ileoanal anastomosis with formation of a pelvic pouch are not regarded as acceptable.

Historically, FAP caused 1 per cent of all colorectal cancers. Surveillance programmes have reduced this incidence, but the prolonged survival of patients postcolectomy has highlighted the other features of FAP, which increasingly create clinical problems. Carcinomatous change occurs in adenomas in the duodenum, particularly around the ampulla of Vater and in the bile duct. It may also occur in the stomach. Follow-up is required to avoid these eventualities. Mesenchymal desmoid tumours, particularly those occurring in the retroperitoneum, can grow to an enormous size. Their position and tendency to re-growth makes them difficult to remove and they may cause devastating consequences due to pressure effects.

The wide range of additional features of FAP led to the description of Gardner's and Turcot's syndromes that have proved to be allelic with FAP. Additional features include osteomas of the mandible and skull, dental abnormalities, sebaceous cysts, and brain tumours. About one-half of patients with Turcot's syndrome have germline *APC* (adenomatous polyposis coli) mutations and develop cerebellar medulloblastomas. It is notable that the other 50 per cent have germline mutations in their DNA mismatch repair genes (that is, *HNPCC*). These individuals undergo somatic *APC* mutations but develop glioblastoma multiforme. This link between HNPCC and mutations in *APC* is intriguing.

FAP is caused by mutations in the *APC* gene on chromosome 5q21. This large 2843 amino-acid protein performs multiple functions in the cell, but in the context of colonic neoplasm development its key role is in the WNT pathway. In the absence of WNT signalling, APC forms a complex with two other proteins, axin and glycogen synthase kinase-3b (GSK-3b). This complex phosphorylates the b-catenin protein, which can then be tagged with ubiquitin and degraded by the proteasome system. In this manner, levels of cellular b-catenin are controlled. b-Catenin plays roles in intracellular signalling from E-cadherin in the epithelial adherens junction (which is also mutated in gastric cancer), but when present in the cell at high levels it can bind a second protein (TCF-4), enter the nucleus, and switch on the expression of a number of genes, including the c-*myc* oncogene and the cyclin D1 gene, and others. In the presence of a WNT signal, GSK-3b is inactivated and b-catenin levels rise to drive gene expression and cellular proliferation. With only mutant APC, the cell is also incapable of degrading b-catenin and again proliferation occurs.

APC expression increases as the colonocyte migrates up the crypt to the lumenal surface. This may reflect a role in controlling cell movement. In FAP, the vast majority of germline mutations are in the *N*-terminal half of the protein and are nonsense mutations leading to truncated proteins. The key region of APC for b-catenin binding lies between amino acids 1000 and 2000. Germline mutations occur almost exclusively before amino acid 1650. Some 85 per cent of sporadic colorectal adenomas and carcinomas also have mutations in the *APC* tumour-suppressor gene. The majority of these occur in the so-called 'mutation cluster region' between amino acids 1280 and 1500. Again, this creates truncated proteins that cannot properly degrade b-catenin. Consistent with Knudsen's hypothesis, the second normal *APC* allele is consistently lost in adenomas, so that the cell has no functional 'gate-keeper' tumour-suppressor protein.

Identical germline *APC* mutations can cause a variety of phenotypes, from polyposis alone to the full spectrum of Gardner's syndrome. This suggests that there are genetic modifier loci for FAP. Mutations at the extreme 5'-end of the gene may be associated with a milder 'attenuated' phenotype. Mutations towards the 3'-end of the gene (around amino acid 2600) cause the familial desmoid syndrome. Congenital hypertrophy of the retinal pigment epithelium (**CHRPE**) is another recognized clinical sign in FAP. Only germline mutations downstream of codon 422 cause CHRPE, for reasons that remain unclear. This means, however, that opthalmoscopic detection of CHRPE cannot be regarded as a reliable screening method.

Determination of the mutant sequence in FAP pedigrees now allows precise genetic counselling. However, the large size of this gene and protein make sequencing it difficult in individual patients. The protein truncation test (**PTT**) is used to detect *APC* mutations because so many generate truncated proteins. These are detected by

electrophoresis after *in vitro* transcription and translation from patients' *APC* mRNA.

The critical role of APC in colorectal adenomas (and carcinomas) has been further emphasized by analysis of sporadic tumours that do not harbour *APC* mutations. These 15 per cent of colorectal neoplasms prove to have mutations in the b-catenin gene itself. Moreover, these mutations alter those amino acids which undergo phosphorylation by the APC–GSK-3b–axin complex. Thus, these mutant forms of b-catenin are constitutively active. This same mechanism seems to apply in melanoma. Mutations in the axin gene can also lead to colorectal neoplasia.

NSAIDs were serendipitously found to reduce the number and size of colorectal adenomas in FAP. The effect has been demonstrated with sulindac in particular. Aspirin also reduces the risk of colorectal cancer. Colorectal cancers overexpress cyclo-oxygenase-2 (COX-2). In *Apc* knockout mice, deletion of the murine *Cox-2* gene causes a significant reduction in the number of polyps formed. Aspirin or selective COX-2 inhibitors may delay the onset of FAP adenomas and hence their progression to carcinoma. The attraction of this possibility is the advantage of postponing elective colectomy into the third decade.

Polymorphic *APC* variants may exist in the population, which, although associated with an increased risk of adenoma development, are of such low penetrance that they do not seem Mendelian in character. This would be consistent with the marked familial clustering seen in colorectal cancer.

Colorectal cancer (Fig. 11)

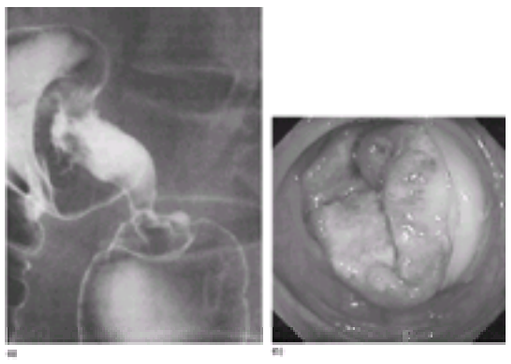

Fig. 11 Colonic carcinoma appearances. (a) Air-contrast barium study showing 'apple-core' stricture. (b) Colonoscopy appearance of encircling 'annular' tumour.

The natural history of colorectal tumorigenesis now provides a rational basis for the introduction of screening programmes in an attempt to control this common malignancy, which is curable if detected early or at the precancerous (polyp) stage. Several screening modalities have been shown to decrease colorectal cancer (**CRC**) mortality, and screening guidelines have been published in several countries. The incidence of the disease is falling in the United Kingdom and United States as a result of increased detection and removal of adenomas.

Epidemiology and aetiology

Colorectal cancer is the most common malignancy in the United Kingdom after lung cancer: 19 000 deaths each year reflect a 5-year survival rate for CRC at all stages of approximately 50 per cent. The lifetime risk of colorectal cancer in the United States approaches 6 per cent. There is a higher incidence of rectal cancer in men. The estimate for the United States in 2000 was 130 200 new cases of colorectal cancer and 56 300 deaths, a lower population death rate than in the United Kingdom. The incidence of cancers of the colon and rectum increases with age, the mean age at diagnosis being 65 years. The 5-year survival rate is dependent upon the tumour stage at diagnosis: Dukes' stage A disease, over 90 per cent; Dukes' B disease, 65 per cent; stage C1 disease, 30 per cent; stage C2 disease, 20 per cent; and stage D disease, a 5-year survival of 2 per cent or less.

A small proportion of patients with Dukes' stage A colorectal cancer succumb to their disease. Although only 15 per cent of cases are diagnosed at this stage, it would be invaluable to identify the small proportion of them that might benefit from adjuvant therapies. This issue becomes more important in patients with Dukes' stage B carcinomas, which represent some 40 per cent of tumours diagnosed. It would be valuable to be able to discriminate those 35 per cent of patients at diagnosis who will go on to develop progressive disease and target adjuvant chemo/radiotherapy on them. Conversely, it would be desirable to avoid exposing patients who have had what proves to be curative surgery to the toxicity of adjuvant chemotherapy.

There are clearly environmental factors that influence the incidence of colorectal cancer. These are presumably mainly dietary. The incidence of colorectal cancer is higher in Northern Europe and North America than in the developing world. The risk of adenoma formation and colon cancer in Japanese peoples rises when they are exposed to a westernized diet. Although carcinogens or co-carcinogens may be produced by bacterial metabolism of bile salts, or from animal fat, or as a result of prolonged transit times of low-fibre diets, the evidence for this is not clear-cut.

It is increasingly recognized that genetic factors other than those causing Mendelian cancer syndromes are important in colorectal carcinoma with, for example, a threefold increased frequency of a family history of bowel cancer in individuals diagnosed as having an adenomatous polyp compared with normal controls. Thus the underlying aetiology of colorectal carcinogenesis is complex. Implantation of the ureters into the sigmoid colon (ureterosigmoidostomy) results in a high incidence of adenomas with subsequent carcinoma development 10 years and more after creation of the ureteric stoma. Long-term inflammation, as in extensive ulcerative colitis of over 20 years' duration (and probably also Crohn's colitis), provides a risk of ulcerative colitis-associated colorectal carcinoma (**UCACRC**). This may affect 5 per cent of these individuals, even where their disease is reasonably well controlled or healed. It may be multifocal. These cancers often have a mucinous appearance, with or without 'signet ring' cells. Ileorectal anastomosis to treat refractory inflammatory bowel disease (**IBD**) also leaves a risk of local malignant change in the rectum. Some protection is afforded by annual or biennial colonoscopy, with serial biopsies to detect any warning epithelial dysplasia.

Hereditary non-polyposis colon cancer

A second, autosomal dominant disease accounts for up to 5 per cent of cases of colorectal cancer. Hereditary non-polyposis colorectal cancer (HNPCC) was originally divided into Lynch syndromes type 1 and 2, with a range of other malignancies associated with the latter. A total of seven different mutant genes have now been characterized to define HNPCC types 1 to 7, superseding the Lynch definition. HNPCC kindreds were initially defined by the so-called 'Amsterdam' criteria, which are:

1. at least three family members in two or more successive generations must have colorectal cancer;
2. one of these must be a first-degree relative of the other two;
3. cancer must be diagnosed before the age of 50 in at least one family member;
4. FAP must be excluded.

HNPCC is associated with other malignancies in mutation carriers: endometrial cancer is the most common, ovarian cancer is frequent, and tumours in other organ systems are less common (breast, stomach, possibly prostate). The risk of uterine cancer may exceed that for colorectal cancer in females in pedigrees, emphasizing the necessity for uterine screening. HNPCC has an approximate penetrance of 74 per cent for colorectal cancer in men by the age of 70 compared with only 30 per cent in females. The risk of uterine cancer is 42 per cent in these women. Hysterectomy is usually accompanied by bilateral oophorectomy because of the risk of subsequent ovarian cancer.

The syndrome arises as a result of the germline transmission of mutations in one of six genes encoding components of the DNA mismatch repair enzyme system. Germline mutations in the TGF-b receptor II gene are now also classified as HNPCC. The encoded proteins repair DNA mismatches arising as a result of replication errors. These tumours were therefore described as RER+. Replication of DNA is particularly prone to error in those regions of DNA known as microsatellites where multiple short nucleotide repeat sequences occur. Loss of DNA repair function leads to the so-called 'microsatellite instability' of these regions. This means that the allele sizes of microsatellites are different in tumours than in normal cells from the same individual. PCR-based methods are readily able to detect this to establish that

a given tumour has an RER+ phenotype. The extent of microsatellite instability varies between tumours and there is some disagreement as to how many loci need to be modified before a tumour can be classified as RER+.

In addition to patients with HNPCC, between 10 and 15 per cent of sporadic colorectal cancers are also RER+ to some extent. The inability to repair errors introduced during DNA synthesis renders the genome in HNPCC cells liable to mutation. Interestingly, the *APC* gene itself appears prone to mutation in mismatch repair deficiency, leading to a frame-shift mutation and premature termination of translation. Thus it is possible that colorectal adenomas arise in patients with HNPCC through a similar final common pathway to that in FAP.

The commonest mutations occur in the mismatch repair genes *MSH2* and *MLH1*. There is some evidence that HNPCC polyps and tumours occur predominantly on the right side of the colon. It has also been suggested that these have a better prognosis, although this may be confounded because right-sided lesions tend to be larger (given the reduced solidity of the stool in the ascending colon) at presentation and therefore likely to be at more advanced stages. It is clear that a variety of mutations can predispose to colorectal cancer, but intriguingly all of these seem to feed into a final pathway of tumorigenesis similar to that originally elucidated for FAP. Patients with HNPCC should be included in genetic counselling and surveillance programmes usually by colonoscopy performed at 2 to 3 yearly intervals.

Colorectal cancer screening and surveillance

A number of screening modalities have been evaluated. These include testing for faecal occult blood, flexible sigmoidoscopy, double-contrast barium enema examination, and colonoscopy. The health economic implications of implementing such screening programmes are considerable. However, there is clear benefit in screening and surveillance of high-risk individuals such as those with previously detected adenomas or with a strong family history. In these cases colonoscopic examination is justifiable, as in the follow-up of individuals who have had carcinomas resected.

In the average-risk population, there is increasing consensus that screening should begin at 50 years of age. A number of protocols are undergoing trial to establish their diagnostic yield in terms of cost per year of life saved. Despite its lack of sensitivity and specificity, annual faecal occult-blood testing (**FOBT**) can be considered. Others advocate flexible sigmoidoscopy every 5 years, with colonoscopy if any adenomas are detected. Whether repeat flexible sigmoidoscopy every 5 years in individuals in whom no polyps are found is worthwhile needs to be established, as its avoidance would generate considerable cost savings. Specific guidelines have been published in the United States and a Cochrane Review of FOBT screening has been published. Cochrane Reviews are in preparation on the benefits of colorectal adenoma surveillance programmes and on detecting colorectal cancer in patients with IBD. Population screening using flexible sigmoidoscopy is the subject of an ongoing, national multicentre study in the United Kingdom. There is the real possibility of achieving significant reductions in the incidence of this common, but avoidable, malignancy by screening. Colonoscopic surveillance of those with adenomas or significant genetic risk is at 2 to 5 year intervals thereafter.

Pathology

Most colorectal cancers occur distally, in the rectum and sigmoid colon. An approximate estimate is that one-third of cancers occur in the rectum, one-third in the sigmoid colon, and one-third more proximally. Carcinomas are typically polypoid masses with central ulceration, eroded edges that bleed easily, and which may result in strictures. Infiltrating scirrhous carcinomas are rare. Colorectal carcinoma initially spreads by local invasion, which accounts for its good prognosis when confined to the bowel wall. Invasion through the mucosal and muscle layers of the bowel may lead to involvement of adjacent organs including the bladder and prostate. Secondary complications may therefore include fistula formation. Venous and lymphatic spread results in the predominance of liver metastases. It is increasingly recognized that even multiple liver metastases may be amenable to surgical resection. Lymphatic spread is to local nodes (Dukes' stage C1 disease) then to more proximal nodes in the mesentery (Dukes' stage C2 disease).

The Dukes' classification of colorectal carcinomas (Fig. 12) remains the mainstay of tumour staging. Stage A disease is confined to the bowel wall with no extension to the serosal fat. Stage B disease involves the full thickness of the bowel wall with extension through to the serosa. Stages C1 and C2 involve the spread of tumour to draining lymph nodes. Stage D disease involves distant spread, primarily to the liver. These different stages very clearly correlate with 5-year survival. The alternative TNM staging system has the advantage over the Dukes' system in distinguishing early tumours involving only the submucosa (T1) and amenable to endoscopic resection, from slightly more advanced tumours (T2) which extend into the muscularis propria. T3 tumours extend into the serosal fat and T4 tumours are those which have perforated or involve the peritoneal surface or other viscera. The extent of histological differentiation is also an important prognostic indicator with poorly differentiated tumours particularly aggressive. As well as liver metastases, secondary deposits appear in the lung (50 per cent), peritoneum (15 per cent), and bones (15 per cent). Unfortunately, approximately 50 per cent of colorectal cancer is stage C or D at diagnosis because it remains asymptomatic, so that the overall 5-year survival rate is reduced. Skewing the stage of detection towards Dukes' A lesions would have a major impact on overall survival.

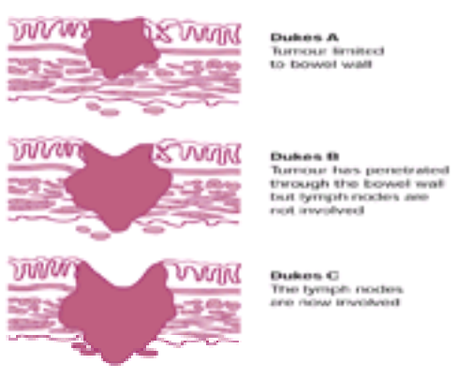

Fig. 12 Dukes' classification of colorectal carcinoma.

Clinical features

The site of a colorectal cancer influences the resultant symptoms. Most colorectal neoplasms grow into the lumen of the bowel where they may cause obstruction or bleed because of their friable epithelial surfaces. Obstruction and bleeding are increasingly likely with more distal lesions as the stool becomes more solid. Blood is typically dark and mixed in with the stool, in contrast to the fresh or dripping bleeding observed from haemorrhoids. Alteration of bowel habit may involve frequency or increased constipation where solid stool flow is obstructed, particularly with left-sided lesions. Ascending colon tumours can grow large without affecting faecal flow. In these cases presentation is often with iron-deficiency anaemia as a consequence of long-standing but invisible blood loss. Diagnosis of right-sided lesions is further complicated by the difficulty of achieving complete evacuation, the challenge of barium enema or scanning studies in this region, and the difficulty of colonoscopic access. Pain in a patient with colorectal cancer suggests obstructive disease or invasion, and weight loss is a late symptom suggestive of advanced disease with poor prognosis. A palpable mass may reflect faecal retention, but the tumour itself may still be resectable. Thus the clinical picture in colorectal cancer is relatively non-specific and must be differentiated from the anorectal bleeding of haemorrhoids or fissures, and the pain and altered bowel habit of irritable bowel disease.

The occurrence of so many tumours in the rectum makes digital rectal examination essential. Flexible sigmoidoscopy has become a routine procedure requiring a simple enema preparation and usually no sedation. It will detect 60 per cent of adenomas and carcinomas. Colonoscopic examination has the advantage that other synchronous polyps or tumours are detected. Other imaging modalities are becoming increasingly important, for example CT scanning as 'virtual colography' or to stage disease before operation in order to detect involvement of adjacent structures such as the ureters. MRI scanning is particularly useful to assess rectosigmoid disease. Transmural ultrasound is used in the rectum for assessing local invasion. Serological tests such as carcinoembryonic antigen levels are of some value in postoperative management and in the detection of tumour recurrence, but are secondary to accurate histological staging.

As a result of these investigations the differential diagnoses can usually be discounted. These include benign lesions such as areas of ischaemia, solitary rectal ulcer syndrome, masses of granulation tissue, endometriosis, or amoebomas, all of which may mimic carcinoma on radiography or endoscopy. An appendix abscess may mimic a caecal carcinoma, as may tuberculosis, actinomycosis, or Crohn's disease. Sigmoid diverticular disease with pericolic abscess formation may mimic distal carcinoma. Other malignancies of the colon, including lymphoma, sarcoma, and carcinoid tumours are rare. Kaposi's sarcoma presents as violaceous nodules in patients with AIDS. A variety of anal tumours occur that reflect the different structures and embryological derivation of this area. They include adenocarcinomas,

condylomas, and squamous carcinomas (which are common in immunosuppressed patients due to papillomavirus infections), and malignant melanomas. Rarely, the anal margin may be the site of premalignant skin conditions such as leucoplakia, Paget's disease, or Bowen's disease.

Treatment

Surgical resection is the primary treatment and is potentially curative. The aim is to remove the neoplasm with an adequate uninvolved resection margin of normal tissue, as well as the entire draining lymphatic field. The need for careful mesorectal dissection to prevent local recurrence is established in rectal cancer surgery. In the presence of metastases, palliative resection of the primary tumour is usually desirable in order to prevent obstruction, so that 90 per cent of patients undergo surgery. The operative mortality for colorectal surgery is less than 1 per cent. Bowel preparation is essential, with oral purgatives and/or enemas, to avoid anastomotic complications. Prophylactic antibiotics minimize postoperative sepsis. Thorough preoperative preparation may be impossible in patients presenting in emergency with perforation or obstruction. Some 25 per cent of patients with colorectal cancer present in this manner, when the hazards of surgery are much increased.

The site of the tumour dictates the operation performed: caecal carcinomas are treated by right hemicolectomy; ascending and transverse colon tumours by extended right hemicolectomy; left hemicolectomy for descending colon cancer; and sigmoid colectomy for sigmoid tumours. All these operations involve resection back to the respective tributaries of the superior and inferior mesenteric arteries.

The operation performed for rectal cancer is also dependent on the tumour's position. An anterior resection is performed where it is possible to leave a disease-free margin above the anal canal. When the cancer is too low for this, an abdominoperineal resection is performed with resection of the distal sigmoid colon, rectum, and anus, and creation of a permanent sigmoid colostomy. Rectal surgery has been transformed by the availability of a variety of stapling instruments to reanastomose the bowel. Low anterior resections are now commonly performed with good results, so that anal excision is avoided. Abdominoperineal resection is unavoidable when the tumour involves the anal sphincter. A temporary colostomy is sometimes advisable, particularly acutely, when there is a high risk of postoperative anastomotic leakage.

There is increasing interest in the use of laparoscopic techniques to remove colorectal tumours. The great advantage of this approach is that surgery is less traumatic and postoperative recovery is accelerated. A variety of techniques have been developed to avoid the problem of disease recurrence at the sites of laparoscopic entry ports. Multicentre, randomized controlled trials are currently comparing outcomes, especially 5-year survival rates after laparoscopic versus open surgery for colorectal cancer. Given the different 5-year survival rates for tumours at different Dukes' stages, the outcomes of colorectal surgery essentially reflect the proportions of patients presenting at these different stages (Table 3).

Dukes' staging is also central to the appropriate use of chemotherapy and radiotherapy. 5-fluorouracil (with folinic acid) prolongs the survival of patients with stage D disease. Randomized trials have also shown that 5-fluorouracil (**5-FU**) improves survival in stage C disease when used as adjuvant therapy to surgery. It is not clear that portal vein infusion of 5-FU provides any additional advantage. The evidence of survival advantage from adjuvant chemotherapy in stage B disease is less clear-cut. The complicating factor is that 60 per cent of these patients will survive for 5 years after surgery alone, and any additional survival advantage from chemotherapy must be balanced against the risk of life-threatening toxicity (stomatitis, leucopenia, etc.) in up to 5 per cent of patients. Intuitively, it has been assumed that agents beneficial in stage C disease should provide a therapeutic benefit in the 40 per cent of stage B patients (and 10 per cent of stage A patients) who do not survive for 5 years after surgery alone. Some newer drugs show promise in the treatment of colorectal cancer: these include other thymidylate synthase inhibitors and drugs that inhibit topoisomerase (the 'tecan' class). However, this begs the question of how patients with tumours with atypically poor prognosis can be identified.

Randomized clinical trials of preoperative radiotherapy versus surgery alone show a reduction in local recurrence rates and survival advantages, particularly in rectal cancer. However, this must be balanced against the disadvantages of radiotherapy: impaired bowel function in up to one-third of patients and minor increases in early postoperative morbidity. Based on the available evidence, preoperative radiotherapy is better than postoperative treatment because the incidence of surgical complications is lower. Thus, adjuvant chemotherapy combined with preoperative radiotherapy is established practice for Dukes' stage C colorectal cancer. Recurrent disease is incurable so complete tumour excision is vital, particularly total mesorectal excision of rectal carcinomas. Therefore, follow-up after potentially curative surgery is primarily aimed at detecting further adenomas or cancers in these patients, who are at increased risk. Colonoscopy at 5 years seems to be as effective as more intensive surveillance programmes.

Further reading

Cochrane Reviews have appeared on the clinical management of gastrointestinal tumours (available at http://www.update-software.com/). Their topics include:

preoperative chemotherapy for resectable thoracic oesophageal cancer

preoperative radiotherapy for oesophageal carcinoma

palliative chemotherapy for advanced or metastatic colorectal cancer

screening for colorectal cancer using the faecal occult-blood test

Protocols have also been published for Cochrane Reviews on:

colorectal adenoma surveillance and colorectal cancer

surgery for obstructing left-sided colorectal cancer: primary or staged resection?

follow-up strategies for non-metastatic colorectal cancer

intravenous 5-FU-based regimes as adjuvant to surgery for colon cancer with local lymph node spread

local surgical treatment in early rectal cancer with or without adjuvant therapy

effect of preoperative radiotherapy and surgery for localized rectal carcinoma

strategies for detecting colon cancer or dysplasia in inflammatory bowel disease.

In addition, relevant material appears in publications from the NHS Centre for Reviews and Dissemination (e.g. Management of upper gastrointestinal cancers, *Reviews and Dissemination*, Vol. 6, 2000). Further authoritative reviews of United Kingdom best practice are published in *Clinical Evidence* (see Issue 4, December 2000). These include meta-analyses of randomized controlled trial evidence for or against:

treatment of gastro-oesophageal reflux disease in preventing progression of Barrett's oesophagus

adjuvant chemotherapy for stomach cancer

radical versus conservative surgical resection for stomach cancer

total mesorectal excision for rectal cancer

particular follow-up strategies after colorectal cancer

preoperative radiotherapy in colorectal cancer

adjuvant chemotherapy in colorectal cancer.

14.16 Vascular and collagen disorders

Graham Neale

Clinical disorders of the gastrointestinal tract caused by vascular and collagen disorders are rare in general medical practice. Vascular insufficiency (Table 1) may cause dramatic disease with infarction, perforation, bleeding, ulceration, or strictures, and in the very sick it may damage mucosal function and lead to ischaemia-reperfusion injury. In contrast, patients with collagen disorders often have abdominal symptoms due to disorder-related vasculitis, but such symptoms rarely dominate the clinical picture.

Causes of segmental mesenteric ischaemia

The blood supply to the gut may be impaired by compression, by intraluminal occlusion of vessels, or by intrinsic vascular pathology, including vasospasm.

Compression of mesenteric vessels

The mesenteric vessels may be compressed by torsion or strangulation of the mesentery, retroperitoneal haematomas, neoplastic infiltration, and rarely by proliferating fibrous tissue such as occurs in retroperitoneal fibrosis or occasionally around carcinoid or desmoid tumours. Venous occlusion with thrombosis is a rare complication of excessive gaseous pressure during laparoscopy.

Intraluminal occlusion of mesenteric vessels

Thrombosis

Thrombosis may occur in arteries or veins. In arteries thrombosis usually occurs on an ulcerated atheromatous plaque but it may occur spontaneously in polycythaemia, sickle cell disease, cryoglobulinaemia, and amyloidosis. Thromboangiitis obliterans (Buerger's disease) is a rare condition which does not usually affect mesenteric vessels but intestinal infarction has been described as a first manifestation of the disorder in women who smoke. Mesenteric arterial thrombosis has also been described in cocaine addicts.

Mesenteric venous thrombosis is less common than arterial occlusion. An inherited thombophilia (such as deficiency of protein C, protein S, or antithrombin III) is the most likely cause. It may also occur in the primary antiphospholipid antibody syndrome and with dysfibrinogenaemia and has been described in women taking oral contraceptives (especially those who smoke) after splenectomy and in association with pancreatitis.

Arterial embolism

Emboli cause up to one-third of cases of mesenteric vascular occlusion. They arise from the heart, especially in patients with mitral stenosis and atrial fibrillation, with myocardial infarction and endomyocardial thrombosis, and with bacterial endocarditis. Paradoxical embolism through a patent foramen ovale and embolism from aortic mural thrombi are uncommon causes.

Diffuse microthrombosis

Diffuse thrombosis of small vessels may occur as a result of disseminated intravascular coagulation. The haemolytic–uraemic syndrome and thrombotic thrombocytopenic purpura are related conditions in which platelet aggregation occurs in small vessels (see Chapter 20.10.6 and Section 22). Renal failure usually dominates the clinical picture, but in most patients there is evidence of widespread involvement of the intestine and related organs. The haemostatic abnormalities and their relationship to microvascular injury are complex and give rise to diverse and often confusing clinical and laboratory findings. Infusions of platelets and fresh plasma are usually beneficial but therapy must be individualized depending on the nature of the underlying pathology and the site and severity of haemorrhage or thrombosis.

Intrinsic vascular pathology

Atheromatous occlusion

Atheroma is the most common cause of mesenteric vascular insufficiency, which often remains undiagnosed in life, probably because the slowness of the pathological process allows for the development of a compensatory collateral circulation. Intestinal infarction secondary to atheromatous occlusion of one major mesenteric vessel is uncommon. Indeed, all three vessels may be occluded without visceral damage.

Inflammation of blood vessels

Vasculitis is primarily a disorder of small vessels and affects many organs (Table 2). Involvement of the mesenteric circulation rarely causes infarction of long segments of the gut but may cause a wide spectrum of gastrointestinal disorders that are described later in this chapter.

Damage to the arterial wall in the splanchnic circulation sometimes occurs a few days after surgical correction of coarctation of the aorta. There is necrotizing arteritis with fibrinoid necrosis which is most marked at arterial bifurcations and appears to be related to the sudden sustained increase in blood pressure. It usually resolves spontaneously but may occasionally lead to intestinal infarction requiring operative intervention.

The walls of the mesenteric arteries may be involved in fibroelastic hyperplasia and in Takayasu's disease. In malignant hypertension, intimal hyperplasia and fibrinoid necrosis of arteriolar walls may lead to patchy ischaemia of the intestines. Irradiation of the abdomen leads to vascular necrosis and thrombosis, which in turn may cause ischaemic ulceration that on healing leaves a fibrosed intima and a poorly perfused segment of intestine.

Recently mesenteric veno-occlusive disease has been described as a discrete entity that may affect adults of any age. Previous cases were regarded as idiopathic

venous thrombosis.

Non-occlusive mesenteric ischaemia (Table 3)

Sporadic and epidemic cases of necrotizing enteritis but without evidence of vascular occlusion have been described from many parts of the world and in all age groups. Neonatal necrotizing enterocolitis occurs in the first week of life of premature and low-birth-weight infants. Artificial hyperosmolar feeds may promote damage, whereas breast milk appears to be protective, possibly by providing passive enteric immunity. Lesions occur most frequently in the stomach, the distal ileum, and the colon; as mucosal integrity disintegrates bacterial invasion enhances the damage. The condition may also occur in infants of normal birth weight who have a hyperviscosity syndrome or who have been exposed to cocaine *in utero*.

In adults, infarction of the gastrointestinal tract without vascular occlusion is seen mainly in the elderly with severe low-output cardiac failure but it has been described in women in middle-life without obvious risk factors. In tropical and subtropical areas the condition is more common and may be related to environmental factors including diet, infection, and infestation.

Non-occlusive focal ischaemia appears to underlie the pathogenesis of uraemic colitis, radiation enteritis, potassium-induced ulcers, and multiple stress ulcers of the upper gastrointestinal tract. The verotoxin of *Escherichia coli* 0157:H7, which causes haemorrhagic colitis, is another aetiological agent. This is a particularly potent cause of disseminated intravascular coagulation, which may occur as a result of the absorption of bacterial endotoxin and thromboplastins from damaged tissues. It is associated with the development of the haemolytic–uraemic syndrome in children and more rarely with thrombotic thrombocytopenic purpura in adults (Table 2).

Intestinal ischaemia: the clinical syndromes

The clinical effects of mesenteric vascular insufficiency will be considered under four headings: acute mesenteric ischaemia, chronic mesenteric ischaemia, ischaemic colitis, and ischaemia-reperfusion injury. Focal ischaemia of the intestine will be considered in the section on collagen disorders.

Acute mesenteric ischaemia

Clinical features

Necrosis, incipient or complete, of that part of the gut supplied by the superior mesenteric artery is life-threatening. The onset is usually abrupt. Abdominal pain is the key symptom and at the onset it is usually colicky in nature. As the condition progresses the pain becomes constant and unremitting. Initially it is felt in the right iliac fossa and then spreads over the entire abdomen. Diarrhoea is usual and the motions may contain blood. Vomiting occurs in some cases but haematemesis is rare. There may be slight tenderness in the right iliac fossa and some exaggeration of bowel sounds. Over the course of hours (or at the most a day or two) the abdomen becomes distended and silent with increasing tenderness and a positive rebound sign. At this stage there are usually signs of peripheral circulatory failure. The patient is pale, anxious, sweating, and tachypnoeic. Later the blood pressure falls and the patient becomes cyanosed and anuric; by now damage to the intestine is irrecoverable.

Diagnosis is often delayed because there are no clinical signs apart from overwhelming patient distress which itself indicates the need for urgent specialist attention. Duplex Doppler ultrasonography and contrast-enhanced magnetic resonance imaging are probably the best means of confirmation but are rarely available. For practical purposes, the diagnosis still depends on the efficiency with which other causes of an apparent abdominal catastrophe can be excluded. Plain radiographs of the abdomen may show non-specific dilatation of loops of intestine with multiple fluid levels. The presence of gas bubbles in the portal vein is diagnostic of intestinal necrosis at a stage when the patient is beyond recovery. Needle aspiration of the peritoneal cavity may be a helpful procedure because intestinal infarction usually produces blood-stained fluid.

Management

Early laparotomy is essential. First the clinician has to combat the effects of loss of water, electrolytes, and protein leading to hypovolaemia and impaired tissue perfusion, bacterial invasion, and disseminated intravascular coagulation. The value of pharmacological agents (such as phenoxybenzamine, glucagon, or dopamine) for improving the mesenteric circulation remains uncertain.

As soon as the patient is sufficiently fit, the abdomen must be opened. If a large vessel is occluded, the surgeon may be able to undertake embolectomy or reconstruct an occluded artery. In both occlusive and non-occlusive vascular disease it is necessary to decide how much intestine to resect. If there is doubt about the viability of the residual intestine the abdomen should be closed and re-explored 24 h later. Infiltrating the coeliac and mesenteric plexuses with local anaesthetic may help relieve vascular spasm and should be used if there is no evidence of vascular occlusion. Treatment with anticoagulants may also be indicated.

Chronic intestinal ischaemia

Chronic intestinal ischaemia is usually due to atheroma. The coeliac axis and superior mesenteric artery are commonly affected and the inferior mesenteric artery to a much lesser extent. Stenotic lesions occur at the aortic origins of the vessels. Diffuse, severe atheroma throughout the intestinal arterial tree is uncommon and therefore arterial reconstruction may be very rewarding.

Clinical features

Patients with chronic ischaemia of the gut suffer poorly localized severe cramping abdominal pain. This occurs every day and is usually worse 20 to 60 min after eating. The pain may be relieved by simple analgesics or by vasodilator drugs. As the condition progresses the patient becomes afraid to eat and loses weight. There are no diagnostic physical signs and in particular it is not helpful to find a vascular bruit. Thus clinicians must request vascular imaging whenever there is reasonable suspicion and other tests (including computed tomographic scanning of the abdomen) have failed to give a diagnosis.

Magnetic resonance imaging is best able to provide functional information about the degree of arterial stenosis and quantitative information about blood flow and blood oxygenation. Unfortunately only a few specialized centres are likely to develop sufficient experience with this sophisticated technique.

Compression of the coeliac-axis

In occasional patients with chronic abdominal pain and an abdominal bruit (which may be exacerbated by inspiration), aortography shows apparent constriction of the coeliac axis by the median arcuate ligament. It has been claimed that the arteries in the territory of the coeliac axis 'steal' blood from that of the superior mesenteric artery, thereby causing an intestinal angina that may be relieved by dividing the median arcuate ligament and possibly by reconstructing the coeliac axis. The validity of this syndrome is uncertain.

Ischaemic colitis

The colon is more prone to ischaemic damage than the small intestine. The transverse and descending segments of the colon are supplied by marginal branches of the middle colic (superior mesenteric territory) and left colic (inferior mesenteric territory) arteries. An arterial and lymphatic watershed exists close to the splenic flexure, which is supported to a variable extent by an additional vascular arcade. This segment of the colon is at risk when the mesenteric circulation is compromised. In addition, distension of the colon may impair blood flow. Thus ischaemic colitis may occur in the segment of intestine immediately proximal to an obstructing lesion (stercoral ulceration) or with colonic pseudo-obstruction. Venous occlusion may also cause ischaemic colitis.

Clinical features

In the acute phase of ischaemic colitis the clinician has to differentiate between mild injury, which responds quickly and effectively to supportive measures and treatment with appropriate antibiotics, and severe injury, in which gangrene may develop. Typically the affected person complains of pain in the left iliac fossa,

nausea, and vomiting followed by the passage of a loose motion containing dark blood.

Marked tenderness in the left iliac fossa is the most constant physical sign. At colonoscopy the mucosa may be blue and swollen without contact bleeding. The rectum is invariably spared. Plain radiographs of the abdomen may show an abnormal segment of large intestine outlined with gas.

Contrast enema examination of the colon is a most useful way of demonstrating ischaemic damage. In the early phase 'thumb printing' is the characteristic sign. This may persist for several days (Fig. 1). Subsequently the mucosal appearance may return to normal or progress to mucosal ulceration, giving an appearance that may be indistinguishable from segmental ulcerative colitis or Crohn's disease. These changes may resolve spontaneously or progress to tubular narrowing of the intestine with or without sacculation on the antimesenteric border.

Fig. 1 Ischaemic colitis: barium enema showing thumb printing at the splenic flexure. (By courtesy of Dr A. Freeman, Addenbrooke's Hospital.)

Ischaemic colitis may be confused with dysenteric conditions, acute diverticular disease of the colon, acute inflammatory bowel disease, perforation of a hollow viscus, or left-sided peritonitis caused by pancreatitis. The most important distinguishing features are the association with degenerative cardiovascular disease and the distinctive, although not pathognomonic, radiographic and colonoscopic appearances.

Management

On establishing the diagnosis of ischaemic colitis the treatment is initially expectant. The patient should be given intravenous fluid as necessary, together with systemic broad-spectrum antibiotics. Well over 90 per cent of recognized cases resolve spontaneously. A stricture may develop in up to a third of patients but this is usually asymptomatic and only rarely needs to be resected. Surgery is indicated if there is evidence of peritonitis, persistent bleeding, or of an underlying colonic disorder (such as carcinoma).

Intestinal reperfusion injury

The gut mucosa may be transiently but seriously damaged after a period of ischaemia which is followed by apparently adequate reperfusion. The damage appears to be caused by the generation of reactive oxygen metabolites (including superoxide, hydrogen peroxide, and hydroxyl radicals). These alter the vascular permeability of endothelial cells and damage epithelial cells by peroxidation of cell membranes. The injured tissues are strongly chemotactic for neutrophils and this leads to an acute inflammatory response. Such damage diminishes the barrier function of the gut, increasing intestinal permeability and allowing the translocation of bacteria. Injury of the intestinal mucosa is now recognized as an important factor in the prognosis of critically ill patients in intensive care. Serial measurements of serum intestinal fatty acid protein (iFABP) have been shown to provide a sensitive marker of damage to intestinal mucosa.

Vasculitis nd the collagen disorders: effects on the gut

The gut may be involved in any of the systemic collagen–vascular disorders. Vasculitis may cause focal ischaemic damage of the intestine (Table 2) but this is a feature of many conditions other than the collagen disorders, for example drug-induced ulceration (for example by potassium salts), the after-effects of blunt trauma to the abdomen, irradiation, and rarely infective disease (for example typhoid or leprosy) (Table 3).

In the collagen disorders the visceral muscle may be damaged and the resulting dysmotility may cause dysphagia, delayed gastric emptying, small intestinal stasis with bacterial overgrowth, or colonic inertia. Gas may infiltrate the tissues, giving rise to pneumatosis intestinalis.

The specific pathological diagnosis is usually based on the systemic features of the illness and the laboratory findings rather than on the mostly non-specific abdominal complications. But the inquisitive physician may also recognize curious associations in patients with multisystem disorders. Thus, intestinal malabsorption and protein-losing enteropathy have been described in association with systemic lupus erythematosus and rheumatoid arthritis, pancreatic insufficiency with systemic sclerosis, acute pancreatitis during the course of Behçet's disease, and apparently classical inflammatory bowel disease with systemic lupus erythematosus.

Systemic sclerosis

In primary systemic sclerosis (see Chapter 18.11.3), fibrous connective tissue proliferates. In the gastrointestinal tract it may replace smooth muscle, especially in the oesophagus (which is involved in 80 per cent of cases), to a lesser extent in the small intestine (although duodenal involvement is quite common), and rather rarely in the colon.

Overt vasculitis is a less common feature but occasionally causes intestinal infarction. Pneumatosis cystoides intestinalis is also described, especially in association with intestinal pseudo-obstruction or a pneumoperitoneum.

Clinical features

In systemic sclerosis progressive dysphagia is the most frequent gastrointestinal symptom. Initially there is a decrease in the incidence and amplitude of contractions of the lower oesophagus and incomplete relaxation of the lower oesophageal sphincter. In addition, the resting tone of the sphincter is reduced, allowing reflux of gastric juices, oesophagitis, shortening of the oesophagus, and occasionally stricture formation. Associated hiatal herniation is common.

More rarely the stomach is involved, causing delayed emptying that on occasion is exacerbated by associated stenosis of the pyloric canal. Changes lower down the gastrointestinal tract also occur. Characteristically the duodenum is dilated, the valvulae of the small intestine are thickened, and pseudodiverticula may form. These changes are associated with abdominal discomfort, distension, and borborygmi, especially after the taking of meals. The impaired motility of the small intestine leads to stasis of its contents and bacterial overgrowth causing malabsorption, especially of fat and vitamin B_{12} (see Chapter 14.9.2) (Fig. 2). Progressive constipation due to impaired colonic motility is uncommon.

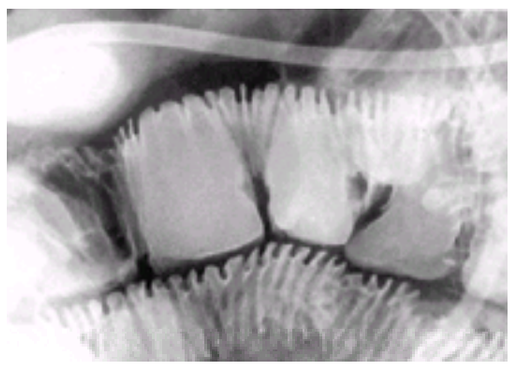

Fig. 2 Systemic sclerosis. Typical 'sacculation' appearance of the bowel.

Management

There is no specific treatment of primary systemic sclerosis. Lesions in the gastrointestinal tract need management on their merits. It is important to recognize early the patient with gastro-oesophageal reflux. A proton pump inhibitor should be given to prevent the ravages of acid-peptic digestion of the oesophageal mucosa. When strictures occur these should be dilated by bouginage. Surgical intervention is occasionally necessary.

A breath test (see Chapter 14.2.3 and Chapter 14.9.2) is a useful screening test for delayed passage of contents and bacterial proliferation in the small intestine. Patients with a positive breath test should be assessed for evidence of malabsorption, and if this is found intermittent therapy with antibiotics for an indefinite period may be of clinical value.

Systemic lupus erythematosus

Systemic lupus erythematosus (see Chapter 18.11.2) may cause abdominal symptoms arising from any part of the gastrointestinal tract. Anorexia, weight loss, nausea, vomiting, and diarrhoea are relatively common. Dysphagia, abdominal pain, distension due to ascites, and gastrointestinal bleeding are less frequent symptoms. Occasionally a patient with systemic lupus erythematosus develops an acute abdomen, which may be due to localized or widespread lupus vasculitis causing ischaemic damage to the gut or its related organs, including the gallbladder and pancreas. Arteriography may be helpful in diagnosis by revealing diffuse irregularities in the branches of mesenteric vessels.

Treatment with oral corticosteroids usually relieves minor abdominal symptoms and will lead to rapid resolution of simple ascites. In the acute stage of the disease, however, surgery may be necessary to deal with infarcted intestine, serious bleeding, or intestinal obstruction.

Other systemic disorders

In rheumatoid arthritis, vasculitis is associated with long-standing disease, seropositivity, and florid subcutaneous nodule formation (see Section 18.11). Occasionally, a severe diffuse and necrotizing angiitis causes infarction in the gallbladder, pancreas, or intestine. Symptoms vary from vague abdominal pain, with or without diarrhoea, to the development of an acute abdomen.

Dermatomyositis rarely causes damage to the viscera although thrombosis of small vessels occasionally causes gastrointestinal ulceration.

In Behçet's syndrome the triad of relapsing iritis, painful ulcers of the mouth, and genital ulceration is only part of the syndrome (see Chapter 18.11.5). Again, vasculitis appears to be the underlying histopathological lesion. In the gastrointestinal tract this may lead to ulceration of the colon, malabsorption (sometimes with lymphangiectasia), and pancreatitis.

Primary vasculitis

Henoch–Schönlein purpura (anaphylactic purpura)

This is a self-limiting disorder of unknown cause characterized by small-vessel vasculitis (see Section 18.11). Gastrointestinal disease occurs in at least two-thirds of cases and is manifest as abdominal pain and gastrointestinal bleeding. Intramural haematomas are common and rarely may be complicated by intussusception, perforation, or an infarcted segment of gut.

Polyarteritis nodosa

Abdominal pain and other gastrointestinal symptoms are common in patients with polyarteritis nodosa. The underlying cause is usually recognized by evidence of systemic disease such as skin lesions, renal involvement, hypertension, and eosinophilia. Mesenteric angiography is useful as a diagnostic tool because up to two-thirds of cases have recognizable aneurysms of mesenteric and renal vessels. A small proportion of patients with polyarteritis have acute abdominal episodes including ulceration, haemorrhage, perforation and segmental necrosis of intestine, cholecystitis, pancreatitis, and hepatic infarction. Kawasaki disease (infantile acute febrile mucocutaneous lymph node syndrome) (see Chapter 18.11.8) proceeds to a disorder indistinguishable histopathologically from infantile periarteritis nodosa. Cardiac involvement is most common, but the gastrointestinal tract is affected in up to a third of cases.

Antineutrophilic cytoplasmic antibody-positive vasculitides

Wegener's granulomatosis, Churg–Strauss syndrome, and microscopic polyarteritis are conditions frequently associated with the finding of antineutrophilic cytoplasmic antibodies. Gastrointestinal symptoms are common in these conditions, although the intra-abdominal pathology has not been well characterized except when angiitis has led to a life-threatening condition such as visceral perforation or infarction.

Giant cell arteritis

This characteristically affects the larger cranial arteries including the ciliary and central retinal arteries (see Chapter 18.11.4) and rarely limb arteries. Very occasionally a similar pathology affects mesenteric arteries and causes bowel infarction.

Localized arteritis

Arteritis has been described causing pathology solely in the appendix, the gallbladder, and the pancreas. The relationship of a localized arteritis to systemic polyarteritis is uncertain. Similarly, localized leucocytoclastic (hypersensitivity) vasculitis has been described in the abdominal cavities.

Other vascular disorders that may affect the gut

Aneurysms of the aorta and its major branches

Rarely, aneurysms fistulate into the stomach or duodenum. This usually causes catastrophic bleeding and rapid death. Even more rarely there is intermittent bleeding (for example from the splenic artery into the stomach), which may be difficult to diagnose.

Superior mesenteric artery syndrome

A syndrome of postprandial epigastric pain, distension, and vomiting may occur in asthenic young people, especially those who have lost weight or who are fixed in a position of hyperextension after spinal injury. Barium studies show a distended proximal duodenum with a sharp cut-off at the line where the superior mesenteric artery crosses the duodenum. Symptoms may be relieved if the patient adopts the prone position after meals and usually disappear as the patient gains weight. Surgery is occasionally necessary. The condition must be distinguished from duodenal ileus caused by mesenteric bands, a condition that is associated with partial malrotation of the midgut.

Haemangioma

Haemangiomas are uncommon but they may cause painless bleeding especially in the jejunum.

Intestinal telangiectasia

These lesions occur most commonly with Osler–Weber–Rendu disease (see Section 22.04.04) and may lead to microscopic bleeding with anaemia, especially in adult life.

Vascular dysplasia

This is a more recently recognized and not uncommon disorder causing occult bleeding from the gut in older subjects. The lesions occur as small arteriovenous malformations or as foci of ectatic capillaries or veins with little supporting stroma. They are found predominantly in the caecum and ascending colon. There may be an association with aortic stenosis but none with cutaneous telangiectases and no familial aggregations have yet been described.

Patients give a history of recurrent anaemia or episodes of bleeding from the gut, have usually been investigated repeatedly without getting a firm diagnosis, and sometimes have had one or more operations (including resection of a segment of the gastrointestinal tract) without relief of symptoms. The diagnosis of vascular dysplasia should be considered in all cases of obscure gastrointestinal haemorrhage and may be made by direct visualization of the intestinal mucosa (Fig. 3) or by selective mesenteric arteriography (Fig. 4). The lesions may be multiple, in which case resection of the affected segment of gut may be necessary. Many patients, however, can be treated successfully by fulguration of the lesion through an endoscope. If the lesion(s) cannot be obliterated, in women a trial of treatment with an oestrogen–progesterone preparation is often effective.

Intramural bleeding

Bleeding into the wall of the bowel may occur as a result of treatment with anticoagulants or from the inflammation of small vessels (as occurs classically in Henoch–Schönlein purpura). The usual presentation is with colicky abdominal pain, with bleeding into the lumen of the gut. Appropriate barium examination may show the classical sign of 'thumb printing'. The condition usually resolves spontaneously providing that the underlying disorder can be treated. A blood transfusion may be needed.

14.17 Gastrointestinal infections

Davidson H. Hamer and Sherwood L. Gorbach

Introduction

Diarrhoea, the most common manifestation of intestinal tract infections, is a leading cause of death in most developing countries where its greatest impact is seen in infants and children. Infectious diarrhoea may be accompanied by numerous complications (Table 1). The financial burden associated with medical care and lost productivity due to infectious diarrhoea amounts to more than 20 billion dollars a year in the United States alone.

The aetiology and severity of gastrointestinal infections are determined by several epidemiological factors. Young children and the elderly are at greatest risk for more severe disease and complications. The presence of underlying medical conditions, especially those that compromise immunity, greatly enhances the risk of acquiring an infection and its ultimate severity. Poor sanitation, inadequate water supplies, and increasing globalization of food transport systems all predispose to the development of large epidemics of food- and water-borne outbreaks of gastrointestinal disease. Seasonal or cyclic weather variations also influence the epidemiology of diarrhoeal disease and food poisoning.

A wide array of bacterial, protozoal, and viral pathogens is responsible for gastrointestinal tract infections. The characteristics of specific organisms are described in detail in Section 7 of this book: here are presented the pathophysiology, common clinical syndromes, diagnosis, management, and prevention of gastrointestinal diseases.

Pathophysiology

Host factors

Normal intestinal flora

The proximal small bowel, including the stomach, duodenum, jejunum, and upper ileum, has a relatively sparse microflora, with most organisms being derived from the oropharynx. Colonization of the upper intestine by Gram-negative bacilli is an abnormal event, one that is characteristic of illness due to pathogens such as *Vibrio cholerae* and *Escherichia coli*. The large bowel has an abundant microflora, with total concentrations of 10^{11} bacteria per gram of content. Anaerobes including *Bacteroides* spp., *Clostridium* spp., and anaerobic streptococci outnumber aerobic bacteria, such as coliforms, by 1000-fold. During an episode of acute diarrhoea, regardless of the aetiology, the colonic flora becomes less anaerobic because of the rapid transit of intestinal contents. As a consequence, strictly anaerobic bacteria decrease in number while there is an increase in coliforms, which are often aberrant types such as *Enterobacter*, *Klebsiella*, and *Proteus* spp. The pathogen itself assumes a dominant position in the flora, so that the major faecal isolate may be *Salmonella* spp. or *V. cholerae.*

In addition to the longitudinal distribution of bacteria in the gastrointestinal tract, the bowel microflora is found both within the lumen and adherent to the mucous layer overlying epithelial cells. Invasive pathogens such as *Campylobacter*, *Shigella*, *Salmonella*, and *Yersinia* spp. can penetrate the mucosal surface and infect epithelial cells, or translocate into the mesenteric lymph nodes and bloodstream.

Control mechanisms

At the portal of entry, gastric acid suppresses most organisms that are ingested. In the setting of reduced or absent gastric acid, there is a higher incidence of bacterial colonization of the upper small intestine. Consequently, persons with hypochlorhydria, achlorhydria, or those using drugs such as proton-pump inhibitors that inhibit gastric acid secretion are susceptible to diarrhoeal diseases. A critical element in maintaining the sparse flora of the upper bowel is propulsive motility. The antibacterial properties of biliary fluid may control the intestinal flora. The glycocalyx and intestinal mucins secreted by epithelial cells provide a mechanical barrier to invasion by gut pathogens. Finally, antibacterial substances produced by the normal intestinal microflora help to maintain the stability of normal populations of organisms and to prevent the implantation of pathogens.

Intestinal immunity (see Chapter 14.4)

The intestinal immune system plays a major role in the host's response to enteric pathogens. The human gut contains a large amount of lymphoid tissue in the form of intraepithelial lymphocytes, lamina propria lymphoid cells, and Peyer's patches. The latter are lymphoid aggregates in the mucosa and submucosa of the distal small intestine which serve as sites for the presentation of antigens to B and T lymphocytes. After activation by antigens, bacteria, or viruses in the Peyer's patches, the lymphocytes migrate to the lamina propria and the intraepithelial portion of the intestinal lining where, along with macrophages and other types of white blood cells, they protect the host from specific pathogens. Plasma cells in the lamina propria produce secretory immunoglobulin A, which is released into the intestinal lumen. When the mechanical barrier of the gut fails, then the intraepithelial and lamina propria lymphocytes provide the next level of protection against pathogenic enteric organisms.

Microbial factors

The number of organisms that need to be ingested to establish a gastrointestinal tract infection varies from as few as 10 to 100 in the case of *Shigella* spp. to as many as 10^8 for *V. cholerae*. In the presence of reduced gastric acidity or underlying immunosuppression, the inoculum needed to establish infection is reduced.

Enteric pathogens can cause intestinal disease by means of enterotoxins, adherence to gut mucosa, or invasion of enterocytes.

Toxins

Bacterial enteric pathogens can elaborate enterotoxins that act directly on intestinal epithelial cells (for example, cholera toxin) or preformed toxins that are ingested in contaminated food (for example, *Bacillus cereus* toxin). While invasive bacteria penetrate the mucosal surface of the gut as the primary event, they may also secrete enterotoxins. Production of enterotoxin can be demonstrated in the laboratory by *in vivo* tests—such as the rabbit ileal loop model and the suckling mouse model, or by *in vitro* tests involving a tissue culture line, such as Y-1 adrenal cells or Chinese hamster ovary cells.

Many organisms elaborate enterotoxins that cause fluid and electrolyte secretion in the gut. Diarrhoeal toxins can be grouped into two categories: cytotonic, which produce fluid secretion by activation of intracellular enzymes such as adenylate cyclase, without causing any damage to the epithelial surface; and cytotoxic, which

cause injury to the mucosal cell while also inducing fluid secretion, but not primarily by activation of cyclic nucleotides. *V. cholerae* and enterotoxigenic *Escherichia coli* (**ETEC**) are examples of pathogens that cause dehydrating diarrhoea by producing enterotoxins of the cytotonic type (see Chapter 7.11.7).

Intestinal fluid loss is the primary manifestation of cholera—this results from the action of enterotoxin on the small bowel epithelial cells. These organisms colonize the small intestine, adhering to epithelial cells and then elaborating enterotoxin. There is no invasion of the mucosal surface so there is no evidence of damage to the mucosal architecture and bacteraemia is not a complication. The faecal effluent is watery, often voluminous, and produces the clinical features of dehydration. The most sensitive areas are the upper bowel, particularly the duodenum and upper jejunum; the ileum is less affected, and the colon is usually in a state of absorption since it is relatively insensitive to the toxin. This is a form of 'overflow' diarrhoea, with a large volume of fluid produced in the upper intestine that overwhelms the capacity of the lower bowel to absorb.

ETEC produces two types of enterotoxins: a heat-labile (**LT**) and a heat-stable toxin (**ST**). LT is a protein that is destroyed by heat and acid; like cholera toxin, it activates adenylate cyclase, causing secretion of fluid and electrolytes into the lumen. In contrast, ST can withstand heating to 100 °C and acts by activating guanylate cyclase. Despite the differences between the two toxins, the ultimate effect of both enterotoxins is a non-inflammatory secretory diarrhoea.

Invasion

Whereas toxigenic organisms usually involve the upper intestine, invasive pathogens target the lower intestine, particularly the distal ileum and colon. Histological findings include evidence of mucosal ulceration with acute inflammation in the lamina propria. Principal pathogens in this group are *Salmonella* spp., *Shigella* spp., enterohaemorrhagic *E. coli* (**EHEC**), enteroinvasive *E. coli* (**EIEC**), *Campylobacter spp.,* and *Yersinia* spp. Although there are important differences among these organisms, they all have in common the property of mucosal invasion as the initiating event. To date, three theories have been invoked to explain the mechanism of fluid production in invasive diarrhoea. First, fluid production may result from an enterotoxin, at least in the initial phase of the illness. Most *Shigella* strains elaborate an enterotoxin that differs substantially from cholera toxin, but which does result in fluid and electrolyte secretion by the intestine. A similar toxin has been proposed for *Salmonella spp.,* and there is suggestive evidence that *Campylobacter* and *Yersinia* spp. elaborate enterotoxins. Second, invasive organisms lead to an increased local synthesis of prostaglandins at the site of the intense inflammatory reaction that may be responsible for fluid secretion and diarrhoea. Third, damage to the epithelial surface may prevent reabsorption of fluids from the lumen and thereby result in a net accumulation of fluid in the bowel lumen, resulting in diarrhoea.

A series of pathogenic factors, each controlled by plasmids or chromosomal loci, are used by pathogenic strains of *Salmonella*. Specific plasmids encode for bacterial spread from Peyer's patches to other sites in the body, for the ability of certain strains to survive within macrophages following phagocytosis, and for the ability of salmonellae to elicit transepithelial signalling to neutrophils (see Chapter 7.11.7). Invasion by *Shigella* spp. is also associated with diverse virulence factors related to various stages of invasion. The end result is the death of the intestinal epithelial cell, focal ulcers, and inflammation of the lamina propia. The shigella virulence factors are encoded by chromosomal and plasmid genes, all of which are needed for the full expression of virulence. Various genetic loci encode for an invasion plasmid antigen (*ipa*), which seems to determine recognition of the epithelial cell, *inv* invasion factors, and a series of *vir* loci that are involved in regulation within the infected cell. After penetrating the mucosal surface of the gut, *Shigella* spp. multiply within epithelial cells and extend the infected area by direct cell-to-cell migration of bacilli. *Shigella* species rarely penetrate beyond the intestinal mucosa and therefore do not usually invade the bloodstream.

Adherence

Specific fimbriae or adhesins mediate the attachment of pathogenic bacteria to gut mucosal cells. For example, the attachment of *V. cholerae* is mediated by a fimbrial colonization factor, known as the toxin-coregulated pilus. Some enteric pathogens such as enteropathogenic *E. coli* (**EPEC**) attach to the intestinal mucosa in a characteristic manner, producing ultrastructural changes known as attachment-effacement lesions; this leads to the elongation and destruction of microvilli. Protozoal parasites such as *Giardia lamblia* use a ventral adhesive disc to attach to the mucosal surface of the small intestine. Thus, enteropathogens have devised a number of different ways to adhere to the surface of the gut.

Clinical syndromes of gastrointestinal infections

Gastrointestinal infections usually result in three principal syndromes: non-inflammatory diarrhoea, inflammatory diarrhoea, and systemic disease. Non-inflammatory diarrhoea primarily involves the small intestine, whereas inflammatory diarrhoea predominantly affects the colon. The location of infection influences the clinical characteristics and certain diagnostic features of the diarrhoeal disease (Table 2). Thus, the organisms that target the small intestine tend to produce watery, potentially dehydrating diarrhoea, while those infecting the large intestine cause bloody mucoid diarrhoea associated with tenesmus.

Non-inflammatory diarrhoea

Bacteria

Cholera, the prototypic non-inflammatory diarrhoea, can cause dehydration and death within 3 to 4 h of onset. Like many other infectious diseases, there is a spectrum of clinical manifestations—from an asymptomatic carrier state to severe dehydration with shock. Initial symptoms of vomiting and abdominal distention are rapidly followed by diarrhoea, which accelerates over the next few hours to frequent purging of large volumes of 'rice-water' stools. The acutely ill patient has marked dehydration manifested by poor skin turgor, 'washerwoman's hands', feeble to absent pulses, reduced renal function, and hypovolaemic shock.

Non-01 cholera vibrios have also been associated with severe, dehydrating diarrhoea as well as wound infections and septicaemia. *V. vulnificus* is one of the most important non-cholera vibrios, based on the severity of illness that it causes, especially in patients with underlying liver disease and especially iron-storage disease. This infection can be acquired by direct consumption of seafood, usually raw oysters, or as a wound infection in people who have direct contact with salt water. Since this infection can be lethal in susceptible people, such persons should be warned about eating raw seafood, especially oysters.

ETEC infections are one of the most common causes of diarrhoea in travellers to less developed countries and children living in these regions. The incubation period of this infection is usually between 24 and 48 h, after which the disease often begins with upper intestinal distress, followed soon thereafter by watery diarrhoea. The infection can be extremely mild, with only a few loose movements, or it can be quite severe, mimicking cholera with profuse watery diarrhoea leading to severe dehydration. Other strains of *E. coli* such as enteroaggregative, diffusely adhering, and enteropathogenic *E. coli*, may also be associated with watery diarrhoea.

Viruses (see also Chapter 7.10.8)

Numerous viruses are responsible for as many as 30 to 40 per cent of self-limited episodes of non-inflammatory diarrhoea, especially in children. Rotavirus causes a range of clinical manifestations from asymptomatic carriage to severe, potentially fatal dehydration. The disease occurs primarily in children aged between 3 and 15 months; infections continue into the second year of life, but after this age are less common. Adults can develop mild infections with group A rotaviruses, especially if there is a sick child in the household. The disease process often begins with vomiting, followed shortly thereafter by watery diarrhoea. The incubation period is between 1 and 3 days, with an average duration of illness of 5 to 7 days, although some instances of chronic diarrhoea have been described.

Caliciviruses are single-stranded RNA viruses that are responsible for human and animal infections. Recent molecular studies have shown that the Norwalk and Norwalk-like viruses have a genetic composition that places them in the taxonomic family of Caliciviridae. This family of viruses typically causes disease mainly in infants and young children, especially in day-care centres. The illness is generally mild and indistinguishable from that due to rotavirus or even epidemic Norwalk disease. The Norwalk virus causes explosive epidemics of diarrhoea that sweep through communities with a high attack rate.It shows no respect for age, as it can affect virtually all age groups except infants. Infections caused by the Norwalk agent tend to be relatively mild and short-lived, with common symptoms including diarrhoea, nausea, abdominal pain, vomiting, and myalgias. Generally, the clinical illness lasts no longer than 24 to 48 h.

Astroviruses are responsible for outbreaks of diarrhoea in day-care centres and in communities with infants.The disease is characterized by watery or mucoid stools, nausea, vomiting, and, occasionally, fever, but it tends to be milder than rotavirus diarrhoea as there is less dehydration. Adenovirus serotypes 40 and 41 are responsible for day-care centre and nosocomial outbreaks of gastroenteritis in children under two years of age. As opposed to rotavirus or Norwalk virus, infection with enteric adenovirus has a long incubation period lasting approximately 8 to 10 days, and the illness can be prolonged for as long as 2 weeks.

Other infestations (also see Section 7)

Giardia lamblia is responsible for clinical syndromes ranging from asymptomatic cyst passage, to self-limited diarrhoea, to chronic diarrhoea with malabsorption and weight loss. After an incubation period between 1 and 2 weeks, patients experience the onset of frequent, loose to watery bowel movements associated with abdominal cramps, bloating, belching, nausea, anorexia, and flatulence.

Patients with cryptosporidiosis present with watery diarrhoea associated with abdominal pain, nausea, vomiting, low-grade fever, malaise, and anorexia. Faecal output may be voluminous and dehydrating in immunocompromised patients, particularly those with underlying human immunodeficiency virus (**HIV**) infection. Symptoms usually resolve by 5 to 10 days. Infection with *Cyclospora cayetanensis* is manifested by anorexia, intermittent diarrhoea, and nausea. Diarrhoea is usually self-limiting, but it can last for several weeks in immunocompetent patients and result in significant weight loss. *Isospora belli* also causes a self-limited illness characterized by watery, non-bloody diarrhoea, abdominal cramping, anorexia, weight loss, and, less commonly, fever. Any of the parasitic infections is more severe and longer lasting in immunocompromised patients, such as those with HIV or organ transplants.

Food poisoning

Food poisoning is most commonly caused by the consumption of food contaminated with bacteria or bacterial toxins. Food poisoning can also be due to parasites (for example, trichinosis), viruses (e.g., hepatitis A), and other toxins (e.g., mushrooms see Section 8.3). The most well-recognized causes of bacterial food poisoning are the following: *Clostridium perfringens, Staphylococcus aureus, Vibrio* spp. (including *V. cholerae* and *V. parahaemolyticus*), *Bacillus cereus, Salmonella* spp., *C. botulinum, Shigella* spp., toxigenic *E. coli* (ETEC and EHEC), and certain species of *Campylobacter, Yersinia, Listeria,* and *Aeromonas.*

An enterotoxin elaborated by type A strains of *C. perfringens* is responsible for food-borne outbreaks with high attack rates but which are of short duration. *C. perfringens* food poisoning is characterized by severe, crampy abdominal pain and watery diarrhoea, usually without vomiting, beginning 8 to 24 h after the incriminating meal. Fever, chills, headache, or other signs of infection are usually absent. Strains of *C. perfringens* type C elaborate a similar enterotoxin that has been implicated in outbreaks of enteritis necroticans secondary to the consumption of rancid meat in Europe, also known as 'pigbel' in Papua New Guinea. This is a much more severe, necrotizing disease of the small intestine and carries a high mortality rate.

Staphylococcal food poisoning presents with severe vomiting, nausea, and abdominal cramps, often followed by diarrhoea. *B. cereus* is an aerobic, spore-forming, Gram-positive rod that has been associated with two clinical types of food poisoning—a diarrhoea syndrome and a vomiting syndrome. The latter has a short incubation period of about 2 h, after which nearly all affected persons experience vomiting and abdominal cramps. In contrast, the diarrhoea syndrome has a median incubation period of 9 h; clinical illness is characterized by diarrhoea, abdominal cramps, and vomiting. *B. cereus* is particularly associated with the ingestion of contaminated rice that has been kept for a long time in a warm or partially cooked state in take-away food outlets. Fevers are uncommon with all three of these bacterial toxin-mediated syndromes. Episodes of staphylococcal and *B. cereus* food poisoning are short-lived, usually resolving within 24 h. Often the staphylococcus has been introduced by contamination from a small abscess, whitlow, or other discharging lesion present during preparation of food, which is allowed to remain warm and not fully cooked before serving.

Travellers' diarrhoea

People who travel from industrialized countries to less developed areas of the world are at risk of contracting traveller's diarrhoea, with as many as 25 to 50 per cent or more suffering from one or more episodes of diarrhoea. The greatest frequency of diarrhoea occurs in students or low-budget tourists. Business travellers are at intermediate risk, while travellers who are visiting relatives have the lowest risk. Young travellers—particularly those 20 to 29 years old—have the highest risk, whereas the lowest rates of travellers' diarrhoea are noted in those over 55 years of age. The disease does not begin immediately but generally starts 2 to 3 days after the traveller's arrival. While most people have three to five watery, loose stools daily, about 20 per cent can have as many as 6 to 15. A minority of patients, approximately 2 to 10 per cent, has fever, bloody stools, or both—these people are more likely to have shigellosis. Diarrhoea is frequently associated with gas, cramps, fatigue, nausea, abdominal pain, fever, and anorexia. The illness usually resolves without specific therapy within 3 to 5 days, although a few unfortunate travellers will have persistent diarrhoea.

Infectious micro-organisms in contaminated food and drink are the main source of travellers' diarrhoea. Especially risky foods include uncooked vegetables, meat, and seafood. Tap water, ice, unpasteurized milk and dairy products, salads, and unpeeled fruits are also associated with an increased risk. Although an array of pathogens has been found, the leading culprits are various forms of *E. coli,* particularly ETEC. *C. jejuni* is encountered in a significant proportion of cases, particularly during cooler seasons. Viruses, *Shigella*, *Salmonella, Giardia, Cryptosporidium,* and *Cyclospora* spp. are responsible for a minority of travellers' diarrhoea cases.

Prudent selection of beverages and foods can help reduce the risk of developing travellers' diarrhoea. Bottled carbonated beverages, hot coffee or tea, beer, and boiled water are generally safe choices for fluids. Avoiding salads, unpeeled fruit, ice, and undercooked or raw meat, poultry, and seafood can help lower the risk. Because the venue of food consumption determines the risk of contracting travellers' diarrhoea, travellers should be advised to avoid eating food from street vendors. While studies have shown high protection rates when prophylactic antimicrobial agents such as ciprofloxacin or cotrimoxazole are taken, this approach is generally not advised because of the risk of side-effects and emergence of antibiotic-resistant enteric flora.

Chronic non-inflammatory diarrhoea

Certain pathogens cause chronic diarrhoea of small intestinal origin. Some patients with giardiasis develop chronic diarrhoea associated with fatigue, steatorrhoea, weight loss, and intermittent constipation, along with malabsorption of fat, vitamins A and B_{12}, protein, and D-xylose. Acquired lactose intolerance is common, but a lactose-free diet should be recommended in such cases. Cryptosporidiosis can become a chronic, dehydrating diarrhoea in immunocompromised patients, especially in those with the acquired immunodeficiency syndrome (**AIDS**). Complications of chronic cryptosporidiosis include malabsorption, wasting, and biliary tract disease. Patients with AIDS are also at risk for chronic, non-inflammatory diarrhoea due to diffusely adherent *E. coli*, microsporidia, and *Isospora* and *Cyclospora* spp.

About 1 to 3 per cent of travellers returning from a developing country will have persistent diarrhoea that may last for 1 month or more. *Giardia*, *Cyclospora*, and, rarely, *Shigella*, *Salmonella* spp., or *C. jejuni* may be responsible for persistent diarrhoea in travellers. A causative agent is not identified in many travellers suffering from prolonged diarrhoea. Some of these unfortunate individuals will respond to empirical therapy with broad-spectrum antibiotics since they have 'tropical jejunitis' or a mild form of tropical sprue.

Bacterial overgrowth in the small intestine can result in chronic diarrhoea, steatorrhoea, bloating, abdominal pain, and wasting. Factors contributing to the development of this problem include achlorhydria, decreased motility (as may be seen in diabetes mellitus or scleroderma), and stasis due to diverticula or blind loops of bowel. Treatment with amoxicillin/clavulanic acid, erythromycin, or tetracycline in conjunction with a lactose-free diet will often lead to resolution of the diarrhoea.

Inflammatory diarrhoea

Acute inflammatory diarrhoea is the result of infection with bacterial enteropathogens such as *Shigella*, *Campylobacter*, *Salmonella* spp., EHEC, *V. parahaemolyticus*, and *C. difficile*. Among the parasites, *Entamoeba histolytica* is the most common cause of dysenteric illness although *Balantidium coli*, *Schistosoma mansoni*, *S. japonicum*, *Trichuris trichiura*, hookworms, and *Trichinella spiralis* can all cause bloody, mucoid diarrhoea (see Section 7).

Dysentery is an oft-used term that refers to a diarrhoeal stool that contains an inflammatory exudate composed of blood and polymorphonuclear leucocytes. Patients with bacillary dysentery classically present with crampy abdominal pain, rectal burning ('tenesmus'), and fever, associated with multiple small-volume, bloody mucoid, bowel movements. The most constant findings are lower abdominal pain and diarrhoea. Fever is present in less than half of patients and the typical dysentery stool, consisting of blood and mucus, in only one-third. Sigmoidoscopy reveals acute mucosal inflammation with ulcerations and focal haemorrhage.

Bacteria

The *Shiga* bacillus, *S. dysenteriae* type 1, produces the most severe form of dysentery, while *S. sonnei* produces the mild disease. *S. flexneri* is the most commonly encountered serogroup in tropical countries, whereas *S. sonnei* is the most common in industrialized nations. Many patients with shigellosis manifest a biphasic

illness. The initial symptoms of fever, abdominal pain, and watery, non-bloody diarrhoea result from the action of enterotoxin. The second phase, starting 3 to 5 days after the onset of symptoms, is notable for tenesmus and small-volume bloody stools. This period corresponds to invasion of the colonic epithelium and acute colitis. Infection with *S. dysenteriae* type 1 and malnutrition, especially in young children, are factors associated with a more severe course. Complications of shigellosis include intestinal perforation, protein-losing enteropathy, hypoglycaemia, seizures, thrombocytopenia, and haemolytic–uraemic syndrome—the latter three being particularly common in children.

Campylobacter species, especially *C. jejuni*, have gained in prominence as invasive diarrhoeal pathogens. Clinically, disease manifestations range from frank dysentery, to watery diarrhoea, to asymptomatic excretion. Most patients have diarrhoea, fever, and abdominal pain—about 50 per cent will note bloody stools. Constitutional symptoms such as headache, myalgias, backache, malaise, anorexia, and vomiting are often present. The illness usually resolves in less than 1 week, although symptoms can persist for 2 weeks or more, and relapses occur in as many as one-quarter of patients. Rare complications include gastrointestinal haemorrhage, toxic megacolon, pancreatitis, cholecystitis, haemolytic uraemic syndrome, bacteraemia, meningitis, and reactive arthritis, and Guillain-Barré syndrome.

Recent years have seen an increasing frequency of outbreaks of *Salmonella enteritidis* associated with the consumption of uncooked or raw eggs. Salmonella gastroenteritis is characterized by initial symptoms of nausea and vomiting, followed by abdominal cramps and diarrhoea which is accompanied by fever in about 50 per cent of persons. The diarrhoea varies from a few loose stools, to dysentery with grossly bloody, purulent faeces, to a cholera-like syndrome.

Yersinia enterocolitica can cause illness ranging from acute non-bloody diarrhoea to invasive colitis and ileitis. Fever, abdominal cramps, and haem-positive diarrhoea that may persist for several weeks characterize yersinia enterocolitis. *V. parahaemolyticus* outbreaks have been associated with the consumption of raw fish or shellfish. Illness is generally characterized by explosive, watery diarrhoea, abdominal cramps, nausea, vomiting, and headaches. In some cases a bloody dysenteric syndrome is observed.

EIEC strains are capable of invading epithelial cells and producing a shiga-like toxin. Patients with EIEC present with diarrhoea, tenesmus, fever, and abdominal cramps. EHEC strains possess at least two virulence factors that produce intestinal damage: an adherence mechanism causing attachment-effacement lesions similar to those seen with EPEC; and the production of two shiga-like cytotoxins (SLT I and II). Some EHEC strains produce only SLT I or II, whereas others produce both toxins. After a mean incubation of 3 to 4 days, illness begins with watery, non-bloody diarrhoea associated with severe abdominal cramping, nausea, vomiting, chills, and low-grade fever. The diarrhoea then often progresses to visibly bloody stools. Leucocytosis with a shift to the left is usually present, but anaemia is uncommon unless infection is complicated by the development of the haemolytic–uraemic syndrome (**HUS**) or thrombotic thrombocytopenic purpura (**TTP**). The median duration of diarrhoea is 3 to 8 days—longer durations have been described in children and persons with bloody diarrhoea.

Parasites

While infection with a number of different intestinal nematodes and trematodes can be associated with an inflammatory diarrhoea, *E. histolytica* is by far the most common parasitic cause of dysenteric illness (see Chapter 7.13.1). Approximately 50 million cases of invasive colitis due to *E. histolytica* occur worldwide each year, primarily in developing countries. In industrialized countries, populations at high risk of infection include institutionalized persons, especially the mentally impaired, recent immigrants, returning travellers, and sexually active male homosexuals. Malnutrition, malignancy, glucocorticoid use, pregnancy, and young age are risk factors for greater severity of infection.

There are two distinct species of *Entamoeba* that can be differentiated on the basis of antigenic structure, isoenzyme analysis, host specificity, *in vitro* growth characteristics, *in vivo* virulence, and DNA characterization. The two species, *E. histolytica* and *E. dispar*, have the same lifecycle and are morphologically identical. However, *E. dispar* is associated with an asymptomatic carrier state, while *E. histolytica* is capable of invading tissue and causing symptomatic infection.

A spectrum of clinical illness occurs with *E. histolytica* infections including asymptomatic carriage, non-bloody diarrhoea, acute dysenteric colitis, fulminant colitis with perforation, chronic non-dysenteric colitis, and the formation of an amoeboma, an annular lesion of the colon that can be confused with colon cancer. Patients with acute amoebic dysentery usually present with a 1- to 3-week history of bloody diarrhoea, tenesmus, and abdominal pain. Fever and dehydration are present in a minority of patients. Complications of amoebic colitis include intestinal perforation and toxic megacolon. Although nearly all patients have blood in the stool, faecal leucocytes are usually absent, probably as a result of the lysis of inflammatory cells by trophozoites. Amoebic liver abscess can occur with or independent of acute colitis. The fulminant variant of amoebic colitis is characterized by the rapid onset of fever, bloody mucoid diarrhoea, diffuse abdominal pain with peritoneal signs, and leucocytosis. Chronic non-dysenteric amoebiasis is a syndrome usually lasting more than 1 year with intermittent diarrhoea, mucus, abdominal pain, flatulence, and weight loss.

Antibiotic-associated colitis

Although the mechanism has not been fully elucidated, it appears that the normal bowel flora inhibits overgrowth by *C. difficile* in the large intestine. Factors such as antibiotic use or chemotherapy disrupt the suppressive effects of the microflora and allow *C. difficile* to propagate and to secrete its toxins. This organism produces two cytotoxins, one of which, cytotoxin A, appears to be responsible for damaging the colonic mucosa, while the other, cytotoxin B, is used for diagnosis based on its cytotoxic effects in tissue culture.

Antibiotic-associated diarrhoea and colitis due to toxin-producing strains of *C. difficile* can be community-acquired or acquired in hospitals and chronic-care facilities. Recent treatment with antibiotics, especially cephalosporins and clindamycin, or chemotherapeutic agents such as methotrexate precedes the development of illness. Clinical findings range from asymptomatic carriage to fulminant colitis with perforation. Symptomatic patients have frequent, malodorous bowel movements that are not grossly bloody. Associated signs and symptoms include crampy abdominal pain, fever, and abdominal tenderness. Leucocytosis with an increase of immature neutrophil forms is often present. Complications of *C. difficile* colitis include toxic megacolon, perforation, electrolyte disturbances, and hypoalbuminaemia.

Invasive infections

There are many infections of the gastrointestinal tract that do not present with diarrhoea, but instead are manifested by a systemic illness in which constitutional symptoms and signs predominate. Enteric fever, particularly that caused by *S. typhi*, may be the most common invasive bacterial infection worldwide.

Typhoid fever

After ingestion in contaminated food or water, *S. typhi* penetrates the small bowel mucosa and makes its way rapidly to the lymphatics, the mesenteric nodes, and finally the bloodstream. Following an initial bacteraemia, the organism is sequestered in cells of the reticuloendothelial system where it multiplies and re-emerges several days later in recurrent waves of bacteraemia, an event that initiates the symptomatic phase of infection.

Typhoid fever is a febrile illness of prolonged duration, characterized by hectic fever, delirium, persistent bacteraemia, splenomegaly, abdominal pain, and a variety of systemic manifestations. Pulse–temperature dissociation is present in some patients. In approximately 50 per cent of patients, there is no change in bowel habits; in fact, constipation is more common than diarrhoea in children with typhoid fever. As a result of recurrent waves of bacteraemia, patients with typhoid fever can develop pneumonia, pyelonephritis, osteomyelitis, septic arthritis, and meningitis. Intestinal haemorrhage and perforation, the most common complications, often occur in the third week of infection or during convalescence.

While *S. typhi* is the main cause of typhoid fever, other serotypes of *Salmonella* occasionally produce a similar clinical picture, known as enteric or paratyphoid fever. These serotypes include *S. paratyphi, S. schottmülleri* (formerly *S. paratyphi B*), and *S. hirschfeldii* (formerly *S. paratyphi C*), as well as others such as *S. typhimurium.*

Parasitic infestations

Certain gastrointestinal parasites are associated with systemic signs and symptoms during the extraintestinal stages of their lifecycles. Gut infections with *Strongyloides stercoralis* manifest with vague symptoms such as abdominal pain, bloating, and diarrhoea, frequently associated with eosinophilia. During the migration of this parasite through the skin and lung, specific symptoms attributable to the local inflammatory response in these tissues may occur. Hyperinfection or disseminated strongyloidiasis develops in immunocompromised patients, especially those with HIV infection, haematological malignancies, or those treated with systemic steroids or other immunosuppressive agents. Individuals with the hyperinfection syndrome have heavy worm burdens that can lead to intestinal obstruction,

meningitis, respiratory failure, or Gram-negative bacteraemia.

Other intestinal parasites such as hookworm, *T. trichiura*, and *Schistosoma* species can cause gradual blood loss from the intestine that, in prolonged infections, can lead to clubbing, severe malnutrition, pica, stunting of growth, and congestive heart failure secondary to severe anaemia. Chronic infections with all *Schistosoma* species with the exception of *S. haematobium* can cause significant morbidity and mortality as a result of granuloma formation in the intestine and liver. The resulting hepatic fibrosis leads to portal hypertension that can eventually be complicated by splenomegaly, oesophageal varices, haematemesis, and death.

Intestinal tuberculosis

Mycobacterium tuberculosis is responsible for most cases of intestinal tuberculosis. In some developing countries, however, cases caused by *M. bovis,* an organism found in unpasteurized dairy products, still occur. The most frequent sites of intestinal involvement are the distal ileum and caecum, although any region of the gastrointestinal tract can be involved. Most patients with intestinal tuberculosis are asymptomatic. The most common complaint is chronic, non-specific abdominal pain. Weight loss, fever, diarrhoea or constipation, and blood in the stool may be present. An abdominal mass, commonly located in the right lower quadrant of the abdomen, is appreciated in about two-thirds of patients. Complications include haemorrhage, obstruction, perforation, fistula formation, and malabsorption.

Peritoneal tuberculosis results from the haematogenous spread of *M. tuberculosis* to mesenteric lymph nodes. Ascites is the most common presenting feature and is often associated with fever, lethargy, and weight loss. The ascitic fluid is notable for an elevated white blood cell count with a lymphocytic predominance, and a high albumin concentration.

Diagnosis and management of gastrointestinal infections

Diagnosis

Although there is considerable overlap in presenting signs and symptoms, nevertheless a pathophysiological approach can be used to make a presumptive aetiological diagnosis in patients with infectious diarrhoea (Table 2). By separating micro-organisms that target the upper small intestine from those that attack the large bowel, the clinician can categorize the general type of pathogen based on the initial symptoms and the type of diarrhoea. In the case of the non-inflammatory bowel pathogens, microscopy of the stool reveals no leucocytes or erythrocytes, whereas these are often abundant in the faeces of patients with invasive diarrhoeal pathogens. Several organisms including *Salmonella*, *Yersinia* spp., *V. parahaemolyticus,* and *C. difficile* produce variable findings on microscopic examination of stools. Depending on the invasiveness of the strain and the extent of colonic involvement , there can be few to many red blood cells and/or polymorphonuclear leucocytes in the stool.

A diagnostic algorithm can be used to help decide which patients should be treated symptomatically and which require further diagnostic studies and treatment (Fig. 1). Approximately 90 per cent of cases of acute diarrhoea fall into the 'no studies–no treatment' category. Because of the significant morbidity and cost associated with infectious diarrhoea, making a specific laboratory diagnosis can be useful epidemiologically, diagnostically, and therapeutically. A definitive diagnosis is achieved mainly through study of faecal specimens, using bacteriological culture, viral culture, or direct electron microscopy for viral particles, and identification of microbial antigens (viruses, bacteria, parasites, or toxins). DNA probes, polymerase chain reaction, and immunodiagnostic tests can now be used to identify several pathogens in stool specimens. Although some diseases can be diagnosed by elevations of serum antibody titres, this method is usually retrospective and often inaccurate.

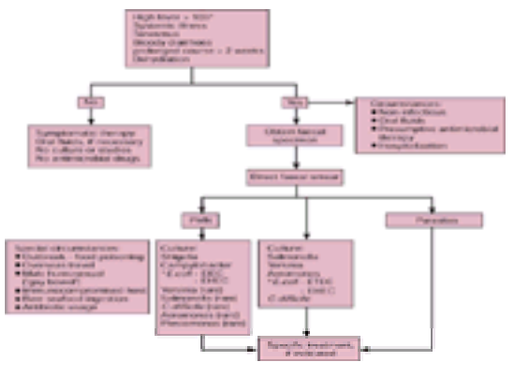

Fig. 1 Algorithm for the diagnosis and treatment of diarrhoea.

Invasive procedures such as sigmoidoscopy or upper endoscopy generally play a limited role in the diagnosis of bacterial infections of the gastrointestinal tract. If performed, proctoscopy or sigmoidoscopy of patients with colitis due to *Shigella* spp., *Salmonella* spp., and other invasive pathogens will show a diffusely ulcerated, haemorrhagic, and friable colonic mucosa. Large bowel involvement with *C. difficile* manifests as an acute inflammatory colitis with or without pseudomembranes. While the demonstration of pseudomembranes by colonoscopy can provide a rapid diagnosis, this method is relatively insensitive. Sigmoidoscopy with biopsy of the rectal mucosa is often helpful in identifying parasitic infections such as *E. histolytica* or *S. mansoni*. Endoscopy with duodenal aspirates or biopsies may help to establish the diagnosis of giardiasis, cryptosporidiosis, microsporidiosis, or strongyloidiasis. These procedures should be carried out during the evaluation of patients with chronic diarrhoea if stool cultures and examinations for ova and parasites have failed to elucidate the aetiology.

Differential diagnosis

Non-inflammatory diarrhoea

A large number of non-infectious causes of food poisoning such as heavy metals (for example, arsenic or cadmium), mushrooms (for example, *Amanita phalloides*), and other chemical substances can result in acute diarrhoea, nausea, and vomiting. Various toxin-mediated forms of shellfish or seafood poisoning, including ciguatera, scombroid, and toxic encephalopathic shellfish poisoning, can all present with nausea, vomiting, and diarrhoea as part of a constellation of symptoms. A history of recent seafood consumption and the presence of other characteristic symptoms or signs should alert the clinician to the cause.

Endocrine disorders associated with diarrhoea include thyrotoxicosis and Addison's disease. Some secretory tumours such as carcinoid, medullary tumour of the thyroid, and vasoactive intestinal peptide-secreting adenomas have watery diarrhoea as a prominent symptom. Chronic, non-bloody diarrhoea is seen in patients with coeliac disease, laxative abuse, Whipple's disease, short-gut syndrome, and pancreatic insufficiency.

Inflammatory diarrhoea

Bloody diarrhoea due to invasive enteropathogens is difficult to distinguish from that caused by inflammatory bowel disease. Two features help to distinguish dysentery from an acute attack of idiopathic ulcerative colitis: a positive culture for a pathogen and a self-limited course without relapse. However, positive cultures are encountered in only 40 to 60 per cent of reported dysentery cases. Biopsy of colonic mucosa from patients with both bacterial dysentery and ulcerative colitis show oedema, neutrophils in the lamina propria, and superficial cryptitis with preservation of the normal crypt pattern. Yet, biopsy from idiopathic ulcerative colitis also reveals signs of chronicity such as crypt distortion and plasmacytosis in the lamina propria. In clinical practice, the main diagnostic quandary is the patient with severe, acute colitis who has failed to respond to antimicrobial therapy. Presumptive treatment should include a fluoroquinolone for bacterial pathogens and metronidazole for protozoa. The decision to use other treatments, such as corticosteroids and antimetabolites, rests on the distinction between these diseases, although it may be difficult to make this decision based on culture or histopathological findings. In addition to inflammatory bowel disease, often non-infectious causes such as ischaemic colitis, acute diverticulitis, and, rarely, colon cancer can present with bloody diarrhoea.

Enteric fever

Because the initial presentation of typhoid and paratyphoid fever is pyrexia, there is a large differential diagnosis during the early stages of enteric fever. Depending on epidemiological and clinical factors, a range of infectious (for example, malaria, Gram-positive sepsis, brucellosis, occult abscess) and non-infectious (for example, rheumatological diseases and malignancy) aetiologies need to be considered. Blood cultures are an essential part of the diagnostic evaluation for enteric fever.

Management

Rehydration

Since the most devastating consequences of acute infectious diarrhoea result from fluid losses, the major goal of treatment is the replacement of fluid and electrolytes. While the intravenous route of administration has been traditionally used, oral rehydration solutions (**ORS**) have been shown to be equally effective physiologically and logistically more practical and less costly to administer, especially in developing countries. ORS is the treatment of choice for mild-to-moderate diarrhoea in both children and adults, providing vomiting is not a major feature of the gastrointestinal infection. ORS can also be used in severely dehydrated patients after initial parenteral rehydration.

Although there is no doubt about the value of ORS in treating dehydrating diarrhoea, the optimal concentration of sodium that should be used remains in dispute, particularly in regard to the treatment of mild-to-moderate diarrhoea in well-nourished children in industrialized countries. The high concentration of sodium (90 mmol) in the standard World Health Organization ORS formulation may cause hypernatraemia and even seizures in children with non-cholera watery diarrhoea. Consequently, lower concentrations of sodium and a reduced osmolarity solution have been found to be effective for rehydration and not to be associated with any serious adverse clinical events. The substitution of starch derived from rice or cereals for glucose in ORS has been another approach. Rice-based salt solutions produce lower stool losses, a shorter duration of diarrhoea, and greater fluid and electrolyte absorption than do glucose-based solutions in treating childhood and adult diarrhoea.

Diet

The traditional approach to an acute diarrhoeal illness, dietary abstinence, restricts the intake of necessary calories, fluids, and electrolytes. During an acute attack, the patient often finds it more comfortable to avoid spicy, high-fat, and high-fibre foods, all of which can increase stool volume and intestinal motility. Although giving the bowel a rest provides symptomatic relief, continued oral intake of fluids and foods is critical for both rehydration and the prevention of malnutrition. In children, it is particularly important to restart feeding as soon as the child is willing to accept oral intake.

Because certain foods and fluids can increase intestinal motility, it is wise to avoid fluids such as coffee, tea, cocoa, and alcoholic beverages. Ingestion of milk and dairy products can potentiate fluid secretion and increase stool volume. Besides the oral rehydration therapy outlined above, acceptable beverages for mildly dehydrated adults include fruit juices and various bottled soft drinks. Carbonated drinks should be allowed to 'de-fizz' by letting them stand in a glass before ingestion. Soft, easily digestible foods are generally acceptable to the patient with acute diarrhoea.

Antimicrobial therapy

Since most patients with infectious diarrhoea, even those with a recognized pathogen, have a mild, self-limited course, neither a stool culture nor specific treatment is required for such cases (Fig. 1). For more severe cases, however, empirical antimicrobial therapy should be instituted, pending the results of stool and blood cultures. Gastrointestinal infections likely to respond to antibiotic treatment include cholera, giardiasis, cyclosporiasis, shigellosis, *E. coli* diarrhoea in infants, symptomatic travellers' diarrhoea, *C. difficile* diarrhoea, and typhoid fever. The choice of antimicrobial drug should be based on *in vitro* sensitivity patterns, which vary from region to region. A fluoroquinolone antibiotic is a good choice for empirical therapy, since these agents have broad-spectrum activity against virtually all bacterial pathogens responsible for acute infectious diarrhoea (except *C. difficile*) and resistance to this drug remains limited in most parts of the world. In patients with severe community-acquired diarrhoea—characterized by more than four stools per day lasting for at least 3 days or more with at least one associated symptom such as fever, abdominal pain, or vomiting—there is a high likelihood of isolating a bacterial pathogen. In this setting, a short course of a fluoroquinolone, namely 1 to 3 days' duration, will generally provide prompt relief with a low risk of adverse effects. Fluoroquinolones will not be effective for parasitic infections—specific antiparasitic drugs should be prescribed after identification of the offending pathogen in stool smears.

There are conflicting reports regarding the efficacy of antimicrobial drugs in several important infections, such as those caused by *Campylobacter* spp., and insufficient data for infections caused by *Yersinia and Aeromonas* spp., vibrios, and several forms of *E. coli.* In cases of EHEC, there is evidence that antibiotics are not helpful and may even be harmful.

The duration of antimicrobial therapy has not been clearly defined. While courses of anywhere from 3 to 10 days of treatment have been recommended, there are several studies that included severe forms of diarrhoea which suggested that a single dose is as effective as more prolonged therapy. For example, single-dose fluoroquinolone therapy is highly effective for infections due to *V. cholerae, V. parahaemolyticus*, and most *Shigella* species. On the other hand, short-course treatment of salmonella gastroenteritis with fleroxacin has not been found to be clinically beneficial. When treatment is indicated, a number of studies have shown that the combination of an antimicrobial drug and an antimotility drug provides the most rapid relief of diarrhoea.

Antidiarrhoeal agents (Table 3)

Antimotility drugs are particularly useful in controlling moderate-to-severe diarrhoea. These agents disrupt propulsive motility by decreasing jejunal motor activity. Opiates may decrease fluid secretion, enhance mucosal absorption, and increase rectal sphincter tone. The overall effect is to normalize fluid transport, slow transit time, reduce fluid losses, and ameliorate abdominal cramping.

Loperamide is the best agent because it does not carry a risk of habituation or depression of the respiratory centre. Treatment with loperamide produces rapid improvement, often within the first day of therapy. Although there has been a long-standing concern that antimotility agents might exacerbate cases of dysentery, this has largely been dispelled by clinical experience. Patients with shigellosis, even *S. dysenteriae* type 1, have been treated with loperamide alone and have had a normal resolution of symptoms without evidence of prolonging the illness or delaying excretion of the pathogen. However, as a general rule, antimotility drugs should not be used in patients with acute severe colitis, whether infectious or non-infectious in origin.

Bismuth subsalicylate (**BSS**), an insoluble complex of trivalent bismuth and salicylate, is effective in treating mild-to-moderate forms of diarrhoea. Bismuth possesses antimicrobial properties, while the salicylate moiety has antisecretory properties. In trials of diarrhoea among travellers in Mexico and West Africa, BSS reduced the frequency of diarrhoea significantly relative to placebo, but results were generally better when a high dose (for example, 4.2 g per day) was used. A number of studies have shown that the combination of an antimicrobial drug and an antimotility drug provides the most rapid relief of diarrhoea.

Prevention

Strict adherence to food and water precautions as outlined above will help travellers to less developed areas of the world to decrease their risk of acquiring gastrointestinal infections. Parasitic infections, such as strongyloidiasis and hookworms, can be avoided by the use of footwear. Avoiding contact with fresh water such as rivers and lakes in endemic areas serves to prevent schistosomiasis.

Immunization represents an ideal way to prevent certain bacterial and viral diseases, but has not yet proved successful for combating many gastrointestinal pathogens. The cholera vaccine that has been available for decades suffers from low efficacy, a moderate risk of side-effects, and a short duration of action. Newer oral cholera vaccines, including inactivated and live-attenuated forms, appear to be more promising. Immunization has been partially effective for the prevention of typhoid fever, especially in endemic areas. Although the efficacy of the currently available typhoid vaccines has not been determined in persons from industrialized regions, these vaccines are widely used for the prevention of typhoid fever in travellers to developing countries.

14.18.1 The structure and function of the liver, biliary tract, and pancreas

A. E. S. Gimson

The liver and biliary tract

The liver weighs 1.2 to 1.5 kg and has a highly vascular architecture. The classic descriptions of liver anatomy demonstrating the complexity of different parenchymal and non-parenchymal elements have a long history, but only recently have they been united with an increasing understanding of the intricate functional organization and physiological compartmentalization of liver structure. This has had a profound effect on our understanding of the control of physiological processes and the development of liver surgery. A grasp of the hepatic anatomy is key to an appreciation of these complex functional arrangements.

Morphological anatomy

This describes the classic structure of the liver into two lobes, right and left, and the accompanying vascular structures, lymphatics, and biliary tract.

The liver, situated in the right upper quadrant of the abdomen, is covered by Glisson's capsule, a visceral continuation of the peritoneum. Three ligaments attach to surrounding structures—the falciform ligament anterior and superiorly, and the two posterior triangular ligaments which enclose the retrohepatic vena cava and the small bare area of the liver. Inferiorly Glisson's capsule attaches to the lesser curve of the stomach and at the hepatic hilus encases the hepatic pedicle consisting of hepatic artery, portal vein, and common hepatic bile duct.

Hepatic lobes

The two major lobes, right and left, and two accessory lobes, quadrate and caudate, are defined by points of surface anatomy (Fig. 1(a)). The larger right lobe comprises the dome of the liver under the diaphragm and is limited anteriorly and medially by the falciform ligament and posteriorly by the right border of the inferior vena cava. The quadrate lobe inferiorly abuts on to the antrum of the stomach and first part of the duodenum and is bordered by the posterior transverse hilar fissure, the gallbladder fossa laterally, and the umbilical fissure medially. The caudate lobe lies posterior and superior to the quadrate lobe limited by the vena cava and the ligamentum venosum. Finally, the left lobe has the umbilical fissure medially and the falciform ligament anteriorly.

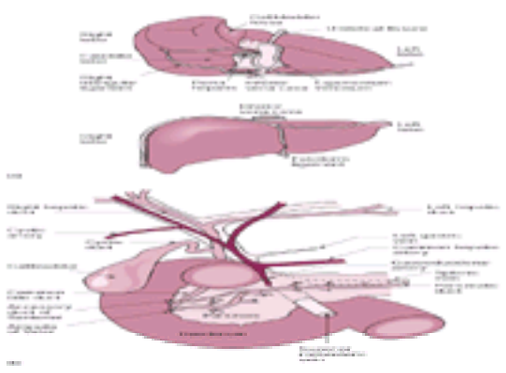

Fig. 1 (a) Lobar anatomy and relations. (b) Hilar, portal biliary tract, and pancreatic anatomy.

Vascular anatomy

The portal vein, hepatic duct, and hepatic artery form the hepatic pedicle with the bile duct anterior in the free edge of the lesser omentum and the portal vein posteriorly (Fig. 1(b)). The latter is formed by the confluence of the superior mesenteric vein and the splenic veins running posteriorly in the pedicle, dividing into left and right branches to supply each lobe. The left gastric vein also drains into the portal vein and may, in the presence of portal hypertension, be a major feeding vessel for gastro-oesophageal varices.

The hepatic artery arises from the coeliac axis as the common hepatic artery before dividing into a gastroduodenal and the main hepatic artery. There are several common anatomical variants of the arterial supply of the liver, which are of no functional significance but which are of importance in liver transplantation and during surgical resection. The standard division into single left and right hepatic arteries is present in approximately 70 per cent of cases (Fig. 1(b)), but common variants include: a separate second right hepatic artery (10 per cent), a separate right and left hepatic arteries (8 per cent), and origin of the main hepatic artery off the superior mesenteric artery (2.5 per cent). Variants of the left hepatic arterial supply also occur with a separate left hepatic artery arising from the left gastric artery in 10 per cent of cases.

Venous drainage of the liver is through the three main hepatic veins, right, left, and middle, the latter two coalescing before joining the inferior vena cava. The caudate lobe drains separately through an array of small spigelian veins directly into the inferior vena cava. The functional anatomy of the liver (see below) describes the relationship between the main divisions of the portal vein and their draining hepatic veins running in the right, left, and main scissures (Fig. 2).

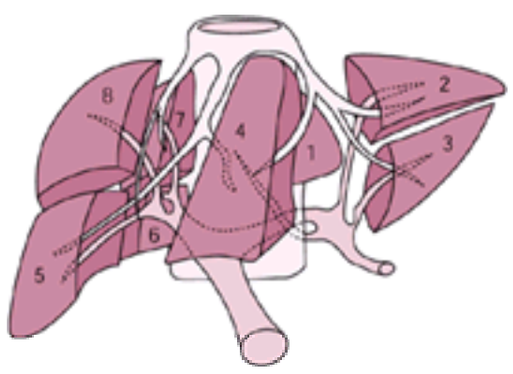

Fig. 2 Functional anatomy of the liver with Couinaud's segments.

Biliary anatomy

Biliary canaliculi drain into left and right hepatic bile ducts forming the common hepatic duct until entry of the cystic duct after which it is designated the common bile duct and has a diameter of less than 8 mm. The left hepatic duct follows a nearly horizontal course, partially extrahepatic. Anatomical variants are again quite frequent, and are surgically important, the most common being drainage of the cystic duct directly into the right hepatic duct. The common bile duct passes behind the first part of the duodenum, through pancreatic tissue to the ampulla of Vater joining drainage of the pancreatic duct (Fig. 1(b)). The gallbladder lies in a shallow depression in the underside of the liver, may contain up to 50 ml of bile, and is connected to the cystic duct with a spiral valve.

Lymphatics

The liver has a high blood flow and a highly permeable microcirculation. The consequent production of interstitial fluid, intrahepatic lymph, is formed in the perisinusoidal space of Disse between the hepatocytes and sinusoidal lining endothelium. Lymphatic vessels drain via the portal tracts, closely applied to the hepatic arterial branches, to the hilum and thence to the thoracic duct. A smaller proportion drains with the hepatic veins and some interstitial fluid drains through Glisson's capsule into the peritoneum. Lymph flow acts to drain from the liver that interstitial fluid and protein that forms inevitably through microvascular filtration. The lymph flow rate in mammalian liver is approximately 0.5 ml/kg of liver per minute making up 25 to 50 per cent of thoracic duct lymph flow and may be increased either by elevated microvascular pressure (hydrostatic pressure) through increased hepatic venous pressure or increased inflow pressure, or by reduced transcapillary oncotic pressure.

Nervous system

Both sympathetic and parasympathetic efferent innervation of the liver are described, an anterior plexus around the hepatic artery and posterior around the portal vein. Sympathetic stimulation increases glucose release and glycogenolysis, and reduces oxygen consumption, ammonia uptake, and bile formation. Hepatic vascular resistance also rises as does portal pressure and there is rapid expulsion of blood out of the liver into the systemic circulation. An intrinsic nervous system with a wide variety of neurotransmitters including noradrenaline, prostanoids, neuropeptide Y, substance P, and vasoactive intestinal peptide is closely located to smooth muscle cells, fibroblasts, endothelial lining cells, and biliary epithelium within the liver and may be involved in chemoreception and osmoreception.

Extrinsic nervous regulation of hepatic physiological processes seems to be of minor importance as there is no apparent impairment of liver metabolism or bile formation following orthotopic liver transplantation. It may be more relevant during pathophysiological stress: the existence of a hepatorenal reflex is patients with cirrhosis has been postulated whereby an increase in sinusoidal pressure is associated with increased efferent renal sympathetic activity and reduced renal blood flow. In animal models of chronic liver disease, the metabolic consequences of sympathetic nerve stimulation are impaired but the haemodynamic responses exaggerated.

Functional anatomy

Following the initial descriptions by Cantlie in 1898, there has been an increasing appreciation of the importance of the functional anatomy of the liver, the culmination of which was the description by Couinaud of the present eight liver segments that underpins all modern hepatic surgery. Each segment is a complete functional unit with a single portal pedicle and a hepatic vein (Fig. 2). There are four portal pedicles, two for each lobe, each supplying a sector of the liver, divided from each other by the three hepatic veins lying in a right, middle, and left scissure. This separates the liver into a right and left liver, different from lobes, with independent vascular supply and biliary drainage. Within each sector of the liver there are further subdivisions into segments. The caudate lobe (segment 1) has its own venous drainage, manifest during the Budd–Chiari syndrome with thrombosis of hepatic veins when all venous drainage attempts to pass through this segment with consequent lobar hypertrophy.

The left liver consists of the left posterior sector of segment 2 alone, and a left anterior sector of segment 3 medially and segment 4 laterally separated by the umbilical fissure. The right liver comprises a posterior sector of segment 7 superiorly and segment 6 inferiorly and an anterior sector of segment 5 inferiorly and segment 8, being most of the dome of the liver, superiorly (Fig. 2).

Structural organization

Within the functional segments of the liver the structural unit is the hepatic lobule, a polyhedron (2 mm by 0.7 mm) surrounded by four to six portal tracts containing hepatic arterial and portal venous branches from which blood perfuses through sinusoids, surrounded by walls of hepatocytes that are a single cell thick and lined by specialized endothelial cells with 'windows' (fenestrae), to the centrilobular region and the central hepatic veins (Fig. 3).

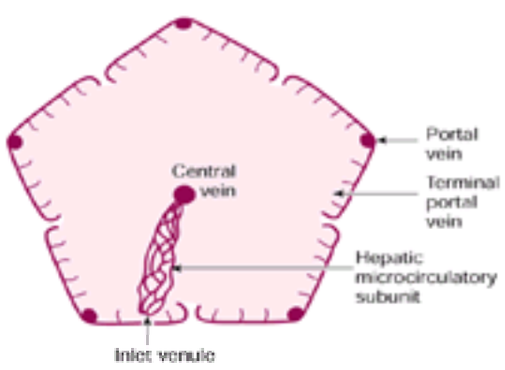

Fig. 3 Hexagonal lobule with portal venous branches and hepatic microcirculatory subunit—sinusoids.

The portal vein branches give off numerous terminal portal venules that run around the lobules in the interlobular septa accompanied by arterioles and bile ductules, and subsequently branch into inlet venules which each supply a hepatic microcirculatory subunit consisting at the base of numerous interconnected sinusoids and, at the apex, the central vein (Fig. 3).

Sinusoids

Sinusoids are specialized capillaries without a basement membrane and lined with endothelial lining cells through which proteins of low molecular weight may percolate into the space of Disse. The sinusoidal membrane of the surrounding hepatocytes is covered by microvilli that increase the surface area sixfold (Fig. 4). Within the sinusoids, Kupffer cells and liver-associated lymphocytes may be found, and within the space of Disse, the hepatic stellate cells (also called Ito, fat storage, or perisinusoidal cells), which respectively make up 2, 0.2, and 1.4 per cent of the lobular parenchyma (Table 1).

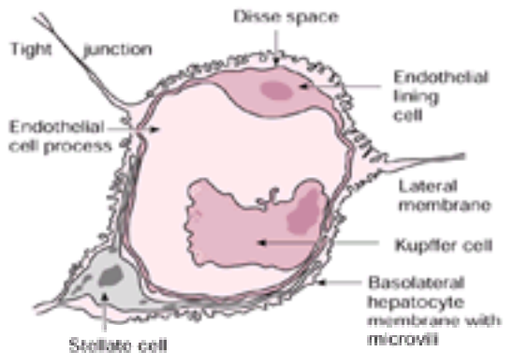

Fig. 4 Hepatic sinusoid, sinusoidal cells, and functional spaces.

Biliary canaliculi

Bile secreted through the canalicular membrane of the hepatocyte collects in biliary canaliculi, which pass around hepatocytes until draining through the short canal of Hering into the bile ductule. Cholangioles are lined by three or four cells that eventually become cuboidal epithelium.

The volume and flow rate of bile are low; secretion into the duodenum is controlled by gallbladder contraction and sphincter of Oddi tone. Agents that cause gallbladder contraction, including cholecystokinin, secretin, and motilin, also relax the sphincter of Oddi (Table 2). Factors modulating biliary motility have received increased attention recently with the realization that the syndrome of biliary dysmotility may be the cause of biliary-type pain in some cases. Changes in gallbladder motility may also be important in gallstone pathogenesis.

Cellular elements

Hepatocytes are arranged in unicellular plates (Remak's plates) that branch and divide around sinusoids, and are covered by specific membranes at each surface: sinusoidal (70 per cent of surface area) for exchange of material between the Disse space and intracellular compartment (endo- and exocytosis); canalicular membrane (15 per cent) for exchange with the smallest of biliary canaliculi or hemicanals; and lateral membrane (15 per cent) separated from the former by tight junctions and involved in intercellular transport between hepatocytes. There is abundant smooth and rough endoplasmic reticulum, numerous mitochondria, and glycogen. There is an extensive cytoskeleton. Other cells making up 6 per cent of all parenchyma include sinusoidal-lining endothelial cells, Kupffer cells, hepatic stellate cells (Ito cells, fat-storing cells), and pit cells (intrahepatic lymphocytes) (Table 1). These cells each differ in morphology, patterns of function, reactions to stimuli and disease, and expression of surface molecules and receptors. Interplay between these cells is critical, with communication via tight junctions allowing complex modulation of hepatocyte growth and function by sinusoidal lining cells. Parenchymal cells may clear mediators, including cytokines, secreted by endothelial lining and Kupffer cells. Waves of cellular activity may pass down the length of sinusoids. Importantly some cells show heterogeneity of function relative to their zonal location. Periportal hepatocytes differ from perivenous cells in both the direction of carbohydrate metabolism and ammonia/glutamine synthesis. Ito cells show zonal differences in desmin and cytokeratin staining, vitamin A storage, and a-smooth muscle actin.

Endothelial lining cells

These cells are central to the processes that control entry and exit trafficking of molecules from the sinusoidal flow into the Disse space. Fenestrae with a diameter of 100 nm, occupying up to 8 per cent of the sinusoidal surface, act as a physical barrier to access of parenchymal cells by large molecules including lipids, cholesterol, vitamin A, and possibly some viruses. Endothelial cells also possess numerous specialized endocytotic mechanisms, some linked to specific receptors including mannose, transferrin, caeruloplasmin, modified high-density lipoprotein (**HDL**), low-density lipoprotein (**LDL**), glucosaminoglycans, and hyaluronic acid. Non-specific endocytosis of molecules and small particles up to 0.1 µm also occurs. Endothelial cells are also capable of expressing a range of surface adhesion molecules including E- and P-selectins, intercellular adhesion molecule 1 (**ICAM-1**), and lymphocyte function-associated antigen-4 (**LFA-4**) that enhance polymorphonuclear leucocyte and lymphocyte adherence, activation, and migration towards sites of inflammation.

Kupffer cells

These cells represent part of the mononuclear phagocyte system and are adherent to the sinusoidal surface of endothelial lining cells, predominantly in a periportal distribution. Covered with numerous microvilli and with a number of intracytoplasmic vesicles, their main function is to phagocytose a range of particulate material including cellular debris, senescent red blood cells, parasites, bacteria, endotoxin, and tumour cells. Phagocytosis is via a range of mechanisms including coated pits, macropinocytotic vesicles, and phagosomes aided by opsonization of particles by fibronectin or opsonin. Kupffer cells may be activated by molecules including *Escherichia coli* endotoxin, interferon-g, tumour necrosis factor-a (**TNF-a**), and arachidonic acid as well as zymosan and phorbol myristate to release a range of inflammatory mediators that include oxygen radical species, nitric oxide, proteases, TNF-a, interleukins 1, 6, and 10 (**IL-1**, **-6**, **-10**), transforming growth factor-b (**TGF-b**), prostanoids, and interferon-a and -g. Some of these may act in an autocrine or paracrine loop to further activate other Kupffer cells. These inflammatory products have a range of effects including significant modulation of parenchymal cell function (downregulation of albumin synthesis and upregulation of acute-phase protein gene expression), and induction of adherence of polymorphonuclear leucocytes and lymphocytes to endothelial lining cells due to enhanced expression of endothelial adhesion molecules.

Hepatic stellate cells

Stellate cells (Ito cells, fat-storing cells) have a similar morphology to fibroblasts with the addition of fat droplets, and are located within the Disse space. A fine branching array of cytoplasmic processes circle sinusoids under the endothelial cells. Stellate cells contain most of the body's stores of vitamin A. Retinoids are taken up from chylomicrons by specific receptors on hepatocytes and stellate cells and stored within the latter. These cells are central to the process of hepatic fibrogenesis, responding to mediators released by parenchymal and Kupffer cells, causing transformation into myofibroblasts. TGF-b initiates this process, stimulating production by the transformed stellate cell of extracellular matrix products (collagen type I, III, and IV, fibronectin, laminin, chondroitin sulphate, and hyaluronic acid) in addition to products for matrix degradation (collagenase, metalloproteinase, and its inhibitor TIMP-1). Activation of stellate cells is also an important mechanism for control of sinusoidal perfusion, through cytoskeletal actin within branching cellular processes beneath the endothelium.

Pit cells

Similar to large granular lymphocytes and located in clefts within endothelial lining cells, pit cells have natural killer cell properties with spontaneous activity against tumour cells in the absence of prior activation. They may also play a role in hepatic regeneration

Physiological processes

Hepatic blood flow

The liver receives approximately 25 per cent of cardiac output, one-third from the hepatic artery and two-thirds from the portal vein with a plasma flow at rest of 1600 ml/min in women and 1800 ml/min in men. Hepatic blood flow increases after feeding and with expiration and decreases with standing, inspiration, and sleep. In contrast to other organs, metabolic autoregulation of blood flow is not observed. Changes in hepatic oxygen consumption do not seem to control hepatic blood flow. Vascular autoregulation of hepatic arterial blood flow mediated by adenosine is present, but may not be of great physiological importance. Hepatic arterial resistance increases with increasing hepatic venous pressure due to a stepwise myogenic response in the hepatic artery to increased pressure. There is an important reciprocity between portal venous and hepatic arterial flow with a reduction in portal venous input being associated with significant compensatory decrease in hepatic arterial resistance and rise in arterial flow. The mechanism for this relationship is unproven but may be due to adenosine-mediated arterial vasodilatation.

The portal venous system is passive, without pressure-dependent autoregulation, and the major physiological factors controlling flow are those modulating supply to

the intestines and spleen. The sites of portal venous resistance are not fully defined in humans but may be at sinusoidal or post-sinusoidal levels. The significant capacitance of the hepatic circulation, with blood comprising up to 20 per cent of liver volume, is reflected in the important role of the liver and splanchnic circulation in acting as a blood reservoir. Sympathetic nerve stimulation may reduce hepatic blood volume by up to 50 per cent.

Sinusoidal perfusion

Blood pressure in sinusoids ranges from 4.8 to 1.7 mmHg, with flows of 270 to 410 ml/s. There is likely to be considerable heterogeneity of the unidirectional sinusoidal flow, control for which can be considered as either passive (haemodynamic) or active. Passive control mechanisms include: (i) the arterial input pressure and flow at the level of the arteriosinous twig at the origin of the sinusoid; and (ii) changes in right atrial pressure, central venous pressure, and hepatic venous pressure that are transmitted to the sinusoid from the centrilobular veins. Active control mechanisms include: (i) the presence of 'functional' sphincters at the inlet and outlet of the sinusoid due to indentations by the cell bodies of sinusoidal lining cells, which under different physiological stimuli may change dimension and alter sinusoidal perfusion; (ii) plugging by leucocytes, which are less compressible than erythrocytes and may under physiological stimuli adhere to endothelial lining cells; (iii) activation of Kupffer cells within sinusoids and release of other vasoactive mediators including nitric oxide, cytokines, and prostanoids; and (iv) transformation of hepatic stellate cells into activated contractile myofibroblasts that constrict the sinusoidal lumen. Sinusoidal flow will also affect the transendothelial traffic into and out of the Disse space by the processes of forced sieving and endothelial massage that may affect, respectively, the passage of lipoprotein particles and the appropriate mixing of the interstitial fluid. Therefore, sinusoidal flow is likely to have a profound effect on numerous hepatic metabolic functions and clearance of xenobiotics.

Bile formation

The formation of bile by hepatocytes and its modification by bile ductular epithelium serves many functions (Table 3). In humans the daily production of 600 ml of bile is made up of 75 per cent of canalicular origin and 25 per cent from ductules. Bile is formed by osmotic filtration, with the secretion of the two primary bile salt anions, taurine and glycine conjugates of cholic acid and chenodeoxycholic acid, across the canalicular membrane by an active transport mechanism against a concentration gradient of 5000:1 (Fig. 5). Negatively charged intercellular tight junctions prevent back diffusion of these anions, allowing the selective passage of cations, predominantly sodium, and to a smaller extent potassium, calcium, and magnesium, followed by the passive transit of water, transcellularly or between cells. The resulting bile salt-dependent bile flow makes up 50 per cent of canalicular bile flow, with the remaining bile salt-independent flow resulting from the active secretion of bicarbonate and glutathione.

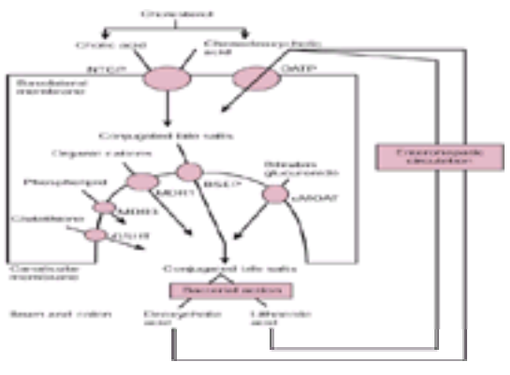

Fig. 5 Bile salt metabolism and enterohepatic pathway. NTCP, Na-taurocholate cotransporters; conjugated bile salt uptake from portal blood. OATP, organic anion transporter; bile salt, organic anion, and amphipathic solutes uptake. BSEP, bile salt export pump; ATP-dependent bile export—bile salt-dependent bile flow. MDR1, multidrug resistance-1 P glycoprotein; organic cation, xenobiotic export. MDR3, multidrug resistance-3 P glycoprotein; translocation of phosphatidylcholine. cMOAT, multispecific organic anion transporters; bilirubin glucuronide export; bile salt-independent bile flow. GSHT, glutathione transporter; gluthathione transport independent of bile flow.

Bile in biliary ductules is further modified by reabsorption of glucose, amino acids, and bile salts, as well as active secretion. Reabsorption of bile salts, the cholehepatic shunt pathway, occurs after their protonation in bile with the generation of further bicarbonate into bile stimulating bile flow. Active secretion of bicarbonate and chloride within ductules is mediated by the secretin receptor and the cystic fibrosis transmembrane receptor. Gallbladder epithelium further modifies and concentrates bile by an active anion transport process.

Bile salt conjugates secreted from hepatocytes into bile are deconjugated in the jejeunum and ileum with reabsorption and reuptake by the liver—this enterohepatic circulation conserves bile acids and maintains their high concentration within bile. The 5 per cent of bile acids passing through the ileocaecal valve are fully deconjugated by colonic bacteria and reabsorbed as the secondary bile acids deoxycholic acid and lithocolic acid, which are in turn secreted as taurine and glycine conjugates.

Metabolic processes

Hepatic metabolic processes have a central role in protein, carbohydrate, and lipid metabolism and fuel economy, orchestrating a diverse interplay between central splanchnic and peripheral organs. Interruption to these processes results in the major metabolic consequences of acute and chronic liver disease. Modulation of these metabolic processes can occur at a number of levels. Transport of molecules across membranes and through cells is an important control mechanism as are rate-limiting enzyme levels, controlled at a number of transcriptional and translational points. There is important zonal heterogeneity of hepatocyte function, with periportal zone 1 cells with a higher oxidative capacity and larger mitochondria involved in gluconeogenesis, b-oxidation of fatty acids, amino acid catabolism, ureagenesis, cholesterol synthesis, and bile secretion, whereas perivenular cells are more involved with glycolysis, lipogenesis, ammonia clearance with glutamine synthesis, detoxification, and biotransformation.

Bilirubin metabolism (Fig. 6) (see Chapter 14.19.3)

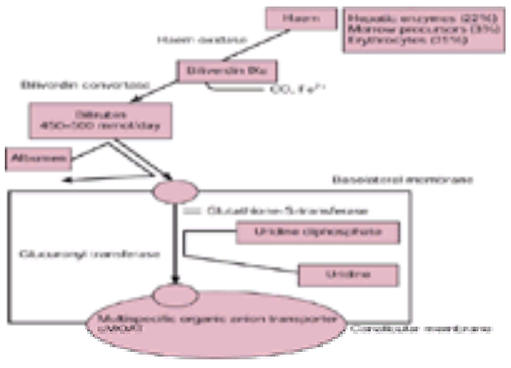

Fig. 6 Metabolism of haem and bilirubin with clearance through canalicular membrane to bile.

The first step in the production of bilirubin is the formation of biliverdin IXa by the action of haem oxidase on haem-containing proteins including catalases, cytochromes as well as haemoglobin in senescent red cells, with the release of carbon monoxide and Fe^{2+}. Biliverdin convertase within the cytosol reduces biliverdin to unconjugated bilirubin. Both biliverdin convertase and haem oxidase are predominantly found within reticuloendothelial cells.

Bilirubin is transported within plasma bound with high affinity to albumin. A few substances may displace bilirubin from albumin including sulphonamides and fatty acids. Unbound bilirubin, which is insoluble in water, is only present in nanogram quantities but may cause significant cellular toxicity in neonates and in the Crigler–Najjar syndrome.

Bilirubin uptake by hepatocytes occurs via an organic anion-binding protein receptor. Within the hepatocyte the unbound bilirubin is transported by organelles and a number of transport proteins including glutathione- *S*-transferase (ligandin) to the endoplasmic reticulum. This reduces back diffusion into sinusoids of the lipid-soluble unbound bilirubin. Glucuronidation to the mono- and diglucuronides renders bilirubin water soluble. Secretion across the canalicular membrane occurs at the canalicular multispecific membrane organic anion transporter.

Bile salt metabolism (Fig. 5)

In addition to their role in digestion, bile acids are the principal mechanism for clearance and metabolism of cholesterol, which acts as a substrate for their synthesis and in turn promotes biliary cholesterol secretion as lamellar vesicles. The first step in bile acid synthesis is rate limiting and involves cholesterol 7a-hydroxylase. Transcriptional control of the cholesterol 7a-hydroxylase gene has been demonstrated with thyroxine and glucocorticoids increasing, and glucagon decreasing, gene expression. Preformed (non-dietary) cholesterol and bile acids may also control this enzyme. The close association between bile acid and cholesterol metabolism is reflected in the often parallel activation of 7a-hydroxylase and HMG-CoA reductase, which is of critical importance in bile acid synthesis. The two major bile acids, cholic acid (60 per cent of bile acid pool) and chenodeoxycholic acid are secreted into bile as taurine and glycine conjugates.

Carbohydrate metabolism (Fig. 7)

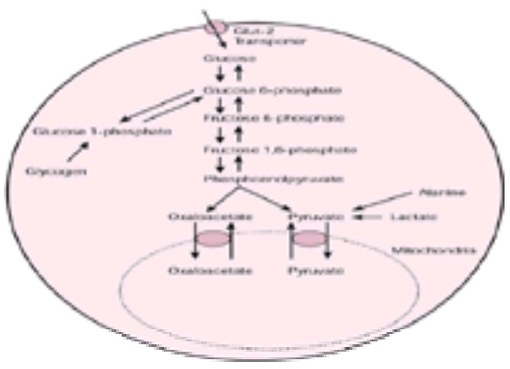

Fig. 7 Carbohydrate metabolism and pathways for glycolysis and glycogenesis.

The liver has a central role in maintaining blood glucose within a narrow margin. During fasting, hepatic glucose release is contributed to by both glycogenolysis (33 per cent) and gluconeogenesis (67 per cent) from lactate, pyruvate, glycerol, and the glucogenic amino acids alanine and glutamine. This process is regulated by at least four levels: (i) hormonal control, with glucagon accounting for up to two-thirds of basal fasted glucose output, and cortisol, growth hormone, and catecholamines also contributing; (ii) the supply of substrates, fatty acids, lactate, pyruvate, and amino acids for hepatic gluconeogenesis; (iii) metabolic regulation of hepatic enzyme activity; and (iv) the degree of hepatocellular hydration. The direction of gluconeogenesis or glycogenolysis is controlled at the level of three paired enzyme cycles—glucose/glucose-6-phosphate, fructose-6-phosphate/fructose-1,6-bisphosphate, and pyruvate/phosphoenolpyruvate. In contrast, after a glucose load, insulin suppresses hepatic glucose release and activates glucose synthetase, whilst autoregulation of hepatic glucose extraction by glucose itself within the portal venous circulation is an important factor in controlling the distribution of the load between liver and peripheral tissues.

Amino acid and ammonia metabolism

The liver is the most important organ in controlling the plasma concentration of amino acids. During prolonged starvation, hepatic proteolysis stimulated by glucagon increases splanchnic export of amino acids, whereas during the post-prandial absorptive state, amino acid uptake is significantly increased. The gluconeogenic amino acids are preferentially extracted and metabolized, whereas the branch-chain amino acids valine, leucine, and isoleucine are only cleared in the liver for protein synthesis and are catabolized in the muscle. During sepsis and under the influence of cytokines IL-1, IL-6, and TNF-a, the liver may significantly enhance gluconeogenesis and protein synthesis of acute-phase reactants (C-reactive protein, serum amyloid A).

The liver has a critical role in clearing portal venous ammonia generated within the gut lumen, by both formation of carbamoyl phosphate and entry into the urea cycle in periportal hepatocytes, and glutamine synthetase-driven glutamine synthesis in perivenous hepatocytes.

Protein synthesis

Most circulating plasma proteins with the exception of immunoglobulins and von Willebrand factor are produced by hepatocytes. The major controlling factors for this constitutive protein secretion are substrate delivery and the degree of hydration of hepatocytes. Acute-phase protein secretion is also specifically controlled by cytokines with a reciprocal relationship to albumin and other carrier protein synthesis.

Lipid and lipoprotein metabolism (Fig. 8) (see Chapter 11.6)

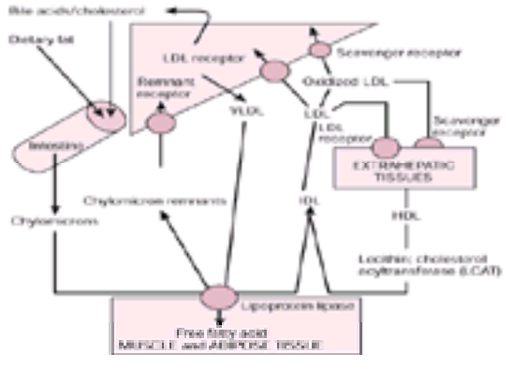

Fig. 8 Lipoprotein metabolism.

Plasma lipoproteins are particles with an outer layer of cholesterol, phospholipids, and apoproteins and an inner core of cholesterol esters and triglycerides. The various lipoproteins differ in the relative proportions of these elements. Dietary derived chylomicrons, consisting of more than 90 per cent triglyceride, are processed within muscle and adipose tissue by lipoprotein lipase, extracting free fatty acids and the remnant, enriched in cholesterol, are extracted by the liver—an exogenous lipid pathway. During carbohydrate feeding, free fatty acids formed within the liver are exported as very-low-density lipoprotein (**VLDL**) and taken up by muscle and adipose tissue with extraction of free fatty acids, leaving intermediate-density lipoprotein and subsequently low-density lipoprotein (LDL). Specific LDL receptors on hepatocytes or scavenger receptors on Kupffer cells remove LDL where cholesterol may be utilized for bile salt metabolism or excreted into bile. Peripheral LDL receptors in extrahepatic tissues also extract cholesterol. Export of cholesterol from peripheral tissues in high-density lipoprotein is modified in plasma by lecithin;

cholesterol acyltransferase (LCAT) and LDL is formed for further recirculation.

Pancreas structure and function

A retroperitoneal organ receiving arterial supply from splenic, superior mesenteric, and gastroduodenal arteries, the pancreas is composed of an exocrine portion centred on acini producing digestive enzymes draining through a ductal system into the duodenum, and the islets of Langerhans which make up 1 to 2 per cent of the whole volume and are predominantly located along arterioles.

Pancreas development and congenital anomalies

The pancreas develops from ventral and dorsal buds of the primitive duodenum. With rotation around the duodenum the two portions fuse together and the duct originating from the dorsal portion (duct of Santorini) forms the accessory duct whilst the main drainage of the gland is through the duct of Wirsung to the ampulla of Vater. Failure of ductal fusion, pancreas divisum, in which most of the gland drains through the duct of Santorini to the minor papilla, occurs in approximately 8 per cent of the population, and in a small proportion may lead to recurrent acute pancreatitis. Annular pancreas results from pancreatic tissue remaining wrapped around the duodenum during rotation of the ventral portion. Ectopic pancreatic tissue may occur in a submucosal location within the stomach and duodenum.

Exocrine pancreas

The pancreas secretes up to 2 litres of fluid per day although resting secretion rates are very low (0.3 ml/min). Acini are located in lobules draining into extralobular ducts. Cells lining the ducts secrete bicarbonate, the major anion within pancreatic juice. The acinar cells are pyramidal with the nucleus and endoplasmic reticulum towards the base and zymogen storage granules towards the apex and draining duct. Two classes of proteolytic enzymes are secreted—the serine proteases and the exopeptidases. Serine proteases all require activation either by intestinal endopeptidase in the case of trypsinogen or by trypsin itself in the case of chymotrypsin, elastase, and protease E. Serine protease act at various cleavage points whereas the carboxypeptidases A and B (exopeptidases) cleave C-terminal amino acids. The lipolytic enzymes include phospholipase A_2, lipase, and carboxylesterase. Other proteins found in pancreatic secretions include lysosomal proteins, ribonucleases, and amylase.

Control of the secretory process involves hormones as well as sympathetic and parasympathetic nerve fibres. Secretin is the main stimulus to ductal bicarbonate secretion, whereas cholecystokinin, acetylcholine, and to a lesser extent gastrin and neurotensin stimulate zymogen release of digestive enzymes at the apical membrane. Although often described as having cephalic, gastric, and intestinal phases to indicate the origin of the pancreatic stimulus, this distinction is physiologically artificial since the phases run concurrently. Somatostatin and glucagon inhibit pancreatic pro-enzyme secretion.

Endocrine pancreas

Islets of Langerhans represent an endocrine organ consisting of four cell types: A cells secreting glucagon, B cells secreting insulin, D cells secreting somatostatin, and PP cells secreting pancreatic polypeptide. B cells constitute 80 per cent of islet volume and form the central core around which the others cells form a mantle. The principal physiological function of these cells is to maintain stable glucose concentration irrespective of substrate delivery.

B cells act as a sensor of glucose concentration over a wide range, with rapid equilibration of glucose levels across the cell membrane by the GLUT-2 transporter. The molecular basis for this sensor is considered to be glucokinase, the activity of which closely follows glucose levels. Enhanced glucose metabolism increases adenosine triphosphate/adenosine diphosphate ratios, which in turn blocks potassium ionchannels, andthe subsequent change in membrane potential allows an influx of calcium that promotes exocytosis of insulin-containing granules. Many other hormones, neuropeptides, and neurotransmitters also modulate glucose-dependent insulin secretion (Table 4).

14.18.2Ct and mri of the liver and pancreas

C. S. Ng, D. J. Lomas, and A. K. Dixon

Introduction

Computed tomography (**CT**) and magnetic resonance imaging (**MRI**) are cross-sectional imaging techniques which allow excellent, non-invasive evaluation of the anatomical and parenchymal detail of both these organs. Diffuse and focal lesions can be demonstrated, and information on the associated vascular and biliary structures can also be obtained.

Both imaging techniques rely on the detection of a variety of physical properties of tissues, in the case of CT, on X-ray attenuation (essentially physical density); and in the case of MRI, on multiple factors including the radiofrequency response, proton density, and T_1 (longitudinal spin–lattice) relaxation and T_2 (transverse spin–spin) relaxation times of tissues. The successful detection of focal lesions within tissues depends on the ability of the imaging technique to identify sufficient differences in the relevant physical properties between the lesions and background parenchyma of the organ in question.

Major technological advances have been made in recent years in the speed of image acquisition in both CT and MRI. The main contributions have been, in the case of CT, 'spiral' (or 'helical') and multidetector technology; and in the case of MRI, improvements in the speed at which magnetic field gradients can be switched. These advances now permit breath-hold imaging in both CT and MRI. This has reduced breathing-related imaging artefacts, and has permitted the introduction of multiphasic or dynamic enhancement techniques following a bolus intravenous injection of contrast medium. This in turn has improved lesion detection and characterization. Multiplanar or three-dimensional reformation of data can, on occasions, improve the spatial appreciation of the anatomy.

In general, body CT is more widely available than MRI. Combined with its relative flexibility in imaging more than one body region, CT can be regarded as the current optimal investigation for these organs, even though ultrasound is often used as a preliminary and sometimes definitive investigation. The lesion-detection sensitivities for CT and MRI are comparable. Unfortunately, some lesions can be overlooked by both, or one or other investigation. In general, MRI has an advantage over CT in characterizing lesions, and is often used as a problem-solving examination. Although lesions as small as 2 or 3 mm can be demonstrated, lesions smaller than 10 mm are very difficult to characterize. If necessary, and technically feasible, tissue specimens for cytopathology or histopathology can be obtained by imaging-guided, fine-needle aspiration (**FNA**) or histological core biopsy (Fig. 1). New developments such as CT fluoroscopy and open MRI machines are likely to improve the interventional scope of these techniques, which can include therapy (for example, radiofrequency or laser ablation of neoplastic lesions). However, such techniques are still under evaluation and only available in a very limited number of centres. Some of the relative merits of CT and MRI are presented in Table 1. In many instances, other imaging techniques, such as ultrasound, angiography, and nuclear medicine, provide complementary information.

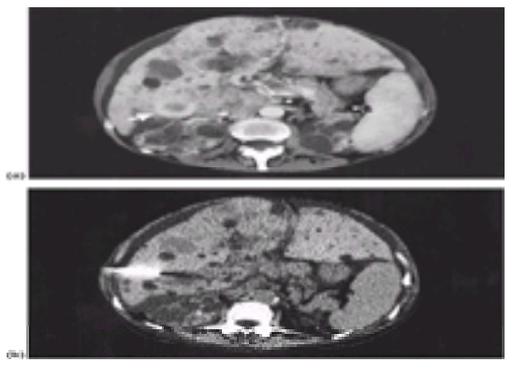

Fig. 1 (a) and (b). CT-guided biopsy of ring-enhancing liver lesion (arrow) in a complicated patient with polycystic liver and renal disease. This yielded adenocarcinoma. Note ascites.

CT and MRI of the liver

Modern spiral CT machines are able to obtain images of the liver in a single breath-hold (in the order of 15 to 25 s). Lesion detection is improved with the use of iodinated intravenous contrast media. In certain circumstances, the sensitivity and specificity of lesion detection is further improved by 'biphasic' imaging during the infusion of intravenous contrast media (that is, during arterial-dominant and portal-dominant phases). This is particularly true for hypervascular lesions, such as hepatoma, which may only be detected in the arterial-dominant phase of intravenous contrast medium infusion (Fig. 2). For the clinician, this means that the likely diagnosis(es) and clinical questions must be conveyed to the radiologists in order to adapt the CT protocol appropriately.

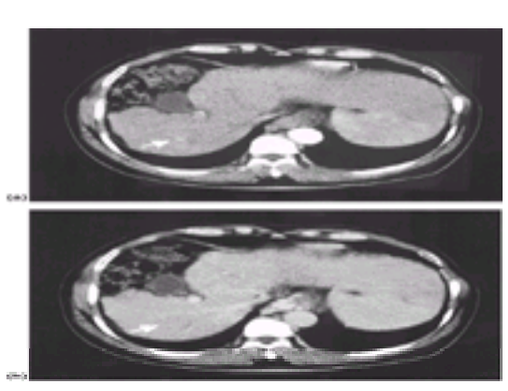

Fig. 2 CT showing hepatoma within a cirrhotic liver. Note the small shrunken right lobe. The small hepatoma (arrow) shows well in the arterial phase (a) due to the increased arterial supply. It is very much more difficult to see in the corresponding portal phase image (b), the conventional method of examining the liver.

MR imaging of the liver centres on T_1-weighted and T_2-weighted images (the latter employing 'conventional' or 'fast' spin-echo sequences, often with 'fat suppression') (Fig. 3). As with CT, breath-hold imaging is now possible, and 'dynamic' images during infusion of intravenous contrast media (for example,

gadolinium–diethylene-triamine-pentaacetic acid; **Gd-DTPA**) can add sensitivity and specificity. The addition of 'liver-specific' agents may also contribute to lesion detection (for example, paramagnetic iron particles which are taken up by Kupffer cells) or manganese-based agents (which are taken up by hepatocytes). Flow-sensitive sequences can provide information on the patency or involvement of the major hepatic vessels.

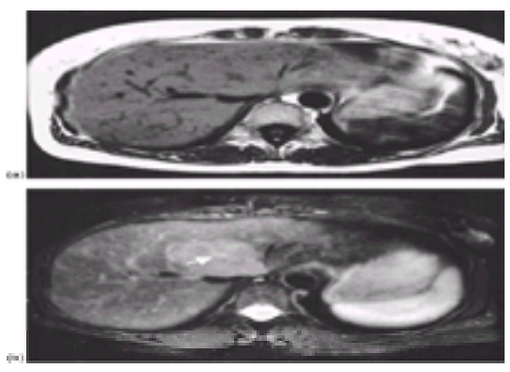

Fig. 3 Liver MRI. (a) T_1-weighted image. At first glance this appears normal. The intrahepatic veins are seen as signal voids because of the flowing blood. (b) T_2-weighted image. A large high-signal intensity lesion in segment IV is now apparent. This was focal nodular hyperplasia with a small central scar (arrow), which can just be identified on the T_1-weighted image in retrospect.

CT arterioportography and CT following intra-arterial introduction of Lipiodol are further techniques that attempt to improve lesion detection; but these are invasive, requiring selective mesenteric intra-arterial catheterization. Both are subject to important artefacts, mainly due to minor anatomical vascular variants, which can cause false-positive results.

Focal liver lesions

The detection of focal liver lesions plays an important role in the management of patients with known or suspected malignancy. However, the differentiation between benign and malignant lesions can be extremely challenging. The former include cysts, focal nodular hyperplasia (Fig. 3), haemangiomas (Fig. 4), adenomas, focal fatty infiltration (and sparing), regenerating nodules in cirrhosis, and small abscesses/granulomas. Difficulties arise when lesions do not display their characteristic imaging appearances, and particularly when they are small (<1 cm). In addition, there is considerable overlap in the appearances of benign and malignant lesions. The overall accuracy of CT in the diagnosis of hepatic metastases is in the region of 60 to 80 per cent; high-quality MRI yields slightly better results. Intraoperative ultrasound is generally considered to provide the best sensitivity. A key problem is the interpretation of a solitary small lesion in a patient with a known malignancy; such lesions are now commonly identified due to the advances in imaging technology; most will prove to be benign, even in patients with known malignancy.

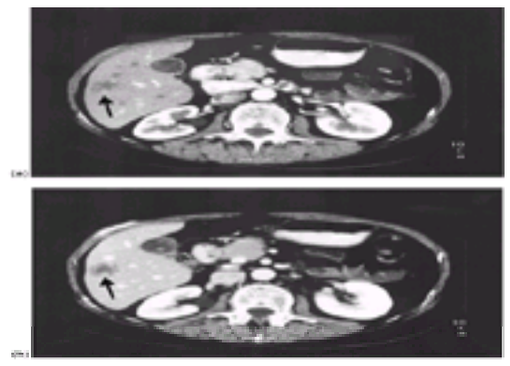

Fig. 4 CT showing liver haemangioma. On unenhanced images, the lesion had the same CT attenuation as blood in the aorta. It still shows as a low attenuation in the arterial phase (a). In the portal phase (b), it is filling in from venous lakes in the periphery (arrow).

Surgical resection for hepatic lesions, particularly metastases from colorectal carcinoma (Fig. 5), is a therapeutic option in many centres. CT and MRI can be used to determine the anatomical relationships of the tumour(s). For these purposes, the ability to delineate the functional divisions of the liver (Couinaud's nomenclature) is particularly useful from a surgical point of view (Fig. 6).

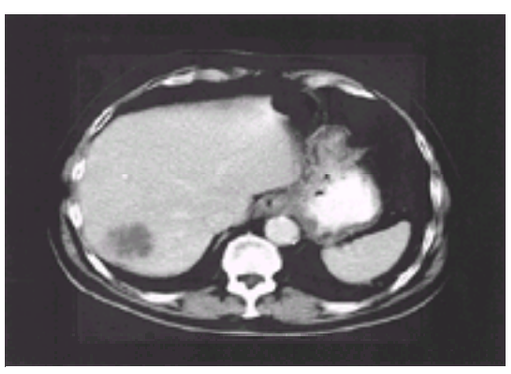

Fig. 5 CT showing liver metastasis from colorectal carcinoma.

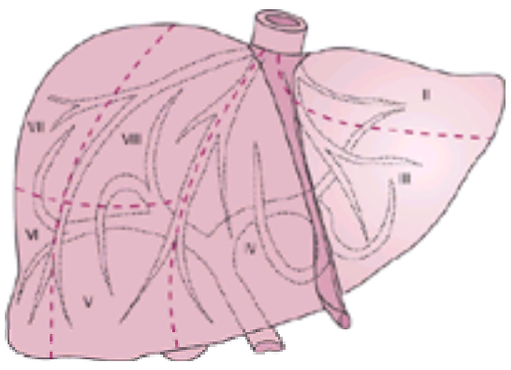

Fig. 6 Functional division of the liver and its segments according to Couinaud's nomenclature. (Reproduced from Merran S, Hureau J, Dixon AK, eds. (1989). *CT and MRI radiological anatomy*, with permission from Butterworth Heinemann.)

Diffuse liver lesions

Cirrhosis may be suggested in the presence of a distorted liver, an irregular liver surface, multiple hepatic nodules, or signs of portal hypertension (splenomegaly, ascites, or varices). However, in general, diffuse liver processes, which can include tumours and inflammatory conditions, are not reliably detected or characterized. Notable exceptions are the striking low CT attenuation caused by fatty infiltration (Fig. 7), and the abnormally high CT attenuation and low T_2-weighted MR signal intensity caused by heavy metal excess (usually iron; occasionally iodine following prolonged amiodarone therapy) (Table 2). In this regard, it is worth noting that the excess of copper found in Wilson's disease does not result in high CT attenuation; the excess is only in the microgram range; and the accompanying cirrhosis tends to reduce the attenuation.

Fig. 7 CT showing a fatty liver and chronic pancreatitis. Dilated pancreatic duct (arrow), and calcification in pancreatic body (arrow). Note the markedly low attenuation of the liver (the normal density relationship of unenhanced hepatic vessels and liver is reversed), due to diffuse fatty infiltration (steatosis), which is turn is most commonly from alcoholic excess.

Abnormalities involving the vascular tree can, on occasion, be detected, for example invasion or occlusion of the portal or hepatic veins by a tumour or thrombus. MRI, with its flow-sensitive capability, is superior to CT in this regard. Budd–Chiari syndrome produces a recognizable, but not entirely specific, parenchymal enhancement pattern. However, the key feature of an occlusion or thrombus within hepatic veins is not always reliably demonstrated by CT or MRI (nor indeed Doppler ultrasonography).

CT and MRI of the pancreas

The pancreas lies in a retroperitoneal location and its orientation in an oblique transverse plane is ideally suited to the axial planes of CT and MRI. Surrounding bowel and retroperitoneal fat are frequently helpful in delineating the pancreas in CT and MRI; conversely, these factors typically hinder ultrasound visualization of the organ. Although breath-hold, thin-section CT images of the pancreas are still anatomically superior to those obtained from MRI, the opportunities of magnetic resonance cholangiopancreatography (**MRCP**) images (heavily T_2-weighted, fluid-sensitive images) on modern MRI machines offer unique supplementary information about the biliary tree. The complementary role of endoscopic ultrasound, which continues to expand, should not be forgotten.

Acute pancreatitis

CT is generally considered the imaging investigation of choice, and can be valuable when the diagnosis is in doubt (Fig. 8(a)). On occasions, the causative distal common bile duct calculus can be identified (calculi in this location can be difficult to identify on ultrasound). Complications of acute pancreatitis may also be identified, these include necrotizing pancreatitis, abscess and/or pseudocyst formation, splenic vein thrombosis, and pseudoaneurysm formation. An assessment of the amount of viable pancreatic tissue can be made from the proportion of pancreas that enhances following administration of intravenous contrast media (Fig. 9). Differentiation between a simple pseudocyst and an infected collection can be difficult (Fig. 8(b)), but CT-guided diagnostic aspiration and/or drainage of collections can be undertaken.

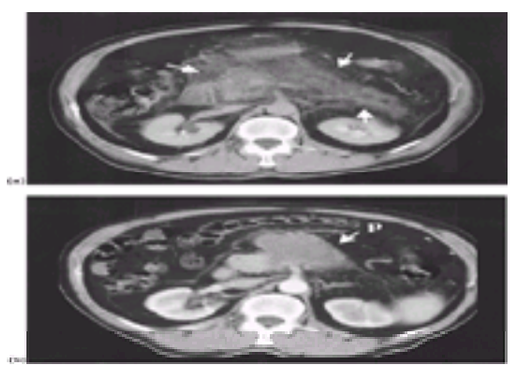

Fig. 8 CT showing acute pancreatitis progressing to pseudocyst formation. (a) In the acute phase note the poorly defined tissue planes (arrows), especially around the pancreatic head and Gerota's fascia. (b) One year later, the tissue planes around the pancreatic head are well defined, despite the distortion caused by the pseudocyst (p).

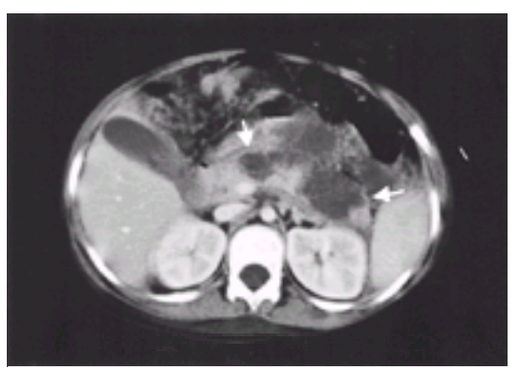

Fig. 9 CT of an acute necrotizing pancreatitis. Note ill-defined tissue planes due to retroperitoneal inflammation and non-enhancing foci following intravenous contrast medium (arrows), indicating areas of pancreatic necrosis.

Chronic pancreatitis

A diagnosis of chronic pancreatitis can be inferred on CT if there are the typical appearances of an atrophied gland with associated coarse parenchymal calcification and a dilated pancreatic duct (Fig. 7). However, the dilated and beaded pancreatic duct pattern that is the hallmark of early chronic pancreatitis on endoscopic retrograde cholangiography (**ERCP**) cannot be demonstrated by CT. At present, MRCP can only identify quite severe changes reliably; ERCP remains the 'gold standard' for subtle changes.

Focal pancreatic lesions

These include adenomas, adenocarcinomas (the most common), islet-cell tumours, cysts (which may be congenital, benign, or malignant), and focal pancreatitis. The role of imaging is in identifying the lesions, assessing treatment response, and evaluating surgical resectability.

Characterization of focal pancreatic lesions by CT or MRI is not well refined. Although, hypervascular lesions are typical of islet-cell tumours (Fig. 10), the majority of pancreatic lesions are hypovascular and there is considerable overlap in appearances. In particular, differentiation between pancreatic adenocarcinoma (Fig. 11) and focal pancreatitis can be difficult. So too may be the distinction between pancreatic pseudocyst, cystadenoma, and cystadenocarcinoma. In such circumstances, it may be necessary to perform to image-guided, fine-needle aspiration or biopsy. However, it should be emphasized that obtaining diagnostic material (for example, from pancreatic adenocarcinomas) is notoriously difficult, even for the surgeon who may have the pancreas exposed.

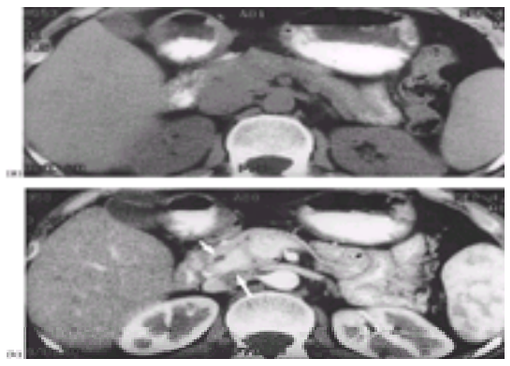

Fig. 10 (a) and (b). CT showing an islet-cell tumour of the pancreas. High-density lesion (arrow) adjacent to a normal common bile duct (small arrow) visualized on the arterial-dominant image (b) of intravenous contrast-medium enhancement (but not on the unenhanced image (a)).

Fig. 11 CT showing a small pancreatic head carcinoma. A low-attenuation tumour (straight arrow), medial to a biliary stent, occupies the uncinate process and extends towards the normal pancreatic head. The superior mesenteric vein (curved arrow) and smaller accompanying artery are opacified well; they have normal adjacent fat planes.

The accuracy of CT and MRI in assessing resectability in pancreatic adenocarcinoma is comparable.

Diffuse pancreatic changes

CT can show fatty changes within the pancreas. In type II diabetes, the outline of the pancreas can become irregular with increased fat within. In cystic fibrosis, the pancreas becomes fatty and will eventually atrophy. Similar appearances can be demonstrated by MRI.

14.18.3.1Acute pancreatitis

C. W. Imrie

Incidence and epidemiology

In different countries incidence figures vary from 40 to 500 new cases of acute pancreatitis per million of the population arise each year. Biliary disease and alcohol abuse are the main associated factors, gallstones accounting for 40 to 70 per cent of all cases. Older men and most women have biliary pancreatitis, while younger men develop pancreatitis due to alcohol abuse, as shown by studies of urban populations. This is typified by a study from Gothenburg, where, from the late 1950s to the mid 1970s, there was a change from a 68 per cent association with biliary disease to exactly same proportion with pancreatitis due to alcohol abuse.

In recent large population studies from Scotland and Finland the incidence of the disease has risen steadily to the current 400 patients per million population per year (higher figures from the United States are less reliable). From 1960 onwards, the mortality has reduced: it was 7.5 per cent overall in 1985 to 1994 with half the deaths occurring in the first week of illness. Death is usually due to multiple organ failure in which respiratory failure predominates.

Aetiological factors (Table 1)

Major factors

Biliary disease and alcohol abuse together account for over 80 per cent of patients in most prospective studies. With recent diagnostic advances, particularly the early use of endoscopic retrograde cholangiopancreatography (**ERCP**) and endoscopic ultrasound (**EUS**), it is clear that almost all the remaining patients have very small stones. Biliary sludge or bile crystals may also be indicative of a tendency to stone formation. Studies in the United Kingdom reveal that 40 to 65 per cent of patients have small gallstones. In Ohio in the United States a similar incidence has been detected, while in Argentina over 80 per cent of patients have been shown, by faecal sieving, to have small gallstones. The means by which the transient migration of small stones causes acute pancreatitis is not understood, but small stones which more easily exit the gall bladder to impact (usually transiently) in the ampullary area of the bile duct are a major factor.

Pancreatitis due to alcohol abuse occurs in over 80 per cent of patients from New York, and around 70 per cent in Helsinki. This association is usually found in young males who drink in excess of 80 g alcohol per day. Up to 10 per cent of patients have both biliary disease and abuse alcohol. Alcohol may provoke acute pancreatitis by acinar stimulation with simultaneous ampullary spasm.

Minor factors (Table 1)

Iatrogenic causes

Surgical or endoscopic procedures involving the ampulla of Vater can induce pancreatitis. The frequency of post-ERCP pancreatitis is increasing, even though the procedure only carries a risk for acute pancreatitis of about 1 per cent. Following a therapeutic endoscopic sphincterotomy the risk of acute pancreatitis is approximately 3 per cent. It is possible that failure to clear the duct of stones and inadequate sphincterotomies are the two most common predisposing features because they often allow stones to impact at the ampullary area. Manometric studies by patients themselves in a small group of patients with sphincter of Oddi dysfunction (SOD) are associated with acute pancreatitis in around 30 per cent of cases.

Viral infection

Viral infection, particularly mumps, coxsackie B, and viral hepatitis, can cause acute pancreatitis which is often missed. One clinical feature that may prove useful is prodromal diarrhoea, which is rare in all other types of acute pancreatitis.

Drug-induced acute pancreatitis

The drugs most commonly implicated in acute pancreatitis are valproic acid, azathioprine, L-asparaginase, and corticosteroids. However, unless viral titres have been determined, together with adequate biliary investigations, it is unwise to ascribe acute pancreatitis to a particular drug. Repeat exposure to the same drug again causing acute pancreatitis is the strongest evidence of a direct association.

Hyperparathyroidism

This is now recognized to be an uncommon accompaniment of acute pancreatitis. Indeed, many of the reported patients have also had gallstones. The association is calculated at 0.1 per cent. Removal of a parathyroid adenoma usually prevents further acute pancreatitis since persistent hypercalcaemia appears to be the provoking

factor.

Hyperlipoproteinaemia

Patients with type I and V hyperlipoproteinaemia (see Chapter 11.6) may develop acute pancreatitis. The significance of this association can be difficult to validate. It has been found that acute pancreatitis associated with hyperlipoproteinaemia is rare in patients who do not, at the same time, have a high alcohol intake. Nevertheless, several experimental studies point to the importance of this association; patients with primary hyperlipoproteinaemia with chylomicronaemia and hypertriglyceridaemia are prone to attacks of acute pancreatitis in the absence of alcohol ingestion.

Hypothermia

This is a particularly important association in the elderly when pancreatitis may be associated with myxoedema coma. In younger patients, alcohol abuse may be linked, particularly if patients fall asleep out of doors or in a cold, unheated house.

Blunt trauma (Fig. 1)

This is a notable cause of acute pancreatitis, particularly in young children. Sports injuries from rugby, football, ice hockey, martial arts, and similar activities may result in acute pancreatitis, usually from a crush injury to the body of the pancreas against the vertebral column. Of greater importance numerically are victims of road traffic accidents when the diagonal section of seat belts is sometimes incriminated.

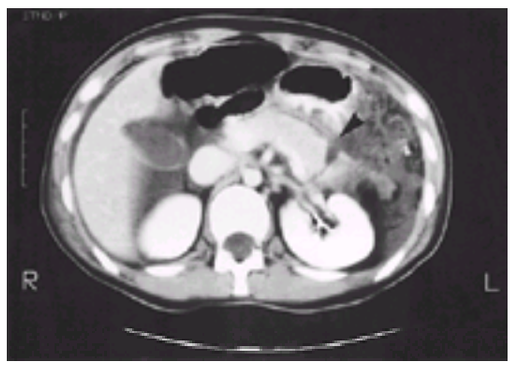

Fig. 1 Blunt trauma causing pancreatitis by transection at the arrowpoint on the CT scan.

Periampullary adenoma or cancer

This is an important association, best diagnosed by ERCP. With the increase in this approach to diagnosis, tumours at or close to the ampulla have been shown to have a greater association with acute pancreatitis then hyperparathyroidism (0.4 per cent). Effective treatment of the tumour abolishes recurrent attacks. This usually involves surgical resection, but in older less fit patients endoscopic laser therapy can be effective.

Hereditary

This form is increasingly being studied since the discovery of two genetic familial defects of trypsinogen (*N21I* and *RII7H*) have been identified with clinical acute pancreatitis usually presenting in children and young adults. Chronic pancreatitis follows from 20 to 50 years and an appreciable incidence of pancreatic carcinoma by 65 to 70 years. These cationic trypsinogen defects are autosomal dominant and shed light on the mechanism of acute pancreatitis.

Least common causes

The unusual causes of acute pancreatitis are listed in Table 2. The link with pancreatic cancer and metastases to the pancreas is well documented.

Microscopic pathology

All patients with acute pancreatitis have microscopic evidence of necrosis, while macroscopic changes, particularly black discoloration, are confined to the most severe cases. It is more frequent for this gross degree of necrosis to occur in the peripancreatic fatty tissue than in the pancreas itself. When present in the pancreas there is usually a panlobular necrosis and it is impossible to delineate where the disease initiated.

In a classical paper, Foulis claimed that the most common microscopic abnormality seen in humans, periductal necrosis, is typical of biliary and alcohol causation. Less commonly a perilobular necrosis is found, usually in patients with hypothermia or gross hypotension.

In experimental acute pancreatitis the initial lesion is now considered to be intracellular, featuring coalescence of lysozymes and zymogen granules. Acinar cell disruption is found with many of the hyperstimulation models such as caerulin-induced acute pancreatitis. It is now believed that this initial event may be associated with oxidative stress. Although this is very difficult to prove, it has formed the basis of some putative approaches to treatment.

Clinical presentation and laboratory abnormalities

Clinical features

Sudden onset of upper abdominal pain with vomiting is the most common manner of presentation.

The pain may focus in the epigastrium or right or left upper quadrant with penetration through to the back. Occasionally it encircles the upper abdomen. Patients who have experienced both a myocardial infarct and acute pancreatitis usually describe the latter pain as being much more severe. However, it tends to lessen in severity progressively over the first 72 h, and it is not usually a significant factor beyond this time. The pain on presentation is very similar to that of a perforated duodenal ulcer, but vomiting is less common in those with perforated ulcers.

Up to 90 per cent of patients with acute pancreatitis have troublesome vomiting in the first 12 h of illness, and this contributes to hypovolaemia and hypotension.

Patients with stones in the common bile duct may well be jaundiced and cholangitis can supervene in a minority. Much milder degrees of jaundice may occur from external compression of the lower bile duct in patients with alcohol-induced disease.

Hypotensive shock only occurs in very severe cases, but loss of circulating volume due to the extravasation of albumin, coupled with vomiting, leads to dehydration; the patient is thirsty, but fears drinking because of vomiting.

Bowel sounds are rarely present in the early phase of the disease and paralytic ileus may occasionally extend beyond 4 days. Despite these observations early nasojejunal feeding is possible even in clinically severe acute pancreatitis, and this is now a new therapeutic approach often begun within 48 h of the onset of disease.

The course of mild acute pancreatitis

Those patients who fail to meet objective criteria of severe acute pancreatitis tend to have a low mortality (maximum 2 per cent) and rarely need to be in hospital beyond 7 to 10 days. Simple therapeutic measures normally suffice through the first 24 to 48 h, at which time nasogastric suction and urinary catheterization can usually be discontinued. It is safer to assume that a patient may move into the more severe group and to provide early monitoring of the volume of nasogastric aspirate and hourly urinary output to maintain adequate fluid replacement. Even in this category of patients it may occasionally be necessary to provide 4 to 5 litres of intravenous fluid in the first 24 h of the illness. It is important to lower the risk of further attacks by clearing gallstones in the same admission.

The course of severe acute pancreatitis

Patients who meet objective criteria of severe acute pancreatitis may be pyrexial and are hypotensive, markedly tachypnoeic, and suffer from abdominal ascites, pleural effusions, and prolonged paralytic ileus. Body wall staining at the umbilical area (Cullen's sign) or in the flanks (Grey Turner's sign) can occur, usually appearing around the fourth day of illness.

Respiratory insufficiency or failure

Hypoxaemia is the hallmark of acute pancreatitis and reflects its severity. The basic mechanism of the hypoxaemia is unknown but high levels of various cytokines, as well as leucocyte elastase, are implicated, together with factors that contribute to localized intravascular coagulation. Shunting of blood occurs in the pulmonary vascular bed and accounts for up to 30 per cent of the cardiac output.

The initial clinical sign, which may easily be overlooked, is a fast respiratory rate; the patient may be cyanosed but there is no substitute for the measurement of arterial oxygen pressure. Almost all of the systems for objective monitoring of severity of disease include an arterial oxygen pressure of less than 60 mm Hg (8 kPa) as an index of severity. Hypoxaemia can usually be reversed by the provision of humidified oxygen, and in severe cases the pattern is similar to adult respiratory distress syndrome of other causes. Pleural effusions may be large enough to warrant aspiration, and when humidified oxygen is insufficient to reverse the hypoxaemia, assisted ventilation is necessary. Hyaline membrane formation has been found in severe cases, and even in milder cases complete reversal of the respiratory insufficiency takes many weeks.

Basal atelectasis and respiratory compromise are very common and must be expected. Urine output and arterial oxygen saturation must be monitored. Pulse oximetry is useful in monitoring, but arterial gas analysis may be needed three or four times in the first 24 h in order to make sensible decisions about humidified oxygen therapy and possible ventilator support. Single organ insufficiency or failure necessitates high-dependency care and often full intensive care management, as this may presage multiorgan failure.

The cardiovascular system

The initial hypovolaemia is of great importance in cardiac and renal function. Where cardiac output is more compromised and simple fluid replacement does not restore circulating volume, support drugs such as catecholamines may well be necessary. In the most severe acute pancreatitis the cardiovascular changes are very similar to those encountered in septic shock, with a high cardiac output and low peripheral vascular resistance. Stress on the heart may cause arrhythmias and ischaemic changes.

Renal impairment

Patients with acute pancreatitis are at risk from the development of acute renal failure which is related to hypovolaemic shock and the acute inflammatory changes associated with the illness.

The single most important corrective measure is to provide adequate fluid replacement. Low-dose dopamine may be a useful drug, and diuretics such as frusemide and mannitol may still have a place.

Additional measures are required in any patient failing to produce 30 ml of urine per hour. Most respond to increasing the rate of intravenous fluid replacement but more vigorous measures are necessary in the sickest patients, including haemoperfusion peritoneal dialysis or haemodialysis.

Biochemical abnormalities

A multitude of biochemical phenomena are found in acute pancreatitis—various pancreatic enzymes are released that are useful as diagnostic markers. With acinar cell disruption, high serum activities of amylase, lipase, trypsin, chymotrypsin, phospholipase, elastase, as well as breakdown products such as trypsinogen activation peptide and phospholipase activation peptide, are all found. The cheapest and most durable of these measurements as a diagnostic marker has been the total activity of serum amylase. Levels over four times the upper limit of normal in blood are usually taken as diagnostic of acute pancreatitis, provided the clinical course corresponds. The serum lipase activity is a more specific measure and is now almost as cheap to measure; levels of twice the upper limit of normal are significant. Other body fluids contain elevated activities of these enzymes.

Measurements of serum trypsin and chymotrypsin activity or antigens are expensive and the antiprotease defence mechanisms are efficient at releasing a_2-macroglobulin and a_1-antiprotease (also known as a_1-anti-trypsin) which rapidly counteract free trypsin and chymotrypsin within body fluids. Thus measurement of both trypsin and chymotrypsin can be unrewarding while measurement of urinary trypsinogen activation peptide shows good potential. This small peptide molecule is excreted in urine very early in the disease course in patients with severe acute pancreatitis. It is therefore a good measure of the degree of disruption of acinar cells and a commercial assay is now available. This may be a valuable investigation for both diagnosis and for gauging severity of acute pancreatitis.

For many years it was believed that the antiprotease defence mechanisms required supplementation in patients with acute pancreatitis. Thus aprotinin (Trasylol), gabexate mesilate (FOY), and purified plasma derivatives have been administered intravenously in the hope of improving the clinical course. It is now clear, however, that the antiprotease defence system is intact and that there is no need to boost it—a conclusion that is supported by many clinical trials. Aprotinin was also given into the peritoneal cavity in the hope that it would improve survival and reduce complications, but was unsuccessful.

Very high concentrations of circulating cytokines are found in the blood at an early stage in the disease. The proinflammatory tumour necrosis factor-a, platelet activating factor, and interleukin 6 are present in greatest concentration in those with severe pancreatitis. The stimulus to the release of cytokines is thought to be endotoxin, probably from the gut, and there is great interest in the possibility of administering agents that inhibit endotoxin or the cytokines as a potential therapy. Alternatively exogenous interleukin 10 (an anti-inflammatory cytokine) may move from experimental to clinical use, but early clinical studies of post-ERCP pancreatitis have produced conflicting results.

Calcium-albumin

It has long been known that hypocalcaemia is a feature of acute pancreatitis; however, a significant proportion of patients have only a drop in protein-bound calcium and the primary pathology is the loss of albumin from the intravascular space rather than decreased ionized calcium. However, even after correction factors are applied there is an undoubted tendency for serum ionized calcium to fall; this is usually counteracted by a marked elevation in parathyroid hormone.

Haematological abnormalities

There is marked haemoconcentration associated with hypovolaemia so that initial haemoglobin levels of over 16 g/100 ml may be found. After rehydration, the haemoglobin level falls but it is unusual for blood transfusion to be required as the degree of haemorrhage in and around the pancreas is usually not of great moment. Later in the course of the disease, bleeding from gastric erosions, peptic ulcer, or haemorrhage into a pseudocyst may require blood products and endoscopic, angiographic, or surgical intervention.

In addition the acute-phase response results in high levels of liver-derived C-reactive protein, a $_1$-antiprotease, factor V, factor VIII, and fibrinogen. Platelet and a_2-macroglobulin levels fall in the first week, usually returning to normal by days 8 to 10. The common finding in patients with severe acute pancreatitis is hypercoagulation, and disseminated intravascular coagulation, while it does occur, is very uncommon; its management is considered in Section 22. The rapidity of mediator response makes leucocyte elastase, tumour necrosis factor-a, and interleukin 6 potentially excellent markers of severity; C-reactive protein levels in excess of 150 mg/litre, are another useful marker of severity.

Pyrexia

This reflects cell damage and necrosis as with any condition associated with tissue destruction. A low-grade fever is typical of the first 3 to 4 days of illness. Especially in those who have the clinical signs of obstructive jaundice, ascending cholangitis should be suspected and appropriate antimicrobials given. In the most severely ill patients, transudation of bacteria from the transverse colon into necrotic tissue around the pancreas, and occasionally in the gland itself, has been detected within 48 to 96 h of onset, although it is more typical to find such sepsis at a later stage.

Making an accurate diagnosis

The diagnosis is usually made from the clinical presentation, particularly the rapid onset of upper abdominal pain and vomiting. Gross elevations of amylase and lipase in blood usually support the diagnosis, while urinary amylase levels of greater than four times the upper limit of normal can be helpful in less typical cases.

Peritoneal aspiration (after catheterization of the urinary bladder and nasogastric intubation) can be used where diagnostic doubt still exists. The aspiration of more than 20 ml of free fluid without bacterial contamination (evident by smell and Gram stain) is indicative of a severe form of the disease. The darker the colour of the fluid, the more severe the disease. This procedure is especially effective in patients with alcohol-induced acute pancreatitis. The presence of bacterial contamination indicates an alternative diagnosis and the need for an immediate laparotomy, as visceral perforation of the duodenum or small bowel is more likely.

Computed tomography (**CT**) will reveal pancreatic swelling, fluid collection, and change in density of the gland. Contrast enhanced CT scanning is mandatory to identify areas of pancreatic ischaemia and infarction. Magnetic resonance (**MR**) scanning may ultimately replace contrast enhanced CT scanning in this area. Either CT or MR can help in the difficult diagnosis.

Differential diagnosis (Table 3)

A dissecting aortic aneurysm usually presents with an initial history of chest pain in a known hypertensive; abdominal pain and loss of arterial pulses may occur later. A minor degree of pancreatitis due to ischaemia of the pancreas should not obscure the main diagnosis. Elevated amylase activities are frequently present in patients with renal failure, while a lifetime of high amylase occurs in those with macroamylasaemia; failure to filter the amylase complex results in very low urine levels.

High amylase activity in ectopic pregnancy derives from the fallopian tubes but the clinical presentation should not be mistaken for acute pancreatitis. Patients with diabetic ketoacidosis may occasionally have very high levels of amylase but this should not distract from the diagnosis.

Small bowel obstruction is associated with multiple gas–fluid interfaces on erect abdominal radiographs. The differentiation from an early perforated duodenal ulcer (less than 5 h) will rest on the combination of the finding of free gas under the diaphragm on radiographs and the lack of a significant rise in blood amylase to greater than twice the upper limits at the acute stage of illness. A more difficult diagnostic problem arises in the patient who has had a perforated duodenal ulcer for some hours because a marked elevation of serum amylase can occur. Similarly, mesenteric ischaemia or infarction can be associated with biochemical changes akin to those of acute pancreatitis, but in both these situations bacterial contamination of the peritoneal cavity will be detected by peritoneal aspiration.

Grading disease severity

The importance of objective grading of disease severity is that less experienced clinicians can direct the more serious cases to high-dependency or intensive care facilities at an early stage of their illness, or instigate contrast enhanced CT scanning and early ERCP for patients who will derive most benefit. Grading is also useful for trials of different forms of therapy.

The original Ranson grading system of 11 prognostic factors was developed for patients with acute pancreatitis due to alcohol abuse but later a system was introduced for those with gallstones. An alternative single system, validated for both the common causes, is the Glasgow scoring system of eight prognostic factors (Table 4). Validation came from a multicentre randomized British study that assessed the place of peritoneal lavage in the management of severe acute pancreatitis.

Atlanta criteria

In 1992 in Atlanta an international conference on disease nomenclature decided that severe acute pancreatitis was the presence of failure of one or more organs or the development of a major later complication—infected necrosis, abscess, or pseudocyst.

CT scanning

This can be very useful in confirming the diagnosis and also to grade severity of disease (Table 5). This is not a more accurate system of grading than the Glasgow score but it is very helpful in assessing an individual patient (Fig. 2). It is expensive and is not usually necessary in the initial few days of illness. The area of non-perfused pancreas corresponds to the extent of necrosis. Greater than 50 per cent necrosis (especially if the head of the pancreas is involved) is associated with the most severe disease.

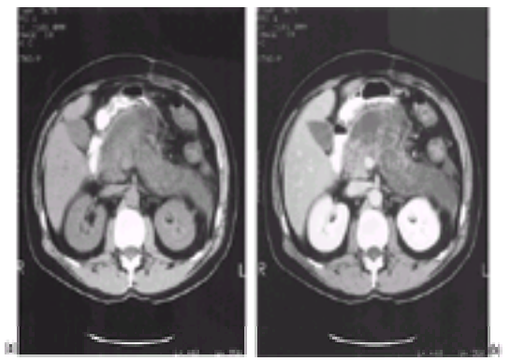

Fig. 2 (a) Severe acute pancreatitis with diffuse pancreatic swelling (CT scan). (b) Same scale level as in (a) with angiogram enhancement, revealing hypodense areas of poor perfusion.

The APACHE II system (Fig. 3)

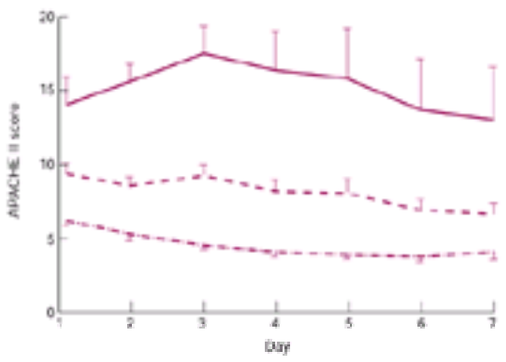

Fig. 3 Mean daily APACHE II scores by outcome in 119 patients with an uncomplicated course (–• – •–), 26 patients with a complicated course (– – – –), and 12 patients with a fatal outcome (—). The differences between fatal and uncomplicated and between complicated and uncomplicated were highly significant ($p < 0.001$) for each day (Mann–Whitney U test). (Published with permission from the *British Journal of Surgery*.)

This can be used to grade the severity of many diseases and has been shown to be useful in acute pancreatitis. It takes time for an individual clinician to learn to use the system, but it has the advantage that it can be applied throughout the first week of illness. The higher the score the worse the prognosis. Patients with the most severe acute pancreatitis have scores in excess of 10. A recent large (more than 1500 patients) clinical study assessing the potential role of a platelet activating factor antagonist in the management of higher-risk patients revealed major concerns about an entry criterion of an admission APACHE score of greater 6 or greater to select patients as the mortality rate in each of three groups of approximately 500 patients was less than 10 per cent.

Organ failure scoring

Clinical assessment by an expert is probably better than any of the other systems described at identifying the most ill patients. Quantification of the clinical assessment by scoring 0 to 4 points for each of several organ systems has revealed that 44 per cent of patients with an APACHE II score of 6 or more will show an organ failure score of 2 or more at admission. Most of these improve with supportive intravenous fluids and oxygen, but roughly a third continue with this degree of organ failure score or deteriorate.

It is this dynamic aspect of organ failure that is not recognized by the Atlanta criteria and probably caused most problems in previous grading systems. In the group who do not improve after admission with an organ failure score of 2 or more, and those who later develop this feature, we have found (in prospective data collected from 121 patients in Glasgow) a mortality in excess of 50 per cent. The application of such a scoring system for organ compromise and failure has the promise of greater accurary than Ranson, Glasgow, or APACHE II methods.

Obesity

Morbid obesity is usually described as a body mass index of over 40 kg/m^2. Acute pancreatitis carries a significantly higher mortality and morbidity in patients with a body mass index greater than 30 kg/m^2 (obesity) mainly because of increased risk of hypoxaemia but also from other associated factors.

C-reactive protein

Being an acute-phase reactant the main value of this marker is around 36 to 48 h of illness when the baseline levels of less than 10 mg/litre are far greater in those with severe acute pancreatitis. A cut-off at 150 mg/litre is a useful guide in groups of patients being assessed, but rogue results occur (Fig. 4). Of all the simple markers of severity, most experience has been gained with C-reactive protein. Values between 200 and 600 mg/litre are found in the most severely ill patients. The test is cheap and easily performed.

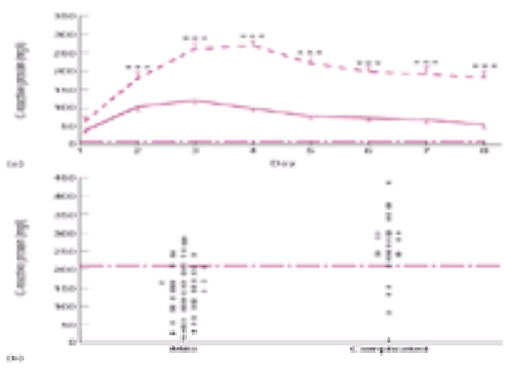

Fig. 4 (a) Sequential C-reactive protein concentrations in 47 patients with mild pancreatitis (—) and 25 with complicated attacks (– – –). Results are expressed as mean ± standard error of the mean: *$p < 0.05$; **$p < 0.01$; ***$p < 0.01$ (mild versus complicated); (— —), upper limit of normal for C-reactive protein. (b) Scattergram showing discrimination between mild and complicated attacks of pancreatitis based on the peak C-reactive protein concentration recorded on days 2 to 4 (— —). The peak concentration providing the best discrimination was greater than or equal to 210 mg/litre. (Published with permission from the *British Journal of Surgery*.)

Serum amyloid A

Prelimary studies measuring this substance hold considerable promise that it may be the most useful single marker of disease severity.

Trypsinogen activation peptide

The activation of trypsinogen releases trypsin and a small peptide (trypsinogen activation peptide) that passes unchanged in the urine, where its level can be used as a marker of severity. It has now been employed in two clinical studies with the promise of this being a valuable step forward in assessment of severity.

Clinical management

Pain is usually treated with intramuscular pethidine or buphrenorphine; intravenous benzodiazepines may also be required in severe cases. The effect of the combination of intravenous midazolam and pethidine can be particularly difficult to predict and the combination must be used with great care. Morphine has a strong spastic effect on the sphincter of Oddi and is contraindicated. Haloperidol is useful in managing the agitation of alcoholics with acute pancreatitis.

Correction of hypovolaemia requires the rapid infusion of high-volume electrolyte solutions. There is a tendency to underestimate fluid requirements in the initial 12 h of treatment and monitoring the central venous pressure is essential.

Catheterization of the bladder to monitor urine output should be done immediately and a minimum flow of 30 ml/h obtained. Nasogastric aspiration is beneficial and both this and urinary catheterization can be discontinued at an early stage if the disease proves to be mild. In such patients there is little justification for the routine use of antibiotics or H_2-receptor antagonists as nearly all of them improve within a few days. If gallstones have been identified by ultrasound scanning, laparoscopic or open cholecystectomy should be done in the same admission to minimize the risk of recurrent attack. In older and infirm patients, ERCP sphincterotomy alone is

considered a satisfactory alternative.

The severely ill patient

Those who are graded as having severe acute pancreatitis are usually particularly ill at the time of admission or within 24 h and warrant high-dependency or intensive care therapy. Monitoring for system failures and biochemical or haematological abnormalities is now routine. An algorithm for suggested steps in the management of severe acute pancreatitis (Fig. 5) is based on the United Kingdom National Guidelines published in 1998.

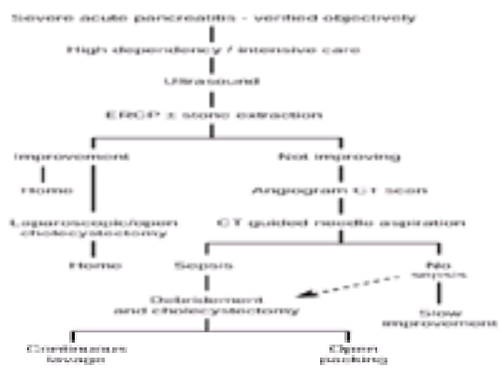

Fig. 5 Summary of management of acute pancreatitis.

In addition to monitoring individual systems and providing support, early ultrasound scan and liver function test data may indicate consideration for diagnostic and therapeutic ERCP. Two controlled studies and a large body of clinical data indicate that endoscopic sphincterotomy in those with severe gallstone acute pancreatitis provides a significant therapeutic advantage. It has also been the author's experience that rapid improvement can occur in some of the most severely ill patients soon after early endoscopic duct clearance. The greatest advantage is in jaundiced patients with or without cholangitis. Intravenous antimicrobial therapy (as a single IV bolus) is recommended as a prophylactic measure during sphincterotomy and the drugs most widely used include the second-generation cephalosporins.

The prophylactic administration of parenteral imipenem to patients with objectively graded severe acute pancreatitis throughout the first 2 weeks of illness has been found to be of value in several studies, possibly because of its high tissue penetration. We advocate a more selective use of antibiotics depending on specific indications such as proven cholangitis, the use of ERCP, and evidence of infection by culture of organisms at percutaneous fine needle aspirate in patients with infected necrosis. Fungal infection can be a problem in long-term management of those with severe acute pancreatitis when broad-spectrum antibiotics are given for more than 10 days. The mortality of candida septicaemia was about 50 per cent in two recently published experiences.

Another approach has been to strive to reduce the concentration of intestinal organisms by selective gut decontamination combined with intravenous antimicrobial therapy, but this has only been done in one study of over 100 patients in The Netherlands; Gram-negative and fungal sepsis was reduced.

The reason for this attention to the lowering of the risk from sepsis is the belief that transudation of organisms from the transverse colon into the peripancreatic necrotic tissue is a life-threatening complication of this disease. While this is usually a late complication after the first week of illness, it has been claimed that it may occur much earlier. The majority expert view currently recommends parenteral use of broad spectrum antibiotics for the initial 10 to 14 days of illness in clinically severe disease but the randomized studies each contain fewer than 80 patients and the case has yet to be proved that parenteral antibiotics confer benefit other than lowering the incidence of pancreatic infection. Neither mortality nor morbidity have been significantly reduced.

Early nasoenteral feeding

The biggest single change in therapy of severe acute pancreatitis has been the revolutionary advocacy of early nasojejunal feeding previously considered impossible due to the supposed stimulatory effect on the inflamed pancreas. Clinical studies began with the experimental evidence (in acute pancreatitis) of very early loss of small bowel mucosal integrity and the possible protective effect of a peptide and carbohydrate feed. Encouragement was also provided by data from comparative studies of patients fed by intravenous and percutaneous jejunostomy in United States trauma units, which showed clinical advantage in terms of shorter intensive care and total hospital stay for enteral feeding.

A randomized study of 38 objectively graded patients with severe acute pancreatitis found that it was both safer and cheaper (fewer infective complications and £30 versus £100 per day) to immediately use nasojejunal feeding than parenteral feeding. Although there was no mortality difference, other trials demonstrated that early nasojejunal feeding was better than parenteral feeding in terms of enhanced antioxidant capacity, decreased levels of endotoxin antibodies, and a faster resolution of markers of systemic inflammatory response.

Clinical studies from Brussels and Glasgow involving almost 100 patients with severe acute pancreatitis have verified the practicality of early nasoenteral feeding within 48 h of onset, and this approach has now become standard practice in many hospitals. This is a rare instance of a clinical advance proving cheaper than its predecessor.

The role of surgery

Patients who develop infection in the necrotic tissue around the pancreas and in the pancreas itself require open surgical debridement of the necrotic tissue by a combination of gentle finger and forceps dissection; the necrotic material will not readily drain along percutaneously introduced tubes. After removal of the infected tissue there are two options. One is to establish a postoperative lavage system, which may necessitate up to three inflow and three outflow drains because of the tendency for retroperitoneal extension of the infected necrosis down the paracolic gutters and upwards towards the diaphragm. Alternatively, if venous ooze of blood is a particular problem, packing of the abdominal cavity with large cotton packs wrapped in non-adhesive paraffin gauze, together with limited or non-closure of the abdominal wall, has been advocated. Such patients are invariably in intensive care on ventilator therapy. The packs should be changed at intervals of 48 to 72 h, with removal of any extension of infection or necrosis. Abdominal wall closure and postoperative lavage may be established after the second or subsequent operations.

Debate continues as to whether only patients with infected necrosis warrant such surgical intervention Proof of infection depends on either the presence of retroperitoneal gas radiologically or the results of fine needle aspiration guided by ultrasound or CT scanning. Most experts advocate that uninfected necrosis can be managed successfully without surgical intervention, while others are concerned about the limitations of methods for detecting infection, and would therefore widen indications for surgical intervention. Irrespective of approach, the proportions of patients coming to this surgery vary between 4 and 15 per cent of those with objectively graded severe acute pancreatitis. Recently a method of minimally invasive decompression of pus and subsequent removal of necrotic tissue has been pioneered utilizing either a left flank retroperitoneal approach (80 per cent) or right anterior drainage (20 per cent); this is a promising development since it is less traumatic than open operation. A randomized comparison of the standard open approach with this minimally invasive one is now necessary to strive to identify which patients derive most benefit from each approach. Retroperitoneal pancreatic necrosectomy involves following the route of a radiologically placed guidewire at the time of fine needle aspiration (FNA). The track is dilated to 10 mm diameter using the Amplatz dilator system.

Gallstone eradication

Cholecystectomy and common duct clearance are indicated within the same admission in patients with stones or biliary sludge. The later complication of pancreatic pseudocyst has a higher morbidity and mortality in those with biliary than alcohol-abuse pancreatitis. This is largely attributable to postoperative complications of sepsis and haemorrhage, which are much more common in the gallstone group, particularly if they have not had the gallbladder removed at the primary operation. Thus all patients with severe acute pancreatitis coming to surgery should have a cholecystectomy, especially as it is often impossible to identify small stones/sand by either ultrasonography or palpation at operation.

Pancreatic pseudocyst

This condition is probably overdiagnosed. The 1992 Atlanta conference on nomenclature agreed that the fibrous wall around a pseudocyst took approximately 4 weeks to develop from the onset of acute pancreatitis. It recommended that the term 'acute fluid collection' be used at an earlier stage in the disease process because these frequently disappear spontaneously. Even established pseudocysts can spontaneously resolve in around 50 per cent of patients. For those not resolving, synthetic somatostatin therapy (octreotide) given subcutaneously three times a day may be helpful in speeding resolution although there is no evidence base for this view as no controlled study has yet been carried out.

Percutaneous aspiration alone invariably results in recollection of the fluid quite rapidly, while infection is potentially associated with long-term percutaneous drainage. In younger patients pseudocysts are best dealt with by internal surgical drainage to the stomach or a defunctioned Roux loop of jejunum. Cystogastrostomy has been done laparoscopically, an approach that can also be used combined with a cholecystectomy. Pancreatic pseudocyst most commonly occurs in the lesser sac and often represents a closed pancreatic fistula, as a breach in the main or major pancreatic duct can be demonstrated at ERCP. This investigation is potentially hazardous as it may lead to the introduction of infection and should not be done without an appropriate antimicrobial in the injection fluid or planned endoscopic or surgical drainage. In recent years endoscopic transgastric/duodenal decompression of pancreatic pseudocysts has been increasingly employed but the evidence that this is superior to surgery has yet to be provided. Likewise the alternative of the placement of a plastic stent along the main pancreatic duct across the breach in the duct has yet to be critically assessed against other approaches, but it can be very useful and is sometimes combined with transgastric/duodenal stent decompression. Endoscopic ultrasound increases safety by accurately identifying the optimum site of pseudocyst drainage.

Pancreatic ascites

This condition occurs either when a pancreatic pseudocyst spontaneously decompresses into the gut or peritoneal cavity or a major pancreatic duct disrupts after trauma (Fig. 1) or pancreatitis, with escape of pancreatic juice into the peritoneal cavity. Treatment comprises either a combination of intravenous nutrition and octreotide therapy or surgical excision of the disconnected segment of pancreas. Success has also been obtained with intrapancreatic main-duct stents placed endoscopically.

Rare complications

Rarer complications of severe acute pancreatitis include splenic vein thrombosis and subcutaneous fat necrosis. The latter condition can mimic erythema nodosum.

14.18.3.2Chronic pancreatitis

P. P. Toskes

Introduction

Patients with chronic pancreatitis usually come to medical attention with abdominal pain or maldigestion (diarrhoea, steatorrhoea, weight loss), but the frequency of chronic pancreatitis has been underestimated because of inadequate investigation of these symptoms. The realization that impaired pancreatic exocrine function can occur without obvious dilatation of the main duct, that is 'small-duct disease', has greatly influenced management. Symptomatic variability and the many causes of this disease have made its classification difficult.

There are three forms of chronic pancreatitis now recognized: (1) chronic calcifying, (2) chronic obstructive, and (3) chronic inflammatory. Alcohol abuse and/or malnutrition are the most common causes of the calcifying type. Obstruction of the main pancreatic duct with secondary fibrosis in that part of the pancreas proximal to the obstruction leads to the obstructive type. Chronic inflammatory pancreatitis is not well characterized and many patients with chronic pancreatitis of unknown cause fall into this group. Often irreversible changes occur in the gland, making a cure improbable. Nevertheless, the chief complaints of pain and/or maldigestion can be effectively treated.

Histologically, in advanced stages of chronic pancreatitis, the gland may be fibrotic and calcified and the main duct may be dilated. Inflammation and sclerosis with progressive damage to the acini and ducts are the histological hallmarks of chronic pancreatitis. Islet cells are usually lost more slowly than the exocrine part, so that diabetes is a late feature.

Aetiology

Table 1 classifies chronic pancreatitis into a number of different conditions associated with this disease. Chronic alcoholism and cystic fibrosis are the most frequent causes in adults and children, respectively. Gallstones rarely cause chronic pancreatitis because a cholecystectomy is almost always performed after the first or second attack of acute pancreatitis related to gallstones, after which the pancreas recovers. Hypertriglyceridaemia may cause chronic as well as acute pancreatitis. Some patients with chronic pancreatitis may have suffered autoimmune pancreatitis: they have had enlargement of the pancreas, strictures of the pancreatic duct, autoantibodies in the serum, elevated plasma immunoglobulins, and histology showing a dense lymphocytic infiltrate. A few have responded to steroid therapy. Tropical pancreatitis (Africa and Asia) is characterized by calcific disease, glucose intolerance, and infrequent pain. Pancreatic exocrine impairment occurs in patients with haemochromatosis and a_1-antitrypsin deficiency, but the pancreatic disease is usually asymptomatic. Secondary pancreatic exocrine insufficiency may occur after gastric surgery, leading to postcibal (postprandial) asynchrony; usually the maldigestion is not very severe. Similarly, the acid hypersecretion associated with gastrinoma may irreversibly inactivate lipase, causing steatorrhoea. Hereditary pancreatitis and developmental anomalies leading to pancreatitis are discussed later.

Idiopathic chronic pancreatitis remains controversial and may account for up to 20 per cent of cases of chronic pancreatitis, depending on the population. Many patients with idiopathic pancreatitis present solely with unexplained abdominal pain and no evidence of maldigestion. These patients have small-duct disease, often without overt radiographic abnormalities. Direct intubation (hormone stimulation) tests are essential to identify this condition, although they are not universally carried out. Endoscopic retrograde cholangiopancreatography (**ERCP**), which is often used to diagnose chronic pancreatitis, may miss up to 30 per cent of patients with chronic pancreatitis who have abnormal hormone-stimulation tests. One questions how many patients with unexplained abdominal pain may indeed suffer from small-duct chronic pancreatitis! Some will be thought to have non-ulcer dyspepsia; others with idiopathic pancreatitis may present at an older age with painless diarrhoea, steatorrhoea, and secondary diabetes mellitus and often have pancreatic calcification.

Several investigators have documented mutations of the cystic-fibrosis, transmembrane-conductance regulator (**CFTR**) gene which functions as a cyclic AMP-regulated chloride channel in idiopathic chronic pancreatitis. More than 900 mutant alleles of the *CFTR* gene have been identified. Attempts to elucidate the relationship between the genotype and pancreatic manifestations have been hampered by the number of mutations. Two reports have shown *CF* (cystic fibrosis) gene mutations in 13 to 40 per cent of patients with idiopathic chronic pancreatitis (the observed frequency of a single *CFTR* mutation was 11 times greater than expected); moreover, the frequency of two mutant alleles was increased 80-fold. Most of these patients were adults with chronic pancreatitis, none of whom had any clinical evidence of pulmonary disease; the results of sweat chloride measurements were not diagnostic of cystic fibrosis. A further study examining all known *CFTR* mutations noted abnormalities in 55 per cent of 16 patients, 14 of whom had idiopathic chronic pancreatitis. Some of these patients with either one or two mutations had evidence of defective CFTR-mediated ion transport in nasal epithelium. It is not yet clear whether these CFTR abnormalities are primarily responsible for chronic pancreatitis or whether they are, at least in some cases, unrelated.

Pathophysiology

Although alcohol-induced chronic pancreatitis has been studied extensively, it remains uncertain as to whether the biochemical and histological lesions are caused by a reduced secretion of pancreatic-stone protein or alcohol toxicity. Ingestion of alcohol may decrease the stone protein secretion below a critical level, allowing calcium and other secretory components to precipitate and obstruct pancreatic ductules. On the other hand, alcohol may cause abnormalities in acinar cells, leading to an imbalance of proteases and their cognate inhibitors, resulting in the initiation of a necroinflammatory process. In tropical pancreatitis, a combination of protein deficiency and a dietary toxin that occurs in cassava or sorghum may be responsible. A primary defect in the permeability of the ductal epithelium to electrolytes in patients with cystic fibrosis reduces secretory fluxes, so that the hyperconcentrated proteinaceous fluid precipitates and obstructs the pancreatic ducts. The pathophysiology of the other causes of chronic pancreatitis is not understood.

Although it is widely believed that when a patient develops their first attack of acute alcoholic pancreatitis they have already sustained chronic damage to the pancreas, contemporary investigations indicate that some individuals who do not abuse alcohol regularly develop acute pancreatitis after ingesting uncommonly large quantities of alcohol (binge-drinking).

Incidence

The exact prevalence and incidence of chronic pancreatitis is unknown. Most opinions are based on clinical experiences, which vary greatly. The prevalence in autopsy studies varies from 0.04 to 5.0 per cent. The only prospective study (Copenhagen Pancreatic Study) found a prevalence of 26.4 cases per 100 000 population and an incidence of 8.2 new cases per 100 000 per year. However, this study mainly reflects alcohol-induced pancreatitis.

Clinical features

Abdominal pain is the cardinal symptom of chronic pancreatitis; its pattern, severity, and frequency vary considerably. Whereas the pain of acute pancreatitis is often located in the epigastrium and bores through to the back, the pain of chronic pancreatitis has no characteristic features and may be constant or intermittent. Eating

often increases the severity of the pain, resulting in the avoidance of food and a subsequent weight loss. The pain may be mild, requiring no therapy, or severe, leading to the frequent use of analgesics and narcotic addiction.

Patients with abdominal pain may develop steatorrhoea and/or diarrhoea, or the abdominal pain may remain their primary symptom. Approximately 15 per cent of patients never suffer with abdominal pain but present with steatorrhoea, diarrhoea, and weight loss. In those who only have abdominal pain, there are few physical findings except for abdominal tenderness and mild pyrexia. There is a marked disparity between the severity of the abdominal pain and the physical findings.

Signs and symptoms of liver disease may be present in patients with maldigestion and weight loss due to alcohol-induced pancreatitis. Clinically apparent deficiencies of fat-soluble vitamins or vitamin B_{12} are un-common.

Diagnosis

Computed tomographic (**CT**) scans may reveal diffuse enlargement of the pancreas and, occasionally, a pseudocyst (Fig. 1). Ultrasonography may reveal calcification and dilatation of the pancreatic duct (Fig. 2); calcification may also be seen on plain abdominal radiographs (Fig. 3). Blood tests rarely contribute to a diagnosis of chronic pancreatitis. The plasma activities of pancreatic enzymes (amylase, lipase, trypsin) are usually normal except in patients who have a pseudocyst of the pancreas. There may be evidence of cholestasis (elevated alkaline phosphatase, elevated bilirubin) caused by inflammatory reactions around the common bile duct. Some patients with severe disease may have raised fasting blood-glucose levels.

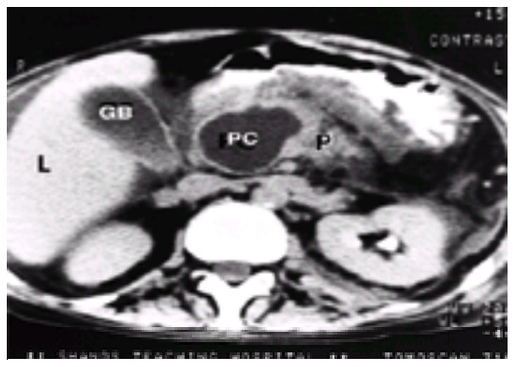

Fig. 1 CT scan demonstrating a pseudocyst (PC) in the head of the pancreas, diffuse enlargement of the pancreas (P), a normal liver (L), and normal gallbladder (GB).

Fig. 2 Ultrasonogram of chronic pancreatitis. The large closed arrow points to pancreatic calcification; the small closed arrow shows a dilated pancreatic duct; and the open arrow identifies the splenic vein.

Fig. 3 Plain film of the abdomen showing diffuse pancreatic calcification; the arrow points to one of the calcified areas.

Table 2 lists selected tests of pancreatic function and structure, but abnormalities of function generally precede abnormalities in structure. The most sensitive tests are at the top of the table, the least sensitive at the bottom. Currently, the most accurate means of detecting chronic pancreatitis is a combination of a hormone-stimulation test and ERCP. As many as 30 per cent of patients with chronic pancreatitis may have a normal ERCP but an abnormal hormone-stimulation test. Occasionally the converse will be true. The two significant causes of a false-positive (abnormal) ERCP are normal ageing and recent acute pancreatitis. Ageing does not appear to affect the hormone-stimulation test. Simple, non-invasive tests (bentiromide, pancreolauryl, trypsin) are not sensitive and are used to confirm the clinical impression. The same can be said for radiography other than ERCP.

Almost any test listed in Table 2 will identify patients with severe disease, but a hormone-stimulation test is often needed to diagnose those with abdominal pain only. Although it is generally accepted that a hormone-stimulation test is the most sensitive way to detect mild to moderate impairment of exocrine function, comparisons of the true 'gold standard' (histological examination of the pancreas) with any pancreatic test have been lacking until recently. The hormone-stimulation test correlates with the pancreatic histological findings obtained at surgery. A recent study found that the most discriminatory function was the maximum bicarbonate concentration, followed by volume and amylase output. A significant correlation was found between pancreatic function and histology. In 29 of the patients with histologically confirmed pancreatitis, the cholecystokinin–secretin test had a sensitivity of 79 per cent and ERCP 66 per cent. A simple, inexpensive test that has a sensitivity and specificity approaching that of hormone stimulation is needed. A cost-effective approach to the evaluation of patients suspected of having chronic pancreatitis would first be to use a simple non-invasive test like serum trypsin (or bentiromide) and to initiate pancreatic enzyme therapy if the result was abnormal. However, if this first-order test was normal, the next step would be to perform a hormone-stimulation test, and finally, if needed, an ERCP.

Relatively recent techniques for imaging the pancreas include magnetic resonance cholangiopancreatography (**MRCP**) and endoscopic ultrasonography (**EUS**). MRCP provides a satisfactory morphological assessment of the main pancreatic duct. However, this technique does not provide detailed imaging of the secondary ducts or even the main pancreatic duct if it is small. MRCP has been utilized successfully in elderly patients where the risk of pancreatitis from ERCP has influenced the clinician to not perform an ERCP. Endoscopic ultrasonography provides a detailed assessment of both the pancreatic duct and parenchyma. A total of nine abnormal features have been defined, and more than three criteria have been required in most studies for a diagnosis of chronic pancreatitis. EUS has replaced

ERCP as a diagnostic modality in selected patients with suspected chronic pancreatitis. What is not yet clear is how sensitive and specific EUS is in defining abnormalities in patients considered to have early or mild chronic pancreatitis. In patients in whom only the hormone-stimulation test has been found to be abnormal will EUS be helpful in diagnosing chronic pancreatitis, but its sensitivity and specificity require further study.

Management

The cornerstone of the medical management of chronic pancreatitis is the use of pancreatic enzyme formulations. The principles of therapy are similar for treating pain or steatorrhoea. A potent enzyme formulation must be used to ensure that the relevant enzymes (protease for pain, lipase for steatorrhoea) escape destruction by gastric acid and reach the duodenum.

Abstinence from alcohol is recommended. The diet should be moderate in fat (30 per cent), high in protein (24 per cent), and low in carbohydrate (40 per cent). Non-narcotic analgesics are the pain-relieving medications of choice.

To date, three controlled trails have shown that pancreatic enzymes decrease abdominal pain in some patients with chronic pancreatitis. Pain relief was obtained in 75 per cent of the patients evaluated. Those most likely to respond have small-duct disease, that is to say a minimal to moderate impairment of exocrine function (abnormal hormone-stimulation test, minimal abnormalities on ERCP, normal fat absorption) (Fig. 4). Patients with severe (large-duct) disease (abnormal hormone-stimulation test, marked abnormalities on ERCP, steatorrhoea) (Fig. 5) do not respond well to enzyme therapy for pain. These clinical observations fit well with findings in experimental animals and humans, which demonstrate the negative-feedback regulation of pancreatic secretion controlled by the amount of proteases within the proximal small intestine. Treatment comprising eight tablets or capsules of a potent, non-enteric-coated enzyme preparation should be given at mealtimes and at bedtime, with appropriate adjuvant therapy (Table 3). Enteric-coated preparations are not the prepar-ations of choice because they often release their proteases in the jejunum or ileum rather than the duodenum, thus failing to deliver to the feedback-sensitive segment of the intestine; these preparations may also cause acute colonic disease and rupture.

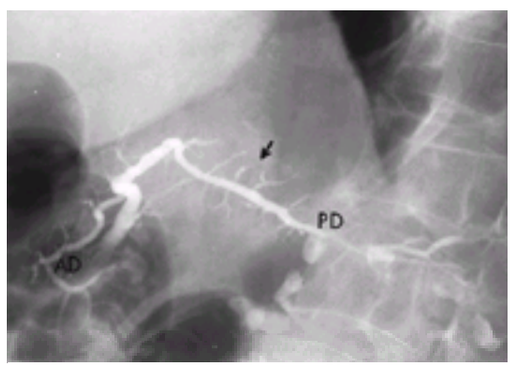

Fig. 4 Early ERCP changes of chronic pancreatitis. A non-dilated main pancreatic duct (PD) and accessory duct (AD) with mild dilatation and clubbing of the side branches (arrow) are shown.

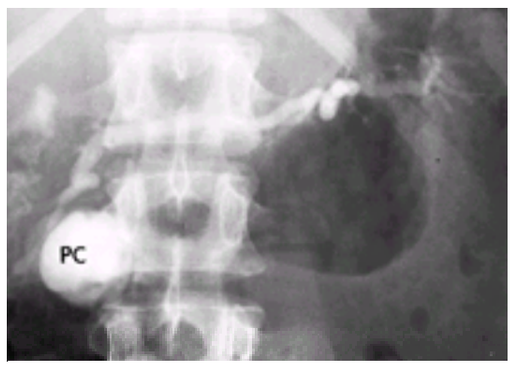

Fig. 5 ERCP showing a dilated main pancreatic duct with a communicating pseudocyst (PC).

Figure 6 outlines an approach to patients with abdominal pain thought to be caused by chronic pancreatitis. After other causes of abdominal pain have been excluded, an ultrasonography should be obtained. If no pseudocyst or mass is found, a hormone-stimulation test should be performed; this will invariably be abnormal in patients with abdominal pain secondary to chronic pancreatitis. A 4-week trial of pancreatic enzymes (with adjuvant) is indicated, as described above. If pain is not relieved, ERCP is appropriate to characterize the pancreatitis as small- or large-duct disease, and possibly to define the surgical approach.

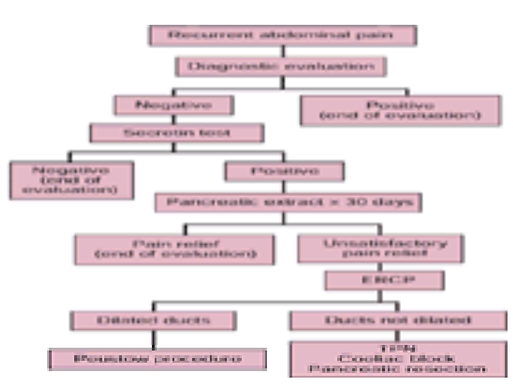

Fig. 6 Approach to the management of chronic pancreatitis and abdominal pain.

If there is large-duct disease (diameter of the main pancreatic duct greater than 7 mm), a lateral pancreaticojejunostomy (Peustow procedure) should be performed. Immediate pain relief occurs in 80 per cent of patients, with satisfactory pain relief sustained in about 50 per cent at 1 to 3 years' follow-up. If the ducts are not significantly dilated, most patients can eventually have their pain controlled by adjusting the enzyme and adjuvant therapy; for example, substitution of a proton-pump inhibitor for an H_2-receptor antagonist, total parenteral nutrition with no food orally for several weeks, or by performing a nerve block. It is now rare for a major pancreatic resection to be undertaken to control pain. In some preliminary controlled trials, octreotide in doses up to 200 µg three times daily given subcutaneously has been effective in reducing pain in patients with severe chronic pancreatitis. Whether ductal decompression or major resection are performed, enzyme therapy for enhancing digestion should be given.

Endoscopic therapy for the pain of chronic pancreatitis has been disappointing. This therapy has included dilatation or stenting of duct strictures, removal of calculi, and treatment of biliary obstruction. With the exception of acute biliary decompression, none of these therapies has been shown to be effective. Complications such as bleeding, sepsis, pancreatitis, and perforation have occurred after stent placement; moreover, stents can induce progressive ductal changes similar to the

abnormalities seen in chronic pancreatitis.

Steatorrhoea in chronic pancreatitis is a late finding and does not occur until lipase secretion is reduced by 90 per cent. With eight conventional or three enteric-coated enzyme tablets or capsules (Table 3), control of steatorrhoea and diarrhoea, and weight gain, can be readily achieved, even though some steatorrhoea persists. Formulations containing 25 000 units or more of lipase have recently been associated with the occurrence of colonic strictures in patients with cystic fibrosis who were taking large doses of these high-potency preparations. In the United States, all pancreatic enzyme preparations with more than 20 000 units of lipase per capsule have been taken out of clinical use.

Decreasing the amount of long-chain triglycerides in the diet and/or adding medium-chain triglycerides (which do not require pancreatic lipase for absorption) should decrease the steatorrhoea and enhance weight gain and energy.

Complications

Table 4 lists the structural and metabolic complications of chronic pancreatitis. Inflammatory masses are common. Ultrasonography and computed tomography greatly assist in discriminating phlegmon from a pseudocyst and from an abscess. The management of pseudocysts is currently being re-evaluated. Most clinicians have used drainage if the pseudocyst persists for longer than 7 weeks. However, the ability of pseudocysts to undergo late resolution may have been underestimated and the incidence of serious complications exaggerated. In patients with minimal symptoms who have pseudocysts and do not actively abuse alcohol, a mature pseudocyst that has benign radiological appearances should be observed: nine out of ten such pseudocysts will resolve without complications.

Pancreatic ascites occurs when there is a rent in the pancreatic duct or a leaking pseudocyst. The amylase content in the ascitic fluid is extraordinarily high, averaging 20 000 IU/l. True pancreatic ascites should be distinguished from 'reactive ascites' in patients with pancreatitis. In reactive ascites the amylase content of the fluid while increased, is not nearly as high as in the pancreatic ascites. Pancreatic stimulation should be avoided in patients with pancreatic ascites, they should receive total parenteral nutrition and no food by mouth; proton-pump inhibitors or H_2-antagonists will reduce pancreatic stimulation resulting from gastric acid release into the duodenum. Surgery may be needed if the ascites persists after several weeks of conservative therapy. An ERCP may be needed to determine the site of duct leakage.

Although obstruction of the common bile duct is common, it may be temporary, due to the resolution of inflammation. Biliary obstruction due to fibrosis of the pancreas rarely leads to cholangitis. Conservative management is justified unless the alkaline phosphatase level remains very high or cholangitis develops. In a few patients, the obstruction may require surgical relief by anastomosing the dilated common bile duct to the duodenum or jejunum.

Gastrointestinal bleeding may arise from portal hypertension associated with splenic vein thrombosis caused by inflammation of the tail of the pancreas. Bleeding may also occur if a pseudocyst erodes into the duodenum or from a pseudoaneurysm within the wall of a pseudocyst. However, the most common cause of bleeding in chronic pancreatitis is a related duodenal ulcer or alcohol-induced gastritis.

Up to 30 per cent of patients with chronic pancreatitis have impaired glucose tolerance. Although pancreatic diabetes is usually manageable, destruction of glucagon-containing cells may render hypoglycaemia more likely. Diabetes retinopathy occurs as often in pancreatic diabetes as in other types of diabetes mellitus. Retinopathy due to a zinc or vitamin A deficiency may occur.

Cobalamin (vitamin B_{12}) malabsorption is common in chronic pancreatitis, but clinical vitamin B_{12} deficiency is rare. It is caused by the failure to release free cobalamin by proteolysis of transcobalamin complexes. The exogenous administration of pancreatic enzymes corrects the maldigestion.

Hereditary and familial diseases

Hereditary pancreatitis

Familial or hereditary pancreatitis is an autosomal dominant disorder with approximately 80 per cent penetrance. About 1 per cent of all cases of chronic pancreatitis is due to hereditary pancreatitis. Often these patients present in childhood with recurrent acute pancreatitis which causes chronic pancreatitis and often pancreatic insufficiency. The lifetime risk of developing pancreatic cancer is quite high. The genetic abnormality is a defect in the cationic trypsinogen gene that maps to chromosome 7, which appears to interfere with the inactivation of trypsin after it is cleaved. These findings should prove to be revealing about the pathogenesis of idiopathic chronic pancreatitis.

Schwachmann's syndrome (pancreatic insufficiency and bone marrow disease)

This familial disorder affects the pancreas, bone marrow, and skeletal system. It is second only to cystic fibrosis as a cause of pancreatic insufficiency in infants. Unlike cystic fibrosis the sweat chloride test is normal. Neonates with this condition present with severe steatorrhoea. The associated neutropenia leads to frequent infections. The steatorrhoea is well treated by pancreatic enzymes, but severe skeletal defects result in dwarfism; there is a high lifetime risk of transformation into acute myeloid leukaemia for patients with Schwachmann's syndrome.

Isolated pancreatic enzyme deficiencies

Protease deficiencies result from a lack of enterokinase (proximal small-intestine mucosal enzyme) or trypsinogen. The addition of exogenous enterokinase to duodenal secretions will differentiate these two deficiencies; it will not activate duodenal secretions lacking trypsinogen. Both conditions respond to pancreatic enzyme therapy. Lipase and colipase deficiencies are also rare isolated deficiencies that cause steatorrhoea. Patients with these pancreatic lipase deficiencies retain a residual fat-absorbing capacity, presumably from the action of other lipases such as gastric lipase.

Developmental anomalies

Annular pancreas

A failure of the ventral and dorsal anlage of the pancreas to unite produces a ring of pancreatic tissue encircling the duodenum. This may lead to intestinal obstruction in the neonate or the adult. Non-specific symptoms of postprandial fullness, nausea, abdominal pain, and vomiting may be present for years before the diagnosis is made. The radiographs show fixed symmetrical dilatation of the proximal duodenum, with bulging of the recesses on either side of the annular band, effacement of the duodenal mucosa without obstruction of the mucosa, and accentuation of the findings in the right anterior oblique position. The differential diagnosis should include duodenal webs, tumours of the pancreas or duodenum, postbulbar peptic ulcer, Crohn's disease of the proximal intestine, and adhesions. Patients with an annular pancreas have an increased incidence of pancreatitis and peptic ulcer. Because of these and other intestinal complications, surgery may be necessary, even though the condition has been present for years. Retrocolic duodenojejunostomy is the procedure of choice, although some surgeons prefer a Billroth II gastrectomy with gastroenterostomy and vagotomy.

Pancreas divisum

Pancreas divisum is the most common, congenital, anatomical abnormality of the human pancreas. It occurs when the ventral and dorsal parts of the pancreas fail to fuse, so that pancreatic drainage is accomplished mainly through the accessory papilla. Current evidence indicates that this anomaly predisposes, albeit infrequently, to the development of pancreatitis. The combination of a pancreas divisum and a small accessory orifice could result in dorsal-duct obstruction. The challenge is to identify this subset of patients. Cannulation of the dorsal duct by ERCP is not as easy as cannulation of the ventral duct. Patients with pancreatitis and pancreas divisum demonstrated by ERCP should be treated conservatively, including pancreatic enzyme therapy. Many of them have idiopathic pancreatitis unrelated to the pancreas divisum and will respond well to pancreatic enzymes. Endoscopic or surgical intervention is indicated only when these methods fail. Surgical ductal decompression is indicated if marked dilatation of the dorsal duct can be demonstrated. However, the appropriate therapy for those patients without dilatation of the dorsal duct is not yet defined. It should be emphasized that the ERCP appearance of pancreas divisum (that is, a small-calibre ventral duct with an arborizing pattern) may be confused with an obstructed main pancreatic duct caused by a pancreatic tumour.

14.18.3.3 Tumours of the pancreas

Julian Britton

Every year an average of 10 individuals from a Western population of 100 000 people will develop a tumour of the pancreas. Nine of the 10 with ductal adenocarcinoma will be dead a year later. Very few will survive 5 years. Two-thirds of patients are over the age of 65 years and there are slightly more men than women. The incidence of pancreatic cancer is increasing and we have little understanding of the cause. Smoking is a definite risk factor and about one in seven patients either have or develop diabetes mellitus before the cancer becomes evident. Hereditary chronic pancreatitis, which is rare and for which the causative gene has recently been identified, is associated with an increased risk of developing pancreatic cancer. It is less certain that chronic pancreatitis due to other causes is a risk factor.

Pathology

Malignant tumours of the exocrine pancreas are the commonest histological type. Endocrine tumours and benign tumours are rare (Table 1). In clinical practice, two-thirds of ductal adenocarcinomas occur in the head and uncinate process of the gland. All the adenocarcinomas grow locally and then spread to the regional lymph nodes and the liver. Perineural and vascular invasion are common features on histology. Occasional patients develop secondaries in the lung. Cystic adenocarcinoma is a separate histological type with a better prognosis. Cystic/papillary tumours occur exclusively in young women. They grow to a large size and rarely metastasize. Adenocarcinomas of the ampulla, the bile duct, and the duodenum are separate and distinct tumours with a better prognosis.

Insulinomas are the most common endocrine tumour of the pancreas. Most are small, benign, and hard to find, but 10 per cent are multifocal or malignant. Gastrinomas have usually spread to the liver by the time they are discovered. About one in five islet cell tumours do not secrete sufficient hormones to produce clinical symptoms.

Breast cancer occasionally metastasizes to the pancreas and lymphoma can cause obstructive jaundice.

Diagnosis

A short history of epigastric abdominal pain which radiates through to the back, jaundice, and weight loss are the cardinal symptoms of a cancer in the head of the pancreas. About half the patients also complain of itching. Examination reveals a wasted and jaundiced patient with an enlarged palpable gall bladder (Courvoisier's sign) (Fig. 1).

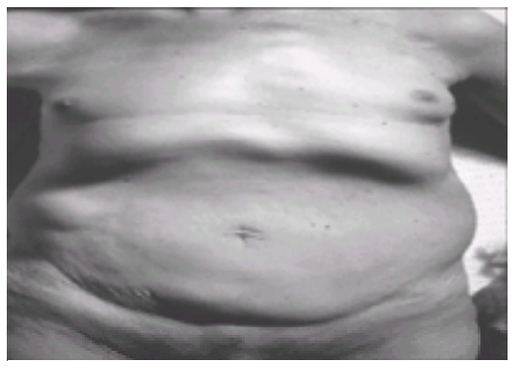

Fig. 1 This patient has cancer of the head of the pancreas and demonstrates Courvoisier's sign. The jaundice, the distended gall bladder, and the loss of weight are easy to see.

Not all patients have a palpable gall bladder and not all tumours in the head and uncinate process of the gland cause jaundice. These tumours and tumours in the body and tail of the gland present with pain and disturbance of digestion. The symptoms are often initially diagnosed as gastritis or peptic ulceration. Occasional patients present with acute pancreatitis or thrombophlebitis migrans. Pancreatic tumours are rarely palpable, and they present late in the course of the disease.

Insulinomas release insulin and present with intermittent hypoglycaemia. Excess gastrin leads to severe peptic ulceration and steatorrhoea and vasoactive intestinal polypeptide causes diarrhoea. Often, however, the clinical picture is subtle and the key to diagnosis is appropriate biochemical analysis once the diagnosis is entertained. Non-functioning endocrine tumours behave like ductal adenocarcinoma and are discovered on investigation.

Investigation

Ultrasonography

Ultrasound examination of the bile ducts and the pancreas is the first investigation when a tumour in the pancreas is suspected. Dilatation of the bile ducts is easy to see. Experienced ultrasonographers may be able to identify the level of the obstruction or to see a mass in the pancreas. More commonly part or all of the pancreas is obscured by gas in the stomach, duodenum, or transverse colon. When ultrasound is unhelpful and there is a reasonable suspicion of pancreatic pathology then computed tomography is mandatory (Fig. 2). This is usually the only way to identify cancer of the body and tail of the gland. Magnetic resonance imaging is an alternative and has the advantage of imaging the pancreas and also obtaining a pancreatogram and a cholangiogram.

Fig. 2 The body and tail of the pancreas are swollen and enlarged and there is streaking in the peripancreatic fat. This patient had a biopsy proven carcinoma of the pancreas, but it can be very difficult to tell pancreatic cancer from chronic pancreatitis on radiological grounds.

Endoscopic cholangio- and pancreatography, and percutaneous transhepatic cholangiography

Endoscopic cholangio- and pancreatography is the next preferred investigation. In cancer of the head of the gland, the bile duct and the pancreatic duct are usually narrow and irregular (the double-duct sign). In about three-quarters of these patients it is then possible to place a stent across the obstruction in the bile duct and so relieve the jaundice and pruritus. Percutaneous transhepatic cholangiography will also outline a biliary stricture but there is always a small risk of peritonitis because the needle, catheter and guide wire all cross the peritoneal cavity. However, it is slightly easier to place a biliary stent by this route (Fig. 3).

Fig. 3 Percutaneous transhepatic insertion of a biliary stent to relieve obstructive jaundice due to cancer of the pancreas. The catheter system to insert the self-expanding metal stent can be seen in the top left of the picture.

Biopsy

Biopsy of the duodenal wall is possible at endoscopic retrograde cholangiopancreatography and biliary strictures can be brushed over a guide wire for cytology. Alternatively a percutaneous biopsy can be obtained using computed tomography or ultrasonic guidance.

Computed tomography, magnetic resonance imaging, and angiography

Irregularity or narrowing of the arteries or veins around the pancreas on angiography indicate that a tumour is not resectable. Modern methods of imaging using three phase computed tomography or magnetic resonance imaging with suitable contrast agents can give the same information without a direct arterial injection. They are also more reliable at identifying liver metastases and a pancreatic resection is not justified if they are found.

Tumour markers

No serum marker has yet been found to be useful in the diagnosis of pancreatic cancer. During treatment an elevated CA 19-9 level will usually fall and this can be helpful in management.

Endocrine tumours

A high concentration of serum insulin in association with a low serum glucose is the key diagnostic feature of an insulinoma. Raised levels of other hormones will identify patients with other types of islet cell tumour. Although the tumours always develop in the pancreas or the duodenal wall most of them are less than a centimetre in size and they are hard to find. Ultrasound or computed tomography scanning and angiography are not worthwhile. Magnetic resonance imaging of the pancreas and endoscopic ultrasound are still developing and may be helpful. In most patients, once the diagnosis is established, a laparotomy by an experienced surgeon is the next best investigation. Most tumours can be seen or felt (Fig. 4), but when this is not the case intraoperative ultrasound with the probe applied directly to the pancreas will find the tumour. Transhepatic portal venous sampling, which will locate a tumour to a particular area within the pancreas, is best used after an initial unavailing laparotomy.

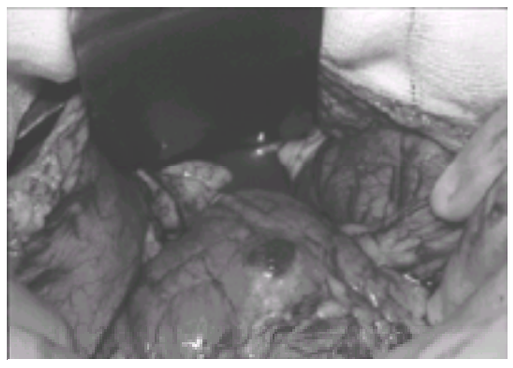

Fig. 4 The insulinoma is easily seen as a red swelling on the anterior surface of the body of the pancreas. It was a simple matter to enucleate the tumour. Leakage of pancreatic juice is rarely a problem afterwards.

Strategies for investigation

Cancer of the head of the pancreas commonly presents with jaundice. These patients need an urgent ultrasound examination which will confirm dilatation of the bile ducts. Either endoscopic retrograde cholangio-pancreatography or percutaneous transhepatic cholangiography should be performed next and the choice depends on

the available skills and local preference. In most patients, the jaundice can be relieved at the same time by inserting a stent across the biliary stricture. It is then necessary to identify those patients who would most likely benefit from surgery. Pancreatic resection is still a major procedure, despite a mortality rate now below 5 per cent. It is therefore preferable to offer radical surgery to patients under the age of 65 years, without significant other disease and whose tumour is less than 5 cm in diameter and apparently confined to the pancreas. Before surgery, this small group of patients should have portal venography carried out under computed tomography examination. In a few more patients this will show that the tumour is not resectable. The remaining patients should be offered an operation. Cancer of the body and tail of the pancreas is diagnosed on cross-sectional imaging and in most instances the computed tomography scan will also confirm that the tumour is not resectable.

Most patients with adenocarcinoma of the pancreas require palliative care. Biopsy of the pancreas or a liver metastasis is essential to confirm the diagnosis if chemotherapy is contemplated and is important for most other patients. Biopsy is not generally recommended in patients who are offered surgery because of the risk of seeding the tumour, despite the fact that a few are subsequently discovered to have a benign stricture.

Treatment

Palliation

Itching and intolerable pain are the two symptoms that require treatment. Itching rapidly improves once the bile duct is drained and the jaundice fades. Plastic stents last for an average of 4 months and can then be changed. Metal stents last rather longer. Most patients only survive a few months and never require a change of stent.

Pain from cancer of the pancreas is difficult to control. Early assistance should be sought from a specialist in palliative care. Regular opiate analgesia is usually required but a coeliac plexus block provides worthwhile pain relief in many cases. At operation 20 ml of absolute alcohol can be injected around the coeliac plexus to ablate sensory pathways. In other patients, the injection can be given by inserting the needle from the back alongside the lumbar spine and under the guidance of computed tomography.

A few patients will develop obstruction of the gastric outlet which will require a gastrojejunostomy. Surgical bypass of the biliary tract is now rarely required.

Radiotherapy has no part to play in palliation but many patients will wish to discuss chemotherapy with an oncologist. New drugs are being developed, and ideally most patients should be entered into a trial. About one in five patients will show some response to chemotherapy.

Surgery

Surgical resection of a localized pancreatic cancer is the only treatment that currently offers the possibility of long-term survival. Patients with apparently resectable tumours after investigation should therefore be offered an operation. A preliminary laparoscopy will identify patients with liver metastases which are too small to identify on scanning. Laparoscopic ultrasound in expert hands can identify involvement of the superior mesenteric or portal vein which also precludes resection. If the patient passes these tests the tumour should be assessed at a laparotomy. A trial dissection must show that the portal vein can be dissected off the tumour and that the superior mesenteric artery can be preserved. If this is the case then a pancreaticoduodenectomy (Whipple's operation) should be done (Fig. 5). The head and uncinate process of the pancreas along with the attached duodenum is removed. The antrum of the stomach is excised and the common bile duct is divided just above the duodenum. Some surgeons also remove the gall bladder. There are many techniques for restoring continuity. The pancreatic anastomosis is the most difficult and a pancreatic fistula is the cause of most postoperative complications. Occasionally a total pancreatectomy is required because the whole gland is diseased. In those rare cases in whom resection of a cancer in the body and tail of the gland is possible a splenectomy is always required as well. Even then tumour is often left around the origin of the splenic artery and postoperative radiotherapy to this area may be justified.

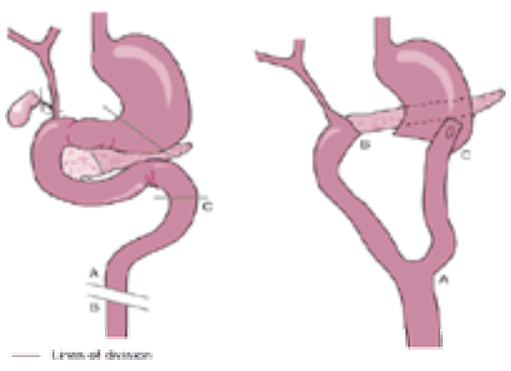

Fig. 5 The drawing on the left shows the structures that are removed in a classical pancreaticoduodenectomy (Whipple's operation). One method of restoring continuity is shown on the right.

Insulinomas are well circumscribed and can be enucleated from the pancreas by careful blunt dissection. Multifocal tumours require a pancreatic resection or even total pancreatectomy. Metastases in the liver can be enucleated, although medical management is often more appropriate.

Prognosis

Most insulinomas are benign and patients are cured when the tumour is removed. Malignant endocrine tumours metastasize and kill patients either because of their mass effect or as a consequence of intractable hypoglycaemia, diarrhoea, and hypokalaemia or peptic ulceration unless the hormonal effects can be effectively blocked.

Overall the prognosis of adenocarcinoma of the pancreas is very poor. Ninety per cent of patients are dead within 12 months of diagnosis. In the small proportion who undergo successful surgery, about one in five will survive 5 years. This will include some patients with lymph node metastases at the time of the original surgery. A significant proportion of the long-term survivors of resection will develop both endocrine and exocrine pancreatic insufficiency. This will require replacement with insulin and enzyme supplements but surprisingly, digestion is often remarkably normal: the diabetes is not usually difficult to control and most survivors can lead a near normal life.

Overall most patients with pancreatic adenocarcinoma die rapidly once the diagnosis is made but a few will survive for a long time after successful surgery. Improving outcome in the future will depend on understanding the cause of this disease.

14.19.1 Congenital disorders of the liver, biliary tract, and pancreas

J. A. Summerfield

Pathogenesis of congenital disorders of the biliary tract

During the fourth week of gestation the liver arises as a bud of cells (the hepatic diverticulum) from the ventral wall of the foregut. At about the eighth week of gestation a layer of liver precursor cells around the portal vein branches differentiate to form a sleeve, termed the ductal plate. This sleeve duplicates to form a double layer of cells which by twelve weeks is remodelled by dilatation of segments of the double-layered ductal plate to form tubules hat become the intrahepatic bile ducts. Non-tubular parts of the plate disappear and the bile ducts form part of the portal tracts.

Congenital disorders of the biliary tract are classified into two main groups: diseases characterized by inflammatory destruction of the bile ducts (the biliary atresias) and diseases marked by ectasia of the bile ducts with varying degrees of fibrosis (the fibropolycystic diseases). Both of these groups of disorders are related to the persistence or lack of remodelling of the embryonic ductal plate. They are termed 'ductal plate malformations'.

Ductal plate malformations can be seen on ultrasound or CT scans as a circular lumen containing a fibrovascular cord. Figure 1 shows ductal plate malformations in a CT scan of a patient with Caroli's disease (a fibropolycystic disease).

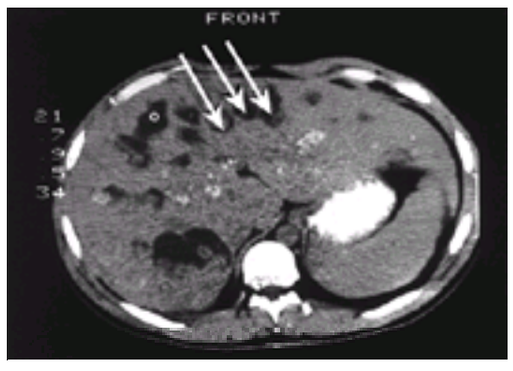

Fig. 1 Caroli's disease. Intravenous contrast enhanced CT scan of the liver shows dilated intrahepatic bile ducts containing filling defects which are portal vein branches (arrowed). This is an example of a ductal plate malformation. (From Sherlock S, Summerfield JA (1991), with permission.)

Biliary atresia

Classification

Biliary atresias are classified into extrahepatic biliary atresia and intrahepatic biliary atresia (paucity of intrahepatic bile ducts). Biliary atresia does not represent agenesis of the bile ducts but is the result of progressive bile duct destruction from an inflammatory disease of unknown cause. In extrahepatic biliary atresia the destructive cholangitis affects not only part or the whole of the extrahepatic bile duct but also intrahepatic bile ducts and leads to paucity of intrahepatic bile ducts. In intrahepatic biliary atresia the destructive cholangitis is restricted to the intrahepatic bile ducts. Intrahepatic biliary atresia can be classified further into a non-syndromatic or a syndromatic type (Alagille's syndrome or arteriohepatic dysplasia). About a quarter of patients with extrahepatic biliary atresia have evidence of ductal plate malformation indicating that the destructive cholangitis started early in fetal life.

Symptoms and signs

Biliary atresia presents as cholestatic jaundice starting after the first two weeks of life. The infant develops jaundice with pale stools, dark urine, and hepatomegaly. Itching is often prominent. Bile pigments may stain the growing teeth greenish. The jaundice steadily deepens and xanthomas of the palm and knees, rickets, a bleeding tendency, and growth failure may develop. Biliary atresia may eventually causes biliary cirrhosis with pigmentation (due to melanin), portal hypertension, ascites, and liver failure.

The progress of biliary atresia depends on the type. Infants with extrahepatic biliary atresia (usually girls) have a steadily deepening jaundice and biliary cirrhosis soon develops. Untreated, these children usually die by six months of age. The fate of infants with intrahepatic biliary atresia depends on whether they have a syndromatic or non-syndromatic atresia. Children with non-syndromatic intrahepatic biliary atresia survive longer than those with extrahepatic biliary atresia, but biliary cirrhosis eventually develops in later childhood. In contrast, patients with syndromatic intrahepatic biliary atresia (Alagille's syndrome) tend to recover normal liver function as they become adolescent. Infants with Alagille's syndrome can be recognized by the associated features, which include a characteristic facies (a flattened and triangular-shaped face), pulmonary stenosis, vertebral abnormalities, and a change in the eyes (embryotoxon). Some patients have growth and mental retardation. Alagille's syndrome is associated with mutations in the Jagged 1 gene which encodes a Notch ligand.

Differential diagnosis

Jaundice is common in early infancy. In the early neonatal period jaundice is usually due to haemolysis and impaired bilirubin conjugation. After two weeks, jaundice is usually cholestatic. There are many causes of cholestasis in infancy and childhood. The most common are extrahepatic and intrahepatic biliary atresias, neonatal

hepatitis (such as hepatitis A, B, and C, rubella, and cytomegalovirus infection), metabolic causes (such as galactosaemia, a $_1$-antitrypsin deficiency, and tyrosinaemia), and the 'inspissated bile syndrome' (congenital spherocytosis).

Laboratory investigations

Liver function tests show a cholestatic (biliary obstructive) pattern. Serum bilirubin and alkaline phosphatase levels are markedly raised with only modest elevations of serum transaminases. Later, very high levels of serum cholesterol may develop.

Histological examination of the liver cannot distinguish between intrahepatic and extrahepatic biliary atresia. Liver biopsy shows severe centrizonal cholestasis and a prominent giant-cell reaction. In the portal tracts bile ducts are reduced. Later in the course of the disease the portal tracts are devoid of bile ducts and biliary cirrhosis is present.

Imaging

The initial step in the management of infants with cholestasis is to differentiate between intrahepatic and extrahepatic biliary atresia. Since the clinical and laboratory findings are similar, this distinction requires imaging techniques. In extrahepatic biliary atresia, scintiscanning with $^{99}Tc^{m}$-labelled HIDA (dimethyl acetanilide iminodiacetic acid) shows accumulation of the label in the liver but none enters the biliary tree. Percutaneous and endoscopic cholangiography provide more precise anatomical detail.

Treatment and prognosis

General supportive measures include parenteral administration of fat-soluble vitamins A, D, K, and E. Medium-chain triglycerides as a source of fat, cholestyramine to relieve itching, and ursodeoxycholic acid as a choleretic help some patients.

Extrahepatic biliary atresia

Hepatic portoenterostomy (Kasai's operation) has been the treatment of choice for extrahepatic biliary atresia and is still widely performed. Approximately 25 to 35 per cent of patients who undergo a Kasai portoenterostomy will survive more than 10 years without liver transplantation. A third of the patients drain bile but develop complications of cirrhosis and require liver transplantation before the age of 10. For the remaining third of patients, bile flow is inadequate following portoenterostomy and the children develop progressive fibrosis and cirrhosis. The portoenterostomy should be done before there is irreversible sclerosis of the intrahepatic bile ducts. Consequently, a prompt evaluation for conjugated hyperbilirubinaemia is indicated for any infant older than 14 days with jaundice.

Intrahepatic biliary atresia

All infants should receive general supportive measures. Definitive treatment depends on the type of intrahepatic biliary atresia. Non-syndromatic intrahepatic biliary atresia eventually progresses to biliary cirrhosis and liver failure. Liver transplantation should be performed before the onset of liver failure. Syndromatic intrahepatic biliary atresia (Alagille's syndrome) has a good prognosis in most children and few develop biliary cirrhosis. General supportive measures are usually sufficient until the cholestasis disappears.

Fibropolycystic disease

Fibropolycystic disease encompasses a family of rare congenital hepatobiliary diseases that arise due to malformations of the embryonic ductal plate. These diseases include fibropolycystic disease (polycystic liver), congenital hepatic fibrosis, congenital intrahepatic biliary dilatation (Caroli's disease, Fig. 1), choledochal cysts, and microhamartomas (von Meyenberg complexes). Many patients will have more than one disease. The combination of congenital hepatic fibrosis and Caroli's disease is characteristic as these patients develop first variceal haemorrhage (due to congenital hepatic fibrosis) and later recurrent cholangitis (due to Caroli's disease). Associated kidney defects are common. Malignant change may complicate congenital hepatic fibrosis, Caroli's disease, choledochal cysts, and microhamartomas. These diseases are of widely differing severity and the prognosis in an individual patient is determined by the fibropolycystic diseases present.

Polycystic liver disease

The infantile type is inherited as an autosomal recessive disease and is usually rapidly fatal due to the associated renal disease. Adult polycystic liver disease is more common and has a dominant inheritance. The patient is usually a woman presenting in the fourth or fifth decade. The liver contains many thin-walled cysts filled with a clear or brownish liquid (due to altered blood). The cysts vary in size from a pinhead to about 10 cm in diameter. The remainder of the liver is normal. Patients present with right upper quadrant pain and increasing girth. Examination reveals an enlarged liver as the cause of the upper abdominal swelling. Liver function tests are normal. Provided no other fibropolycystic diseases are present, polycystic liver disease is benign. Some patients with polycystic liver disease also have polycystic kidneys or nephrocalcinosis. The associated renal disease may cause serious complications including renal failure. The diagnosis can be confirmed by ultrasound or CT scanning, which show numerous thin-walled cysts of low density (Fig. 2). The enlarged polycystic liver causes some patients considerable discomfort. It is best treated by percutaneous aspiration of the larger cysts using ultrasound guidance in order to reduce liver size. Percutaneous aspiration treatment can be performed repeatedly.

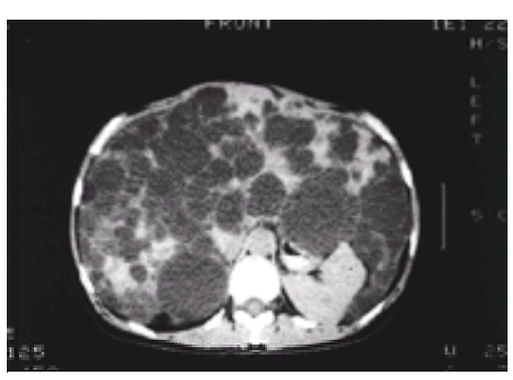

Fig. 2 Polycystic liver disease. CT scanning shows the liver contains many cysts of low density indicating that they are fluid filled. (From Sherlock S, Summerfield JA (1991), with permission.)

Congenital hepatic fibrosis

This is a rare autosomal recessive condition which is usually diagnosed before 10 years of age. The main complication is portal hypertension. Children present with a large, very hard liver and splenomegaly or bleeding from oesophageal varices. Congenital hepatic fibrosis may be misdiagnosed as cirrhosis. Liver function tests are normal or only slightly deranged. Ultrasound scans show the liver contains many bright areas due to the dense bands of fibrous tissue. The diagnosis is made by liver biopsy which shows normal liver parenchyma surrounded by fibrous septa containing structures resembling bile ducts.

Patients with congenital hepatic fibrosis bleed repeatedly from oesophageal varices, but because liver function is well preserved they do not develop portosystemic encephalopathy. Portocaval shunts will stop the variceal bleeding and are well tolerated. Liver transplantation has also been used successfully.

The long-term prognosis in congenital hepatic fibrosis is usually determined by the associated renal disease. Renal lesions include renal dysplasia, medullary cystic disease, and infantile or adult-type polycystic kidneys. The kidneys are rarely normal and renal failure eventually develops in many patients. However, renal

transplants have been successful.

Congenital intrahepatic biliary dilatation (Caroli's syndrome)

In Caroli's syndrome the common bile duct is normal but the intrahepatic ducts have bulbous dilatations with normal ducts between (Fig. 3). The mode of inheritance is unknown. While the cystic dilatations of the bile ducts remain uninfected the patient is symptom free. Eventually, ascending infection leads to cholangitis, which can be intractable with the formation of gallstones and liver abscesses. Caroli's syndrome usually presents in early adulthood as cholangitis. Most patients are male. Liver function tests show cholestasis with elevations of serum bilirubin and alkaline phosphatase and modest elevations of the transaminases. The diagnosis is made by endoscopic cholangiography. CT scans can also demonstrate the syndrome (Fig. 1). The natural history of Caroli's disease is of recurrent cholangitis which is very resistant to antibiotics. Biliary cirrhosis eventually develops. Bile duct cancer develops in about 10 per cent of cases. Treatment is difficult, antibiotics are usually only partially effective and liver transplantation is compromised by the extensive sepsis.

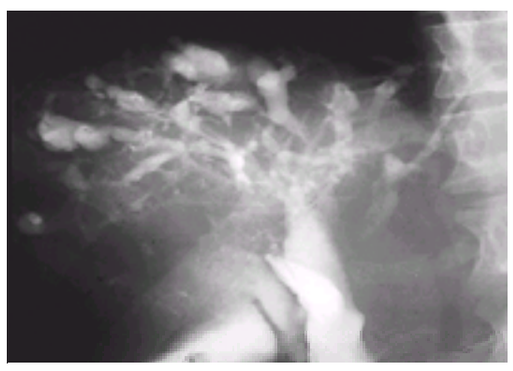

Fig. 3. Caroli's disease. An endoscopic cholangiogram shows bulbous dilatations of the intrahepatic bile ducts. The rest of the biliary tree is normal. (From Sherlock S, Summerfield JA (1991), with permission.)

About half the patients with congenital hepatic fibrosis or Caroli's disease will also have the other disease. The clinical presentation in these patients is distinctive. As in Caroli's disease, males predominate. The first complication is variceal haemorrhage followed about 10 years later by recurrent cholangitis.

Choledochal cyst

Choledochal cyst is a congenital dilatation of part or the whole of the common bile duct (Fig. 4). It is more common in girls and usually presents in childhood but may appear in early adulthood. Choledochal cysts classically cause a triad of intermittent pain, jaundice, and a right hypochondrial mass. Choledochal cysts are particularly common in Japanese and Chinese individuals. Liver function tests show cholestasis, similar to Caroli's disease. Ultrasound and CT scans show cystic dilatation of the bile duct. The diagnosis is made by endoscopic or percutaneous cholangiography. Choledochal cysts should be treated by surgical excision because of the risk of bile duct malignancy. Caroli's disease is a common associated disease.

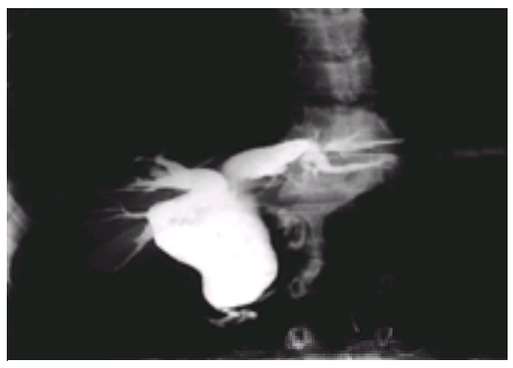

Fig. 4 Choledochal cyst in a 20-year-old woman. The endoscopic cholangiogram shows a massively dilated common bile duct. The gallbladder was normal but obscured by the dilated bile duct. (From Sherlock S, Summerfield JA (1991), with permission.)

Microhamartomas (von Meyenberg complexes)

Microhamartomas are groups of rounded biliary channels embedded in a collagen stroma located around portal tracts. The appearances are of localized islands of congenital hepatic fibrosis. Microhamartomas are usually asymptomatic and discovered incidentally on liver biopsy. They may be associated with other fibropolycystic diseases and are a rare cause of portal hypertension. Bile duct and pancreatic cancers are commoner in these patients.

Congenital disorders of the pancreas

Agenesis of the pancreas

Pancreatic agenesis is rare and may occur as an isolated anomaly or be associated with other defects. These children usually die soon after birth. Agenesis of either the dorsal or ventral pancreas may occur, although agenesis usually involves the dorsal segment.

Annular pancreas

This is a rare condition where pancreatic tissue encircles the descending duodenum. It results from persistence of part of the ventral pancreas during embryonic development. Annular pancreas is the most common cause of duodenal obstruction in infancy and often involves growth of pancreatic tissue into the duodenal wall. However, the clinical presentation is variable and annular pancreas may first present as an incidental finding at surgery or autopsy.

Pancreas divisum

Pancreas divisum results from failure of fusion of the ducts of the dorsal and ventral portions of the pancreas. The body and tail of the pancreas drain through the narrow duct of Santorini into the accessory papilla. Only the head of the pancreas drains into the ampulla of Vater (Fig. 5). This is the commonest congenital abnormality of the pancreas occurring in about five per cent of patients. Pancreas divisum appears to be associated with an increased incidence of pancreatitis affecting the body and tail of the pancreas which drains into the accessory papilla. Endoscopic sphincterotomy of the accessory papilla is reported to lead to clinical improvement in this type of pancreatitis.

Fig. 5 Pancreas divisum. An endoscopic pancreatogram following injection of contrast medium into the ampulla of Vater shows only the ducts of the head of the pancreas, characterized by a trefoil pattern. The body and tail of the pancreas drain via the accessory ampulla.

Hereditary pancreatitis

This rare form of pancreatitis is inherited as an autosomal dominant disorder. Recurrent attacks of abdominal pain start in childhood or the second decade. Hereditary pancreatitis tends to be troublesome rather than life-threatening and attacks become less severe as the patient gets older. They often disappear by middle age. Hereditary pancreatitis is associated with mutations in the cationic trypsinogen gene, which probably render the protease more resistant to autocatalytic trypsinogen breakdown.

Other rare abnormalities causing pancreatic disease

Congenital abnormalities adjacent to the pancreas are rare causes of pancreatitis. These include duodenal diverticulum, duplication of the duodenum, stenosis of the sphincter of Oddi, and choledochal cyst. These abnormalities seem to cause pancreatitis by obstructing the pancreatic duct.

14.19.2 Diseases of the gallbladder and biliary tree

J. A. Summerfield

Anatomy

The biliary system comprises the collection of ducts extending from the biliary canaliculus of each hepatocyte to the ampulla of Vater opening into the duodenum. The biliary canaliculi drain into interlobular and then septal bile ducts. These further ramify to form the intrahepatic bile ducts which are visible on cholangiography (Fig. 1). They eventually form the right and left hepatic ducts draining bile from the right and left lobes of the liver, respectively. The junction of the hepatic ducts at the porta hepatis forms the common hepatic duct. The cystic duct, linking the gallbladder to the bile duct, arises from the lower end of the common hepatic duct. The gallbladder rests in a fossa under the right lobe of the liver. Anatomical variations in the size and position of the gallbladder and the insertion of the cystic duct into the bile duct are of major surgical importance. The common hepatic duct becomes the common bile duct below the insertion of the cystic duct. The common bile duct passes through the head of the pancreas and the sphincter of Oddi to drain into the duodenum via the ampulla of Vater. The bile duct usually exits through a common channel with the pancreatic duct in the ampulla of Vater, although anatomical variations are frequent.

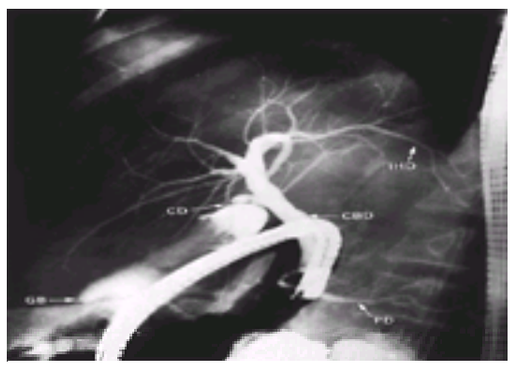

Fig. 1 The normal biliary tree. The intrahepatic bile ducts (IHD) taper smoothly and extend deep into the liver. The gallbladder (GB) drains via the cystic duct (CD) into the common bile duct (CBD). The pancreatic duct (PD) has also been opacificed in this endoscopic retrograde cholangiogram.

The investigation of biliary disease

Objectives

The clinical and laboratory features of biliary disease may also be caused by hepatic disorders. Consequently, the primary objective of investigations is to establish that the cause is due to biliary and not hepatic disease. The secondary objective is to define the anatomy of the lesion to permit a rational choice of the many surgical and non-surgical therapeutic options which are now available. To achieve these objectives requires not only a careful history and physical examination, but also the use of various imaging techniques and sometimes aspiration liver biopsy.

Symptoms and signs

Disorders of the biliary system usually give rise to the symptoms and signs of biliary obstruction (cholestasis). The repertoire is rather limited: pain, jaundice, itching, nausea and vomiting, fevers, and rigors. The pain can range from abdominal discomfort described as 'dyspepsia' to severe right hypochondrial colic caused by a sudden rise in biliary pressure. Jaundice, dark urine, and pale stools indicate obstruction of the bile duct. Itching is an important sign of biliary obstruction. Nausea and vomiting may be prominent in sudden obstruction of the bile duct, usually by a gallstone. The milder symptoms of flatulence and intolerance of fatty food are more common. Fever and rigors indicate bacterial infection of the biliary tract, which frequently accompanies partial obstruction. In jaundiced patients weight loss is usual and results from fat malabsorption due to the lack of bile acids reaching the gut; it may also indicate a malignant tumour. Prolonged biliary obstruction leads to skin changes: increased pigmentation (due to melanin) and cholesterol deposits (xanthelasma and xanthoma). Finally, biliary cirrhosis may develop causing the signs of portal venous hypertension and liver cell failure.

Laboratory investigations

In general, disorders of the biliary system give rise to the biochemical picture of biliary obstruction (cholestasis). A notable exception is gallstones in the gallbladder (cholelithiasis) where the liver function tests are usually normal. In cholestasis, the serum bilirubin concentration may be normal or raised and most of the bilirubin is esterified (conjugated). Bilirubinuria is present. The disappearance of urobilinogen from the urine indicates complete biliary obstruction. Elevation of the serum alkaline phosphatase is an important but not invariable sign of biliary obstruction; the rise is usually greater than three times normal. Other biliary canalicular enzymes accumulate in the blood, including g-glutamyl transpeptidase. This enzyme is only found in the liver and is estimated if there is doubt as to whether the alkaline phosphatase is of bony or hepatic origin. This may be required in children and patients with malignancy. Serum transaminases, such as aspartate aminotransferase, show only modest elevation in contrast to the rises which ccur in hepatitis. The serum cholesterol concentration rises and may cause abnormalities of red cell shape (target cells) (see Section 22). A raised concentration of serum bile acids is a sensitive index of biliary disease. A prolonged prothrombin time reflects intestinal malabsorption of fat-soluble vitamin K owing to a lack of bile acids. Vitamin A and D deficiency may also develop. The serum albumin and gammaglobulin levels are normal until biliary cirrhosis develops. A polymorphonuclear leucocytosis accompanies bacterial infections of the biliary system.

Imaging techniques

A plain radiograph of the abdomen may reveal an enlarged liver, calcified gallstones, or air in the biliary tree. Plain radiographs of the abdomen are now rarely performed. The preferred first investigation is ultrasonography (Fig. 2). Computed tomography (**CT** scan) and magnetic resonance imaging (**MRI**) are used in complicated diagnostic problems. These tests reveal dilated bile ducts and may also indicate the position of the obstruction in the biliary tree and dense structures such as gallstones. Hepatic scintiscanning with $^{99}Tc^{m}$-labelled HIDA (dimethyl acetanilide iminodiacetic acid) is an alternative and is of value in the diagnosis of acute cholecystitis. Oral cholecystograms are rarely performed nowadays but are useful to determine whether the gallbladder is functioning in patients with gallstones being assessed for oral bile acid dissolution therapy (see below). Intravenous cholangiography is obsolete. However, these non-invasive investigations usually provide insufficient anatomical detail for diagnosis or planning of treatment. An invasive cholangiographic technique such as percutaneous transhepatic cholangiography (**PTC**) or endoscopic retrograde cholangiopancreatography (**ERCP**) is necessary. ERCP is the preferred investigation in the first instance. PTC is reserved for patients in whom ERCP fails. Both these techniques carry small risks including haemorrhage, biliary peritonitis, and cholangitis (with PTC), and bowel perforation, cholangitis, and pancreatitis (with ERCP). Should cholangiography reveal a normal biliary system in a jaundiced patient, a liver biopsy is indicated.

Fig. 2 Ultrasound scan of the gallbladder shows gallstones (arrowed) as bright round objects which cast acoustic shadows.

This diagnostic approach is ideal but expensive both in terms of human and material resources. The apparatus required is costly and procedures such as ERCP require considerable expertise. Obviously local factors will determine the diagnostic pathway that is adopted. Nevertheless, these techniques have revolutionized the management of patients with biliary disease. It is now a routine matter to achieve a precise diagnosis rapidly. In addition, a series of non-operative therapeutic options ranging from the introduction of endoprostheses for the management of benign and malignant biliary structures to endoscopic sphincterotomy for the removal of the biliary calculi are direct consequences of these diagnostic approaches. Developments in MRI indicate that soon ERCP may be superseded by the non-invasive technique of magnetic resonance cholangiography (MRC).

Bile composition and gallstone formation

Bile composition

Bile is secreted by the hepatocytes and its water and electrolyte composition altered during its passage down the biliary system. Between meals much of the bile is diverted to the gallbladder where it is concentrated by the removal of sodium, chloride, bicarbonate, and water. In response to food, the gallbladder contracts, emptying bile into the duodenum. Apart from water (97 per cent) the major components of bile are bile acids, phospholipids, and cholesterol. Bile is also the major excretory route of other compounds including bilirubin and certain drugs and their metabolites. Cholesterol is insoluble in water but is held in solution by the detergent action of bile acids with the aid of phospholipids.

Cholesterol is synthesized primarily in the liver and small intestine. The rate-limiting enzyme for cholesterol production is hydroxymethylglutaryl-CoA reductase, which catalyses the first step, the conversion of acetate to mevalonate. Subsequently, non-esterified (free) cholesterol is secreted into bile. Dietary cholesterol also contributes to biliary cholesterol secretion. The control of cholesterol metabolism is complex. It is not yet clear what proportion of biliary cholesterol is derived from circulating lipoproteins and what proportion is newly synthesized by the liver.

The primary bile acids, cholic and chenodeoxycholic acid, are synthesized in the liver from cholesterol. The economy of the bile acid pool is preserved by efficient reabsorption, principally in the terminal ileum. About 95 per cent of the bile acids are reabsorbed and pass back to the liver in the portal venous system (enterohepatic circulation). The remainder enters the colon where bacteria form the secondary bile acids, deoxycholic and lithocholic acid, from cholic and chenodeoxycholic acid, respectively. Some of the secondary bile acids are absorbed from the colon but most are excreted in the faeces. The normal bile acid pool is about 3 to 5 g and circulates 6 to 10 times each day. Synthesis is controlled by the negative feedback of bile acids returning in the portal venous blood, which act on the rate-limiting hepatic enzyme, cholesterol-7a-hydroxylase. The principal phospholipid in bile is lecithin. It is produced in the liver and secreted into the bile. In the intestine lecithin is hydrolysed to lysolecithin by pancreatic phospholipase and is subsequently reabsorbed.

Above a certain level (the critical micellar concentration) bile acids coalesce to form micelles that have a hydrophilic external surface and hydrophobic internal surface. Cholesterol is incorporated into the hydrophobic interior. Phospholipids are inserted into the micellar wall so that the micelles are enlarged; these 'mixed micelles' are thus able to hold more cholesterol.

Consequently, the solubility of cholesterol in bile depends on the concentrations of bile acid and phospholipid. In the presence of a relative excess of bile acids and phospholipid (on a molar basis) the cholesterol-holding capacity of bile is increased and it is said to be unsaturated. However, if there are insufficient micelles of bile

acid and phospholipid to hold the cholesterol, the solution is referred to as saturated and the excess cholesterol tends to precipitate. With a knowledge of the molar concentration of cholesterol, phospholipid, and bile acids, the cholesterol saturation of bile can be predicted using triangular co-ordinate diagrams.

Gallstone formation

Gallstone disease is common and afflicts between 10 and 20 per cent of the world's population. Gallstones are classified according to their composition into two main groups: cholesterol stones and bile pigment stones. Cholesterol stones are composed mainly of cholesterol (more than 70 per cent) and can be subdivided into pure cholesterol stones (usually solitary) and mixed stones which contain cholesterol in a matrix of calcium bilirubinate, calcium phosphate, and protein (Fig. 3 and Fig. 4). Mixed stones are usually multiple and faceted. Bile pigment stones can also be divided into two main groups. Brown pigment stones are soft and friable and consist of calcium bilirubinate, cholesterol, and calcium soaps. Pure pigment stones ('black stones') are black, hard, and brittle and contain an insoluble black pigment, calcium bilirubinate, calcium carbonate and phosphate, calcium salts of fatty acids, and bile acids. All pigment stones contain a large amount of mucoprotein matrix (up to 70 per cent). Gallstones are rare before the age of 10 years. The incidence increases progressively with age. Cholesterol gallstones account for about 75 per cent of the gallstones in Europe and the United States.

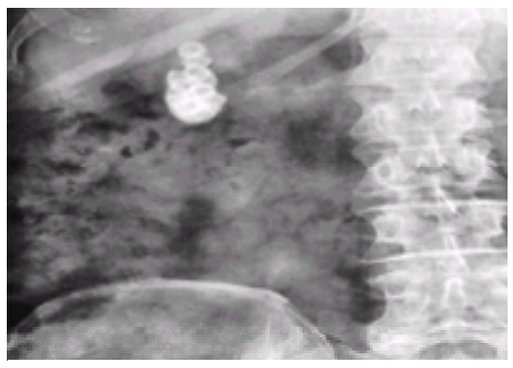

Fig. 3 Calcified gallstones. Gallstones contain sufficient calcium to be visible on a plain abdominal radiograph in about 10 per cent of patients. The gallbladder stones are surrounded by a ring of calcium slats. (Reproduced from Sherlock S, Summerfield JA, 1979, *A colour atlas of liver disease*, Wolfe Medical Publications, London, with permission.)

Fig. 4 Cholesterol gallstones. An intravenous cholangiogram has opacified the gallbladder showing multiple faceted radiolucent gallstones. These are typical features of cholesterol stones.

Cholesterol gallstones

Cholesterol gallstones result from the secretion of cholesterol-saturated bile by the liver. The cause of the saturation is unclear. Patients with gallstones usually have a smaller bile acid pool than controls and it circulates more frequently. The rapid recycling of bile acids may be responsible for the smaller bile acid pool by excessive inhibition of the enzyme which controls bile acid synthesis, cholesterol-7a-hydroxylase. However, diminished bile acid synthesis is probably not the most important factor in the production of saturated bile. This appears to be an elevated biliary cholesterol secretion rate, due either to increased hepatic cholesterol synthesis or increased transfer of plasma lipoprotein cholesterol into bile. Nevertheless, saturated bile may be encountered in normal subjects, especially during fasting. It is therefore likely that other factors such as the condition of the gallbladder, the mechanism of seeding (nucleation) of gallstones, and the control of gallstone growth are important. Furthermore, racial differences, advancing age, female sex, obesity, diet, drugs (such as the contraceptive pill and clofibrate), and gastrointestinal disease (such as Crohn's disease) are known to have a significant influence on the development of gallstones.

Bile pigment gallstones

In contrast to cholesterol stones, little is known of the aetiology of bile pigment stones. The soft, friable brown-pigment stones are especially common in the Far East and are associated with *Escherichia coli*, bacteroides, and clostridium infection of the biliary tract. It is probable that these bacteria contribute to stone formation by producing b-glucuronidase that deconjugates bilirubin diglucuronide to form free unconjugated bilirubin. This combines with calcium to form sparingly soluble calcium bilirubinate that precipitates.

The black, hard, and brittle pure-pigment stones are the type commonly encountered in the West. The incidence of pure pigment stones increases with age and they are found in patients with cirrhosis, chronic bile duct obstruction (such as biliary strictures), chronic haemolytic anaemias including haemolysis induced by prosthetic heart valves, and malaria. Pure pigment stones affect both sexes equally. The mechanism of stones production is unclear, but does not appear to be due to cholesterol saturation of hepatic or gallbladder bile. About 50 per cent of all pigment stones are radio-opaque and they account for about 70 per cent of all opaque stones.

Natural history of gallstones

The majority of gallstones remain in the gallbladder (cholelithiasis) and may give rise to no symptoms ('silent' gallstones), being discovered incidentally during investigation or at autopsy. Impaction of a gallstone in the neck of the gallbladder results in gallbladder inflammation and the symptoms and signs of acute or chronic cholecystitis. Acute cholecystitis will subside if the stone spontaneously disempacts, or may progress to gangrene and perforation of the gallbladder or empyema of the gallbladder. Gallstones may pass through the cystic duct into the bile duct (choledocholithiasis) resulting in biliary obstruction and jaundice. Bacterial infection (cholangitis) commonly accompanies choledocholithiasis and can lead to a liver abscess. Gallstones may perforate through the inflamed gallbladder wall to form an internal fistula, usually to the small intestine or colon. A large gallstone passing into the small intestine may impact in the ileum resulting in intestinal obstruction (gallstone ileus). Finally, surgical treatment for gallstones, while usually curative, may result in a postcholecystectomy syndrome or a benign stricture of the bile duct.

Treatment

The usual treatment for gallstones remains cholecystectomy although medical treatments may be employed in selected patients (see below). The advent of laparoscopic cholecystectomy has swung the balance in favour of surgery since this technique carries so little morbidity and a very short hospital stay. Treatment is obviously indicated for symptomatic gallstones and for their complications. However, in patients in whom 'silent' gallstones are discovered incidentally and in patients with minimal symptoms it is by no means clear that treatment is always the best solution. The problem revolves around the probability of serious complications in the future. It is appropriate to offer treatment to young patients (who, with many years ahead of them, will have a greater likelihood of developing the complications of

gallstones) and to advise against treatment in the elderly with other major medical problems. However, in fit middle-aged patients with no or minimal symptoms it is reasonable to tell the patient of the finding and to withhold surgery until it is warranted by symptoms or complications.

Gallstone dissolution and disruption

Cholesterol gallstones can be removed from the gallbladder and bile ducts in a proportion of patients by medical treatments. These techniques avoid the discomfort, disability, and risks of general anaesthesia and surgical exploration of the abdomen and bile ducts. However, with the widespread availability of laparoscopic cholecystectomy these techniques are now used rarely. There are two types of medical method: chemical agents that dissolve gallstones, and physical methods such as endoscopic sphincterotomy and extracorporeal shock-wave lithotripsy (**ESWL**). Judicious combinations of chemical and physical methods yield the best results.

Chemical methods

Oral bile acid therapy

Oral treatment with chenodeoxycholic acid or ursodeoxycholic acid can dissolve cholesterol gallstones. These bile acids, normal constituents of bile, reduce the cholesterol saturation of bile and result in the leaching of cholesterol from gallstones. They act by reducing the hepatic synthesis and biliary excretion of cholesterol. Ursodeoxycholic acid has advantages over chenodeoxycholic acid in that it does not cause diarrhoea or elevations of serum transaminases. These bile acids differ in the way that they remove cholesterol from gallstones and have been shown to dissolve gallstones better in combination than singly. Combination therapy is the preferred treatment.

Contact dissolution of allstones

Cholesterol stones in the gallbladder can be dissolved by the direct instillation of methyl tertbutyl ether (**MTBE**) into the gallbladder via a percutaneous catheter. MTBE is a foul-smelling, volatile, inflammable colourless liquid that remains liquid at body temperature. The gallbladder is catheterized by the transhepatic route, entering it through the area of attachment of the gallbladder to the liver and MTBE is continually infused and aspirated with vigour until the stones have disappeared (which typically takes 5 to 7 h).

Physical methods

Extracorporeal shock-wave lithotripsy

ESWL is a non-invasive and safe but expensive way of rapidly shattering gallstones into a coarse powder. The gallbladder must contain no more than three stones to allow accurate focusing of the shock waves.

Endoscopic sphincterotomy

Endoscopic sphincterotomy can remove gallstones from the bile duct. The bile duct is entered by a cannula passed via a duodenoscope and the bile duct is opened by diathermy cutting of the ampulla of Vater. Stones are removed by balloon or wire catheters.

Patient selection and results

Medical treatment with oral bile acid therapy, ESWL, or contact dissolution are suitable for patients with cholesterol gallstones in a functioning gallbladder (as judged by an oral cholecystogram). Calcified gallstones do not dissolve. Radiolucent gallstones are usually, but not always, composed of cholesterol. CT scans are useful for detecting low levels of gallstone calcification. These treatments should be reserved for patients with mild or no symptoms in whom the risk of cholecystectomy is high, including those with pre-existing disease, the elderly, and the very obese. They are also of value in patients who refuse surgery. Drugs which increase the cholesterol saturation of bile should be avoided; these include oestrogens, the oral contraceptive pill, and clofibrate.

Oral bile acid therapy is protracted but safe. It dissolves gallstones in about 25 per cent of patients fulfilling the selection criteria by 6 months. It should not be taken during pregnancy. The preferred treatment is combination therapy with chenodeoxycholic acid (7 mg/kg) and ursodeoxycholic acid (7 mg/kg). Proprietary combination tablets are available. Gallstone dissolution usually requires 6 to 24 months of therapy depending on stone size. Oral cholecystograms are performed every 6 months to assess progress. Combining oral bile acid therapy with ESWL speeds up the process greatly: gallstones will be cleared in more than 90 per cent of patients within 18 months. Furthermore, slightly calcified gallstones can be treated in this way. MTBE therapy is invasive and the ether is unpleasant to use, but dissolution is rapid. Endoscopic sphincterotomy removes gallstones from the common bile duct. Any type of stone can be removed up to about 20 mm in diameter.

Side-effects and toxicity

The most frequent side-effect of oral bile acid therapy is diarrhoea. It is dose related and usually mild and transient. It can be minimized by slowly increasing the dose to the required level. Transient elevations of serum transaminase activity are also common; liver function tests should be monitored. Ursodeoxycholic acid may cause calcification of gallstones. Gallstone recurrence remains a major problem with oral bile acid therapy. One year after gallstone dissolution about 30 per cent of patients will have had a recurrence. Unwanted effects of ESWL include biliary colic, skin petechias, and haematuria. The principal unwanted side-effects of MTBE are sedation, burning upper abdominal pain, nausea, and vomiting. Endoscopic sphincterotomy can cause gastrointestinal haemorrhage and acute pancreatitis.

Acute cholecystitis

Aetiology

Acute cholecystitis is associated with gallstones in over 90 per cent of patients. It follows the impaction of a gallstone in the cystic duct. Continued secretion by the gallbladder leads to a rise in pressure. Inflammation of the gallbladder wall results from the toxic effects of the retained bile and bacterial infection. The gallbladder bile is usually turbid but may become frank pus (empyema of the gallbladder). Intestinal organisms, especially anaerobes, are commonly cultured from the gallbladder. Ischaemia in the distended gallbladder wall may lead to infarction and perforation. Generalized peritonitis may follow, but the leak is usually localized to form a chronic abscess cavity. Some patients have repeated attacks of acute cholecystitis which are probably exacerbations of chronic cholecystitis. Acute cholecystitis in the abscence of gallstones (acalculous cholecystitis) is usually very rare. However, acalculous cholecystitis is a particular problem in patients with the acquired immunodeficiency syndrome (**AIDS**). Cytomegalovirus and cryptosporidium are the most commonly associated organisms in acalculous cholecystitis in AIDS.

Symptoms and signs

The typical patient is an obese, middle-aged female, and the acute attack is often precipitated by a large or fatty meal. However, there are many exceptions to this pattern. The principal symptom is pain, of fairly sudden onset, which is severe, continuous or minimally fluctuating, and localized to the epigastrium or right hypochondrium. The pain often radiates to the back. The constancy of the pain is in contrast to the repeated short bouts of biliary colic. In uncomplicated cases the pain gradually subsides over 12 to 18 h. Flatulence and nausea are common but persistent vomiting suggests the presence of a stone in the common bile duct. Examination reveals an ill, sweating patient with shallow, jerky respiration. Fever indicates a complicating bacterial cholangitis. Jaundice may accompany acute cholecystitis but is usually a sign of a stone in the bile duct. The abdomen moves poorly with respiration. Right hypochondrial tenderness is present and is exacerbated by inspiration (Murphy's sign). Muscle guarding and rebound tenderness are common. The gallbladder is usually impalpable but occasionally a tender mass of omentum and gallbladder may be felt under the liver.

Laboratory investigations

The white cell count is usually moderately elevated (12 to 15 × 10^{9}/l) due to a polymorphonuclear leucocytosis. Serum bilirubin concentrations between 17 and 68 µmol/l (1 and 4 mg/dl) may be seen in uncomplicated acute cholecystitis, but should raise the suspicion of a stone in the bile duct. Modest rises in the serum alkaline phosphatase, aspartate transaminase, and amylase may also be seen. An abdominal radiograph will show gallstones in about 10 per cent of patients. Ultrasound

scanning of the gallbladder is the preferred first investigation. Scintiscanning with $^{99}Tc^{m}$-labelled HIDA provides similar information. It is important to establish the correct diagnosis before surgery is performed.

Differential diagnosis

Acute cholecystitis may be confused with other abdominal emergencies including perforated peptic ulcer, acute pancreatitis, retrocaecal appendicitis, perforated carcinoma or diverticulum of the hepatic flexure of the colon, and liver abscess. Cardiac infarction and pneumonia with right-sided pleurisy should also be considered.

Complications

Gangrene of the gallbladder

Pain, tenderness, and fever progressively increasing or persisting for longer than 24 to 48 h are indications of gangrene of the gallbladder. The prognosis is poor if necrosis and perforation occur. In patients who are elderly and obese, perforation of the gallbladder can occur without definite signs. Perforation into an adjacent viscus may produce a cholecystenteric fistula and may lead to gallstone ileus.

Cholangitis

Intermittent high temperatures often accompanied by rigors indicate bacterial infection of the bile duct and usually follow the passage of a stone into the bile duct.

Treatment

In most patients acute cholecystitis subsides in a few days with conservative treatment. Cholecystectomy is performed either a few days after the symptoms have settled or 2 to 3 months later. In the latter event, if the symptoms recur during the interval, cholecystectomy is performed without delay. Immediate surgery is mandatory if signs of gangrene or perforation develop.

Conservative treatment

Oral feeding is stopped. Intravenous fluids, and analgesia with nalbuphine or pethidine (demerol) and atropine are administered. Antibiotics are given to all but the most mild cases; tetracycline, amoxicillin, or a cephalosporin are satisfactory for general use. The patient should be observed frequently with abdominal examination and sequential leucocyte counts to detect signs of gangrene of the gallbladder or cholangitis.

Surgical treatment

Cholecystectomy is the operation of choice. Laparoscopic cholecystectomy is the preferred approach. About 10 per cent of patients with acute cholecystitis will have stones in the common bile duct. The bile ducts should be assessed by ERCP and bile duct stones removed by endoscopic sphincterotomy. If an open cholecystectomy is performed, intraoperative cholangiography may be performed to determine whether bile duct stones are present. In high-risk patients and when technical difficulties are encountered a cholecystotomy may be performed.

Chronic cholecystitis

This is the most common form of gallbladder disease that results from gallstones. Pathologically it is characterized by chronic inflammation and thickening of the gallbladder wall. In addition to stones the gallbladder may contain a brown sediment ('biliary mud'). A proportion of these patients have cholesterolosis of the gallbladder ('strawberry gallbladder'). This describes the deposition of yellow specks of cholesterol in the pink gallbladder wall and is a consequence of cholesterol-saturated bile. Cholesterolosis of the gallbladder is asymptomatic but about half the patients develop gallstones. Chronic cholecystitis usually develops insidiously but may follow an attack of acute cholecystitis.

Symptoms and signs

Some patients complain of bouts of constant right hypochondrial or epigastric pain. If it is intermittent, that is, biliary colic, the height of the pain is separated by 15- to 60-min intervals. The pain may last several hours or be as brief as 15 to 20 min. It may radiate to the right shoulder or the back. More commonly the symptoms are vague and ill-defined and include abdominal discomfort and distension, nausea, flatulence, and intolerance of fatty foods. Unfortunately, many patients who do not have chronic cholecystitis complain of these symptoms. Examination of the abdomen may reveal tenderness over the gallbladder and a positive Murphy's sign. Laboratory investigations are usually unhelpful.

Imaging techniques

An ultrasound scan is used to detect gallstones. A plain radiograph of the abdomen may reveal calcified stones or opacification of the gallbladder caused by high concentrations of calcium carbonate ('limey bile') but is not often used now. If these investigations fail to show stones, but stones are still suspected on clinical grounds, an ERCP should be performed before surgery is undertaken.

Differential diagnosis

Dyspepsia and fat intolerance are common symptoms that may be caused by many conditions including peptic ulcers, hiatus hernia, irritable bowel syndrome, chronic relapsing pancreatitis, and tumours of the stomach, pancreas, colon, or gallbladder. Other functional disorders may also mimic chronic cholecystitis.

Complications

The complications of chronic cholecystitis include acute exacerbations (acute cholecystitis), passage of stones into the bile duct (choledocholithiasis or Mirizzi's syndrome), pancreatitis, cholecystenteric fistula formation and gallstone ileus, and rarely carcinoma of the gallbladder. Occasionally the accumulation of mucus and gallstones produces hydrops of the gallbladder, which is characterized by a tender mass without the symptoms of acute cholecystitis.

Treatment

In established cases of chronic cholecystitis the treatment of choice is cholecystectomy. When the diagnosis is in doubt, especially when vague symptoms are associated with a well-functioning gallbladder containing stones, a conservative approach is worth trying. This includes weight reduction and a low-fat diet, especially if fatty food is associated with the symptoms. Oral bile acid therapy may also be considered (see above).

Prognosis

Chronic cholecystitis carries a good prognosis. Cholecystectomy is curative and should have a mortality below 1 per cent. However, if cholecystectomy is performed indiscriminately on patients with 'dyspeptic' symptoms who happen to have incidental gallstones, the results will be unpredictable and often unsatisfactory.

Choledocholithiasis

Most stones in the common bile duct originate in the gallbladder. About 15 per cent of patients with cholelithiasis have common duct stones. This proportion rises with age so that in the elderly nearly 50 per cent of patients with cholelithiasis may have common duct stones. Stones may develop in the bile duct in diseases causing chronic biliary obstruction such as benign bile duct strictures and sclerosing cholangitis.

Clinical features

The classic triad of symptoms is right upper abdominal pain, jaundice, and fever. The abdominal pain is typically colicky, severe, and persists for hours. It is often associated with vomiting. Fever and rigors indicate cholangitis, which commonly accompanies bile duct stones. Jaundice is variable; it may be mild or deep and is often intermittent. The urine is dark due to conjugated bilirubin and the faeces are pale. Frequently, the amount of pigment in the faeces varies. Itching may be prominent. However, common bile duct stones may also be silent, especially in the elderly. Alternatively, only one of the triad of symptoms may be present; the patient presenting with jaundice, abdominal pain, or cholangitis. The liver is moderately enlarged and there may be tenderness in the right upper quadrant. Prolonged biliary obstruction lasting months or years eventually leads to biliary cirrhosis with portal venous hypertension and liver cell failure.

Laboratory investigations

Liver function tests show a cholestatic (biliary obstructive) pattern. The prothrombin time may be prolonged due to inadequate absorption of vitamin K. A polymorphonuclear leucocytosis is common and indicates biliary infection. Blood cultures should be performed repeatedly during the fevers to isolate the organism and determine sensitivities.

Imaging techniques

A plain radiograph of the abdomen will show calcified gallstones in 10 per cent of patients, but is rarely performed now. Ultrasonography is useful for demonstrating the dilated biliary tree that results from obstruction and may reveal biliary gallstones. Unfortunately, ultrasound frequently fails to detect common duct stones obstructing the lower end of the bile duct. Cholangiography by ERCP is required in these patients (Fig. 5). Common bile duct stones should be removed by endoscopic sphincterotomy before the patient is submitted to cholecystectomy.

Fig. 5 Choledocholithiasis. An endoscopic retrograde cholangiogram shows multiple faceted radiolucent stones in a dilated bile duct. The gallbladder has not been opacified.

Differential diagnosis

Common duct stones are the most common cause of cholestatic (biliary obstructive) jaundice. Next in frequency are carcinomas of the head of the pancreas, bile duct, and ampulla of Vater (Table 1). Intrahepatic diseases may also cause a cholestatic jaundice; the causes include viral and alcoholic hepatitis, drugs, and pregnancy.

Treatment

Common bile duct stones must be removed. The optimal treatment is endoscopic sphincterotomy to remove bile duct stones followed by laparoscopic cholecystectomy. This approach avoids the hazards of open exploration of the common bile duct. Endoscopic removal of common duct gallstones without cholecystectomy is appropriate in patients unfit for surgery. Few patients will have further problems from the gallbladder that remains. Stones overlooked at surgery (residual calculi) are best treated by endoscopic sphincterotomy or, if a T-tube is in place, removed by a steerable basket-catheter manipulated down the T-tube track. Open exploration of the common bile duct is required if gallstones are too large to be removed endoscopically (more than 2 cm). Preoperative preparation includes appropriate antibiotics for cholangitis, the correction of fluid and electrolyte balance, nutrition, and anaemia, and if the prothrombin time is prolonged, parenteral vitamin K.

Postcholecystectomy syndromes

After cholecystectomy a proportion of patients continue to complain of symptoms such as right upper quadrant pain, flatulence, and fatty food intolerance. However, the vast majority of patients with gallstones are improved by surgery. The persistence of symptoms in many is probably a consequence of the wrong diagnosis being made before surgery and other diseases such as oesophagitis, pancreatitis, or functional bowel disease should be sought. In others, technical problems during surgery may have resulted in a benign post-traumatic biliary stricture or residual calculi. However, there remains a group of patients where the cause appears to be due to less common biliary disorders such as long, dilated cystic duct remnants, amputation neuromas of the cystic duct, and spasm or stenosis of the sphincter of Oddi. The biliary tract must be carefully investigated in these patients, especially if colicky pain, fever, jaundice, or cholestatic liver function tests persist. Biliary tract manometry is of value when spasm or stenosis of the sphincter of Oddi is suspected.

Biliary infections

Bacterial cholangitis (suppurative cholangitis)

This is usually associated with common bile duct calculi and benign biliary structures. Malignant structures produce complete obstruction and the bile remains sterile. Other conditions associated with cholangitis are biliary enteric fistulas—both spontaneous and surgical—sclerosing cholangitis, and congenital intrahepatic biliary dilation (Caroli's disease). Organisms of the gut flora are usually cultured in these infections, including aerobes such as *E. coli*, *Streptococcus faecalis*, *Proteus vulgaris* and staphylococci, and anaerobes such as bacteroides, aerobacter, and anaerobic steptrococci.

Clinical features and treatment

The onset of malaise, fever, and rigors is followed by pain, vomiting, jaundice, and itching. The urine turns dark and the faeces pale. The biliary obstructive features are probably due to oedema of the bile duct wall. Recurrent attacks are common. Hepatic abscesses may result. Repeated blood cultures are performed during the fever to isolate the organisms. Culture of a liver biopsy fragment may also yield the organism. The main element of treatment is drainage of the biliary tract, which is best achieved by emergency endoscopic sphincterotomy. Additionally, appropriate antibiotics such as cefuroxime and metronidazole are given. For recurrent attacks of cholangitis, tetracycline, amoxicillin, or cephalexin are usually effective.

Infestations

Infestations (see Section 7) with the roundworm *Ascaris lumbricoides* and the liver fluke *Clonorchis sinensis* are particular problems of the Far East. Both lead to cholangitis. *C. sinensis* infestation predisposes to bile duct carcinoma and primary liver cancer. The common sheep fluke *Fasciola hepatica* may be encountered as a cause of cholangitis in Europe during wet summers.

Benign biliary strictures

In about 95 per cent of patients these are a consequence of biliary tract surgery. The remainder are caused by gallstones eroding the bile duct and, rarely, blunt injury to the abdomen. Signs of biliary stricture may be detected in the immediate postoperative period but are often delayed. Disasters such as ligation or section of the bile duct present early with jaundice and drainage of bile from the wound drains. With lesser damage to the duct the patient presents after an interval with cholangitis and jaundice. Liver function tests reveal a cholestatic pattern and blood cultures may yield an organism. The precise delineation of the stricture requires ERCP or PTC. Biliary stricture is not a benign condition; untreated it will usually progress to biliary cirrhosis with portal venous hypertension and liver failure. Treatment is surgical and should be performed by a surgeon skilled in this difficult repair.

Malignant biliary stricture

This is most commonly due to adenocarcinoma of the head of the pancreas but may also be caused by adenocarcinomas of the bile ducts, of the ampulla of Vater, and rarely of the gallbladder. Occasionally the cause is lymph node enlargement at the porta hepatis due to malignant metastases or lymphoma.

Symptoms and signs

Cancers of the pancreas and biliary tree (Fig. 6 and Fig. 7) usually affect middle-aged and elderly individuals. The onset is insidious with deepening jaundice, itching, and weight loss. A dull nagging upper abdominal pain which radiates to the back is common. In contrast to choledocholithiasis and benign strictures, cholangitis is unusual. Examination reveals a deeply jaundiced patient often excoriated from scratching. The liver is enlarged but not tender. If the malignant obstruction is below the level of the cystic duct, the gallbladder is distended and may be palpable (Courvoisier's law). The urine is dark and the stools pale. In cancer of the ampulla of Vater, a film of blood on the pale stool may give it a silvery colour ('silver stools').

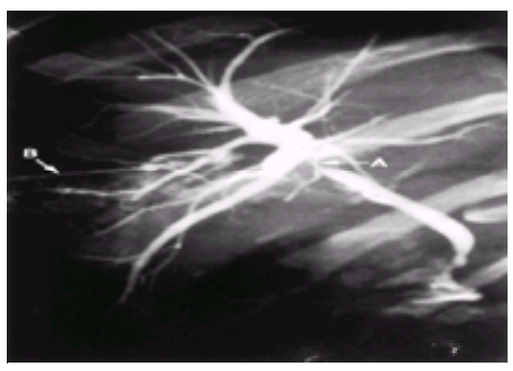

Fig. 6 Carcinoma of the bile duct. A percutaneous transhepatic cholangiogram (PTC) shows a stricture (a) high in the bile duct at the porta hepatis intrahepatic bile ducts are moderately dilated. The transhepatic track of the 'skinny' needle used for the PTC is also visible (b).

Fig. 7 Carcinoma of the pancreas. The percutaneous transhepatic cholangiogram shows a very dilated biliary tree which terminates in a blunt 'nipple-like' obstruction (arrow) at the lower end of the common bile duct. This is the usual finding in the cancers of the head of the pancreas which obstruct the bilary system.

Laboratory investigation

Liver function tests reveal a cholestatic pattern. The serum bilirubin may be very high (600 µmol/l; 35 mg/dl). A microcytic hypochromic anaemia indicates blood loss from the tumour.

Imaging techniques

An ultrasound or CT scan examination will reveal dilatation of the biliary tree and may demonstrate the level of the obstruction. Ultrasound-guided percutaneous needle biopsy may be employed to provide a histological diagnosis. Bile duct carcinoma frequently causes obstruction at the porta hepatis and, consequently, at laparotomy the extrahepatic biliary tract appears non-dilated. Even if operative cholangiography is performed, the constrast medium frequently fails to pass the obstruction and fill the dilated intrahepatic biliary tree. Therefore it is important to establish the diagnosis precisely before surgery is contemplated by performing an ERCP or PTC. This is particularly important because most of these patients are best treated by endoscopic or percutaneous biliary stents rather than surgery (see below).

Treatment

Occasionally small tumours confined to the head of the pancreas and ampulla of Vater may be treated curatively by a Whipple's operation. Unfortunately the great majority of pancreatic and bile duct cancers can only be treated palliatively with a bypass procedure such as a cholecystojejunostomy. The prognosis for these patients is poor. An alternative treatment is endoscopic or percutaneous transhepatic introduction of prostheses (stents) through the biliary stricture. Patients with endoscopic prostheses have the same median survival as those with surgical bypass procedures, but the operative mortality and morbidity rate is much lower for endoscopic prostheses. Endoscopic prostheses are the preferred treatment for unresectable biliary and pancreatic cancers. The prostheses may block after about 3 months and need to be replaced.

Other causes of bile duct obstruction

Pancreatitis may obstruct the common bile duct during its passage through the head of the pancreas. Transient jaundice is common in acute pancreatitis due to compression by pancreatic oedema. In chronic pancreatitis, especially alcoholic, persistent jaundice can develop requiring a surgical bypass procedure such as a cholecystojejunostomy. This biliary obstruction is probably a consequence of pancreatic fibrosis. Pancreatic cysts may rarely cause extrinsic compression of the bile duct. Haemobilia or haemorrhage into the biliary tract is uncommon but may follow trauma, liver biopsy, biliary tumours, and gallstones. In addition to jaundice, the blood clots cause biliary pain. Massive gastrointestinal haemorrhage may occur. The diagnosis of these conditions relies on accurate cholangiography (usually ERCP).

Sclerosing cholangitis

Sclerosing cholangitis is the description applied to multiple strictures and bead-like dilatations of the intrahepatic and extrahepatic biliary tree.

Primary sclerosing cholangitis (Fig. 8)

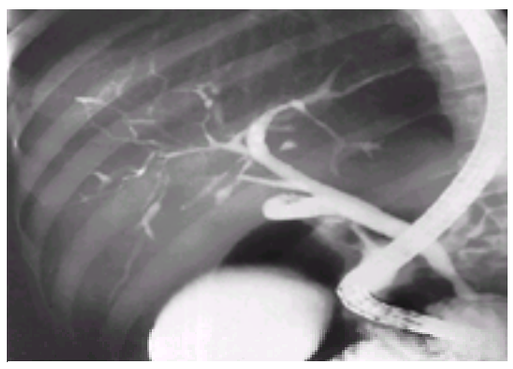

Fig. 8 Primary sclerosing cholangitis. The intrahepatic bile ducts show alternate strictures and dilatations ('beading'). The common bile duct, cystic duct, and gallbladder appear normal in this study but may also be involved.

This should only be diagnosed if the following criteria are satisfied: (i) absence of gallstones; (ii) absence of previous biliary surgery; and (iii) sufficiently long follow-up to exclude carcinoma of the bile duct. Primary sclerosing cholangitis affects males more than females (2:1) and about 70 per cent of patients have ulcerative colitis. The usual clinical presentation is cholestatic jaundice and cholangitis. However, a significant proportion of patients are asymptomatic or present with cirrhosis and portal venous hypertension. There is associated retroperitoneal fibrosis or Riedel's thyroiditis in some cases. Serum biochemistry shows cholestatic liver function tests. A raised serum alkaline phosphatase is almost invariable. Consequently the diagnosis should be considered in patients with cirrhosis whose liver function tests show cholestatic features. The IgM concentration is commonly elevated. Liver biopsy may be helpful and usually indicates large bile duct obstruction. The diagnosis is established by cholangiography with ERCP or PTC. Laparotomy should not be performed. Lone tight strictures and stones can be treated by endoscopic techniques. Primary sclerosing cholangitis is being recognized more frequently as a result of the widespread use of ERCP and PTC. It may be confused with primary biliary cirrhosis, but the serum mitochondrial antibody is always negative in primary sclerosing cholangitis. Treatment is unsatisfactory, neither corticosteriods nor azathioprine are of proven value. Ursodeoxycholic acid improves liver function tests but has not been shown to prolong survival. Pruritus may be helped by cholestyramine. The prognosis is variable but most patients eventually develop cirrhosis and liver failure. Liver transplantation yields excellent results in these patients. Bile duct adenocarcinoma is a late complication.

Secondary sclerosing cholangitis

Several causes of secondary sclerosing cholangitis are now recognized. These include recurrent bacterial cholangitis due to gallstones or benign biliary strictures. Children with primary immunodeficiency syndromes and patients with AIDS also develop sclerosing cholangitis. Cytomegalovirus and cryptosporidium are the organisms most commonly associated with AIDS-related sclerosing cholangitis. Sclerosing cholangitis may also develop in patients treated by hepatic arterial infusion of cytotoxic drugs and after the introduction of caustics into hydatid cysts.

Congenital disorders of the gallbladder and biliary tract

This subject is discussed in Chapter 14.19.1.

14.19.3 Jaundice

R. P. H. Thompson

Jaundice is the clinical sign of hyperbilirubinaemia, and hence usually indicates disease of the liver or biliary tree. The pigment in the tissues in best seen as yellowing of the sclera; eventually the skin and soft palate become tinted, but not saliva or sputum. The urine usually becomes dark. Rarely, carotenaemia, from eating excessive carrots or vitamin A, can mimic jaundice, but its colour is more prominent in the palms than the sclera.

Physiology of bilirubin (Fig. 1)

Fig. 1 The porphyrin–bilirubin pathway.

All haem molecules in haemoglobin or cytochrome enzymes are stoichiometrically (1:1) degraded to bilirubin, especially in the spleen and liver, but also in macrophages in other tissues, including skin, and in renal tubular cells. Haem oxygenase enzymes break open the asymmetric tetrapyrrole haem molecule specifically at the a-methene bridge, releasing carbon monoxide and iron. One principal isomer of biliverdin, namely IXa, is formed, although small amounts of the other three possible isomers (b, g, and †) can be detected in bile. The excretion of carbon monoxide in breath can be used quantitatively to determine the breakdown of haem to bilirubin, of which 200 to 350 mg (340 to 600 µmol) is produced daily. About 85 per cent of biliverdin and bilirubin is derived from the delayed breakdown of the haemoglobin in effete red blood cells, while the remainder is either from the breakdown of haem proteins, chiefly in the liver, or from ineffective erythropoiesis in the bone marrow; these constitute the so-called 'early labelled' bilirubin, defined by isotopic studies *in vivo*.

Biliverdin is green and is directly excreted in bile by birds, amphibians, and reptiles but not by mammals. Biliverdin is reduced by the cytosolic enzyme biliverdin reductase in liver and spleen to the yellow bilirubin IXa, which has then to be excreted. The reason for this difference was obscure, for bilirubin is lipid soluble, and potentially toxic, and has to be conjugated before it is excreted in bile, while biliverdin is water soluble and can be readily excreted in urine and bile by mammals. However, bilirubin is an antioxidant or free radical scavenger in plasma and bile, particularly when bound to copper, and this may be especially important in the neonate, especially when levels of the antioxidant ascorbate are low. Hence bilirubin probably has a function and is not just a waste product. Bilirubin is surprisingly lipid soluble, this being due to internal hydrogen bonding in the molecule so that it forms a tight, non-polar, non-linear, three-dimensional structure. After its release from macrophages, it is firmly bound to plasma albumin, so that none enters the urine. At high concentrations in the blood it slowly diffuses into tissues, where it can be toxic, particularly in the neonatal brain (kernicterus) or kidney. Jaundice is usually less obvious in unconjugated hyperbilirubinaemia since its diffusion into the tissues is more limited.

The circulating pool of bilirubin in the plasma (about 100 µmol) is almost all unconjugated. Routine measurements still rely on the Van den Bergh diazo reaction, which yields either an indirect (unconjugated bilirubin) or direct reaction (conjugated) and, although this overestimates the true level of conjugated bilirubin, the results indicate whether or not circulating bilirubin is wholly unconjugated. The direct and indirect reactions depend on the slow reaction of the unconjugated bilirubin with the reagent, which is accelerated when solvents such as methanol, which break the internal hydrogen bonding, are added. The normal range of plasma bilirubin is wide (about 5 to 19 µmol/l), reflecting wide variation in the rate of conjugation in the liver, and is higher than in most other mammals in whom clearance and excretion are more efficient. The distribution of values is Gaussian, so that the true upper limit of normal is arbitrary (see Gilbert's syndrome). Hepatic enzyme-inducing drugs reduce the plasma level by increasing conjugation and hence clearance.

Bilirubin is selectively removed by hepatocytes from sinusoidal blood, although its plasma clearance (about 50 ml/min) is low compared, for instance, with that of bile acids, and hence its extraction (1.5 per cent of plasma pool/min) is dependent more upon hepatocyte distribution and function than on blood flow. It is initially surprising that bilirubin can be displaced from its plasma binding sites and enter hepatocytes, and specific hepatic cytoplasmic binding proteins have been described. Nevertheless, binding to the active site of the microsomal conjugating enzyme uridyl diphosphate (**UDP**)-glucuronyl transferase should be sufficient to maintain a low level of free bilirubin in the cytoplasm, which, without the need for specific transfer proteins, should alone produce a gradient sufficient to allow bilirubin slowly to enter the hepatocyte. Uptake of bilirubin is facilitated by the direct contact of plasma with the hepatocyte in the interstitial space of Disse through fenestrations in the endothelium of hepatic blood capillaries. Although uptake into the cell predominates, dynamic studies show that there is considerable reflux of bilirubin back out of the cell to the plasma.

Within the hepatocyte bilirubin is principally conjugated by one of the two specific isoforms of the microsomal enzyme UDP-glucuronyl (glucuronate-glucuronosyl) transferase, chiefly with two glucuronic acid moieties. Conjugated bilirubin is excreted out of the endoplasm reticulum and then across the microvillous intercellular canalicular membrane by the anionic conjugate transporter protein (**mrp2**; or cMOAT). Hepatocytes have a separate canalicular bile salt export pump protein (bsep). mrp2 also transports other multivalent anions, such as conjugated bromsulphthalein. Minor quantities of bilirubin are conjugated with one glucuronic acid molecule (monoglucuronide) or with combinations of related sugars (xylose, glucose); a small amount of unconjugated bilirubin also appears in bile. The chemical properties of the conjugated molecules are quite different from those of unconjugated bilirubin, for there is no internal hydrogen bonding of bilirubin—they now become more linear, fully water-soluble molecules and are efficiently excreted in bile. In many liver diseases conjugated bilirubin readily refluxes back into blood and, since it is water soluble and less firmly bound to albumin than unconjugated bilirubin, about 1 per cent is filtered across the glomerular membrane and enters the urine (choluria).

Excretion of conjugated bilirubin is increased by the bile acids that also accumulate in cholestasis. If renal function is normal, renal excretion of bilirubin matches production when conjugated bilirubin levels in the plasma reach about 600 µmol/l. With renal failure, or haemolysis, plasma levels rise higher. Little bilirubin, even conjugated bilirubin, diffuses through renal dialysis membranes.

Recently it has been shown that deconjugated bilirubin can undergo a substantial enterohepatic circulation; it is absorbed from the colon, particularly when there is bile acid malabsorption and hence the concentration of bile acids is increased in the colon, for example as a result of ileal disease or resection. This reabsorption increases the concentration of bilirubin re-excreted in bile, and may in part explain the increased incidence of pigment gallstones in patients with ileal disease. Similarly, fasting increases unconjugated bilirubin levels in the plasma by increasing the reabsorption of bilirubin.

In the distal intestine, conjugated bilirubin is deconjugated and reduced to a series of sterco- and urobilinogens that give the normal colour to faeces. Some colourless urobilinogen is normally absorbed from the colon and undergoes an enterohepatic circulation, with a small amount being excreted in urine. If this circulation and biliary excretion is impaired in liver disease, or increased in haemolysis, then excess urobilinogen is excreted in urine, where it can oxidize on standing to brown urobilins. Urobilinogen is easily detected by routine clinical 'stix'. Ehrlich's aldehyde reagent was at one time used, and when added to urine containing excess urobilinogen it turns it red; the urobilinogen pigment can then be extracted into an organic solvent such as chloroform, unlike the pigment formed from the more polar porphobilinogen adduct in acute porphyria, which remains in the aqueous phase.

Management of jaundice

Complex algorithms of management of the patient with hyperbilirubinaemia or jaundice have been published, but a simple pragmatic approach is proposed here (Fig. 2).

Fig. 2 Investigation of jaundice.

Raised plasma bilirubin levels, and eventually frank jaundice, are due primarily to excessive unconjugated or conjugated bilirubin in blood, depending on whether the abnormality in bilirubin metabolism is in its production and/or conjugation, or in the subsequent hepatic excretion of conjugated bilirubin, respectively. Impaired excretion is almost always combined with impaired bile flow and is best termed cholestasis. When other liver-related blood tests are abnormal, especially the biliary enzymes alkaline phosphatase and g-glutamyl transpeptidase, serum bile acids are also raised, there is often itching, and the microvilli lining the biliary canaliculi are injured. Examination of a liver biopsy specimen taken from a patient with cholestasis under light microscopy may show bile plugs. This finding is, however, often termed 'obstructive jaundice', an unfortunate term, since this implies extrahepatic obstruction of the biliary tree. The molecular events underlying some forms of cholestasis are now being unravelled (see below).

History

Dark urine and, less commonly, pale stools indicate cholestasis. Many drugs, including alcohol, can be a cause of unconjugated and conjugated hyperbilirubinaemia and should be rigorously enquired about. Fever (hepatitis, cholangitis, abscesses), travel (hepatitis, amoebiasis), sexual history (hepatitis A, B, or C), surgery and anaesthesia (postoperative jaundice, see below; biliary tract disease), herbal medicines (e.g. West Indian teas, Chinese herbs), and transfusions and blood products (hepatitis B or C) can be important clues.

Clinical examination

Stigmata of chronic liver disease (e.g. spider naevi, facial telangietases, parotid enlargement, Dupuytren's contractures, muscle wasting, hepatosplenomegaly, and ascites) are important, but do not define the cause of jaundice.

Testing for unconjugated hyperbilirubinaemia

If serum bilirubin alone is abnormal among the liver-related blood tests, unconjugated hyperbilirubinaemia should first be excluded by testing whether the bilirubin in blood is predominantly conjugated or unconjugated. A normal reticulocyte count will usually exclude haemolysis severe enough to cause raised bilirubin levels and blood film examination may be additionally informative. Suspected haemolysis is investigated as described elsewhere. If no cause of unconjugated hyperbilirubinaemia is identified, then benign constitutional unconjugated hyperbilirubinaemia (Gilbert's syndrome) is diagnosed (see below).

Conjugated hyperbilirubinaemia

The familial syndromes without cholestasis (Dubin–Johnson and Rotor) are rare (see below).

Routine liver-related blood tests cannot differentiate between intra- or extrahepatic causes of jaundice, unless the transferases are very high (e.g. more than 1000 IU/l), in which case hepatitis (e.g. viral, alcoholic) is certain. A greatly raised alkaline phosphatase level does not necessarily imply an extrahepatic lesion; intrahepatic causes are common (Table 1). Research methods for assessing liver function (e.g. galactose tolerance test, aminopyrine breath test) are of no value in the management of the patient with jaundice.

Cholestasis should be investigated first with abdominal ultrasonography, which should accurately detect a dilated intra- and/or extrahepatic biliary tree and often also reveal its cause (e.g. gallstones, tumour). Cholecystography or intravenous cholangiography will fail in the presence of jaundice. If biliary disease is thus suspected, then an endoscopic retrograde cholangiogram (ECRP) or, failing that, a fine-needle, percutaneous, transhepatic cholangiogram (PTC), will define the anatomy more accurately and often provide definitive therapy (removal of biliary stones, stenting), thus often avoiding surgery. Magnetic resonance cholangiography (MRC) is increasing in sensitivity and availability and can now produce high-quality non-invasive images of the biliary tree and pancreas; it is useful even for intrahepatic biliary disease. It cannot, of course, be therapeutic. Endoscopic ultrasonography (EUS) can show accurately the presence of stones, biliary or pancreatic tumours, and sclerosing cholangitis, while g-camera scans with technetium-labelled **HIDA** (hepato-iminodiacetic acid) can be used to indicate biliary obstruction, particularly in the neonate, if ultrasonography is normal.

If intrahepatic cholestasis is suspected because of a non-dilated biliary tree on ultrasound, the following tests should be considered: hepatitis A, B, or C serology, autoantibodies (antimitochondrial for primary biliary cirrhosis, smooth muscle and liver–kidney microsomal for autoimmune chronic hepatitis), serum caeruloplasmin and copper for Wilson's disease if less than 40 years of age, or plasma a $_1$-antitrypsin concentrations for homozygous deficiency. Intrahepatic masses on ultrasound will prompt measurement of a-fetoprotein for primary hepatoma and other tumour markers. A percutaneous needle liver biopsy (or aspiration of an abscess) may then be indicated, provided that blood coagulation parameters and the platelet count are normal. Guidelines for liver biopsy have recently been published. A transjugular venous approach for the biopsy is appropriate if the risks of bleeding are increased.

Unconjugated hyperbilirubinaemia

Plasma bilirubin levels are exponentially and positively related to the half-life of circulating red blood cells (i.e. bilirubin load), and negatively to the hepatic clearance rate of bilirubin. This relationship is analogous to that of muscle breakdown, plasma creatinine, and glomerular filtration rate. Hence, as the rate of haemolysis rises or clearance falls, bilirubin levels may rise rapidly in response to small changes of the input load or removal rate from plasma, or both.

Haemolytic jaundice is most commonly encountered in the haemoglobinopathies of sickle-cell anaemia (homozygous SS or heterozygous SC disease) or homozygous thalassaemia major, although dark skin may render it difficult to detect. The 'acholuric jaundice' of hereditary spherocytosis is rare. Mildly elevated bilirubin levels are described in ineffective erythropoiesis of the bone marrow, in vitamin B_{12} deficiency (pernicious anaemia), or in thalassaemia minor.

Drugs may cause haemolysis (e.g. methyl DOPA, sulphasalazine), or impair hepatic bilirubin clearance (e.g. rifampicin). Infections (e.g. malaria) or mismatched blood transfusions can produce massive haemolysis, but this overshadows the raised bilirubin levels. Autoimmune haemolytic anaemia, glucose-6-phosphate dehydrogenase deficiency, and haemolysis due to leaking prosthetic cardiac valves may cause obvious clinical jaundice that may escape diagnosis before the true nature of the hyperbilirubinaemia is recognized.

Familial unconjugated hyperbilirubinaemia

A series of defects of the hepatic conjugating enzyme UDP-glucuronyl transferase produce various degrees of unconjugated hyperbilirubinaemia due to impaired bilirubin clearance; they have long fascinated physiologists and more recently molecular biologists.

At least 3 per cent of the normal adult population have mildly raised unconjugated bilirubin levels in blood that rise excessively on fasting. This 'phenomenon' is commonly termed Gilbert's syndrome, although it is unclear whether the eponym is justified. The raised concentrations of bilirubin develop in early adult life and are often associated with mild degrees of haemolysis. Various associated defects of hepatic drug metabolism have also been described and these are probably linked genetic abnormalities. Any combination of an increased bilirubin load from the haemolysis and a mildly impaired clearance will increase plasma bilirubin concentrations more than would either alone, and hence together they bring the condition to notice. It is probably not a discrete entity but rather different defects of conjugation that elevate bilirubin levels above an arbitrary upper limit of normal. Determination of the bilirubin-conjugating capacity of liver biopsy tissue has shown that the activity of glucuronyl tranferase is reduced by 60 to 70 per cent, and this impairs bilirubin clearance.

Gilbert's syndrome is recognized by a fluctuating, raised serum bilirubin concentration with other routine liver-related blood tests being normal, and a normal reticulocyte count to exclude overt haemolysis. It can be confirmed by measuring the unconjugated fraction of the bilirubin, which should be greater than 90 per cent. Measuring the pronounced increase of plasma bilirubin that occurs after a 48-h fast on 400 kcal/day or provocation with intravenous nicotinic acid are now generally considered to be research procedures of little clinical value. A liver biopsy is rarely needed. Reassurance that the results do not indicate liver disease and will not affect life insurance is important. Plasma bilirubin concentrations rise in patients with Gilbert's syndrome during intercurrent illness when frank jaundice may be observed.

It is said that Gilbert's syndrome can follow an attack of viral hepatitis, although this may be simply due to ascertainment bias in a population with a high underlying prevalence of the biochemical anomaly.

Crigler–Najjar syndromes

Two syndromes of more severe unconjugated hyperbilirubinaemia have been described, namely the rare type I (100 cases reported), which often causes neonatal death, and the more common, and benign type II. Both are due to severe deficiency in the UDP-glucuronyl transferase enzymes.

In type I, first reported in 1952, with an autosomal recessive inheritance, neonates rapidly become progressively jaundiced in the first days of life (bilirubin levels reach 350 to 950 µmol/l) and, if untreated, develop kernicterus or brain damage. Death usually occurs within a year but delayed kernicterus has been reported. There is no conjugated bilirubin in bile, but small quantities of unconjugated bilirubin can be found in bile and cross the intestinal wall.

The inheritance of type II is complex, and is reported both to be dominant with incomplete penetrance or autosomal recessive. Bilirubin levels are lower (less than 350 µmol/l), and persistent mild jaundice is only noticed in childhood. Brain damage does not occur, and the only problem is cosmetic. One-third of the conjugated bilirubin in bile is present as the monogluronide (normally less than 10 per cent).

In the Gunn strain of rat, severe unconjugated hyperbilirubinaemia occurs and glucuronyl transferase activity is absent in the liver, as it is in Crigler–Najjar type I. In type II, enzyme activity is less than 10 per cent of normal, but measurable.

It has long been known that there is a spectrum of bilirubin levels in type II Crigler–Najjar and Gilbert's syndromes and indeed both conditions have been observed within families, suggesting different degrees of enzyme activity. Phenobarbitone or other hepatic microsomal enzyme-inducing agents markedly reduce bilirubin levels in Gilbert's and Crigler–Najjar type II syndromes, although unfortunately not in Crigler–Najjar type I, and increase the activity of glucuronyl transferase. Such treatment, however, is not needed, except possibly for cosmetic purposes.

Molecular analysis of the genes encoding human UDP-glucuronyl transferases has clarified the genetic basis and inheritance of these disorders. The two complementary DNAs for the two human bilirubin UDP-glucuronyl transferase isoforms have been sequenced; they differ from those that encode the other glucuronyl transferases that conjugate, for instance, steroids. The UDP-glucuronyl transferases map to human chromosome 2, where at least seven exons encode the specific mRNAs of the isozymes, together with a common region for the glucuronyl transferases. Analysis of DNA from five patients with type I Crigler–Najjar syndrome has identified homozygous or heterozygous defects in the common structural exons encoding the two bilirubin glucuronyl transferase isoforms—similar defects occur in the Gunn rat.

In Crigler–Najjar type II syndrome, initial studies have found mutations in the upstream regulating region of the gene encoding the active bilirubin glucuronyl transferase isoform. Phenobarbitone induces the expression of the abnormal enzyme, explaining its efficacy in this condition. Probably a heterozygous combination of an abnormality of the promoter region (Gilbert's defect; see below) and this Crigler–Najjar defect is responsible for the phenotype of type II Crigler–Najjar syndrome. This explains the presence of patients with Gilbert's syndrome within families with type II Crigler–Najjar.

The genetic basis of Gilbert's syndrome remains controversial but it appears that it is an autosomal recessive condition in which there is a homozygous abnormality in the promoter region affecting expression of the specific glucuronyl transferase gene. Heterozygotes have normal bilirubin levels. There must be another factor responsible for the increased bilirubin concentrations as the heterozygote abnormality occurs in 40 per cent of healthy individuals without hyperbilirubinaemia. Moreover, some individuals who are homozygous for the defect have normal plasma concentrations of conjugated bilirubin. The bilirubin load from red cell breakdown will influence plasma concentrations.

Crigler–Najjar type I syndrome can now be successfully treated by whole-body blue-light phototherapy for 16 h daily (see below), or by plasmapheresis until orthotopic liver transplantation can be carried out as a definitive cure. Severe kernicterus is a contraindication to transplantation as it is not reversible. About 20 patients have so far received transplants, with two deaths. Hepatocyte transplantation, in which donor hepatocytes are infused into the portal vein, has been partially successful, and clearly has potential for development. Drugs that displace unconjugated bilirubin from albumin (sulphonamides, salicylates, penicillin) will increase brain damage in Crigler–Najjar syndrome and must be avoided.

Neonatal jaundice

Unconjugated hyperbilirubinaemia, often with mild clinical jaundice, occurs in all full-term newborn infants. Bilirubin concentrations are maximal at 2 to 5 days after birth but the plasma bilirubin rarely exceeds 90 µmol/l; neonatal jaundice is more severe in premature infants. It is attributed to a combination of immaturity of hepatic glucuronyl transferase and the added load of bilirubin from rapid haemolysis of surplus fetal red blood cells in the neonatal period. Before birth, fetal bilirubin is

excreted by the mother, and meconium as well as stools are pale because of the reduced excretion of bilirubin.

If haemolysis is increased, as in rhesus or other fetomaternal incompatibility of red cell antigens, causing haemolysis of fetal red blood cells by maternal antibodies, then severe jaundice and kernicterus can occur. Acidosis and some drugs (sulphonamides, salicylates, penicillin) may increase kernicterus by displacing unconjugated bilirubin from albumin. Glucose-6-phosphate deficiency can also cause jaundice and anaemia in the neonatal period and is usually observed in infants of Mediterranean, African, or Chinese ancestry.

Treatment with phenobarbitone induces hepatic glucuronyl transferase but its effect is slow unless given to the mother before birth. Exchange transfusion or plasmapheresis are more effective. Phototherapy, namely exposure of the near-naked infant to blue light in an incubator, is also very effective. Being yellow, bilirubin absorbs light at approximately 450 nm and is sensitive to light, which oxidizes it to water-soluble, non-toxic products. Hence, exposure of the bilirubin in skin capillaries to light reduces plasma concentrations; the breakdown products are excreted safely in urine and bile. Reabsorption of bilirubin from the intestine can also be reduced by giving agar by mouth, thus interrupting the enterohepatic circulation.

Breast feeding slightly increases bilirubin levels and about 1 in 40 breast-fed infants develop jaundice, which remits on transfer to cow's milk for 24 h; this jaundice does not always recur when breast milk is reintroduced. Breast feeding increases the enterohepatic cycling of bilirubin from the intestine, since stool weights and frequency are less than with formula feeds. A further effect of steroid molecules that inhibit glucuronyl transferase activity in the neonatal liver and that are present in breast milk has also been postulated.

Hypothyroidism increases jaundice and should be sought in patients with unexplained hyperbilirubinaemia since it may not be associated with obvious neonatal cretinism. The rare Crigler–Najjar type I syndrome presents with florid jaundice in the first few days of life.

Sickle-cell anaemia and b-thalassaemia

Jaundice is common in homozygous sickle-cell anaemia due to the unconjugated hyperbilirubinaemia from persistent haemolysis. During crises jaundice often deepens in association with increasing anaemia, suggesting accelerated haemolysis although transient bone marrow failure may also occur. Occasionally, conjugated hyperbilirubinaemia with dark urine occurs during these episodes, and hepatic histology may show areas of necrosis due to thrombosis and bile thrombi. Patients with sickle-cell anaemia are also prone to pigment gallstones, due to the excessive bilirubin excreted, and these can cause extrahepatic biliary obstruction. Unconjugated and conjugated hyperbilirubinaemia both occur in homozygous thalassaemia as a result of increased red cell destruction and intramedullary haemolysis associated with ineffective erythropoiesis.

Cholestasis

There are many causes of intrahepatic cholestasis (Table 1).

Neonatal cholestasis

Conjugated hyperbilirubinaemia or cholestasis in the neonate, with dark urine and pale stools, is always pathological and if it continues beyond 2 weeks of age requires urgent investigation. There are many causes.

In many instances the cause is never established and although once called neonatal hepatitis, it is better termed the hepatitis syndrome; hepatic histology shows hepatitis, sometimes with giant cells. Some babies recover, while perhaps half progress to hypoplasia of the intrahepatic bile ducts, which then overlaps with extra- and intrahepatic biliary atresia.

Infections, particularly urinary, can cause transient cholestasis. Syphilis is now rare, as is toxoplasmosis. Various viral infections (rubella, cytomegalovirus) can cause neonatal jaundice. The hepatotrophic hepatitus B virus contracted from an HBe antigen-positive mother rarely causes jaundice. Metabolic diseases that may be causes of neonatal jaundice include galactosaemia, hereditary fructose intolerance (fructosaemia), and tyrosinosis—all of which need to be diagnosed quickly so as to start dietary treatment early—as well as homozygous a_1-antitrypsin deficiency, and intravenous feeding *per se*. Other genetic diseases include trisomy 13 and trisomy 18 (one-quarter of babies developing the hepatitis syndrome) and cystic fibrosis.

Several familial syndromes presenting with neonatal cholestasis have been described, some with other congenital abnormalities, such as arteriohepatic dysplasia (Alagille's syndrome), and others solely with progressive familial cholestasis, with persistent jaundice, raised serum bile acids, hepatosplenomegaly, steatorrhoea, and failure to thrive, such as Byler's syndrome in Amish families. Bile duct hypoplasia, cirrhosis, and liver failure often follow, unless liver transplantation is carried out. There are several different mutations in the various syndromes of progressive familial cholestasis that affect the function of the FIC-1 gene, so that canalicular biliary bile acid and conjugated bilirubin excretion are severely impaired, and hence cholestasis develops.

Extrahepatic cholestasis in the neonate is most commonly due to biliary atresia, but choledochal cyst or bile duct perforation can also cause jaundice at this age. Biliary atresia appears to represent a form of sclerosing cholangitis with progressive loss of intra- and extrahepatic ducts. HIDA scans, percutaneous liver biopsy, and retrograde cholangiography can establish the diagnosis without laparotomy.

Benign recurrent intrahepatic cholestasis

In this rare syndrome, recurrent reversible episodes of cholestasis start in childhood or adult life. Each attack is characterized by jaundice, anorexia, and itching for several months, which then subsides with no residual effects. Hepatic histology only shows cholestasis. Phenobarbitone or ursodeoxycholic acid may shorten and attenuate attacks. A locus for benign recurrent intrahepatic cholestasis has been mapped to chromosome 18, and the abnormality is similar to some cases of progressive familial cholestasis.

Postoperative jaundice

Jaundice due to halothane hepatitis, post-transfusion viral hepatitis, incompatible blood transfusion, drugs, and bile duct damage is described elsewhere.

Prolonged intrahepatic cholestasis used to be common after cardiac surgery, and for no clear reason is much less commonly seen in intensive care units. It is related to the length of surgery and intraoperative cardiac function, and may be due to reduced hepatic blood flow during surgery. Improvement in intra- and postoperative care seems to have improved hepatic function and rendered the syndrome uncommon. Transfused red blood cells are prone to rapid haemolysis and this increases the bilirubin load, while impaired renal function reduces the urinary excretion of conjugated bilirubin. Drug-induced liver injury should be considered.

Cholestasis of pregnancy

Slight impairment of the hepatic excretion of bilirubin can be demonstrated during normal pregnancy or after the administration of oestrogens, but rarely bilirubin and alkaline phosphatase levels rise during the third trimester and intolerable itching and frank jaundice develop, all of which rapidly remit after delivery. The severity of the syndrome increases in successive pregnancies. The fetus is probably not affected, but premature induction of labour may be needed for the mother's sake. The contraceptive pill frequently causes a milder syndrome in the same susceptible women. Ursodeoxycholic acid is reported to ameliorate the condition and is safe, at least during late pregnancy. Phenobarbitone may help the itching, although there may be a small risk of impairing neonatal respiration. Cholestyramine has also been used.

Other causes of jaundice in late pregnancy should be remembered, including acute fatty liver, extrahepatic biliary obstruction, such as from gallstones, and toxaemia.

Pregnancy, by affecting bilirubin excretion, may bring the jaundice of primary biliary cirrhosis or the Dubin–Johnson/Rotor syndromes to notice.

Sepsis

Abnormal liver-related blood tests, and occasionally cholestatic jaundice, often develop during bacterial/viral infections, unrelated to the administration of drugs. In animals this has been shown to be due to endotoxins and cytokines that rapidly down-regulate and translocate the canalicular transport protein mrp2, which excretes conjugated bilirubin into the canaliculus. At the same time other pump proteins are up-regulated, a complex rearrangement that may protect the hepatocyte against oxidative damage. The degradation and impaired synthesis of mrp2 may explain the strange, slow time courses of some of the remitting cholestatic syndromes. Jaundice is especially common in patients with glucose-6-phosphatase deficiency when they develop sepsis, such as pneumonia, since the haemolysis exacerbates the jaundice. The combination of high bilirubin levels and sepsis is particularly damaging to the kidney.

Dubin–Johnson and Rotor syndromes

There are two rare, familial forms of non-haemolytic, conjugated hyperbilirubinaemia without cholestasis.

The Dubin–Johnson syndrome, first described in 1954, is a chronic, relapsing jaundice, without itching or raised serum bile acids. Other liver-related blood tests are normal, but there are associated defects in the excretion of other anions, such as bromsulphthalein, radiographic dyes, and urobilinogen. Hence cholecystography fails, there is excess urobilinogen in the urine, and a delayed rise of the plasma levels of bromsulphthalein after an injection of the dye due to reflux of the conjugated anion from hepatocytes. Jaundice increases during pregnancy or when taking the contraceptive pill because oestrogens impair bilirubin excretion further. A black pigment accumulates in the liver so that at laparoscopy the liver appears strikingly black, as do needle biopsy specimens. Urinary coproporphyrin excretion is abnormal. The inheritance seems to differ between families, and a similar condition occurs in a mutant strain of Corriedale sheep, although in this instance photosensitivity also occurs. Other families have been described in which there are similar findings but no hepatic pigment, the so-called Rotor syndrome. No treatment of either syndrome is required apart from reassurance, and support when seeking life assurance.

14.20.1 Viral hepatitis—clinical aspects

H. J. F. Hodgson

Many viruses can infect the liver (Table 1). In some patients, hepatic involvement is merely one facet of a systemic infection, and the liver involvement is generally trivial, although occasionally it can be dominant. The liver bears the brunt of infection with the major hepatitis viruses. Thus far, five such viruses have been clearly delineated—A, B, C, D, and E. Other hepatitis viruses are being described and their clinical relevance is under investigation. Viral hepatitis is a major clinical problem worldwide, particularly in developing countries, but no society is exempt.

The clinical effects of infection with a hepatitis virus depend on the severity of the inflammation induced in the liver, and on whether the virus is rapidly cleared from the liver or persists long-term. These in turn reflect the characteristics both of the virus and of the host's immune response. The clinical picture of viral hepatitis is very variable, including fatal fulminant acute hepatitis, acute hepatitis with complete recovery, or chronic infection leading to cirrhosis and predisposing to hepatocellular carcinoma. This chapter will describe the clinical and pathological consequences of viral hepatitis in general, identify virus-specific clinical patterns, and discuss the investigation, management, and prophylaxis of viral hepatitis.

Clinical outcome of hepatitis virus infection

The commonest clinically recognized manifestation of viral hepatitis is an episode of acute icteric hepatitis, generally a self-limited condition with a low mortality and complete recovery. In a typical attack, after an initial prodrome lasting from several days to a couple of weeks—comprising malaise, anorexia, mild fever, and upper abdominal discomfort—jaundice appears. The icteric period typically lasts for a few days to a few weeks, after which the jaundice slowly subsides. Pruritis may occur, generally after the onset of jaundice. Development of ascites or oedema is uncommon but may occur in more severe cases. Return to normality after an attack of hepatitis may take several weeks to a few months and residual fatigue is common.

There are a number of variations on the clinical course of acute hepatitis. Often jaundice does not occur (anicteric hepatitis), and the episode is asymptomatic or dismissed as 'flu-like'. This may occur more frequently than clinically recognized attacks. In cholestatic hepatitis, jaundice with pruritus, pale stools, and dark urine persists for up to 2 or 3 months. Before recovery eventually occurs, a small number of patients have relapsing hepatitis with a transient worsening of jaundice after an initial improvement. Acute hepatitis is only rarely fatal. If it is, patients usually rapidly develop hepatic encephalopathy, and the timing of onset of this has been used to define a variety of syndromes of fulminant hepatitis. One definition is that in 'fulminant hepatitis' encephalopathy develops within 2 weeks of jaundice. Encephalopathy occurs later than this in patients with 'subfulminant hepatitis'. Hepatitis A, B, C, and E can all initiate an acute self-limited hepatitis, although hepatitis C is particularly unlikely to give rise to the fulminant form. Only hepatitis B and C have the propensity to cause chronic viral hepatitis: generally an indolent disease, in which viral carriage in the liver persists over years or decades, with inflammation that varies in intensity. Hepatitis D, which coinfects patients infected with hepatitis B, can contribute to either acute or chronic inflammation.

Features of acute hepatitis caused by different viruses

Hepatitis A virus (HAV)

This causes acute self-limited hepatitis, but not chronic viral carriage or chronic liver disease. The RNA virus is acquired orally. The incubation period is between 2 and 6 weeks. Transmission generally follows the ingestion of food or water contaminated with faeces from an HAV-infected individual. Viral shedding in the faeces ceases at approximately the onset of clinical symptoms. Transmission may occur in epidemics, following floods, or after sewage contamination of shellfish beds. The disease is also endemic in all parts of the world. In developing countries, infection is frequent; there is serological evidence of past infection in up to 100 per cent of 10-year-olds in some countries. In Western countries, evidence of prior infection varies, typically ranging from 5 to 40 per cent dependent on age, social class, and other factors. Promiscuous homosexual males have a high incidence of infection. Very rarely, pooled blood products have transmitted the disease parenterally. Clinically the disease is often anicteric or mild, particularly in young children. About 10 per cent of patients have a relapse before recovery. The mortality rate is low, about 0.3 per cent. Deaths occur predominantly in the elderly amongst whom mortality rates may exceed 2 per cent, and pre-existing chronic viral hepatitis B or C may predispose to a fatal outcome. A rare sequel is aplastic anaemia some months after recovery from hepatitis.

Hepatitis B virus (HBV)

Hepatitis B viral infection was recognized by its parenteral transmission route, classically as serum- and then transfusion-associated hepatitis. The incubation period of this DNA virus varies from 4 to 24 weeks. In between 90 and 95 per cent of adult cases the infection is self-limited and the HBV is cleared. In infants, clearance rates are as low as 5 to 10 per cent. The incidence of acute hepatitis B varies widely, and is very high in the Far East and Africa. Transmission may be vertical—that is, infection of a newborn or infant child usually by a chronically infected mother, either at the time of birth or during close family contact. Horizontal transmission routes include blood transfusion and blood products, the use of contaminated needles medically or by drug addicts, exposure in dialysis units, tattooing, and sexual contact. Promiscuous homosexuals and heterosexuals are at risk.

Anicteric attacks of acute HBV are common. If the acute infection is recognized clinically, in addition to the typical clinical features of any acute hepatitis, the preicteric prodrome may include prominent arthritis, fever, and an urticarial rash, due to immune complex deposition. Hepatitis B is fulminant in about 0.3 per cent of cases, and both the strain of HBV and a very active host immune response may contribute. In the great majority of cases, in which HBV is cleared after acute infection, **HBsAg** (hepatitis B surface antigen) disappears from the blood within weeks to a few months. Failure to clear within 6 months defines 'chronic carriage'.

Hepatitis C virus (HCV)

This was recognized as a cause of transfusion-associated hepatitis. The incubation period ranges from 2 to 26 weeks, but usually between 5 and 12. Apart from blood transfusion and blood product administration, drug addiction and renal dialysis are strong epidemiological associations. Sexual transmission and horizontal transmission are uncommon, but not unknown. Fulminant hepatitis due to HCV is rare. Indeed, the initial acute episode is most often subclinical, but after acquiring the infection 85 per cent of individuals fail to clear the virus. HCV infection is therefore usually not recognized until the chronic phase.

Hepatitis D virus (HDV)

The unique position of hepatitis D virus, an RNA virus 'parasitic' on HBV, has been discussed (Chapter 7.10.19). If HBV and HDV coinfect simultaneously, either unremarkable acute hepatitis, or on occasion fulminant disease, result. If HBV is cleared, HDV must be so also. Acute HDV infection can superinfect a chronic HBV carrier, and result in worsening of liver function, particularly if the hepatitis B virus has previously caused significant liver disease. In such a carrier, the superinfection with HDV may be transient, or chronic hepatitis D carriage may persist. Both coinfection and superinfection are recognized initiators of fulminant hepatitis. In the West, intravenous drug abuse is a prominent epidemiological association, but all parenteral modes demonstrated by HBV occur, including sexual transmission. The southern Mediterranean, the Far East, and South America are areas of high or moderate incidence.

Hepatitis E virus (HEV)

This enterally acquired RNA virus, as is HAV, causes acute hepatitis without chronic carriage. Most major epidemics of acute hepatitis in the Indian subcontinent and the Far East are due to the HEV. Such epidemics affect adults as well as children, indicating that immunity in those areas is not regularly acquired in childhood. Flooding and sewage contamination often precede epidemics. The incubation period is about 6 weeks, and faecal excretion of the virus may persist for nearly 2 months after the onset of hepatitis. A striking feature of HEV infection, and the main clinical difference from HAV, is the propensity to induce fulminant hepatitis if acquired during mid-trimester pregnancy, and mortality rates of 10 to 40 per cent are recorded amongst pregnant women.

Other hepatotrophic viruses

Other hepatotrophic viruses remain to be described, in particular to explain non-A/B/C/D/E fulminant and transfusion hepatitis. Although the hepatitis G virus and transfusion-transmitted virus (**TTV**) have been well characterized, they do not appear to give rise to significant disease.

Clinical examination

Jaundice and right upper-quadrant abdominal tenderness characterize acute hepatitis. Skin manifestations include spider naevi (which often disappear after recovery), scratch marks in the pruritic phase, and rarely a vasculitic or urticarial rash. Mild hepatomegaly is common, but a rapid shrinkage in hepatic size may occur in severe or fulminant hepatitis. Splenomegaly is uncommon, and suggests alternative viral causes such as Epstein–Barr virus or cytomegalovirus, or pre-existing liver disease. Marked nausea and persistent vomiting indicate a severe hepatitis and increase the chance of developing hypoglycaemia. Stools become pale and urine darkens as jaundice is established. Ascites and peripheral oedema may occur in prolonged or severe episodes. The most significant clinical indicator of deterioration is the development of hepatic encephalopathy, indicating the onset of hepatic failure.

Laboratory investigations

Virological investigations depend on serological testing as outlined in Table 2. Figure 1 and Figure 2 indicate the typical serological evolution of self-limited episodes of A and B viral hepatitis.

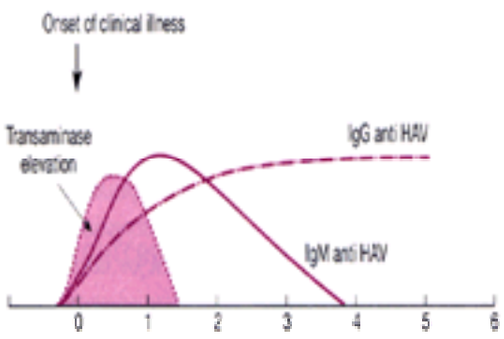

Fig. 1 Typical serology of hepatitis A infection.

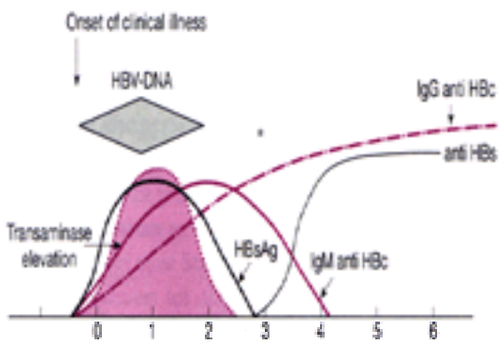

Fig. 2 Serological changes during acute hepatitis B with viral clearance. *, 'Window phase' after elimination of HBsAg and before the emergence of anti-HBs, during which anti-HBc may be the sole indicator of infection.

Typically, hepatocellular enzyme levels in blood (AST, aspartate aminotransferase; ALT alanine aminotransferase) are prominently raised at the time of the onset of symptoms, often more than 10-fold above normal, whilst the serum alkaline phosphatase level is only slightly increased, less than 2.5-fold (Fig. 3). As an episode evolves, transaminase levels fall and alkaline phosphatase may rise, notably if there is prolonged intrahepatic cholestasis. Urinary analysis shows excess urobilinogen in early and late phases of an episode, with excess bilirubin at the height of jaundice. The severity of the attack is best reflected in the synthetic parameters of albumin and clotting factors: in particular, progressive prolongation of the prothrombin time mirrors the onset of liver failure. A low factor V (below about 30 per cent of normal) level has been used as an indicator of irreversible failure.

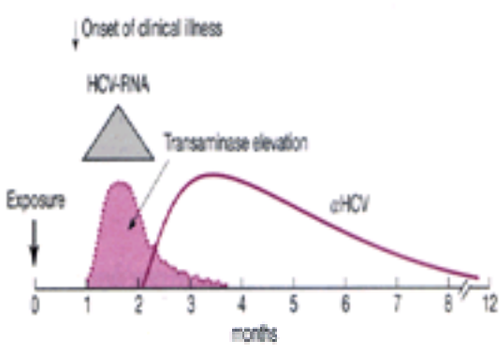

Fig. 3 Serological changes during acute hepatitis C with viral clearance.

Hepatic imaging techniques such as ultrasound contribute to diagnosis primarily by excluding other causes. Patients with uncomplicated hepatitis do not require a liver biopsy, but hepatic histology is very helpful if there is diagnostic uncertainty or an unusual course in severity or duration (Fig. 4 and Plate 1). In such cases, biopsy may require correction of clotting factors and use of the transjugular route or 'plugged' biopsy techniques.

Fig. 4 Haematoxylin and eosin staining of liver biopsies from (a) mild hepatitis with inflammation restricted to the portal tracts and minimal fibrosis, and (b) severely active but still precirrhotic liver with bridging necrosis (by courtesy of Professor P. Dhillon). (See also Plate 1.)

Differential diagnosis

Drug-induced jaundice is the most common differential diagnosis, and its course may be very similar. Drug history and drug screening should particularly enquire about the use of acetaminophen and non-steroidal anti-inflammatory drugs. Other potential drugs and toxins include halothane, antituberculous drugs, carbon tetrachloride, and mushroom poisoning. Alcoholic hepatitis often presents with less marked elevations of serum transaminases and a high circulating leucocyte count. About one-third of patients with autoimmune hepatitis present with a clinical picture of acute hepatitis. Autoantibody testing is generally helpful: the majority of patients with autoimmune disease having high levels of circulating autoantibodies. However, there are often low- or moderate-titre antinuclear and anti-smooth muscle antibodies in uncomplicated viral hepatitis. Similarly, there may be some increase of immunoglobulin levels in acute hepatitis, though not the doubling characteristic of autoimmune hepatitis. Although uncommon, acute Wilson's disease is an important diagnosis to make, because of the high incidence of acute liver failure and the rapid necessity for transplantation. 'Surgical' obstructive jaundice tends not to raise transaminase levels markedly, but serum alkaline phosphatase levels are high. Obstruction is generally confirmed by imaging techniques, notably ultrasound. Individual causes may be suspected from features in the history such as nausea and biliary colic in cholelithiasis, and painless jaundice without systemic upset in an elderly patient with pancreatic cancer. Pregnancy-associated syndromes—acute fatty liver and **HELLP** (haemolysis, elevated liver function tests, low platelets)—are in fact less common in pregnancy than acute hepatitis. Occasionally ischaemia, generally after profound hypotension over many hours, and rapidly progressive malignant infiltration may mimic acute viral hepatitis.

Management

Uncomplicated cases of hepatitis recover spontaneously. Classical studies in military personnel demonstrated no benefit from bed rest, though whether the same applies to the elderly is unknown. In any case malaise and nausea often enforce rest. Clinicians must be alert to signs of impending liver failure and ensure that hypoglycaemia is avoided, if necessary by parenteral administration of glucose. No diets are of established benefit, but dietary fat is often poorly tolerated. There is no rationale for protein restriction unless evidence of hepatic encephalopathy has emerged. Alcohol and potentially hepatotoxic drugs should be withdrawn. Troublesome pruritus can be treated with colestyramine, which is preferable to antihistamines because of potential hepatotoxicity. There is no proven therapy to enhance recovery. Corticosteroids do not speed recovery or improve survival, although they do lower serum bilirubin levels. In hepatitis B, and particularly hepatitis C, the use of interferon has been advocated to enhance the chance of elimination of the virus. There is little evidence of its efficacy with HBV, but some reports in HCV infection are very encouraging.

In fulminant hepatic failure, which in the setting of viral hepatitis carries a mortality risk of 80 per cent, patients should, if possible, undergo orthotopic liver transplantation. Criteria for listing differ in different centres, but include a marked abnormality of clotting parameters (e.g. prolongation of the prothrombin time to >50 s or a factor V level <20–30 per cent) and the development of significant encephalopathy. Patients awaiting transplantation require glucose supplementation, full intensive-care monitoring, and prophylaxis of infection. Some patients require renal support, such as haemofiltration, and ventilation. Some units invasively monitor intracerebral pressure, which may rise dangerously, so that cerebral oedema may be treated with intravenous mannitol.

Prevention of viral hepatitis

Sanitation and hygiene reduce the frequency of the enteric-borne infections HAV and HEV. Passive protection against hepatitis A (to close family contacts) and hepatitis B (after exposure to risk factors such as sexual contact with an individual incubating acute hepatitis B, or a needlestick injury) are available using gammaglobulin preparations (standard preparations for protection against HAV, specific high-titre preparations for HBV). Active immunization to HAV, using formalin-inactivated viral preparations, provides a high level of protective immunity within a few days—suitable, for example, for use prior to travel from the West to highly endemic areas, and also advisable in patients with established chronic liver disease, particularly chronic viral hepatitis. Active immunization to HBV is discussed below, which also protects against HDV. Vaccines are not yet available for HCV or HEV.

Chronic viral hepatitis—hepatitis B

Up to 10 per cent of adults and more than 90 per cent of infants become chronic B carriers after infection, defined by the persistence of HBsAg in the blood for more than 6 months. Subsequently, a low proportion of patients will clear the virus spontaneously each year, but most are infected long-term. Failure to clear the virus is more common in neonates or those infected as infants, in males, and those with natural or iatrogenic immunosuppression. Carriage rates in the population vary widely geographically, and are notably high in the Far East and Southern Africa (10–20 per cent), and low in Northern Europe and North America (<1 per cent).

The consequences of long-term carriage are varied, reflecting the strength of the immune response mounted by the host, the duration of infection, and alteration in the mechanisms of viral replication with time (Fig. 5). Viral mutation may also contribute to modulation of the host response and viral replication. During the early years, the 'replicative' phase, HBeAg (hepatitis B e antigen)-expressing virus replicates independently of the host chromosomes, resulting in the production of fully infectious viral particles in the blood with high levels of HBV-DNA (Table 3). The early replicative phase is associated with a state of relative immune tolerance by the host, and may be very prolonged if infection is acquired as an infant. In the later replicative phase there is expression of immune responses associated with inflammation. Thereafter, HBeAg expression is often lost, HBV-DNA in the blood may be at low or undetectable levels, and HBsAg production may be driven by viral sequences integrated into the genome (integrative phase).

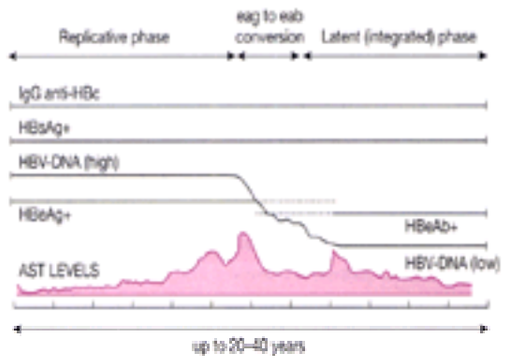

Fig. 5 Serological markers during chronic hepatitis B. Note that HBV mutants not expressing HBeAg may emerge and that HBV-DNA quantitation is required to assess their replicative phase.

Chronic hepatitis B infection is associated with a spectrum of histological damage and clinical manifestations. The inflammatory response to the virus may sometimes be so slight that the histological appearances of the liver are virtually normal, with the exception of evidence of virally infected hepatocytes seen as 'ground-glass' cells on routine eosin staining or by histochemistry. More commonly, the immune response is adequate to inflame the liver but inadequate to clear the virus. The resulting chronic inflammation may be confined to the portal tracts, with a chronic lymphocytic infiltration, associated to varying extent with periportal and/or lobular inflammation, a tendency to develop fibrosis spreading from the portal tracts, and in some cases eventually cirrhosis. These appearances can be categorized in terms of inflammatory activity and fibrosis (Table 4). In general, the replicative phase of HBV infection with HBeAg-positivity, particularly in its later phase, is associated with more marked inflammation than the subsequent HBeAb-positive stage.

Chronic hepatitis B infection may be clinically silent for years, or give rise only to non-specific symptoms of fatigue. The condition may be recognized on screening (for example, during pregnancy) or the investigation of coincidentally detected abnormal liver function tests. Some patients present with non-specific indications of chronic liver disease (malaise or hepatomegaly), or at a late stage with a complication of established cirrhosis. Episodes of enhanced inflammation ('flares') may give rise to transient worsening of liver function tests, particularly transaminase elevations and jaundice at any stage of the disease; precipitating events may include a reduction of prior immunosuppression, or the time of conversion from HBeAg- to HBeAb-positivity. Usually the progression to cirrhosis takes many years, but the rate varies. The incidence of hepatocellular cancer in chronic hepatitis B is high, probably increased 100-fold over non-infected controls. Most, but not all, patients with hepatocellular cancer will have cirrhosis.

Chronic HBV infection may also give rise to a number of extrahepatic manifestations. These include membranous glomerulonephritis, polyarteritis nodosa, and cryoglobulinaemia.

After establishing the diagnosis of chronic HBV infection, it is necessary to define the virological status of the patient with respect to infectivity and viral replication (see Table 3), and the hepatic status with respect to the presence of inflammation and liver damage. Interpretation of viral status may be complicated by the emergence of viral mutants, particularly the 'pre-core' mutant that results in absent HBeAg expression, but which, none the less, is associated with active inflammation and circulating HBV-DNA levels.

Treatment

The general measures relevant to chronic liver disease of any aetiology are discussed elsewhere.

With respect to HBV infection, the prospects for inducing viral clearance in an individual patient are relatively low, but the viral load, infectivity, and intensity of hepatic inflammation can often be reduced. The two current approaches are the use of a-interferons, which have both immunomodulatory and antiviral properties, and the use of inhibitors of viral replication, currently nucleoside analogues.

Patient selection is important. Those with active inflammation, viral replication independent of host DNA, but low levels of HBV-DNA have the greatest potential to benefit. Most patients treated will have circulating HBeAg present. In the absence of elevated transaminases the response to treatment is very poor. Whilst some patients will clear HBsAg from the blood in response to treatment, loss of HbeAg is a more common event.

a-Interferons (**IFN-a**) act predominantly by enhancing T-cell-mediated viral clearance, by processes including the enhancement of hepatocyte class I-HLA expression. Treatment involves parenteral IFN-a (5 MU daily or 10 MU three times weekly, for 4 months). If viral clearance or HBeAg to HBeAb conversion occurs, there is generally an inflammatory flare during the second or third month. Side-effects include malaise, fever (particularly in the first weeks of treatment), anaemia, alopecia, and depression. HBeAg to HBeAb conversion or loss of HBV-DNA occurs in 30 to 40 per cent of cases, HBsAg clearance in about 10 per cent. Women, those with a shorter duration of carriage, occidentals, and those without an additional immunosuppressed background (for example, human immunodeficiency virus (**HIV**) infection) respond more favourably. Relapse after the clearance or sustained loss of HBV replication is rare (5–10 per cent). Successful treatment slows histological progression and reduces liver-related mortality (including hepatocellular cancer).

Nucleoside analogues can inhibit viral reverse transcriptase and inhibit replication. Drugs such as lamivudine are orally bioavailable and now licensed for use. Lamivudine for 12 months markedly reduces HBV-DNA for the duration of treatment, leads to HBeAg to HBeAb conversion in one-third of patients, and reduces inflammatory activity on histological and liver-function test criteria in 50 per cent of cases. However, the loss of HBsAg is infrequent. One difficulty with this drug is that cessation of therapy can occasionally be followed by a disease flare. Moreover, in a significant proportion of cases lamivudine-resistant strains emerge due to mutations in DNA polymerase (*YMDD* mutants). The inflammatory response to this mutant form of the virus may however be diminished. The role of lamivudine and other nucleoside analogues such as famciclovir is under intensive investigation.

Prevention of hepatitis B

Active immunization for the prevention of HBV infection initially involved the use of a vaccine derived from viral proteins in infected blood, but it now uses recombinant HBsAg proteins. Vaccination strategies range from universal vaccination in infancy to the vaccination of only high-risk individuals. In areas of high carriage in the Far East, universal vaccine programmes have already reduced the national incidence of infection, carriage, and hepatocellular cancer. Conventional three-dose immunization in adults leads to protective immunity, as judged by anti-HBsAg, in 90 per cent of individuals.

Passive immunization with anti-HBsAg hyperimmune globulin provides rapid protection after exposure (e.g. after needlestick injury). A combination of passive and active immunization is recommended for children born to infected mothers. In some infants, chronic infection with a mutant 'escape' virus has subsequently occurred.

Chronic hepatitis C

Around 85 per cent of patients who become infected with HCV fail to clear the virus and become chronic carriers. In the majority of cases the initial presentation will have been asymptomatic, and HCV infection is generally recognized in the chronic phase. Following the availability of tests to diagnose HCV infection, it is clear that an asymptomatic indolent necroinflammatory response to the virus in the liver may persist long term, and often, but not inevitably, lead to cirrhosis after 15 to 25 years and predispose to hepatocellular cancer thereafter.

Mechanisms of transmission and prevalence rates vary geographically. In the West, blood transfusion and treatment of clotting disorders with plasma concentrates prior to the early 1990s, and intravenous drug abuse constitute the main routes of transmission. Medical use of unsterilized needles, including in vaccination programmes, tattooing, dentistry, and communal shaving practices, may all contribute worldwide. Vertical transmission is rare. Sexual transmission is low (<5 per cent in stable heterosexual relationships).

As with HBV, the severity of liver damage reflects host–virus responses. Severe inflammation is less common if the virus is acquired in childhood and progression to

cirrhosis less frequent and probably slower. HBV coinfection and alcoholism worsen disease and increase the likelihood and rate of developing cirrhosis. The histological response of the liver shows a similar variety of response to that seen in HBV infection, from minimal to severe portal inflammation, periportal hepatocyte necrosis, and progressive fibrosis leading to cirrhosis. The presence of lymphoid follicles in portal tracts and parenchymal steatosis are characteristic of the response to HCV.

Patients may be diagnosed coincidentally during the investigation of fatigue or abnormal liver function tests, or with manifestations of chronic liver disease. In addition, there are a variety of extrahepatic manifestations thought to reflect either antigen–antibody complex formation or the induction of crossreacting autoimmunity. These include a vasculitic rash associated with cryoglobulinaemia (type 2, polyclonal immunoglobulin plus rheumatoid factor), glomerulonephritis, abnormal thyroid function, thrombocytopenia, and porphyria cutanea tarda. As in HBV, assessment of a patient with HCV involves both the virological and the hepatic status.

The initial screening test for HCV is detection of circulating anti-HCV antibody. If present, confirmation is required either by more specific antibody testing using immunoblots, or more often by using **PCR** (polymerase chain reaction) for viral RNA (Fig. 6). Quantitative PCR and viral genotyping (types 1–4) are becoming more relevant as treatment strategies evolve (see below). Changing sensitivities of antibody tests, and varying techniques for PCR testing, render specialist interpretation mandatory.

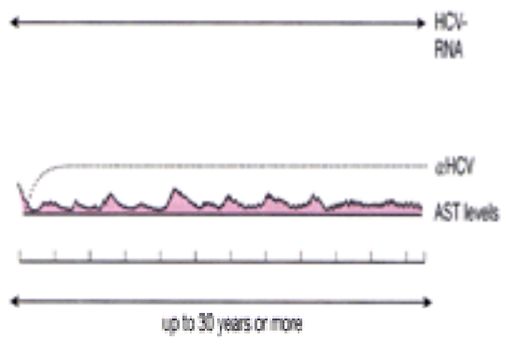

Fig. 6 Serological changes during chronic hepatitis C.

The severity of inflammation in the liver is poorly judged from routine liver function tests such as aminotransferase level measurements. Histological assessment may reveal both significant inflammation and progressive fibrosis despite normal serum enzyme levels, and are necessary if treatment is to be considered. There is consensus that moderate or severe precirrhotic disease as judged by activity grading and well-compensated cirrhosis should be considered for treatment. The position in minimal or mild disease is uncertain, in part because patients with mild disease histologically, and normal aminotransferase levels, do not respond well to current treatment.

Treatment of chronic HCV

The main aim of treatment in chronic HCV infection is to clear the virus, which has been established to be associated with a reduction in necroinflammation and slowing in the rate of accumulation of fibrosis in the liver.

Initial studies using IFN-a monotherapy demonstrated that between 25 and 50 per cent of patients responded temporarily, with normalization of aminotransferase levels and loss of PCR-positivity for viral RNA recorded at the end of 6 months' therapy. However when assessed 6 to 12 months later this response was sustained in far fewer patients—overall sustained virological response rates were only between 10 and 12 per cent. Rates were higher with more prolonged treatment, but did not exceed 20 per cent. Clearance rates were lower with genotype 1 infection and when initial aminotransferase levels were normal.

Subsequently, the combination of interferon with ribavirin has been shown strikingly to enhance sustained response rates, with an approximate doubling of clearance rates after both 24 and 48 weeks. For genotypes 2 and 3 however, 6 months' treatment appears adequate. Currently, for these genotypes, the combination of 3 MU of IFN-alpha three times weekly plus ribavirin 1000 to 1200 mg orally is recommended. For genotype 1, treatment for 12 months is recommended. With this regime, in addition to the side-effects of IFN-a listed discussed above for HBV treatment, ribavirin induces cough, rash dyspnoea, and insomnia in about 25 per cent of patients, and there is predictably a dose-dependent haemolytic anaemia. Both pregnancy and fathering children need to be avoided whilst taking ribavirin. Strategies for the early identification of non-responders, by assessing whether there is a reduction in viral load in the blood, are evolving. The full role of therapy in established cirrhosis, and the long-term benefits of reducing inflammation with these therapies in patients in whom viral clearance has not been achieved, are currently under investigation. Improved interferon formulations (such as interferon conjugated to polyethylene glycol, PEG) and other antiviral drugs are being introduced.

Prevention of hepatitis C

There is no vaccine available for HCV. Passive immunization with HCV-antibody-containing gammaglobulin in not protective.

Hepatitis D

Chronic HDV generally follows superinfection of a chronic HBV carrier in whom ample HbsAg to permit HDV encapsulation is already present. The spectrum of chronic liver disease associated with the double chronic infection is as variable as with HBV alone. Overall, however, the liver tends to be more severely affected, and in 10 to 15 per cent of chronic carriers there may be a rapid (1 to 2 year) evolution to cirrhosis. HDV acts to suppress HBV infection, so that markers of HBV activity, such as HBV-DNA, in the serum may become suppressed. Many patients with HDV may therefore be HBeAb positive.

The treatment of HDV mirrors that for HBV. Prolonged courses of IFN-a (6 or more months) may transiently clear HDV in some patients in whom HbsAg persists. In general, HbsAg clearance is required to cause sustained HDV clearance.

Liver transplantation

Liver transplantation is indicated both in fulminant hepatic failure due to acute hepatitis and in advanced chronic hepatitis with cirrhosis. Recurrence of viral hepatitis after transplantation is a major concern. The use of hyperimmune globulin, interferon, and nucleoside analogues allows control in most cases of HBV. Severe recurrence remains a significant problem after transplantation for HCV.

14.20.2.1 Autoimmune hepatitis

H. J. F. Hodgson

Autoimmune hepatitis describes chronic inflammation in the liver attributed to immune responses against self-antigens in the liver. Patients generally have circulating autoantibodies, and 60 per cent have other autoimmune diseases in addition. In severe cases autoimmune hepatitis can lead to acute liver failure, and untreated there is often progression to cirrhosis. There is generally a good response to corticosteroid therapy.

The term 'autoimmune hepatitis' should be reserved for patients with clinically significant liver disease, and not used to describe the very mild chronic inflammation often seen in the livers of patients with systemic autoimmune conditions. Previous terms for autoimmune hepatitis include 'autoimmune chronic active hepatitis' and 'lupoid hepatitis'.

Aetiology

Autoimmune hepatitis is often familial, and a constellation of autoimmune diseases (for example, thyroiditis, type-1 diabetes) may occur in affected families. Some of the predisposing genetic factors have been characterized. There are strong HLA associations. In the United Kingdom and United States the strongest association is with HLA DR haplotype B1*030 (50 per cent of patients compared with 20 per cent of controls), and a secondary association with *0401, but in other geographical areas there are different associations. The DR4 association is strongest in Japan. Deficiency of the C4 component of complement also predisposes to the disease. In the West, DR3 is associated with more severe disease and a younger onset, and DR4 with an older onset and better treatment response. In most cases there is no clear initiating event for the development of autoimmune hepatitis, but occasionally drugs (a-methyldopa, oxyphenisatine, nitrofurantoin, isoniazid, minocycline, pemoline, dihydralazine, tienilic acid) can precipitate the condition. As discussed below, in some patients with chronic hepatitis C, autoimmune manifestations develop and may contribute to the inflammatory processes in that chronic viral condition.

Histological appearances and immunopathogenesis

The histological appearances used to be referred to as 'chronic active hepatitis', but pathologists now grade chronic hepatitis in respect of aetiology, disease activity (grading), and progression (staging). There is a marked portal tract infiltrate containing both plasma cells and T cells. Cytotoxic T cells spread out across the limiting plate of the portal tract, associated with piecemeal necrosis of periportal hepatocytes, and lymphocytes are often present diffusely within the parenchyma (Fig. 1). Compared with the inflammation seen in chronic hepatitis B and C, the plasma-cell component of the portal tract infiltrate is more prominent, as is regenerative 'rosette' formation by the hepatocytes. The portal tract lymphoid aggregates and steatosis common in hepatitis C are less frequent in autoimmune hepatitis. With progression, periportal fibrosis, bridging necrosis linking portal tracts to central veins, and hyperplasia of regenerating hepatocytes all occur leading to cirrhosis.

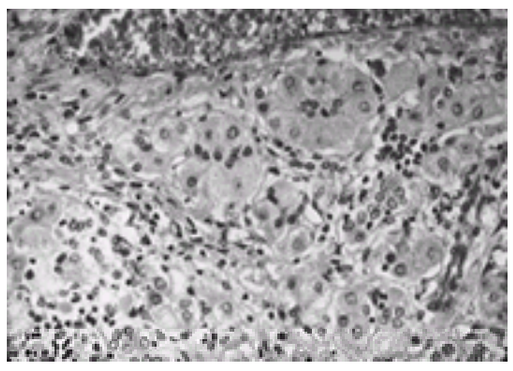

Fig. 1 Haematoxylin and eosin stained liver histology showing 'rosettes' of regenerated hepatocytes, surrounded by lymphocytes that have spread into the hepatic parenchyma.

Antibody and T-cell reactivity to a panel of hepatic antigens, both intracellular and on the cell surface, are described. Some of these may be the primary mechanism of liver damage, and others a secondary response to tissue injury. Cell-surface targets such as the hepatocyte-specific asialoglycoprotein receptor may be particularly relevant to the development of tissue damage.

Epidemiology

Most reported cases are of European ancestry, although cases occur worldwide. Most patients are female—with female:male ratios of up to 8:1 reported in some series. Northern European prevalence figures are about 100 to 200 per 100 000, similar to those for primary biliary cirrhosis and primary sclerosing cholangitis. The age of onset varies widely, but young adults and children are most commonly affected. Perhaps 20 per cent of cases occur after the age of 65.

Clinical manifestations

In about 30 per cent of cases the onset is indistinguishable clinically from acute viral hepatitis, with anorexia, nausea, hepatic discomfort, and the development of jaundice. Other patients present just with malaise, or with extrahepatic manifestations such as arthralgia, arthritis, or fever, and subsequent investigation demonstrates high circulating transaminase levels. Despite an acute onset, many patients have cirrhosis at the time of presentation.

Clinical signs may therefore vary greatly. Cutaneous manifestations of palmar erythema and prominent spider naevi, a maculopapular or acneiform rash, and occasionally abdominal striae (without corticosteroid therapy) may be found both in acute and insidious presentations. In an acute presentation, jaundice and tender hepatomegaly may be prominent, with severe cases demonstrating ascites and most sinisterly the development of encephalopathy. Acute severe autoimmune hepatitis may progress to fulminant hepatic failure. Splenomegaly, which is often marked, indicates that cirrhosis has already developed. There may also be evidence of other autoimmune conditions (Table 1).

Investigations

High transaminase levels, marked hyperglobulinaemia (particularly IgG), and circulating autoantibodies characterize the condition. Transaminase levels are often five or ten times the upper normal limit. Hyperglobulinaemia may include IgG levels of more than 30 g/l when the condition is active. The major serological diagnostic markers are the presence of autoantibodies demonstrated by tissue immunofluorescence, prominently antinuclear antibodies (**ANA**), titre 1:40 or greater, and an anti-smooth muscle (**SMA**) titre 1:80 or greater. In addition, other autoantibodies may be present, in particular to liver–kidney microsomes (liver and proximal renal tubule, LKM-1). However, the antibody profiles in the disease are variable and may alter over time: some cases identified on clinical and histological grounds may lack circulating antibodies on routine testing. Other autoimmune associations of the disease may be manifest with antithyroid, parietal cell, and intrinsic factor antibodies, or antibodies leading to immune thrombocytopenia or haemolysis. Other positive immune tests include a moderate frequency of antibodies to double-stranded and single-stranded DNA. The positive lupus erythematosus cells described in early reports of the condition led to the designation of 'lupoid hepatitis'.

Diagnostic criteria

There are no critical signs, symptoms, or liver test abnormalities that are sufficiently specific to provide diagnostic criteria. The diagnosis is therefore made on a constellation of features, each of which may also occur in other conditions. Diagnosis during the active phase of the disease generally reflects the presence of elevated serum transaminase levels without marked elevation of alkaline phosphatase, elevated globulins, positive antibodies to ANA, SMA, or LKM-1, seronegativity for hepatitis viruses (although the overlap with hepatitis C is discussed below), and characteristic or compatible liver histology. A 'scoring system' to identify definite or probable autoimmune hepatitis from a combination of clinical and histological features has been proposed.

Differential diagnosis

The differential diagnosis during investigation includes not only viral and drug-induced hepatitis, but the metabolic conditions of Wilson's disease and a1-antitrypsin deficiency. Some alcoholic patients may manifest histological appearances overlapping with autoimmune hepatitis. The immune biliary diseases primary biliary cirrhosis (**PBC**) and primary sclerosing cholangitis (**PSC**) are generally easy to differentiate by the predominant elevation of serum alkaline phosphatase and the antimitochondrial antibody in PBC, and antineutrophil cytoplasmic antibodies (**ANCA**) and cholangiography in PSC. However, as already mentioned, each of the suggestive indicators for autoimmune hepatitis may be absent in particular cases, and in some series up to 20 per cent of cases lack any ANA, SMA, and anti-LKM-1 antibodies. Furthermore, there is overlap in the autoimmune profiles of various immunological liver diseases, with, for example, low titres of ANCA often found in autoimmune hepatitis, and SMA in both PBS and PSC. Autoimmune hepatitis is not part of the spectrum of systemic lupus erythematosus.

Autoimmune hepatitis subtypes

A subclassification of autoimmune hepatitis into four groups according to a combination of autoantibody profiles and clinical features has also been suggested (Table 2):

- **Type I**—Classical autoimmune hepatitis with high-titre ANA and SMA. Typically, patients are young adult females. The SMA antibody has anti-F-actin specificity, as can be demonstrated using cell lines as immunofluorescent substrates.
- **Type II**—Anti-LKM-1 antibodies are present, with specificity for a cytochrome P-450 antigen, CYP4502D. The disease may be particularly severe, and tends to affect children. However anti-LKM-1 may also be found in sera from patients with chronic hepatitis C infection, which can itself also predispose to a variety of autoimmune manifestations. It has therefore been suggested that Type-II autoimmune hepatitis should be further subdivided to separate those with a primary autoimmune condition (IIa) from those in whom hepatitis C has triggered an autoimmune response (IIb). This, however, introduces further confusion as some patients with hepatitis C have ANA and SMA but not anti-LKM.
- **Type III**—Antibodies to a soluble liver antigen (**SLA**), often without ANA, SMA, or LKM antibodies.
- **Type IV**—No antibodies detectable.
- The value of this classification has been questioned, and the issue is complex. Many other autoantibodies are being described in these patients, to both intracellular and surface antigens of liver cells (for example: antibodies to the hepatocyte-specific asialoglycoprotein receptor, to other hepatic membrane antigens, and to cytosolic enzymes; and to a 'liver–pancreas' antigen). Furthermore, antibodies identified by immunofluorescence are often relatively non-specific, and reactions to different epitopes may give similar staining patterns. Many of the newly described antibodies are found in more than one type of autoimmune hepatitis and in other immune conditions affecting the liver. Also, as described below, there are well-described 'overlap' cases, with patients with autoimmune hepatitis also showing manifestations of another immune liver disease. Subtyping on autoantibody criteria alone is therefore unlikely to be definitive. The delineation of Type IV, with no detectable autoantibodies, serves to emphasize that if other clinical and laboratory features are present, a trial of corticosteroids may be worthwhile even if autoantibodies have not been identified.

Associated liver diseases and overlap conditions

Up to 10 per cent of cases may show mixed autoimmune hepatitis and immune biliary disease, generally PBC and less frequently PSC. The disease may also coexist with autoimmune cholangitis (which resembles PBC but is antimitochondrial antibody-negative).

Natural history

Untreated, autoimmune hepatitis may occasionally spontaneously remit, but there is a marked tendency for progression with the development of hepatic fibrosis and cirrhosis, and subsequently the complications thereof. Childhood-onset and Type-II autoimmune hepatitis have a bad prognosis. Over half of the patients with severe disease die within 5 years if untreated. Epidemiological features suggest that inapparent autoimmune hepatitis is the cause of a significant number of cases of cryptogenic cirrhosis. Cirrhosis arising as a consequence of autoimmune hepatitis only rarely leads to hepatocellular carcinoma.

Treatment regimes

Specific therapy for autoimmune hepatitis is aimed at reducing or abolishing inflammation. Patients, particularly those with cirrhosis, may require treatment for the complications of portal hypertension and liver failure discussed in Chapter 14.21.2.

There is consensus that severe cases of autoimmune hepatitis should be treated with an immunosuppressive regime for 1 to 2 years. Evidence of benefit is firm in patients with transaminase levels more than five times normal, and those with histological evidence of bridging necrosis on biopsy. Whether patients with mild disease (minor elevations of transaminase, minor inflammation on biopsy without developing fibrosis) benefit from immunosuppressive therapy is unclear, and in such patients a period of observation followed by repeat biopsy to gauge progression may be helpful. The finding of established cirrhosis should not be taken as a reason to prevent treatment, provided there is active inflammation.

Corticosteroid treatment of patients with severe disease reduces inflammation in 80 to 90 per cent of cases, reduces the chance of progression to cirrhosis if it has not already occurred, and prolongs survival. In assessing the short-term effects of corticosteroid or other therapy, responses are characterized as 'complete' if transaminase levels normalize and remain so for a year or more, or if repeat histology shows only minimal activity. A 'partial response' describes improvement but the persistence of transaminase abnormalities at more than twice the upper limit of normal, or persistent histological activity despite the normalization of transaminase levels. In the most successful cases, complete responses with regression of fibrosis and normalization of architecture have been reported.

A variety of corticosteroid-based regimes are in use. Comparative studies demonstrate equivalent anti-inflammatory efficacy of a solely corticosteroid regime of prednisolone 20 mg daily, and a steroid-sparing combination of 75 mg azathioprine plus 10 mg prednisolone, but a lesser incidence of side-effects over 2 years with the latter. Many physicians use higher doses of prednisolone initially, 30 to 45 mg, until there is a definite improvement in liver function tests. Amongst those who respond, corticosteroid treatment will significantly reduce or normalize transaminase levels within a few weeks to a few months. Symptoms tend to resolve over a similar period, but corticosteroids may not abolish inflammation, as judged histologically, for a year or more. Therefore, if a complete clinical and biochemical remission is established, generally within a few months, most physicians advocate treatment for between 1 and 2 years and a repeat liver biopsy after that to see if there is still histological evidence of inflammation. A biopsy at this interval may also demonstrate that cirrhosis has supervened, despite clinical and biochemical control of the disease. If there is no active inflammation, or only mild inflammation, on the follow-up biopsy, cautious withdrawal of corticosteroids—for example, reducing the dose at a rate of 1 mg per month—may allow their discontinuation. However, the chances of relapse are high (perhaps 70 per cent) either during withdrawal or later, in which case immunosuppressive therapy will again be required and should then be continued long-term. When this is required, azathioprine

alone may be all that is required. For patients who have only partially responded to corticosteroids—judged by the failure to reduce transaminase levels significantly or by persisting inflammation on follow-up biopsy—long-term immunosuppression is advocated, and increased corticosteroid or azathioprine dosage may be required to achieve remission.

Minimizing the incidence and severity of corticosteroid side-effects is very important. Glucose intolerance and hypertension should be screened for, and the enhanced risk of infection warrants increased vigilance. Strategies to reduce bone loss include oral supplementation with calcium and vitamin D, or the use of bisphosphonates to restore lost bone mass. The orally administered halogenated corticosteroid budesonide is rapidly metabolized by the liver, and reports indicate that it may be effective in treating autoimmune liver disease with less effect on the pituitary–adrenal axis than prednisolone. Theoretically, lesser effects on bone would also be anticipated.

For patients who fail to respond to corticosteroid-based immunosuppression there is anecdotal evidence of a reasonable response rate to ciclosporin. A number of alternative immunosuppressive agents—methotrexate, mycophenylate, and tacrolimus—have also been anecdotally reported to be useful. Failure to respond should also prompt reconsideration of the diagnosis, in particular exclusion of previously unrecognized Wilson's disease.

In the overlap syndrome of primary biliary cirrhosis-autoimmune hepatitis, the periportal inflammatory element of the condition and the serum transaminase elevations generally respond to corticosteroid therapy, but the biliary component is not improved. Conversely, bile acid therapy with ursodeoxycholic acid can improve the biliary manifestations whilst leaving the transaminase levels and periportal inflammation unaffected. Combination of the two therapeutic approaches may be necessary to restore normal biochemical markers of liver disease. Patients with the autoimmune hepatitis-PSC overlap syndrome respond poorly to treatment.

Prognosis after treatment

Amongst patients presenting without cirrhosis, long-term survival is excellent (over 95 per cent at 10 years), whilst the 10-year survival rate is about 65 per cent if cirrhosis is present initially. Corticosteroid therapy increases the survival of both cirrhotic and non-cirrhotic patients.

Transplantation

Endstage cirrhosis due to autoimmune hepatitis, and acute non-responsive autoimmune hepatitis leading to acute or subacute liver failure, provide firm indications for orthotopic liver transplantation. Failure to achieve an early response in acute disease, with a shrinking liver volume, should prompt consideration of transplantation. Overall, the prognosis after transplantation is good, with 5-year survival rates in excess of 80 per cent, and a similar incidence of acute rejection episodes (50–60 per cent) to that seen in other immunological liver diseases. Autoantibodies persist after transplantation, though at lower titre. There is a tendency for the disease to recur in the transplanted liver, with a frequency of about 20 per cent at 5 years, sometimes necessitating retransplantation. Whether more aggressive immunosuppressive antirejection regimes will prevent this remains to be established.

14.20.2.2Primary biliary cirrhosis

M. F. Bassendine

Primary biliary cirrhosis is a chronic, cholestatic liver disease in which the biliary epithelial cells lining the small intrahepatic bile ducts are the target for immune-mediated damage leading to progressive ductopenia. The cause is unknown but evidence points to an autoimmune aetiology, in particular the strong association with disease-specific autoantibodies. It affects women in over 90 per cent of cases and usually has an insidious onset in middle age. Patients with early disease are often recognized following the incidental discovery of antimitochondrial antibodies or elevated levels of serum alkaline phosphatase. Progression may be slow but eventually many patients develop cirrhosis and, ultimately, death may occur from liver failure or complications of cirrhosis such as bleeding oesophageal varices. It is a common indication for liver transplantation.

Epidemiology

There is a marked geographical variation in the prevalence of the disease; it is commonest in Northern Europe but rare in the Indian subcontinent and Africa. It was rare and accounted for fewer than 5 per cent of patients dying of cirrhosis in Western communities, but its incidence appears to be increasing. In the North-East of England the prevalence rose from 202 per million adults and 541 per million women over 40 in 1987 to 335 per million adults and 940 per million women over 40 in 1994. It remains unclear whether this increase represents better diagnosis or a true increase in prevalence. Death rates from all causes are nearly three times greater in patients with biliary cirrhosis compared with the general population after adjusting for age and sex.

Aetiology and pathogenesis

In common with most autoimmune disorders, genetic factors partially determine susceptibility to primary biliary cirrhosis, but the pattern of inheritance is very complex. Familial clustering is well documented, and the sibling relative risk is 10.5, similar to values seen in other autoimmune disorders where it is thought that genetic factors may contribute up to 50 per cent of the total risk. There is no association of the disorder with major histocompatibility complex (**MHC**) class I antigens but several associations with class II antigens have been reported, in particular HLA DR8 with a two- to sixfold increase in patients compared with controls. Information on MHC class III associations is conflicting. The genetic predisposition conferred by HLA is however neither sufficient nor necessary for disease development and other genes are likely to be involved. The gene encoding cytotoxic T lymphocyte-associated antigen-4 has recently been examined as a candidate gene and this locus is important for conferring susceptibility not only to primary biliary cirrhosis but also to autoimmunity in general.

Over 95 per cent of patients have antibodies to mitochondria, with the dominant autoantibody response being directed against two components (dihydrolipoamide acetyltransferase (E2) and E3-binding protein) of pyruvate dehydrogenase complex (**PDC**) (Table 1). The loss of tolerance to these autoantigens is an early event in this progressive disease with antimitochondrial antibodies (**AMA**) being detectable in serum before abnormalities in liver function and long before the onset of symptoms. One hypothesis is that the development of these AMA marks the exposure of a genetically susceptible individual to an initiating environmental factor. Autoreactive T cells play a central role in the development of various autoimmune diseases and an immunodominant T-cell epitope within pyruvate dehydrogenase complex E2 (peptide 163 to 176) has been identified in patients with primary biliary cirrhosis. T-cell clones reactive to this peptide can also be activated by mimicry peptides derived from several microbial proteins, supporting the hypothesis that autoreactive T cells present in the peripheral blood can be activated and clonally expanded by antigenic stimulation by mimicry peptides derived from environmental non-self antigen.

Aberrant expression of pyruvate dehydrogenase complex occurs on the apical surface of biliary and salivary epithelial cells in patients with primary biliary cirrhosis and secretory IgA autoantibodies have been found in bile and saliva. IgA autoantibodies to pyruvate dehydrogenase complex may thus interact with components of pyruvate dehydrogenase complex within the epithelial cells leading to metabolic consequences and subsequent cell damage.

Antinuclear antibodies occur in a minority of patients with primary biliary cirrhosis (Table 1) and display unique immunofluorescence patterns such as nuclear dots or a nuclear ring-like pattern. Disease-specific nuclear antigens include a 210-kDa glycoprotein of the nuclear pore membrane (gp 210), nucleoporin p62, and Sp100, an interferon-inducible nucleoprotein with a molecular mass of 100 kDa.

Despite progress in characterizing the reactivity of the disease-specific autoantibodies, little is understood of the way in which the autoimmune response is induced or the effector mechanisms that cause tissue damage. The concept of the T_{H1}/T_{H2} paradigm has gained importance in autoimmune reactions; in primary biliary cirrhosis there is dominance of T_{H1} cells. Interferon-g is the main cytokine in the liver and CD8+ cytotoxic T cells infiltrate the portal tract as part of the chronic inflammation that characterizes primary biliary cirrhosis. The cytotoxic lymphocyte must interact closely with its putative target in order to recognize peptide in association with MHC class 1 and this is facilitated by adhesion to intercellular adhesion molecule 1 (ICAM-1) and CD58, both of which are increased on inflamed biliary cells. Biliary epithelial cells undergo apoptosis but the mechanisms involved and the role of the other effector systems are less clear.

Clinical features

Patients with early disease may complain only of fatigue or symptoms of coexisting autoimmune disease. Those with more advanced disease have evidence of cholestasis, with jaundice, pruritus, light stools, easy bruising, and weight loss. The pruritus may first be noticed during pregnancy or when the patient is on the contraceptive pill. Occasionally, patients present with gastrointestinal bleeding from oesophageal varices or associated peptic ulcer.

Findings on examination vary widely. At one extreme, there may be no abnormality, whereas at the other the patient is jaundiced, with scratch marks and signs of long-standing cholestasis. The planus form of xanthoma occurs characteristically as xanthelasmas around the eyes and in the palmar creases. Tuberous lesions develop late on the extensor surfaces around the knees, elbows, wrists, ankle, and on pressure points such as buttocks. Occasionally they affect tendon sheaths and nerves, producing xanthomatous peripheral neuropathy.

The liver is often enlarged and firm, and splenomegaly may be present, with or without portal hypertension. Spider naevi and palmar erythema are less frequent than in patients with alcoholic cirrhosis. Fluid retention with ascites and oedema is usually a late complication, as is bleeding from oesophageal varices. Steatorrhoea occurs primarily in patients who have advanced cholestasis, leading to malabsorption of fat-soluble vitamins, especially vitamin D. Bone pain due to osteomalacia, with tenderness and fractures involving vertebrae, can occur, as can liver failure with encephalopathy. Such late manifestations of disease are now rarely seen in Western countries as liver transplant is performed in most patients before their development. Osteoporosis is also well recognized but may largely reflect the gender and age of patients with primary biliary cirrhosis. Deficiency of vitamin K sometimes results in easy bruising or other haemorrhagic phenomena. Clubbing of the fingers and leuconychia are rare findings. There is an increased incidence of gallstones and peptic ulceration, and features of these conditions may form part of the clinical picture.

Primary biliary cirrhosis is associated with past smoking and a number of other autoimmune diseases. These include Sjögren's syndrome, seropositive and seronegative arthropathy, thyroiditis, scleroderma, and renal tubular acidosis. The CREST syndrome (calcinosis, Raynaud's phenomenon, sclerodactyly, and telangiectasia), pulmonary fibrosis, psoriasis, and coeliac disease have also been reported.

Pathology

The characteristic early lesion of primary biliary cirrhosis is inflammatory duct destruction. Later there is fibrosis, often patchy, and eventually a frank cirrhotic picture. Histologically this disease appears to evolve from a florid duct lesion to cirrhosis. This has led to a morphological classification into four stages. It must be recognized, however, that overlap between stages is common in different parts of the liver. In stage 1, the duct lesion is florid (Fig. 1) with the epithelium irregular, hyperplastic, or ulcerated. There is a heavy infiltrate of lymphocytes, plasma cells, and neutrophils, with occasional eosinophils. Aggregates of histiocytes with granulomas ranging from foci of epithelioid cells to rounded lesions with multinucleated giant cells are present. In stage 2 there is established duct destruction and the bile ducts may be replaced by lymphoid aggregates with fibrosis. In stage 3 there is relatively little inflammation, though lymphoid aggregates may be present and fibrous septa extend from the portal tract. In stage 4 there is an established cirrhosis, paucity of bile ducts, and lymphoid infiltration (Fig. 2). Mallory bodies similar to those seen in alcoholic liver disease may be present adjacent to the areas of inflammation and there is excess stainable copper-binding protein, a reflection of the cholestasis.

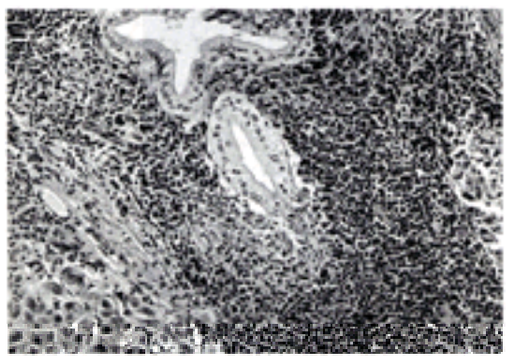

Fig. 1 Bile duct lesion in primary biliary cirrhosis. There is granulomatous destruction of a medium-sized bile-duct radicle in which the epithelium appears hyperplastic. Epithelioid macrophages are surrounded by a chronic inflammatory cell infiltrate. Haematoxylin and eosin stain. (By courtesy of A.D. Burt.)

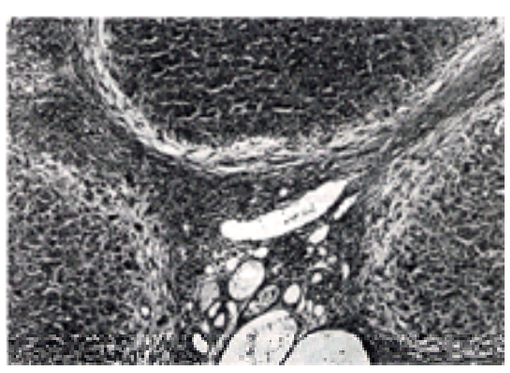

Fig. 2 Stage 4 primary biliary cirrhosis: an established micronodular cirrhosis; the halo effect seen around the nodules is a characteristic feature of biliary cirrhosis. Haematoxylin and eosin stain. (By courtesy of A.D. Burt.)

Malignancy

There is a dramatically increased risk for the development of hepatobiliary malignancies in patients with primary biliary cirrhosis with a reported relative risk of 46 for women and 55 for men. Hepatocellular carcinoma is a recognized complication of cirrhosis from any cause. Men are afflicted at least twice as often as women, and primary biliary cirrhosis is no exception to this rule. Hepatocellular carcinoma is a relatively common cause of death in male patients with concomitant primary biliary cirrhosis and liver cirrhosis and screening with regular liver ultrasound is recommended.

Diagnosis

The diagnosis is based on the serological and biochemical changes, together with the clinical findings and liver histology. A positive AMA may antedate all other abnormalities. Liver function tests reflect cholestasis, with increases in serum alkaline phosphatase and g-glutamyl transferase, but only modest changes in transaminases. At presentation, total serum bilirubin is usually normal or only modestly increased. The serum globulins are usually raised, particularly the IgM, but the serum albumin is usually maintained until late in the disease. Other tests such as erythrocyte sedimentation rate, cholesterol, and autoantibodies other than AMA are less specific. In a patient with a strongly positive AMA and the typical symptoms and biochemical abnormalities, a liver biopsy may not be essential, but is helpful. The features are very specific, and although several different histological stages may be found in one biopsy, the presence of fibrosis or cirrhosis indicates a worse prognosis.

The main differential diagnosis is from other causes of cholestasis. Good ultrasound examination of the liver and biliary tree is mandatory to exclude extrahepatic biliary obstruction or gallstones. Computed tomography, magnetic resonance cholangiopancreatography (**MRCP**), or endoscopic retrograde cholangiopancreatography (**ERCP**) may be necessary for patients without detectable AMA, many of whom have a positive antinuclear antibody and may be thought to have 'autoimmune cholangitis'. There is an overlap with autoimmune hepatitis, which can be diagnosed on liver histology, whilst primary sclerosing cholangitis will be evident on MRCP or ERCP.

Treatment

This consists of therapy aimed at modifying the disease process and progression to cirrhosis, and treatment of symptoms and late complications.

Numerous trials of specific therapy have been undertaken in the last 30 years; the agents that have been assessed are shown in Table 2. Over recent years the naturally occurring bile acid, ursodeoxycholic acid, has become an established treatment for primary biliary cirrhosis. Many randomized controlled trials comparing ursodeoxycholic acid with placebo have been published. All the trials reported an improvement in standard liver enzyme tests and serum bilirubin levels. Results from three large studies have been included in a combined analysis, which indicated that treatment with ursodeoxycholic acid was associated with a significant delay in the time to death or transplantation. However, this was not confirmed in a long-term study (median follow-up of 3.4 years), nor in a meta-analysis of published randomized controlled trials. Data suggest that ursodeoxycholic acid does not prevent ongoing bile-duct destruction but that it exerts its beneficial effect by protecting against the consequences of bile duct destruction. Ursodeoxycholic acid therapy does not benefit the symptom of fatigue and has a variable effect on pruritus. At best ursodeoxycholic acid, in a dose of 12 to 15 mg/kg per day, may retard progression to cirrhosis (histological stage 4), but it does not halt the disease and cannot be seen as a cure. However, it is safe and well tolerated.

Trials of combination therapy using ursodeoxycholic acid with methotrexate, colchicine, predisolone, oral budesonide, and mycophenolate mofetil have been reported; most are too small to evaluate the efficacy adequately, but one pilot study suggests ursodeoxycholic acid plus budesonide is superior in patients with early disease.

Itching can be an intolerable symptom in primary biliary cirrhosis and the first line of treatment is with cholestyramine. Improvement in itching has also been reported with rifampicin and opioid antagonists (nalmifene and naloxone). There is no indication for a fat-free diet unless the patient has symptoms related to steatorrhoea or xanthelasma with high serum cholesterol levels. Supplementation with medium-chain triglycerides may be necessary if adequate weight or nutrition cannot be sustained. A prolonged prothrombin time is treated with intramuscular vitamin K at a dose of 10 mg monthly. Injections of vitamin A (100 000 iu) and vitamin D (100 000 iu) are usually given every 2 months in jaundiced patients and vitamin E supplements may also be required. Osteomalacia is now rare, given such treatment. The principles developed for monitoring and treating postmenopausal osteoporosis can be followed for patients with primary biliary cirrhosis. The complications of portal

hypertension and of liver failure are treated appropriately.

Liver transplantation is now the accepted treatment for endstage primary biliary cirrhosis. Referral to a transplant centre should be considered as the bilirubin approaches 100 µmol/l, although patients with disabling symptoms such as intractable itching may need to be considered individually. Recurrence of primary biliary cirrhosis occurs in about 10 per cent of patients in the first few years after liver transplantation; the cumulative risk increases with time and may be affected by the immunosuppression used.

Prognosis

The progression of primary biliary cirrhosis is extremely variable. Asymptomatic patients have a reduced survival compared with an age-and gender-matched general population and about 40 per cent develop symptoms within 5 to 7 years. The most reliable determinant of prognosis is the serum bilirubin concentration; other factors associated with poor prognosis include weight loss, hepatomegaly, splenomegaly, histological stage, patient age, and impaired liver synthetic function. Several prognostic models have been validated in clinical studies; the most widely used is the Mayo risk score.

Quality of life aspects

Fatigue is present in more than 80 per cent of patients and is one of the worst symptoms. It is not related to disease severity and may be associated with depression. The Fisk Fatigue Severity Score is a reproducible measure of fatigue severity and can be used in the clinical assessment of patients and in therapeutic trials.

14.20.2.3Primary sclerosing cholangitis

R. W. Chapman

Primary sclerosing cholangitis is a chronic cholestatic liver disease characterized by an obliterative inflammatory fibrosis of the biliary tract. It may lead to bile-duct obstruction, biliary cirrhosis, hepatic failure, and in some patients, cholangiocarcinoma. Primary sclerosing cholangitis was initially considered to be a rare disease; however, the advent of endoscopic retrograde cholangiopancreatography (**ERCP**) in the early 1970s established the diagnosis in a progressively larger number of patients. This led to the realization that primary sclerosing cholangitis has a much wider clinical and pathological spectrum than was previously recognized.

The generally accepted diagnostic criteria of primary sclerosing cholangitis are: (i) generalized bleeding and stenosis of the biliary system on cholangiography (Fig. 1); (ii) absence of choledocholithiasis or a history of bile-duct surgery; and (iii) exclusion of bile-duct cancer, usually by prolonged follow-up.

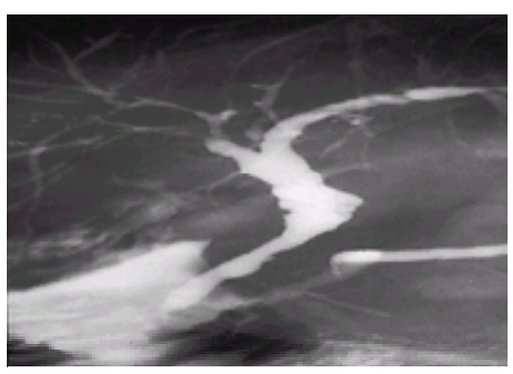

Fig. 1 Endoscopic retrograde cholangiogram showing the typical features of primary sclerosing cholangitis with stricturing and dilatation of the intra- and extrahepatic biliary tree.

The term secondary sclerosing cholangitis is used to describe the typical bile-duct changes when a clear predisposing factor to duct fibrosis, such as previous bile-duct surgery, can be identified. The causes of secondary sclerosing cholangitis are shown in Table 1.

Aetiology

The cause of primary sclerosing cholangitis remains unknown. There is a very close association, however, between primary sclerosing cholangitis and inflammatory bowel disease, particularly ulcerative colitis. Approximately two-thirds of Northern European patients with primary sclerosing cholangitis have coexisting ulcerative colitis, and primary sclerosing cholangitis is the most common form of chronic liver disease found in ulcerative colitis. In Southern Europeans about one-half of patients with primary sclerosing cholangitis will have ulcerative colitis. This difference in populations may be real or may represent differences in case finding as not all the patients studied had had colonoscopy and colonic biopsies performed. Three to 10 per cent of patients with ulcerative colitis will develop primary sclerosing cholangitis, and the prevalence is greater in patients with substantial or total colitis than in those with distal colitis only. In a Swedish study, the prevalence of ulcerative colitis was 171 per 100 000 population and primary sclerosing cholangitis 6.3 per 100 000 population. It is clear that any proposed factors in the aetiopathogenesis of primary sclerosing cholangitis must explain this close association with inflammatory bowel disease. Current studies have suggested that genetic and immunological factors are important in the pathogenesis of primary sclerosing cholangitis.

Immunogenetic factors

Case reports of families in whom members developed ulcerative colitis and primary sclerosing cholangitis led to the search for an HLA association. A close link with the *HLA A1-B8-DR3* haplotype has been found, in common with other organ-specific autoimmune diseases such as autoimmune chronic active hepatitis. *HLA DRw52a*, which is in linkage disequilibrium with *DR3*, is also closely linked to the development of primary sclerosing cholangitis. In British patients who are *DR3* and *Drw52a* negative, an increased prevalence of *HLA DR2* is found. *HLA A1-B8-DR3* and *DR2* are equally distributed in patients with primary sclerosing cholangitis, with or without ulcerative colitis. An independent association with *HLA DR6* has also been documented. It has been suggested that *DRw52a*, *DR6*, and *DR2* encode for amino acids in the HLA b-chain that may enhance antigen presentation by the HLA molecule to the T-cell receptor. Further evidence of an autoimmune basis for this condition has been provided by many studies that have shown humoral and cellular immune abnormalities.

Humoral immune abnormalities

Like primary biliary cirrhosis, a disease with which it shares many features (see Chapter 14.27.2), symptomatic primary sclerosing cholangitis is characterized by hypergammaglobulinaemia, often with a disproportionate elevation of serum IgM concentrations in adult patients. In contrast, high concentrations of serum IgG are found in all children with primary sclerosing cholangitis. Smooth-muscle antibody and antinuclear factor are also found in approximately one-third of patients with primary sclerosing cholangitis, usually in low titres.

Recently, a cytoplasmic antineutrophil antibody was found in the serum of 80 per cent of patients with primary sclerosing cholangitis and approximately 30 per cent of patients with ulcerative colitis. However, it is not specific for primary sclerosing cholangitis and is found in 50 per cent of patients with autoimmune chronic active hepatitis (type 1). It is not found in primary biliary cirrhosis. The antigens in primary sclerosing cholangitis are distinct from those found in Wegener's granulomatosis, which have been shown to be proteinase 3 and myeloperoxidase. Current evidence suggests that the antigen may be a nuclear envelope protein. The pathogenetic significance of the circulating antibody is not clear, but it may prove to be useful in a diagnostic test. Titres of the antibody do not change after hepatic transplantation.

Cellular immune abnormalities

Elevated circulating immune complexes associated with activation of complement via the classic pathway have been found in the serum and bile of patients with primary sclerosing cholangitis. In common with other autoimmune diseases, there are reduced levels of T-suppressor cells circulating in the serum of these patients, leading to an increased ratio of T-helper to T-suppressor cells. Infiltration of portal tracts by increased numbers of mononuclear cells is seen in liver biopsies from patients with primary sclerosing cholangitis. The majority of these cells are activated T lymphocytes.

Current evidence suggests that primary sclerosing cholangitis is an immunologically mediated disease, perhaps triggered in genetically susceptible subjects by acquired toxic or infectious agents, which are presented through antigen-presenting cells to activated T lymphocytes. Unlike normal biliary cells, the biliary epithelial cells in primary sclerosing cholangitis express HLA class II molecules and also intercellular adhesion molecules (**ICAM**) such as ICAM-I. It has not yet been confirmed, however, that bile-duct cells can act as antigen-presenting cells, as expression of other costimulatory molecules such as B7, which are needed for antigen presentation, are not consistently found on biliary epithelial cells (cholangiocytes).

Alternative hypothesis—exposure to bacterial components

An alternative hypothesis has been proposed in which the initial event is the reaction of an immunologically susceptible host to bacterial cell wall products. This reaction would result in hepatic macrophages producing tumour necrosis factor-a and endotoxin. The exposure to bacterial components and increased gut permeability would be increased by the presence of inflammatory bowel disease, but could also, in theory, occur during episodes of gut infection. The resulting increase in peribiliary cytokine and chemokine secretion would attract activated neutrophils, monocyte/macrophages, T cells, and fibroblasts. The deposition of concentric fibrosis could result in atrophy of the biliary epithelial cells secondary to ischaemia. The resulting bile duct loss would lead to progressive cholestasis, fibrosis, and secondary biliary cirrhosis. This hypothesis does not explain the relative scarcity of patients with Crohn's colitis and does not take into account the strong circumstantial evidence of immune mediation and autoimmunity, previously described.

Clinical features

There is a clear male predominance, with a male:female ratio of 2:1. The majority of patients present between the ages of 25 and 40 years, although primary sclerosing cholangitis may be diagnosed at any age. Indeed, it has become recognized recently as an important cause of chronic liver disease in children.

The clinical presentation is variable: some patients may present with fatigue, intermittent jaundice, weight loss, right upper quadrant pain, and pruritus. Attacks of acute cholangitis are surprisingly rare and usually follow instrumental biliary intervention, such as ERCP. Physical examination is abnormal in approximately half of symptomatic patients; the most common findings are jaundice and hepatosplenomegaly. Many patients with primary sclerosing cholangitis are asymptomatic at diagnosis, which is made incidentally when a persistently raised serum alkaline phosphatase is discovered, usually in the setting of ulcerative colitis.

Serum biochemical tests usually indicate cholestasis, but primary sclerosing cholangitis may cause no abnormalities of serum biochemistry. The serum alkaline phosphatase is often raised to greater than three times normal, and mild elevations in liver transaminases are seen in the majority of patients. Serum bilirubin is not usually elevated until later stages of the disease. Levels of bilirubin and alkaline phosphatase may fluctuate widely in an individual patient during the course of the disease. Hypoalbuminaemia is unusual until the disease becomes advanced. As mentioned above, increased serum IgM concentrations are seen in about half of the symptomatic adult patients, but high concentrations of IgG are always found in children with primary sclerosing cholangitis.

In addition to the serum antineutrophil antibodies, low levels of antinuclear antibody and smooth-muscle antibody may be found in approximately one-third of patients, but serum mitochondrial antibodies are absent.

Diagnosis

Radiological features

The cholangiographic appearances on ERCP are usually diagnostic and consist of multiple, irregular stricturing and dilatation (beading of the intrahepatic and extrahepatic biliary ducts) (Fig. 1). Occasionally, involvement is localized to the intrahepatic system, and even more rarely, only the extrahepatic bile ducts may be involved. Small diverticula are found along the common bile duct in about 20 per cent of patients and are pathognomonic (Fig. 2). Magnetic resonance cholangiopancreatography provides a non-invasive method of imaging the biliary tree, and will become the standard technique for the diagnosis of primary sclerosing cholangitis. (Fig. 3) Approximately 20 per cent of patients have stricturing of the main pancreatic duct, although exocrine pancreatic insufficiency is rare.

Fig. 2 Endoscopic retrograde cholangiogram from a patient with primary sclerosing cholangitis showing a diverticular appearance of the common bile duct.

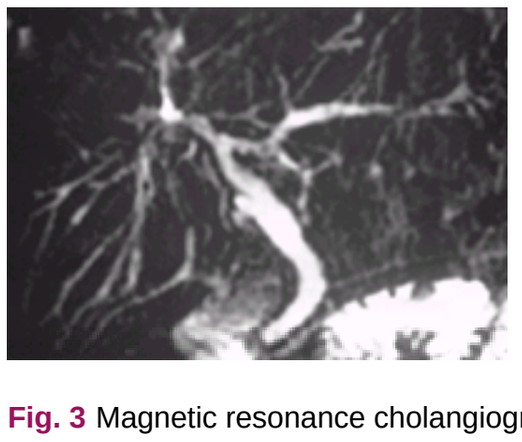

Fig. 3 Magnetic resonance cholangiogram demonstrating hilar stricture and intrahepatic involvement of the biliary tree.

Pathological features

The histological appearances of liver are not usually diagnostic for primary sclerosing cholangitis, although some form of biliary disease can usually be identified. The characteristic early features of primary sclerosing cholangitis are periductal 'onion skin' fibrosis and inflammation, portal oedema, and bile ductular proliferation resulting in the expansion of the portal tracts (Fig. 4). Later, fibrosis spreads into the liver parenchyma to form fibrous septa, leading inevitably to biliary cirrhosis. As in primary biliary cirrhosis, with disease progression an obliterative cholangitis occurs, leading to complete replacement of the intralobular bile ducts by connective

tissue—the so-called vanishing bile-duct syndrome. In addition, piecemeal necrosis, copper-binding protein, cholestasis, and occasional portal phlebitis may be present.

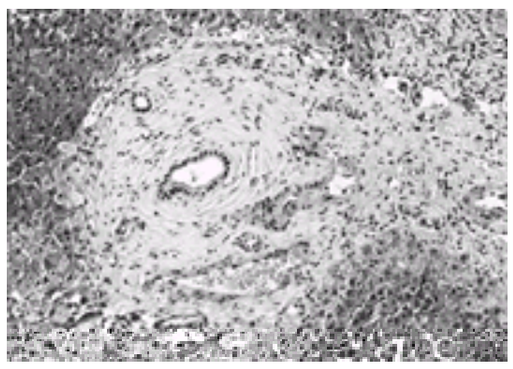

Fig. 4 The hepatic histological changes of early primary sclerosing cholangitis showing a concentric (onion skin) fibrosis around the bile ducts.

Association with other diseases

A large number of diseases have been associated with primary sclerosing cholangitis (Table 2). The most important association, as discussed above, is with inflammatory bowel disease, particularly ulcerative colitis. The extent of the colitis is usually total but symptomatically, and paradoxically, mild, often with no rectal bleeding and characterized by prolonged remission. Rectal sparing is found in 20 per cent of patients with ulcerative colitis and primary sclerosing cholangitis compared with 5 per cent of patients with ulcerative colitis alone. Although the symptoms of ulcerative colitis usually develop before those of primary sclerosing cholangitis, the onset of the latter may precede the symptoms of colitis by some years. The outcome of primary sclerosing cholangitis is completely unrelated to the activity, severity, or clinical course of the colitis, and colectomy has no effect on the progression of the cholangitis. Primary sclerosing cholangitis is less common in Crohn's disease, occurring in less than 1 per cent of patients and only in those with Crohn's colitis. Patients with primary sclerosing cholangitis and ulcerative colitis are at greater risk of developing colorectal dysplasia and colonic cancer than those with ulcerative colitis alone. In a Swedish study, the absolute accumulative risk of developing colorectal dysplasia/cancer in the primary sclerosing cholangitis/ulcerative colitis group was 9, 31, and 50 per cent, respectively, after 10, 20, and 25 years of disease duration. In the group with ulcerative colitis alone, the corresponding risk was 2, 5, and 10 per cent, respectively.

Natural history and prognosis

The course of primary sclerosing cholangitis is highly variable. The median survival from presentation to death or liver transplantation in symptomatic patients is approximately 10 to 12 years, whilst approximately 75 per cent of asymptomatic patients survive 15 years or more. The majority of patients die in hepatic failure following deepening cholestatic jaundice. However, approximately 10 to 30 per cent of patients with long-standing primary sclerosing cholangitis die from the development of bile duct carcinoma, which often follows a very aggressive course. The mean survival after the diagnosis of cholangiocarcinoma is only 9 months. Unfortunately, there are no factors that will predict which patients will develop this cancer. Tumour markers such as CEA and CA 19–9 have been investigated as potential serum markers of the development of bile duct cancer in primary sclerosing cholangitis. Although some centres have found elevations in serum CA 19–9 a useful predictor, these results have not been confirmed in other units. Attempts to model factors that will predict the risk of progression to liver failure and death have yielded conflicting data from different centres. It is probable that the majority of asymptomatic patients will progress insidiously to symptomatic liver disease, liver failure, and death.

Treatment

Symptomatic measures

There is no curative treatment for primary sclerosing cholangitis. This is indicated by the plethora of medical, endoscopic, and surgical approaches that has been advocated.

Management of cholestasis

Symptomatic patients are frequently troubled by pruritus. This is best managed initially by cholestyramine and the dose should be increased until relief is obtained. Second line treatments include rifampicin and the opioid antagonist naltrexone. In addition, replacement of fat-soluble vitamins is necessary when patients become jaundiced. Metabolic bone disease (usually osteoporosis) is a common complication of advanced primary sclerosing cholangitis. Calcium supplementation with vitamin D_3 should be given prophylactically in jaundiced patients and bisphosphonates considered in patients with osteoporosis.

Management of complications

Broad-spectrum antibiotics such as ciprofloxacin should be given for acute attacks of cholangitis, but they have no proven prophylactic value and should not be used in the long term routinely. If cholangiography shows a well-defined obstruction to the main extrahepatic bile ducts, then mechanical relief must be considered. In many patients the best approach is to introduce a prosthesis (stent) through the obstruction. This may be placed non-operatively by the percutaneous transhepatic route or at ERCP. Balloon dilatation of the strictures before stenting may prove useful in a minority of patients with well-defined localized strictures and can lead to a striking improvement in symptoms and serum biochemistry.

Another common complication is the development of small biliary stones (brown pigment) and biliary sludge, which can lead to a rapid clinical or biochemical deterioration. In these patients, endoscopic sphincterotomy with extraction of the biliary debris can be beneficial.

Small duct disease

A few patients with ulcerative colitis will have persistently abnormal cholestatic liver function tests with typical histological appearances such as concentric fibrosis but with normal bile ducts at cholangiography. The term 'small-duct primary sclerosing cholangitis' has been proposed to replace the term 'pericholangitis' in this group of patients as the evidence suggests that these conditions are all part of the same disease spectrum. Only a minority of patients with 'small-duct disease' will progress to develop extrahepatic biliary involvement and they are not predisposed to develop cholangiocarcinoma.

Specific treatment

Medical

The medical treatment of primary sclerosing cholangitis has included trials of corticosteroids, immunosuppressive drugs, cholecystogogues, and antibiotics, either alone or in combination. The results have been universally disappointing, although assessment of treatment of this uncommon disease is difficult because the clinical course fluctuates, survival is variable, and some patients may remain asymptomatic for long periods of time. The role of corticosteroid therapy is unclear. There have been no large controlled trials, but corticosteroids have been used topically and systemically in small and generally uncontrolled studies. However, there is evidence that, even in male patients, metabolic bone disease may be accelerated by corticosteroids and in general they should not be used in this condition.

Ursodeoxycholic acid is a non-hepatotoxic hydrophilic bile acid which has been used widely for the treatment of cholestasis—it reduces levels of cholestatic liver enzymes. Controlled trials in concentrated doses (10 to 15 mg/kg body weight) have shown no effect on symptoms, histology, or survival. Recent trials suggest that

larger doses are needed to produce a beneficial effect, with improvement in histology at 2 years.

A number of immunosuppressant agents have been tried, either alone or in combination, including azathioprine, methotrexate, and cyclosporin. Overall, the results have been disappointing.

Surgical

The role of hepatobiliary surgery in the treatment of primary sclerosing cholangitis remains controversial. Good results have been claimed for the resection of the extrahepatic biliary tree followed by biliary reconstruction with silastic transhepatic stents. However, controlled trials are needed to confirm the efficacy of these and other surgical techniques, as previous biliary surgery will increase perioperative mortality from hepatic transplantation.

Transplantation

Orthotopic liver transplantation is the only option available in young patients with primary sclerosing cholangitis and advanced liver disease. Primary sclerosing cholangitis is now the second most common indication for liver transplantation in the United Kingdom. Recent results have been very encouraging, with 5-year survival rates of 80 to 90 per cent being obtained in most centres. These rates compare favourably with those for other forms of chronic liver disease. It has become clear that primary sclerosing cholangitis recurs in the transplanted liver in 20 per cent of patients at 1 year post-transplant, but only rarely has recurrence led to problems with liver decompensation requiring retransplantation. Proven cholangiocarcinoma is a contradiction to transplantation because the tumour recurs rapidly after transplantation with immunosuppression. As patients suffering from primary sclerosing cholangitis in combination with ulcerative colitis have an increased risk for the development of colon cancer after transplantation, yearly colonoscopy has been recommended in this group. Several centres have noted a worsening in the symptoms of ulcerative colitis after transplantation; the explanation for this phenomenon remains unclear.

14.21.1 Alcoholic liver disease and non-alcoholic steatosis hepatitis

O. F. W. James

Alcoholic liver disease

Only 10 to 30 per cent of heavy, persistent, alcohol drinkers develop cirrhosis, although well over 50 per cent have fatty livers. Individual susceptibility depends on many factors. The contribution of nutrition remains controversial, but is seems possible that both undernutrition and obesity act synergistically with direct alcohol toxicity to increase the likelihood of liver damage. High alcohol consumption in patients infected with hepatitis C virus also increases the possibility of severe liver disease.

In a large group of males with alcoholic cirrhosis, average alcohol consumption was 160 g/day (equivalent to over two bottles of wine, 4.5 litres of normal strength lager or two-thirds of a bottle of spirits) over 8 years. In females the corresponding figure was 110 g/day. It seems likely that almost no risk of significant alcohol-related liver damage exists below about 40 g/day equivalent to 30 units per week in men, rather less in women, assuming no other associated risk factors. Current 'sensible' limits recommended in the United Kingdom are 21 units (200 g) for men and 14 units (130 g) for women, but these figures are arbitrary.

Susceptibility to alcoholism and to alcoholic liver damage each have genetic components; probably one in three alcoholics will have at least one parent who is alcoholic. Analysis of twin studies suggests hereditability of excess drinking of alcohol in the range of 0.3–0.6 (where 0 = no hereditability, 1.0 = complete hereditability).

Pathology

Fatty liver is the first histological lesion; it occurs in most heavy drinkers at one time or another, but is completely reversible on alcohol withdrawal. More serious is alcoholic hepatitis, which may occur in up to 40 per cent chronic ethanol abusers. The most severe changes are seen in the perivenular area; including ballooning and necrosis of liver cells, in some of which Mallory bodies may be seen; pericellular fibrosis around hepatic venules ('chicken wire' fibrosis); and a patchy inflammatory-cell infiltrate, mainly polymorphs, often only seen around a few hepatocytes. Ultimately, fibrous septa link hepatic veins to portal veins and regeneration occurs, disturbing normal liver architecture with the formation of nodules and cirrhosis.

Clinical features

Symptoms and signs of alcoholic liver disease (Table 1) correlate only very broadly with underlying histology or abnormal tests of liver function.

Patients with fatty liver may have no symptoms or complain only of nausea and malaise. Liver function tests may be mildly deranged but in severe cases, there may be cholestasis or even, very rarely, liver failure and portal hypertension.

Mild alcoholic hepatitis is often indistinguishable clinically from fatty liver, with which it usually coexists, but in more severe cases anorexia, nausea, abdominal pain, and weight loss may develop. Severe alcoholic hepatitis, with or without cirrhosis, is a medical emergency; patients are at risk of ascites, bleeding, and encephalopathy. They may also become infected—urinary tract infection, pneumonia, spontaneous bacterial peritonitis, or septicaemia. Detection of such infection is complicated by the fever and leucocytosis caused by the liver disease itself. Those most severely affected may develop profound cholestasis and hypoglycaemia.

The picture in established cirrhosis is variable. In some who have stopped drinking there may be no symptoms and liver function tests may be near normal. More often, patients suffer malaise and will have lost weight and show classical physical signs (Table 1), may be jaundiced, and may bleed from varices. Zieve's syndrome of marked jaundice from a combination of cholestasis and haemolysis with hyperlipidaemia is rare.

History and investigation

Many patients are reluctant to admit their alcoholism, even when liver disease is gross (see Chapter 26.7.2). Liver function tests are often unhelpful in establishing severity, except at the late stage. Early abnormalities may include raised serum g-glutamyl transferase and macrocytosis. Measurement of blood or urinary ethanol is helpful if high levels are found. There may be a disproportionate elevation of serum aspartate transaminase compared to alanine transaminase. Serum ferritin may be very elevated in active heavy drinkers. Alcoholism is a common cause of combined hyperlipidaemia, indeed serum may be very hyperlipaemic. Liver biopsy allows confirmation of histological severity and exclusion of other pathologies. White-out on colloid liver scan implies severe alcoholic hepatitis.

Prognosis

Prognosis is above all related to whether the patient continues to drink or stops. In patients with fatty change alone the outlook is excellent, provided patients stop or substantially cut down drinking, although some may progress to more advanced liver disease. Mild alcoholic hepatitis has a similar prognosis to fatty change. In severe, acute alcoholic hepatitis, whether or not superimposed upon cirrhosis, there is a 12 to 50 per cent mortality within 6 months of presentation. Particularly adverse features are raised bilirubin level and abnormal blood clotting. This had led to the use of a discriminant function to help assess prognosis and decide upon treatment (Table 2). In alcoholic cirrhosis overall survival at 5 years is about 50 per cent, among abstainers 70 per cent, and in those who continue to drink 35 per cent. A second important prognostic feature is age at presentation. In a recent United Kingdom study, 3-year survival was 77 per cent in patients under the age of 60, and 46 per cent in those presenting over that age. Nutrition (possibly reflecting socio-economic status) also influences survival. Unfortunately, hepatocellular cancer can arise in patients with long-standing, often inactive, alcoholic cirrhosis, particularly men.

Treatment (see also Section 26.7)

The best treatment remains total withdrawal of alcohol and subsequent long-term abstinence in all patients with liver disease worse than moderate fatty change alone, in which case, very moderate drinking after a period of abstinence may be an option. Good prognostic features include recognition of the problem by the patient, a supportive family, steady employment, and willingness to accept treatment. No other treatment is required for patients with fatty liver or mild alcoholic hepatitis.

Severe alcoholic hepatitis

Meta-analysis of more than 10 trials of high-dose corticosteroid treatment added to conventional therapy has led to the following recommendations. In patients with discriminant function over 32 (Table 2) but who have no overt sepsis or active bleeding, 40 mg prednisolone for 21 days probably provides a 20 per cent improvement

in mortality. Insulin and glucagon, anabolic steroids, colchicine, enteral and parenteral nutrition, and a variety of other so-called 'hepato-protective drugs' have all been used in trials but without real evidence of benefit with respect to mortality.

Cirrhosis

Treatment is directed against its complications, particularly portal hypertension, ascites, spontaneous bacterial peritonitis, and encephalopathy.

Transplantation

The indications for transplantation in alcoholic cirrhosis are similar to those for other endstage liver diseases (see later), with the caveat that even in advanced alcoholic cirrhosis, abstention can lead to enormous clinical improvement and long-term survival. Many transplant units consider patients only after a 6-month period of abstention, both to detect patients in whom transplantation is no longer necessary and to exclude individuals who continue to drink heavily. Estimated 5-year survival following transplantation is now over 70 per cent.

Non-alcoholic steatosis hepatitis

This is increasingly recognized as an important distinct clinical entity. Originally described in, usually very, obese females and in diabetics, or patients with hyperlipidaemia, also in patients following jejunoilial bypass surgery for obesity. This condition is now recognized in individuals of both sexes who are only marginally obese but who may have changed weight recently. Patients often present because of detection of abnormal liver function tests. It is important to make this diagnosis both for prognostic reasons and to clearly state the non-alcoholic nature of this disease in an individual for purposes of employment and insurance.

Pathology

This is identical to alcoholic liver disease, most patients having simple steatosis, others develop an alcoholic hepatitis-like appearance with or without fibrosis, a small proportion (perhaps 5–10 per cent) develop cirrhosis.

Clinical features

Most are asymptomatic but are 'accused' of having alcoholic liver disease. Up to 40 per cent have persistent right upper abdominal pain and may complain of lethargy and malaise. About 5 to 10 per cent, usually very obese and diabetic, develop cirrhosis with its complications.

Investigations

Patients must have a history of high alcohol consumption exhaustively excluded as a cause for their liver disease. Liver function tests show raised serum transaminases, unlike alcoholic liver disease serum alanine transaminase is raised compared with aspartate transaminase. Serum g-glutamyl transferase is also raised. Liver ultrasound shows a fatty appearance but cannot reliably distinguish the extent of fibrosis.

Prognosis

This is excellent except in the small proportion of those who develop cirrhosis where complications and clinical course are as for other causes of cirrhosis.

Treatment

No treatment has yet been proven to be effective. Probably slow weight reduction, a reduced fat diet, and a period of abstinence from any alcohol consumption are most effective.

14.21.2Cirrhosis, portal hypertension, and ascites

Kevin Moore

Introduction

Ascites is the accumulation of fluid in the peritoneal cavity. It has fascinated doctors for many years, and studies on its pathogenesis were initiated as long ago as the seventeenth century. Richard Lower (1631–1691), a physician based in Oxford, demonstrated that ascites developed in dogs following ligation of the inferior vena cava. Ernest Henry Starling (1866–1927), a physiologist based at University College London, made the greatest contribution to the study of oedema formation, with the demonstration that both hydrostatic forces and oncotic forces were involved. He also showed that the increase in thoracic lymph flow following obstruction of the inferior vena cava is mainly derived from the liver.

Aetiology

Ascites is a common complication of cirrhosis and indicates the presence of portal hypertension and hepatic decompensation. It occurs in at least 50 per cent of patients within 10 years of the diagnosis of cirrhosis, which accounts for over 75 per cent of cases presenting with ascites. Ascites may be due to malignancy, pancreatitis, tuberculosis, cardiac failure, myxoedema, or other rarer causes, each of which may also occur in patients with cirrhosis (Table 1). Ascites does not occur in patients with portal vein thrombosis or other forms of non-cirrhotic portal hypertension such as congenital hepatic fibrosis, except as a transient finding following a gastrointestinal haemorrhage. It frequently occurs in patients with the Budd–Chiari syndrome or late-onset hepatic failure (subfulminant hepatic failure), and, to a lesser extent, where small amounts of peritoneal fluid accumulate in cases of acute liver failure.

Other (rare) causes of ascites include constrictive pericarditis, malnutrition, stromal tumours and Meigs' syndrome, hypothyroidism, Budd–Chiari syndrome, veno-occlusive disease, or lymphatic leak (chylous ascites). Rare infections include candidiasis and filariasis. Granulomatous liver disease such as sarcoidosis may cause severe portal hypertension, and occasional ascites. Although ascites commonly occurs in patients with cardiac failure, it is not usually a presenting feature. Ascites may also occur in the ovarian hyperstimulation syndrome in women undergoing fertility treatment.

Epidemiology

Cirrhosis is the eleventh leading cause of death in the United States. It heralds the beginning of a usually rapid decline of liver function so that about half the patients die within 2 years of the onset of ascites.

Pathogenesis of ascites due to cirrhosis

The presence of portal hypertension is essential for the development of ascites: fluid accumulation does not occur at a portal pressure below 8 mmHg. However, factors other than portal pressure are important, since ascites does not develop spontaneously in patients with portal vein thrombosis. Ascites develops as a consequence of sodium and water retention, which in the presence of portal hypertension causes transudation of fluid into the peritoneal cavity, and together with an increased production of hepatic lymph may cause a massive accumulation of fluid—a moderate to marked ascites will comprise about 5 to 25 litres of fluid. Portal hypertension is an essential prerequisite for the development of ascites, since it does not develop when salt and water retention is due to mineralocorticoid excess (for example, Conn's syndrome or a secreting adrenal carcinoma), in which the cardinal manifestation is hypertension. Whilst it is well recognized that abnormal sodium handling occurs in patients with advanced cirrhosis, it less well known that sodium handling is abnormal even in the preascitic stage. Experiments by Dudley and colleagues have shown that the proximal tubular reabsorption of sodium is enhanced in early cirrhosis, and that some patients exhibit glomerular hyperfiltration. Sodium retention does not occur as a result of hyperaldosteronism, for approximately 60 per cent of patients with ascites have normal aldosterone levels at initial presentation. There is no doubt, however, that aldosterone plays a role in sodium balance, as it increases sodium retention in the distal tubules. The administration of high doses of spironolactone increases natriuresis in patients with cirrhosis and ascites, despite apparently normal plasma aldosterone levels. This has given rise to the concept that renal sensitivity to aldosterone may be enhanced in cirrhosis. Other factors known to be involved in sodium homeostasis include the sympathetic nervous system, which is activated in decompensated liver disease and which enhances sodium reabsorption along the proximal tubules. A third important factor is the rate of sodium delivery to the tubules. Renal blood flow is decreased in cirrhosis, and decreases further with decompensation. During decreased sodium delivery, sodium reabsorption is enhanced. Other factors such as atrial natriuretic peptide, endothelin-1, or urodilatin may be involved, but their role is as yet undefined.

The underlying cause of the activation of sodium-retaining pathways is still disputed, but data are available to support both the underfill and overfill hypotheses. There is no doubt that at different stages of disease development the same patient may exhibit signs of both an expanded and a contracted central blood volume. A unifying hypothesis, known as the 'vasodilatation hypothesis', was put forward to explain the observations regarding the development of salt-retaining states (Fig. 1). In this, the central stimulus for activation of neurohumoral pathways is a decrease in the central blood volume, which differs in severity depending on the intensity of liver disease. Whilst superficially attractive, this hypothesis fails to explain why many patients develop salt retention in the presence of normal aldosterone concentrations, and why systemic vasodilatation is only observed in the supine state.

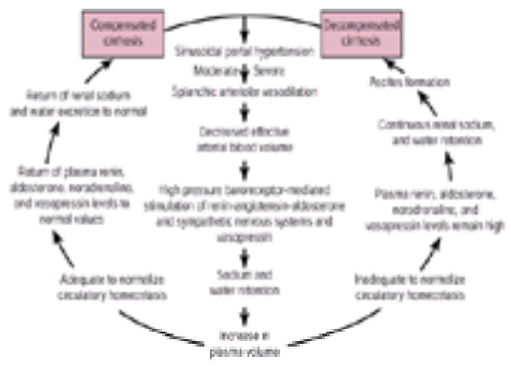

Fig. 1 Outline of peripheral vasodilation hypothesis (Schrier *et al*. (1988). Peripheral arterial vasodilation hypothesis: a proposal for the initiation of renal sodium and water retention in cirrhosis. *Hepatology* **8**, 1151–7).

Clinical features

Ascites is graded 1 to 3 depending on its severity. Grade 1 ascites is mild, and only detectable by ultrasound examination. Grade 2 ascites is moderate, and is manifest by moderate symmetrical distension of the abdomen; whereas grade 3 ascites is large or gross, with marked abdominal distension. A grade 2 ascites is most easily detected by a shifting dullness. Grade 3 ascites is usually tense and easily detected by the presence of a fluid thrill on palpation. There is often divarification of the rectus abdomini muscles, and prominent veins may be evident on the abdominal wall (see Fig. 2). Paraumbilical hernias develop in about 20 per cent of patients with ascites, an incidence that increases to up to 70 per cent in those with long-standing recurrent tense ascites. The main risks are rupture and strangulation. Pleural effusions (hepatic hydrothorax) develop in about 5 per cent of patients with cirrhosis. Hepatic hydrothorax may develop in patients with no discernible ascites. The pleural effusions are right-sided in 85 per cent of cases, left-sided in 13 per cent and bilateral in 2 per cent of cases.

Fig. 2 Alcoholic cirrhosis with ascites is often associated with marked anorexia.

Laboratory diagnosis

The cause of ascites or its precipitation is often self-evident. Where there are no obvious clues to its aetiology, tests must be directed at diagnosing both the presumed cause of liver disease and/or at excluding other causes of ascites such as malignancy or tuberculosis, etc. Other causes of abdominal distension such as huge masses, Meigs' syndrome, or pregnancy should be considered. The essential investigations on admission of a patient to hospital include:

- *Serum urea and electrolyte concentrations*—patients with ascites due to cirrhosis are prone to hyponatraemia or renal impairment, either spontaneously or following diuretic therapy.
- *Ascitic aspiration* with microscopy, determination of albumin or protein content, culture, cytology, and amylase measurement should be performed to confirm or exclude spontaneous bacterial peritonitis, tuberculosis, malignancy, or pancreatic disease. A Gram stain is usually uninformative.
- *Ultrasound scans* are needed to evaluate liver appearance (nodular and cirrhotic) or congested (for example, congestive cardiac failure (CCF)), as well as blood flow in the portal vein (to exclude the portal vein thrombosis that occurs in 8 per cent of patients with cirrhosis, and which may precipitate hepatic decompensation), a semi-quantitation of the amount of ascites, and the presence of tumour in the liver or other masses.

Paracentesis

An ascitic tap is used for either diagnostic purposes or for the therapeutic removal of large volumes of ascites. The most common site for aspirating ascites is about 15 cm lateral to the umbilicus, with care being taken to avoid an enlarged liver or spleen. The epigastric arteries run just lateral to the umbilicus towards the mid-inguinal point and should also be avoided.

For diagnostic purposes, between 20 and 50 ml of ascitic fluid should be withdrawn, and 3 to 5 ml placed under aseptic conditions (i.e. the needle changed) into each of two blood culture bottles (tuberculin cultures have to be requested specifically). Fluid for culture should **not** be sent in plastic containers for culture—when a sample of infected ascites is placed into such containers the culture positivity is only 40 per cent, whereas it is more than 90 per cent positive when inoculated into blood culture bottles. A 5-ml aliquot of fluid should be sent in a plastic container to the microbiology department for a polymorphonuclear neutrophil (PMN) or lymphocyte count. The microbiologist should report a neutrophil count (e.g. < 250 PMNs/mm ^{3}) together with a limited differential (i.e. PMN or lymphocytes). Ascitic fluid occasionally clots, in which case a sample should be placed in a tube containing EDTA (ethylenediaminetetraacetic acid). Coulter-counter estimations of ascitic neutrophil numbers are probably unreliable at the lower end of a pathologically increased white blood cell count. A 5-ml aliquot should be sent for measurement of ascitic protein content or, ideally, ascitic albumin. Ascitic cytology should involve liaison with the cytopathologist. Cytology requires 20 to 50 ml of ascitic fluid. There is little diagnostic value in an analysis of ascitic fluid pH or of lactate or glucose concentrations.

Ascitic fluid investigations

Ascitic protein

The use of ascitic protein in the differential diagnosis of the causes of ascites is much over-rated, and misinterpreted. Conventionally, the type of ascites is divided into exudates and transudates: ascitic protein concentration over 25 g/l or under 25 g/l, respectively. The purpose of this subdivision is to narrow the differential diagnosis of the causes of ascites. However, many physicians assume that cardiac ascites will have a low level of ascitic protein, when this is rarely the case, and that patients with tuberculous peritonitis have a high ascitic protein content, when in fact it is low in 30 per cent of patients. Moreover, about 15 per cent of cases of cirrhotic ascites have an ascitic protein level of more than 25 g/l, while 20 per cent of patients with a malignancy have a low ascitic protein level. The causes of transudative and exudative ascites are given in Table 2. For those patients with cirrhosis, a very low ascitic protein level (< 10 g/l) is associated with an increased risk of spontaneous bacterial peritonitis (**SBP**) at the time of hospital admission. SBP is present in about 15 per cent of all patients admitted with cirrhotic ascites. The use of ascitic protein estimations to subdivide patients into exudative or transudative causes of ascites is considerably enhanced by measuring the difference between ascitic and serum albumin levels (see below).

Serum-ascites albumin gradient

Several studies have compared the value of ascitic protein with serum-ascitic albumin gradient measurements in patients with ascites resulting from cirrhosis and

other causes. In one study comprising 44 patients, it was reported that 5/29 (17 per cent) patients with cirrhotic ascites had an ascitic protein level above 25 g/l, whereas 3/15 (20 per cent) with malignant ascites had an ascitic protein level below 25 g/l. In contrast, the overlap in each group was reduced to 1/29 and 1/15 respectively when a serum-ascitic albumin gradient above 11 g/l was used. Based on the many inaccurate predictions of aetiology based on the measurement of ascitic protein, it is clearly preferable to measure the serum-ascitic albumin gradient in patients presenting with ascites. This method, which involves subtraction of the ascitic albumin concentration from that observed in ascites, very accurately divides patients into two groups: those with a high gradient (>11 g/l) and those with a low gradient (< 11 g/l). The overall accuracy of this method is 97 per cent. (Table 3)

Ascitic amylase

The ascitic fluid amylase level should always be measured in patients with an exudative or unexplained ascites. A very high value is obtained when ascitic fluid results from a pancreatic pseudocyst or mass.

Ascitic fluid microscopy

An ascitic neutrophil count of more than 250 PMNs/mm^3 is diagnostic of spontaneous bacterial peritonitis. An elevated lymphocyte count should raise the possibility of tuberculous peritonitis. Excess red blood cells are most commonly due to a traumatic tap, but should raise the possibility of malignancy.

Ascitic fluid culture

Classically, aspirated fluid is placed in a sterile container and sent to the microbiology department for microscopy and culture. For infected fluid handled in this way, a positive culture will be obtained in only about 40 per cent of samples. However, if ascitic fluid is treated in the same way as blood cultures, and fluid inoculated directly into blood culture bottles at the bedside, the positive culture rate increases to 92 per cent (see above). A single study has evaluated the effectiveness of cytospin with cell lysis to improve the efficacy of culturing ascitic fluid, and again found that direct inoculation of ascitic fluid into blood culture bottles was far superior (79 per cent positivity) compared with the cell-lysis method (46 per cent culture-positive).

Ascitic fluid cytology

Ascitic cytology should involve liaison with the cytopathologist so that the index of suspicion and type of potential tumour are discussed. A 20- to 50-ml sample of ascitic fluid is required to produce a cell concentrate for cytology—obtained by centrifuging the ascites fluid, removing supernatant, and resuspending the cells. A sample of the concentrate then undergoes a cytospin to deposit cells on to microscope slides, following which the cells are stained. Typical stains include the Papanicolaou and May-Grunwald–Giemsa stain.

Ascitic volume

Ascitic volume is not usually determined in clinical practice. It can, however, be quantified radiologically or by indicator-dilution. As a rough guide, patients with barely detectable ascites usually harbour between 1 and 4 litres, those with moderate ascites 4 to 8 litres, and those with marked ascites more than 8 litres of fluid. Ultrasonographic determination of ascitic volume involves measurement of the abdominal circumference and the deepest vertical depth of the fluid, and modelled as a segment of a sphere. Isotopic determination of ascitic volume involves the injection of radiolabelled ^{99}Tc- macroalbumin.

Treatment

Patients with ascites can be divided into those that are easy to treat and those that are difficult. In general, patients with their first presentation of ascites and normal renal function, who have a spot urine sodium concentration of more than 20 mmol/l, or an identifiable source of dietary sodium excess, respond well to simple measures. Likewise, when ascites has developed as a consequence of bleeding or infection, it usually resolves more readily. The treatment of ascites is summarized in Table 4.

Bed rest

Bed rest is probably of no benefit in patients with a preserved renal function, as indicated by a serum creatinine concentration of less than 125 µmol/l and a good initial response to diuretics. However, there is data to suggest that it may be beneficial in those with a poor response to diuretics, but further studies are required.

Dietary salt restriction

There is a general consensus that dietary salt restriction is important in the management of patients with cirrhosis and ascites. However, it is important to maintain an adequate level of nutrition in patients with cirrhosis. Therefore it is generally agreed that sodium intake should be restricted to less than 90 mmol/day, which in effect amounts to a 'no added salt' diet with avoidance of preprepared meals. It is also generally agreed that salt restriction should be an adjunct to diuretic therapy, and that it is rarely effective alone.

Role of water restriction

There are no studies evaluating the role of water restriction on the resolution of ascites. In many studies from the United States and Europe, it has been customary to restrict water intake to between 1 and 1.5 litres/day, a recommendation that has appeared in many major texts for the last 20 to 30 years. It would appear that this treatment has simply crept into current dogma, with no clinical or scientific basis to support this treatment. It is well known that water follows salt, and thus fluid loss will occur with salt restriction or adequate diuresis. In a study of 55 patients with ascites, none of whom had taken any diuretics for 2 weeks, 21 had spontaneous hyponatraemia and 34 were normonatraemic. In all patients with normonatraemia, the free-water clearance was normal. Of those with hyponatraemia, 13 had a marked reduction in free-water clearance and glomerular filtration rate. The remaining 8 hyponatraemic patients had a relatively normal free-water clearance. The patients with hyponatraemia and poor renal function did not respond to diuretic therapy, and had a poor prognosis: 60 per cent inpatient mortality compared with 15 per cent in the remaining patients. Hyponatraemia is caused by excessive water retention, primarily as a result of increased circulating vasopressin levels. Since the hyponatraemia is due to water excess, patients with significant hyponatraemia are usually subject to a water restriction of less than 500 ml/day. The response, however, is slow, and many regard this approach as being relatively ineffective. It is sometimes more prudent to try and improve renal function with volume expansion, in the first instance with colloid.

Thus, patients with ascites who are normonatraemic or mild/moderately hyponatraemic (serum sodium concentration above 125 mmol/l) should not be water-restricted. Water restriction should be reserved for those with severe hyponatraemia in whom the free-water clearance is decreased, after ensuring that their intravascular volume is adequate.

Diuretics

Since they first became available, diuretics have been the mainstay of the treatment of ascites. Diuretic dosage should be increased stepwise if there is an insufficient diuretic response, as defined by a weight loss of less than 1 kg in the first 7 days and/or 2 kg every 7 days thereafter, until the ascites is adequately controlled. The safe upper limit of the rate of weight loss is contentious. However, most experts agree that, in clinical practice, the diuretic dose should be adjusted to achieve a rate of weight loss below an average of 500 g per day in patients without peripheral oedema or 1 kg per day in those with peripheral oedema. Best practice is to add a loop diuretic (furosemide (frusemide) 40 mg/day) once a patient fails to respond to the equivalent of 200 mg spironolactone per day. Many diuretic agents have been evaluated over the years, but in the United Kingdom and Europe this has been mainly confined to spironolactone, amiloride, furosemide (frusemide), and bumetanide.

Diuretic agents

Spironolactone

Spironolactone is an aldosterone antagonist, acting mainly on the distal tubules to increase natriuresis and conserve potassium. In a controlled study comparing the

efficacy of spironolactone in 40 non-azotaemic patients with ascites who were excreting less than 12 mmol of sodium/day, 18 of 19 patients responded to spironolactone alone, whereas only 11 of 21 patients responded to furosemide (frusemide) alone. Most patients responding to spironolactone required 150 mg/day, and a few required 300 mg/day. In all cases diuresis occurred by the third day. For those given furosemide, most responders required 80 mg/day, but a few required 160 mg/day. Furosemide was associated with a decrease in the serum potassium concentration, which necessitated potassium supplementation. In those given spironolactone, serum potassium concentrations increased appreciably. The side-effects of spironolactone include gynaecomastia, hyponatraemia, hyperkalaemia, impotence, menstrual disturbance (although most ascitic patients are amenorrhoeic), and osteomalacia.

Amiloride

Amiloride was first used in 1968, and, combined with either furosemide (frusemide) or ethacrynic acid, resulted in a satisfactory diuresis in most cirrhotic subjects with ascites. In a larger study, Yamada and Reynolds evaluated the efficacy of amiloride in patients with cirrhosis and ascites resistant to bed rest and a very low salt diet (<20 mmol Na/day). When used alone it induced a satisfactory response in 80 per cent of patients at doses of 15 to 30 mg/day.

Furosemide (frusemide)

Furosemide is a loop diuretic that causes a marked natriuresis and diuresis in normal subjects. Its efficacy compared with spironolactone is discussed above. In normal subjects it has a half-life of about 75 min, increasing to about 130 min in patients with cirrhosis. It is generally used as an adjunct to spironolactone treatment and has poor efficacy when used alone in cirrhosis. This is probably because there is salt retention in the distal tubules in the subset of patients with high plasma aldosterone concentrations. Furosemide should be used in a dose not exceeding 160 mg/day; its use is associated with severe electrolyte disturbance, and therefore should be prescribed cautiously.

Complications and benefits of diuretic therapy

Diuretic therapy generally improves morbidity and well being, since it causes resolution of ascites, allows a more liberal diet, decreases portal pressure, and increases the opsonic activity of ascitic fluid thereby decreasing the risk of spontaneous bacterial peritonitis. However, diuretic use is associated with complications in between 10 and 70 per cent of patients. The high incidence of side-effects from diuretics seen earlier is now becoming less common. The main complications of diuretic therapy are shown in Table 5.

Therapeutic paracentesis

Paracentesis has been in use for at least 2000 years, and was widely used in the earlier part of the last century. When diuretics first became available in the 1940s the practice declined but it was still used as an adjunct to therapy until the early 1960s. It gradually fell into disrepute with the recognition that repeated paracentesis resulted in salt depletion and oliguria, and became virtually banned as a treatment. The use of paracentesis re-emerged in the mid-1980s when several controlled clinical studies demonstrated that paracentesis with colloid replacement was safe and associated with fewer complications than diuretic therapy. In a large controlled study, patients with tense ascites were randomized to receive either paracentesis with intravenous albumin (40 g after each paracentesis) or diuretics (spironolactone 200–400 mg/day plus furosemide (frusemide) (40–240 mg/day). Patients with significant renal impairment (serum creatinine concentration > 250 µmol/l) were excluded. Paracentesis (4–6 litres/day) was effective in all patients, and no significant change in electrolytes or renal function was observed. Diuretics were effective in 28 out of 34 patients. There was, however, a significant increase and decrease in serum creatinine and sodium levels, respectively, in the diuretic-treated group, and the duration of inpatient treatment was considerably longer. Total paracentesis does, however, ensure a decrease in blood pressure (Fig. 3) by 7 to 10 mmHg. This research was followed by many other studies evaluating the speed of paracentesis, the haemodynamic changes following paracentesis, and the need for colloid replacement therapy.

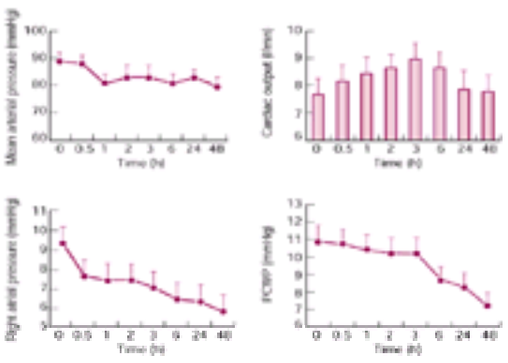

Fig. 3 Haemodynamic changes following acute total paracentesis of approximately 10 litres of ascites over 1 h. Paracentesis was commenced at time 0 h and sequential changes were monitored by a Swan–Ganz catheter, without albumin replacement (modified from Panos *et al*. 1990).

Practical aspects of therapeutic paracentesis

The most important feature of a paracentesis cannula is that it should have multiple side perforations to avoid obstruction by omentum. All ascitic fluid should be drained in a single session as rapidly as possible over 1 to 4 h. If 25 litres of ascites can be drained within 2 to 4 h it is quite safe to do so. The old dogma that rapid paracentesis causes marked hypotension is false, and the haemodynamic changes that occur do so after the removal of as little as 1 litre of ascites. There is a rapid increase in cardiac output, and a corresponding decrease in systemic vascular resistance that peaks at 3 h. There is an immediate fall in right atrial pressure (within 30 min), due to a decrease in intra-abdominal pressure and a decrease in compression of the right atrium. Pulmonary capillary wedge pressure remains constant for 6 h (in the absence of colloid), and decreases after this interval in the absence of colloid replacement. Mean arterial pressure decreases by about 8 mmHg. These changes are shown in Fig. 3. The drainage system should never be left in place overnight since this carries a risk of infection.

Colloid replacement

It is very important that colloid replacement is given following paracentesis to prevent circulatory disturbances. After total paracentesis, synthetic plasma substitutes may be used if the volume of ascites removed is less than 5 litres. However, albumin should be used when more than 5 litres is removed. All or most trials have used albumin at a dose of 8 g/l of ascites removed. There are no data on whether smaller or larger amounts of albumin have differing degrees of efficacy. Based on studies of the haemodynamic changes that follow paracentesis, it is clear that colloid should be given after paracentesis has been completed.

Contraindications to paracentesis

It is generally agreed that there are no contraindications to paracentesis, although studies to date have excluded several subsets of patients, primarily because of inadequate data. In practice, some clinicians have concerns about carrying out paracentesis in patients who have a severe coagulopathy or marked thrombocytopenia in case localized bleeding complications arise, but there are no data to support this view.

Benefits of paracentesis

Paracentesis provides immediate relief from ascites and a tense abdomen. There is a suspicion that paracentesis makes patients more responsive to diuretic therapy. Whilst there is no direct evidence to support this, the observation that plasma arginine vasopressin (**AVP**) levels are proportional to intra-abdominal pressure lends credibility to this idea. Despite the assumption that during paracentesis the observed exacerbation of vasodilatation involves the splanchnic bed, studies have shown that paracentesis causes a significant reduction of portal pressure. A further benefit includes the relief on respiratory muscles. Tense ascites clearly restricts breathing, and increases both the workload of respiration and energy expenditure. Paracentesis provides immediate relief. Likewise, patients who present with fluid overload and ascites can be rapidly relieved by paracentesis. Ascites increases the resting energy expenditure, and this may be improved following paracentesis.

One potential beneficial effect of paracentesis may be to enhance salt and water excretion, due to the acute reductions of renal venous pressure and the increase in renal perfusion that follow. A second and unexpected benefit may relate to water metabolism. Studies by Solis-Herruzo have shown that paracentesis is followed by an acute fall in plasma arginine vasopressin levels—this hormone is implicated in water homeostasis, since it directly affects the water permeability of the collecting tubules and ducts. This acute decrease in plasma concentrations is directly related to intrathoracic or intra-abdominal pressure, since inflation of the abdomen with air to form a pneumoperitoneum, which increases intrathoracic and intra-abdominal pressure, had a similar effect.

Role of albumin infusion

There is a persistent belief that the infusion of albumin is beneficial to patients with cirrhosis. The role of albumin infusion has already been mentioned in the section relating to paracentesis, and it also has a role in the treatment of SBP. The identification of new hepatitis viruses, HIV, and the advent of new-variant Creutzfeldt–Jakob disease should make all clinicians cautious in the administration of human products. During the 1940s, several studies evaluated the effect of fractionated human albumin solution in patients with cirrhosis. These studies demonstrated that the infusion of albumin could correct the low plasma levels observed and result in a modest diuresis in some patients, but overall the results were disappointing.

Role of angiotensin-converting enzyme (ACE) inhibitors

The therapeutic effect of ACE inhibitors is attractive since they directly target the system involved most intimately with salt and water retention. However, the acute administration of either captopril or enalapril may cause an acute fall in blood pressure. Some studies have suggested that in patients with ascites, the chronic administration of enalapril suppressed plasma aldosterone levels and increased urinary sodium excretion and glomerular filtration rate (**GFR**), as well as increasing urinary prostaglandin (**PG**) E_2 and 6-oxo-PGF_{1a}. More studies on the efficacy of these drugs and of angiotensin antagonists on portal pressure and the treatment of ascites are expected. Recent studies have suggested that low doses of ACE inhibitors may enhance salt excretion, but they should be used very carefully.

Treatment of patients with severe liver dysfunction and ascites

Patients with endstage liver disease often have subclinical renal impairment, with a typical GFR of around 60 ml/min. For patients with alcoholic liver disease with or without alcoholic hepatitis, the presence of ascites does not generally affect the clinical outcome, unless the ascites becomes a focus for infection. Up to 90 per cent of patients dying from alcoholic hepatitis develop renal failure. For those with alcoholic hepatitis that resolves spontaneously or with treatment, the ascites usually improves as salt and water excretion increase with improvement of the liver disease. Most patients with severe liver failure have been excluded from clinical studies assessing the efficacy of diuretics or paracentesis. It is recommended that extreme caution is exerted when trying to diurese patients with endstage liver disease. It is probably safer to paracentese such patients rather than give potentially nephrotoxic drugs, although few studies have been conducted in such patients.

Treatment of refractory ascites

Diuretics may be ineffective for a variety of reasons. Approximately 5 to 10 per cent of patients do not respond adequately to diuretics. This may be because the diuretics induce an electrolyte disturbance or encephalopathy, necessitating a temporary and recurrent withdrawal of medication. Alternatively, the patient may be genuinely resistant to the diuretics given. In both these groups, there is invariably significant renal dysfunction when assessed by creatinine clearance or other techniques measuring GFR. Because of confusion over the random use of the term 'refractory ascites' in the literature, in 1994 the International Ascites Club agreed the following definition: 'refractory ascites is defined as ascites that cannot be mobilized or the early recurrence of which cannot be satisfactorily prevented by medical therapy'. It is subdivided into diuretic-resistant ascites and diuretic-intractable ascites (see below); however, it should be noted that the amount of sodium restriction used in the following definitions is now below the recommended sodium restriction:

- *Diuretic-resistant ascites* is defined as an ascites that cannot be mobilized or prevented postparacentesis because of the lack of a response to dietary sodium restriction (<50 mmol/day) and maximal diuretic therapy. Maximal diuretic therapy is defined as spironolactone 400 mg/day together with furosemide (frusemide) 160 mg/day.
- *Diuretic-intractable ascites* is defined as an ascites that cannot be mobilized or prevented postparacentesis because of the development of diuretic-induced complications that preclude the use of an effective or maximal dose of diuretics.

The mainstay of treatment for these patients is repeated paracentesis.

Shunts

Transjugular intrahepatic portosystemic shunts (TIPS) for refractory ascites

Several studies have suggested that TIPS may improve natriuresis in patients with diuretic-resistant ascites. In one study, 50 patients with refractory ascites were treated by TIPS, sufficient to decrease the portal pressure gradient by over 60 per cent. Some 75 per cent of all patients showed complete resolution of their ascites by 3 months, and 20 per cent achieved a partial response. A new onset of hepatic encephalopathy occurred in a further 10 per cent of patients. Other studies, however, have reported a 45 per cent incidence of hepatic encephalopathy post-TIPS, which was severe and disabling in 15 per cent of all treated patients, and this has been confirmed. TIPS was also associated with a decrease in the mean serum creatinine concentration from 133 µmol/l to 80 µmol/l at 6 months. The mean 1-year survival post-TIPS is less than 50 per cent. The effect of TIPS on sodium excretion and renal function is, for some reason, delayed, not being apparent until about 1-month postinsertion. Insertion of a TIPS is associated with a deterioration of liver function, and some patients develop severe haemolysis.

Peritoneovenous shunts (Le Veen shunts or Denver shunts)

Peritoneovenous shunting became very popular in the 1970s, with numerous publications on its benefits to renal function and resolution of ascites. However, it soon became apparent that many shunts became blocked or infected and caused scarring of the peritoneum, which can make liver transplantation difficult. There have been three clinical trials evaluating the efficacy of the peritoneovenous shunt. This technique offers no survival advantage over medical therapy or repeated paracenteses. With respect to its effects on renal function, it has been shown that shunting had no overall effect on mortality in patients with the hepatorenal syndrome.

Prognosis

The occurrence of ascites in patients with cirrhosis is associated with a poor prognosis. Survival rates vary between 50 per cent at 1 to 2 years, but a somewhat better survival in alcoholic patients with ascites who stop drinking. The development of bacterial peritonitis in patients with ascites is associated with a mortality of 75 per cent at 1 year. Thus, the development of this complication is associated with an overall poor prognosis, and, unless contraindicated, all patients should be considered for orthotopic liver transplantation.

Important complications

The complications of ascites are shown in Table 6 and discussed below.

Pleural effusion

Pleural effusions (hepatic hydrothorax) develop in about 5 per cent of patients with cirrhosis. Fluid tracks up into the pleural cavity via defects in the diaphragm (for example, holes or blebs), which occasionally close spontaneously. Hepatic hydrothorax may develop in patients with no discernible ascites. The pleural effusions are right-sided in 85 per cent of cases and bilateral in 2 per cent of cases. To confirm the diagnosis, if doubt exists, a radiotracer should be injected under aseptic conditions into the abdomen and its appearance followed in the pleural fluid. A pleural effusion should be managed as for conventional ascites unless it is unresponsive and causing severe dyspnoea, in which case a TIPS (transjugular intrahepatic portosystemic shunt) should be inserted. TIPS is a highly effective treatment for hepatic hydrothorax.

Paraumbilical hernia

Paraumbilical hernias develop in about 20 per cent of patients with ascites, an incidence that increases up to 70 per cent in those with long-standing recurrent tense ascites. The main risks are rupture and strangulation.

Hepatorenal syndrome

Hepatorenal syndrome is the development of renal failure in patients with advanced liver disease (acute or chronic) in the absence of any pathological cause of renal failure. It is due to a reduction of renal blood flow, an increased renal sympathetic drive, and increased circulating or increased renal production of various vasoactive mediators such as endothelin-1, cysteinyl-leukotrienes, thromboxane A_2, or F(2)-isoprostanes. This syndrome is discussed in detail elsewhere.

Hypercatabolic state

Many patients with ascites present in a hypercatabolic state. This may be secondary to the low-grade endotoxaemia present in many patients, together with their general state of malnutrition. This can be reversed, particularly in alcoholic patients who stop drinking and improve their nutritional lifestyle. However, successful TIPS can also improve the nutritional status of these patients, although this may of course be secondary to their cessation of alcohol intake.

Respiratory difficulties

Increasing abdominal distension due to the accumulation of peritoneal fluid increases the effort required for breathing. Occasionally, this may precipitate extreme difficulty in breathing and should be treated by rapid paracentesis.

Spontaneous bacterial peritonitis (SBP)

The spectrum of bacterial peritonitis includes spontaneous bacterial peritonitis, monomicrobial bacterascites, culture-negative neutroascites, and secondary bacterial peritonitis. Spontaneous bacterial peritonitis is now defined as the combination of a positive ascitic fluid culture, an ascitic fluid neutrophil count of more than 250 cells/mm^3, and no evident intra-abdominal source of infection. Secondary bacterial peritonitis is identical, except that an intra-abdominal source is apparent and the organisms are frequently polymicrobial.

The risk of SBP has been evaluated. Of patients presenting with ascites, about 11 per cent will develop SBP within 1 year and 15 per cent within 3 years. For those with an ascitic protein level below 10 g/l the risk is 24 per cent within 3 years. For patients admitted to hospital with ascites with or without other complications (for example, bleeding) the incidence of SBP on admission, based on a review of several reports, is about 10 per cent.

The symptoms of SBP are shown in Table 7.

The pathogenesis of bacterial peritonitis is shown below in Fig. 4. It is apparent that a source for bacteraemia gives rise to organisms in the hepatic lymph and thence the ascitic fluid. Before an inflammatory reaction occurs, an ascitic tap will yield a positive culture, but a low neutrophil count. This is termed 'monomicrobial bacterascites'. If there is a polymicrobial growth with a low ascitic neutrophil count, then the tap is likely to have been traumatic. This occurs in 0.6 per cent of all ascitic taps. In the absence of any intervention it is estimated that two-thirds of these cases will resolve as a consequence of complement-mediated bacterial lysis: that is to say, it will not develop into SBP but will be resolved by the normal antimicrobial defences of the body. If the organisms multiply and neutrophils are mobilized, the ascitic neutrophil count increases. An ascitic tap at this stage yields a positive culture and an elevated white blood cell count. If the infection resolves at this stage (that is, the organisms are lysed) and an ascitic tap is then performed, the ascitic neutrophil count will be increased but the ascitic fluid will be sterile. This is termed 'culture-negative neutrocytic ascites' (**CNNA**). The most common cause is, however, a poor culture technique. As shown, the opsonic activity is important in determining whether the monomicrobial bacterascites resolves or develops into SBP. The organisms isolated are shown in Table 8, and the risk factors for the development of SBP are summarized in Table 9 and discussed below.

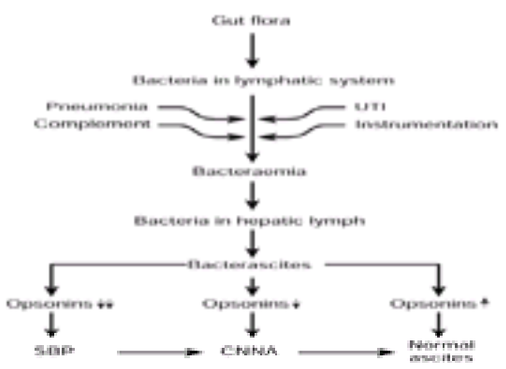

Fig. 4 Pathogenesis of spontaneous bacterial peritonitis. Bacteria can enter ascites through the lymphatic system. In many cases this is resolved through complement mediated bacterial lysis. When opsonins are decreased (e.g. low ascitic protein) or host defence is poor, bacteria multiply and cause spontaneous bacterial peritonitis (SBP). CNNA = culture negative neutrocytic ascites.

Risk factors

Decreased opsonic activity

The protein concentration of ascitic fluid does not change with the advent of SBP. Patients with a low protein content have an increased risk of developing SBP, compared to those with a high ascitic protein content. Patients with cirrhotic and nephrotic ascites are prone to infection, whereas those with malignant ascites or cardiac ascites are not. The risk of SBP is increased sixfold for those with an ascitic protein of less than 10 g/l. When bacteria enter ascitic fluid they may be lysed by the activity of complement if they are serum-sensitive, or they may be coated with opsonins such as IgG or the third component of the complement pathway (C3). Complement deficiency also predisposes to infection. The opsonic activity of ascitic fluid correlates with the total protein, as well as that of CH100 (total haemolytic complement), C3, and C4 concentration. These concentrations may be increased by diuresis, thus decreasing the risk of SBP. Paradoxically, diuretics may also increase the neutrophil count in ascitic fluid.

Recent instrumentation

Recent instrumentation such as endoscopy or sigmoidoscopy increases the risk of SBP. However, the risk of developing SBP is not increased by paracentesis. A study compared the risk of SBP in two groups of patients and found that it was slightly less, if anything, in those treated with paracentesis than in those treated with diuretics.

Gastrointestinal haemorrhage

There is a 21 per cent incidence of SBP in patients admitted to hospital with a gastrointestinal haemorrhage. Whilst it is assumed that bleeding predisposes to infection, there is data to suggest that infection may predispose to bleeding. Since the incidence of SBP immediately following a gastrointestinal bleed is high, many clinicians now advocate the prophylactic use of broad-spectrum antibiotics in such situations.

Previous spontaneous bacterial peritonitis

SBP is a recurrent condition. The recurrence rate for SBP is 47 per cent at 6 months and 69 per cent at 1 year.

Treatment of SBP

The mortality associated with SBP is approximately 30 per cent in most series. Therefore, SBP must be treated as soon as a presumptive diagnosis is made following microscopy of ascitic fluid. For patients with bacterascites but no rise in the neutrophil count, the ascitic tap should be repeated, while those with an increased neutrophil count should be treated. The following therapeutic regimen is used in the United Kingdom, which is based on the types of organism most frequently encountered during SBP: treatment is continued until complete resolution of all signs of infection and the ascitic neutrophil count decreases to within the normal range. This is generally achieved within 1 week of treatment. Appropriate antibiotics include cefotaxime, ciprofloxacin with amoxicillin, and piperacillin with tazlocillin (PIP/TAZ). Recent studies from Barcelona have also shown that the administration of albumin at a dose of 1.5 g/kg at the time of diagnosis and 1 g/kg at 48 h decreases the incidence of renal dysfunction, and improves survival. The treatment of SBP is summarized in Table 10.

Prevention and control

The prevention and control of ascites have already been covered under the treatment of ascites. Currently there is an ongoing National Institutes of Health (**NIH**)-funded multicentre study evaluating the efficacy of b-blockade on the development of portal hypertension, but the results of this are not yet available. However, there have been many studies investigating prophylaxis against SBP.

Prophylaxis against SBP

Many clinicians in the United Kingdom now use ciprofloxacin. A French study has evaluated the efficacy of this antibiotic in patients with cirrhosis who have an ascitic protein level below 15 g/l. This study observed that the administration of 750 mg ciprofloxacin given in a single dose per week decreased the incidence of SBP from 22 per cent to 4 per cent at 6 months, with a corresponding decrease in hospital admission over this period (18 days to 9 days). These authors concluded that prophylaxis with ciprofloxacin was effective, and cost-analysis studies have shown such antimicrobial prophylaxis to be cost-effective.

Special problems in pregnant women

Women with cirrhosis and ascites rarely, if ever, become pregnant, since ovulation has usually ceased before the onset of ascites.

Occupational, quality of life, and psychological aspects

Ascites is significant because it indicates the development of hepatic decompensation, and a corresponding poor prognosis. It also carries a significant morbidity—increasing the workload on the patient, causing backache, etc.—and may be associated with the development of electrolyte disturbance and hepatic encephalopathy. It has enormous cost implications to the National Health Service in terms of repeated hospital admissions, long-term treatment of salt and water retention, and iatrogenic complications. It may also be complicated by the development of spontaneous bacterial peritonitis, which is itself associated with gastrointestinal haemorrhage, and a high mortality.

Areas of controversy

Current areas of controversy include the use of albumin or plasma substitutes following paracentesis. Although albumin has been shown to be superior to plasma substitutes in preventing the activation of hormonal systems that indicate hypovolaemia, there is no hard data to show that albumin is more effective than colloid substitutes in terms of overall patient survival or duration of hospital stay. There is also controversy over the issue of central blood volume, with two groups reporting diametrically opposite findings. This is a crucial argument since the current peripheral vasodilatation hypothesis is based on the premise of a decreased central blood volume. Studies by Mauro Bernardi's group have shown that vasodilatation disappears during upright posture, and it appears that patients may exhibit features of both underfill and overfill depending on their posture and severity of liver disease.

Areas needing further research

Ideally, longitudinal studies conducted over many years need to be performed in newly diagnosed patients with cirrhosis, including baseline clinical, hormonal, and sodium-balance studies, as well as long-term (10 years or more) investigations of systemic haemodynamics and portal pressure. Why do patients develop vasodilatation? Although current ideas favour a role for nitric oxide, the evidence to support this is unclear. Why do patients develop ascites after liver transplantation? This complication is unusual but can be very striking and disruptive to management. Finally, controlled studies are needed to determine whether it is beneficial to paracentese patients with spontaneous bacterial peritonitis.

14.21.3 Hepatocellular failure

E. Anthony Jones

Introduction

Hepatocellular failure is the syndrome that occurs when loss of hepatocytes and/or hypofunction of hepatocytes exceeds the capacity of hepatocytes to regenerate and/or repair hepatocellular injury. Its clinical manifestations include hepatic encephalopathy, a haemorrhagic diathesis, ascites, and hepatocellular jaundice. The syndrome may complicate any disease in which the pathophysiology includes hepatocellular necrosis or apoptosis, or hypofunction of hepatocellular organelles. The duration of evidence of hepatic dysfunction before the onset of hepatocellular failure is variable, ranging from a few days to many years. The term hepatocellular failure does not necessarily imply impaired function of hepatic cells other than hepatocytes. Although many biochemical lesions induced by specific chemical, immunological, or cytopathic hepatotoxic factors have been documented, with the notable exception of hypoxia, the precise mechanisms by which such factors induce hepatocellular failure are poorly understood. Factors that may contribute to hepatocellular injury include immunological damage mediated by cytotoxic T lymphocytes, macrophage activation, direct cytopathic effects of viruses, cytokine-induced activation of cellular interactions, and oxidative stress. An influx of calcium ions into hepatocytes appears to be a late phenomenon in the sequence of biochemical events culminating in hepatocellular necrosis.

Definitions

Acute hepatocellular failure

The syndrome of hepatocellular jaundice, hypertransaminasaemia, and prolongation of the prothrombin time associated with an acute liver disease.

Fulminant hepatic failure

Classically defined as the syndrome of acute hepatocellular failure complicated by hepatic encephalopathy occurring within 8 weeks of the onset of clinical evidence of liver disease. The King's College Hospital (London) group have introduced the terms hyperacute liver failure for the occurrence of encephalopathy within 7 days of the onset of jaundice and late-onset liver failure for the syndrome in which hepatic encephalopathy occurs 8 to 24 weeks after the onset of clinical evidence of liver disease. In addition, the Beaujon Hospital (Paris) group has proposed that the term fulminant hepatic failure be applied to acute liver failure with a plasma factor V level less than 50 per cent of normal and hepatic encephalopathy occurring less than 2 weeks after the onset of jaundice, and that the term subfulminant hepatic failure be used for acute liver failure with a plasma factor V level less than 50 per cent of normal and hepatic encephalopathy occurring 2 weeks to 3 months after the onset of jaundice.

Chronic hepatocellular failure

This is the syndrome of decompensated chronic liver disease, which is chronic hepatocellular disease complicated by hepatic encephalopathy, coagulopathy, ascites, and/or hepatocellular jaundice.

Hepatic encephalopathy (portosystemic encephalopathy)

This is the complex neuropsychiatric syndrome attributable to impaired hepatocellular function and increased portosystemic shunting. The terms hepatic encephalopathy and portosystemic encephalopathy are usually used interchangeably. However, whereas the term portosystemic encephalopathy may be appropriate for encephalopathy complicating increased portosystemic shunting in the absence of overt hepatocellular failure, it may be inappropriate to use the term hepatic encephalopathy in this context.

Aetiology

Acute hepatocellular failure

The most common causes of fulminant hepatic failure are acute viral hepatitis and drugs. About one-third of cases appear to be due to non-A, non-B, non-C hepatitis of undetermined aetiology. Markers of acute infection with specific hepatitis viruses (such as IgM anti-HAV, IgM anti-HBc, IgM anti-HDV) may be useful in suggesting the aetiology. A syndrome similar to acute liver failure with encephalopathy associated with infection by other viruses (such as herpes, varicella) may occur, particularly in immunocompromised patients. Only drugs that can cause acute hepatocellular injury (rather than cholestasis) have the potential of inducing fulminant hepatic failure. Examples are paracetamol, halothane, and antiretoviral drugs. Fulminant hepatic failure caused by poisoning may be due to *Amanita* mushrooms or industrial solvents, particularly chlorinated hydrocarbons. Hypoxic hepatocellular injury may be attributable to reduced hepatic perfusion, but rarely leads to fulminant hepatic failure (for example following cardiac arrest). Important vascular causes of fulminant hepatic failure include the Budd–Chiari syndrome and veno-occlusive disease. The latter may be induced by pyrrolizidine alkaloids, chemotherapy, or irradiation. A rare cause of fulminant hepatic failure is heat stroke. Intravascular haemolysis suggests Wilson's disease. Autoimmune chronic active hepatitis may present with a syndrome similar to subfulminant hepatic failure with type 1 antibodies to liver and kidney microsomes. Fulminant hepatic failure may be precipitated by partial hepatectomy (removal of more than 80 per cent of a normal liver). Fulminant hepatic failure soon after orthotopic liver transplantation may be due to hyperacute allograft rejection or hepatic arterial thrombosis. In carriers of the hepatitis B or C viruses, fulminant hepatic failure may be precipitated by modulation of the host's immune response to the virus as a consequence of

immunosuppressive chemotherapy or its withdrawal. In Reye's syndrome a fulminant hepatic failure-like syndrome may occur, but there are, in addition, mitochondrial changes in the brain which are not specific for liver failure.

Chronic hepatocellular failure

Chronic hepatocellular failure may complicate any progressive chronic hepatocellular disease or any lesion causing chronic hepatic central venous congestion.

Manifestations

Cardinal features

Hepatic encephalopathy

Impaired mental function in liver failure may lead to a wide spectrum of psychiatric and neurological changes. Impaired psychometric test results and/or abnormal brain electrophysiological function in a patient with chronic liver disease, in whom a routine neurological examination is normal, may imply subclinical hepatic encephalopathy. The earliest clinical signs are psychiatric and behavioural changes. These changes are primarily due to subtle impairment of intellectual function that reflects predominantly bilateral forebrain dysfunction. Conventionally, four clinical stages of hepatic encephalopathy are recognized (Table 1). Increased muscle tone with cogwheel and neck rigidity, and myoclonic twitching may occur. Asterixis ('liver flap') can often be elicited (Table 1, Fig. 1). The mouth may be difficult to open. With progression, deep tendon reflexes may be increased and subsequently decreased. One or both plantar responses may be extensor. With progression, the frequency of the electroencephalogram decreases and its amplitude increases. With further progression, the amplitude decreases and triphasic waves may occur. Both the clinical and electrophysiological manifestations of hepatic encephalopathy are non-specific. Hepatic encephalopathy complicating chronic liver disease may be acute or chronic. When acute it is usually associated with one or more recognized precipitating factors (Table 2). With the notable exception of sedative hypnotic drugs, the mechanisms by which common precipitating factors exacerbate encephalopathy are poorly understood. Failure to identify a precipitating factor may imply deterioration of hepatocellular function. The term chronic portosystemic encephalopathy is often preferred when hepatic encephalopathy complicating chronic liver disease is persistent or episodic.

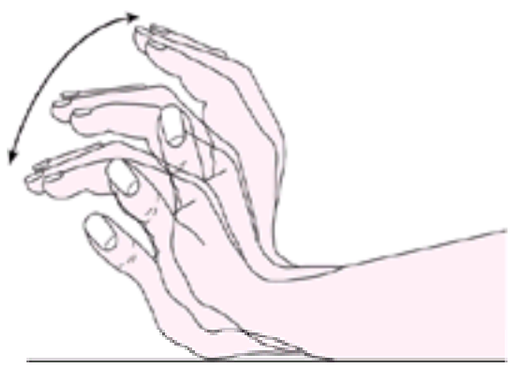

Fig. 1 The 'liver flap' is a slow, flapping tremor (one flap every 1 to 2 s), which can be elicited by asking the patient to dorsiflex the hands with the arms outstretched and the fingers extended and parted. It is due to neuromuscular incoordination between flexor and extensor muscles (negative myoclonus). The hands tend to fall forward, but this involuntary movement is rapidly corrected by readoption of the dorsiflexed position, thereby creating a 'flap'. The same phenomenon may be elicited by asking the patient to squeeze the physician's extended finger. Neuromuscular incoordination is indicated by repeated intensification and relaxation of the intensity of the squeeze ('milkmaid's grip').

Hepatic encephalopathy is considered to be a reversible metabolic encephalopathy with a multifactorial pathogenesis. Traditionally, gut factors have been considered to play important roles (Table 2 and Table 3). In liver failure there is decreased hepatic extraction and metabolism of constituents of portal venous plasma and decreased exposure of hepatocytes to these constituents as a consequence of their passage through intrahepatic and extrahepatic portosystemic venous collateral channels. Consequently, constituents of portal venous plasma tend to accumulate in the systemic circulation. If some of these compounds are neuroactive and can cross the blood–brain barrier, modulation of brain function may occur. The blood–brain barrier is normally highly permeable to non-polar substances, such as non-ionic ammonia and benzodiazepines, but has a low permeability to polar compounds. However, in liver failure the permeability of the barrier to polar compounds, such as the inhibitory neurotransmitter GABA, may increase. Most of the manifestations of hepatic encephalopathy appear to be attributable to a global suppression of central nervous system function, due predominantly to a net increase in inhibitory neurotransmission, as a consequence of increased neurotransmission mediated by inhibitory neurotransmitters (such as GABA) and/or decreased neurotransmission mediated by excitatory neurotransmitters (such as glutamate). Currently, the two factors considered to be most important in pathogenesis are raised brain concentrations of ammonia and increased GABA-mediated neurotransmission.

Increased GABAergic neurotransmission is associated with impaired motor function and decreased consciousness, two of the cardinal manifestations of hepatic encephalopathy. Potential mechanisms for increased GABAergic tone in hepatic encephalopathy include: (i) increased availability of GABA at $GABA_A$ receptors in synaptic clefts; (ii) increased astrocytic synthesis and release of neurosteroids that are agonists of the $GABA_A$ receptor; and (iii) increased brain concentrations of natural benzodiazepine receptor agonist ligands.

Ammonia was originally implicated in pathogenesis because it was recognized to be neurotoxic, plasma concentrations tend to be raised in liver failure, and lasma ammonia readily enters the brain. Plasma ammonia concentrations higher than those usually found in liver failure (more than 1 mmol/l) are associated with increased neuronal excitation and seizures. In contrast, plasma ammonia concentrations typically found in patients with precoma stages of hepatic encephalopathy (stages I to III) (100 to 400 µmol/l) may enhance neuronal inhibition by: (i) directly facilitating GABA-gated chloride conductance; (ii) selectively increasing the binding of agonist ligands to the $GABA_A$/benzodiazepine receptor complex; and (iii) stimulating astrocytic synthesis and release of neurosteroids that are potent $GABA_A$ receptor agonists.

Possible roles for neurotransmitter systems, other than the GABA system, have been postulated. Some of the symptomatology of hepatic encephalopathy can be explained by disturbances in functional loops of basal ganglia, which could arise as a consequence of an imbalance between glutamatergic and GABAergic neurotransmission.

Haemorrhagic diathesis

The basis of the haemorrhagic diathesis is multifactorial. Of major importance is impaired synthesis of hepatocyte-derived blood clotting factors; this leads to prolongation of the prothrombin time (see Chapter 22.5.1), which is not corrected by parenteral vitamin K. Thrombocytopenia is often present; it may be secondary to the hypersplenism of portal hypertension (see Chapter 14.21.2). However, in fulminant hepatic failure, platelet structure and function are abnormal and the capillary bleeding time is greater than that predicted from the platelet count. Mild disseminated intravascular coagulation is often detectable, but is rarely of clinical significance. Upper gastrointestinal haemorrhage (for example from gastritis, gastro-oesophageal varices, or ulcers) frequently occurs. A common clinical manifestation of the bleeding tendency is bruising around venepuncture sites.

Ascites

Ascites due to hepatocellular failure complicates lesions that cause sinusoidal portal hypertension (such as cirrhosis) or impaired hepatic venous drainage. However, hepatocellular failure is not invariable when ascites is associated with hepatic venous congestion (see Chapter 14.21.2).

Hepatocellular jaundice

The jaundice of hepatocellular failure has an orange tint and is attributable to conjugated hyperbilirubinaemia due to impaired secretion of conjugated bilirubin into the bile canaliculus; the transport maximum for conjugated bilirubin across the bile canaliculus is reduced relative to bilirubin production and conjugation (see Chapter 14.19.3). In acute hepatitis the degree of conjugated hyperbilirubinaemia reflects the extent of hepatocellular necrosis, but even when jaundice is deep, other features of hepatocellular failure (such as a prolonged prothrombin time) are often absent, reflecting the large normal hepatic reserve. In contrast, in chronic non-cholestatic liver disease, hepatocellular jaundice usually reflects severe hepatocellular failure.

Other features

Increased susceptibility to infection

About 80 per cent of infections are bacterial, but about one-third are complicated by tissue invasion by fungi (such as aspergillosis, candidiasis). There may be no fever or leucocytosis. The mortality is high. Fungal infection is suggested by antibiotic-resistant fever. The increased frequency of infections may be related to reduced levels of complement components and opsonins, reduced phagocytic and bactericidal properties of polymorphonuclear leucocytes, and reduced clearance function of Kupffer cells. Spontaneous bacterial peritonitis is a common complication of ascites (see Chapter 14.21.2).

Fetor hepaticus

Fetor hepaticus is the term applied to a particular smell of the breath that commonly occurs in patients with cirrhosis and extensive portosystemic shunts or fulminant hepatic failure. Descriptions vary and include a sweetish, slightly pungent, or faecal smell, similar to that of a rotten apple, mice, or a freshly opened corpse. Being subjective there is considerable variation in its recognition. It has been attributed to gut-derived, sulphur-containing products of methionine metabolism.

Acid–base and electrolyte changes

A wide range of abnormalities occur, particularly in fulminant hepatic failure, and may contribute to altered neurological and cardiac function. Hyponatraemia may be due to impaired free-water clearance, failure of the sodium pump, or diuretics. Hypernatraemia is usually iatrogenic. Respiratory alkalosis, secondary to hyperventilation of central origin, is common in fulminant hepatic failure. Loop diuretics often precipitate a hypokalaemic metabolic alkalosis. Metabolic acidosis may be associated with extensive tissue damage, hypoxia, and lactic acidaemia. Respiratory acidosis may be associated with hypercapnia and respiratory infection.

Cerebral oedema and raised intracranial pressure

Cerebral oedema and raised intracranial pressure frequently complicate fulminant hepatic failure, occurring in about 80 per cent of patients with stage IV encephalopathy, but are uncommon in patients with chronic hepatocellular failure. These complications may be classified separately from hepatic encephalopathy. Herniation of the cingulate, uncus, or cerebellar tonsil secondary to raised intracranial pressure is a frequent cause of death in fulminant hepatic failure. Antemortem diagnosis of cerebral oedema and raised intracranial pressure is suggested by sudden deterioration of consciousness, increased muscle tone, unequal pupils, abnormally reacting pupils, myoclonus, focal seizures, decerebrate posturing, fixed pupils with spontaneous respiration, and/or absent ciliospinal reflexes. Sudden changes in pulse and blood pressure unrelated to haemorrhage, rapid deterioration of the electroencephalogram, sweating, tachycardia, arrhythmias, intermittent systemic hypertension, sudden severe hypotension, bursts of hyperventilation, and fever may all be manifestations of raised intracranial pressure. Papilloedema is rare. Signs of raised intracranial pressure become apparent when intracranial pressure exceeds 30 mmHg. A failure of cellular osmoregulation, with intracellular accumulation of osmolytes, such as glutamine, appears to be a pathogenic mechamism (cytotoxic). Compensatory loss of other intracellular osmolytes, such as inositol, may be more effective in chronic liver disease than in fulminant hepatic failure. Increased blood-to-brain transfer of fluid across the blood–brain barrier (vasogenic), and expansion of the extravascular space (interstitial or hydrocephalic) may also contribute to pathogenesis.

Hypoglycaemia

Severe hypoglycaemia (blood glucose less than 40 mg/dl) occurs in about 40 per cent of patients with fulminant hepatic failure (particularly children) and may exacerbate encephalopathy. The clinical and electroencephalographic features of hepatic and hypoglycaemic encephalopathies are similar. In acute liver failure, hypoglycaemia may occur in the absence of hepatic encephalopathy. Hypoglycaemia may develop rapidly and may recur with sepsis. It is due primarily to impaired hepatic glucose release secondary to glycogen depletion. In contrast to hepatic encephalopathy, hypoglycaemic coma may cause irreversible brain damage.

Cardiovascular changes

Hepatocellular failure is associated with systemic vasodilation and a hyperdynamic circulation. Cardiac output is increased, peripheral vascular resistance decreased, blood pressure reduced, and splanchnic and capillary flow increased, but perfusion of the renal cortex is decreased. Features of a hyperdynamic circulation include a bounding pulse, capillary pulsation, vasodilated extremities, a precordial heave, and an ejection systolic murmur. The increased cardiac output has been attributed to an increased vascular capacitance and hence relative hypovolaemia with low jugular venous pressure.

Recently, endogenous cannabinoids acting at vascular CB_1 receptors have been implicated in this state of vasodilation. Arrhythmias, other than sinus tachycardia, frequently occur with hypoxia and stage IV encephalopathy due to fulminant hepatic failure. Cardiac arrest (unrelated to respiratory arrest) may occur.

Hepatorenal syndrome

Renal failure is common and may be rapidly progressive. In only a minority of cases is it attributable to hypovolaemia or a lesion of the urinary tract. It is typically functional and characterized by reduced glomerular filtration rate and oliguria. Acute tubular necrosis may supervene. Absorption of large quantities of nitrogenous substances from the gut after a gastrointestinal haemorrhage may contribute to azotaemia. Plasma urea and creatinine are not reliable indices of renal function in fulminant hepatic failure; hepatic synthesis of urea is reduced and tubular secretion of creatinine is increased. Functional renal failure is associated with intense renal arterial vasoconstriction. The kidneys in this syndrome function normally when transplanted into subjects without liver disease. Several humoral systems have been implicated in pathogenesis (see Chapter 14.20.2).

Hepatopulmonary syndrome

This syndrome is defined as the triad of liver disease, intrapulmonary peripheral vascular dilatation with decreased pulmonary vascular resistance (right to left shunt), and an increased alveolar–arterial oxygen gradient. Hypoxaemia (PaO_2 less than 70 mmHg) is common and may be associated with cyanosis. The hypoxaemia is usually reversed by 100 per cent oxygen and is attributable to abnormal ventilation–perfusion ratios and impaired diffusion capacity, but uncommonly in cirrhosis hypoxaemia, not reversible by 100 per cent oxygen, may be due to large pulmonary arteriovenous shunts. Portopulmonary shunting and pulmonary hypertension may develop. Chest radiographs may show a high diaphragm, basal pulmonary infiltrates, or pulmonary oedema. Pulmonary oedema, not attributable to left ventricular failure, occurs in fulminant hepatic failure. Respiratory arrest of central origin may occur. The mechanism of the pulmonary vasodilation is unknown. Oxygen does not diffuse readily into the centre of dilated vessels and increased cardiac output limits the time for gas exchange.

Skin changes

Recognition of certain skin changes in a patient with chronic liver disease alerts the clinician to the possibility of incipient or overt chronic hepatocellular failure. However, no skin changes are specific for hepatocellular failure. Spider naevi are often present in patients with cirrhosis. They consist of a central protuberant arteriole from which small vessels radiate in a manner that has been likened to the appearance of a spider's legs (Fig. 2 and Plate 1). Their diameter is usually less than 0.5 cm. They occur in the area of drainage of the superior vena cava and should be distinguished from telangiectasia, corkscrew scleral vessels, and purpura. Development of new 'spiders' suggests progressive hepatocellular disease. Palmar erythema occurs less frequently than spider naevi. It is characterized by an exaggeration of the normal mottling of palmar surfaces of the hands, resulting in well-demarcated redness of the thenar and hypothenar eminences, and of the pulps of the fingers (Fig. 3 and Plate 2). Dilated, thread-like blood vessels in the skin, having an apparently random distribution, may occur, and may resemble a United States dollar note ('paper money' skin). White nails with loss of demarcation of the lunulae (leuconychia, Terry's nails) (Fig. 4 and Plate 3) and finger clubbing

(Lovibond's angle greater than 180°) (Fig. 5 and Plate 4) may also occur.

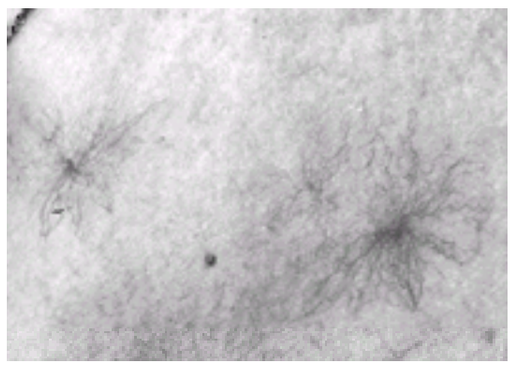

Fig. 2 Spider naevi in a patient with cirrhosis. (See also Plate 1.)

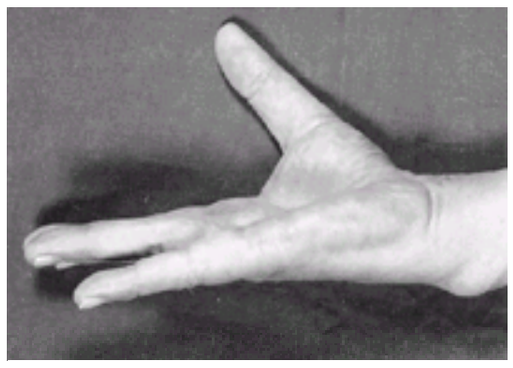

Fig. 3 Palmer erythema in a patient with cirrhosis. (See also Plate 2.)

Fig. 4 White nails in a patient with cirrhosis. (See also Plate 3.)

Fig. 5 Finger clubbing in a patient with cirrhosis. (See also Plate 4.)

Endocrine changes

Chronic liver disease may be associated with reduced concentrations of testosterone. Some male patients with cirrhosis develop hypogonadism and feminization. The former is characterized by testicular atrophy, decreased potency and libido, and a reduced need to shave; the latter is characterized by gynaecomastia and female hair distribution and body habitus. Some female patients with cirrhosis develop infertility, scanty irregular menstruation, and an asexual appearance due to loss of female characteristics. Unilateral or bilateral (tender) gynaecomastia may be a complication of cirrhosis (Fig. 6) or spironolactone therapy.

Fig. 6 Gynaecomastia in a male patient with cirrhosis.

Fatigue

Severe disabling fatigue that seems to be out of proportion to a patient's general condition may occur in chronic liver disease, before the onset of overt hepatocellular failure.

Abnormal protein metabolism

In cirrhosis the degree of hypoalbuminaemia reflects both decreased hepatic synthesis and an increase in plasma volume. Because of albumin's long plasma half-life, hypoalbuminaemia may not be present early in the course of fulminant hepatic failure. Chronic hepatocellular failure is associated with increased protein catabolism and a loss of skeletal muscle mass.

Fever

A low-grade fever may occur with severe active hepatocellular disease (such as acute alcoholic hepatitis) in the absence of infection.

Anaemia

A normochromic normocytic anaemia is a feature of chronic hepatocellular failure.

Osteopenia

Osteopenia is common in patients with decompensated cirrhosis.

Diagnosis

The syndrome of hepatocellular failure constitutes a clinical spectrum from acute liver failure at one extreme to decompensated chronic hepatocellular disease at the other. A patient dying of hepatocellular failure usually exhibits all four of the cardinal manifestations with or without complicating sepsis.

Hepatic encephalopathy

This is a clinical diagnosis that is usually made by recognizing the presence of encephalopathy and excluding non-hepatic causes. No individual clinical or laboratory abnormality is specific for hepatic encephalopathy. Special attention is paid to changes in personality, hypersomnia, and deterioration of performance at work or school. Asterixis (liver flap) is not pathognomonic. Signs of portal hypertension, non-specific cutaneous stigmata of liver disease, and/or fetor hepaticus may be present. It is necessary to recognize disorders with neurological manifestations that may mimic hepatic encephalopathy, such as Wernicke's encephalopathy, alcohol intoxication, or subdural haematoma. More than one type of encephalopathy may coexist. Psychometric tests are useful in detecting and monitoring subtle mental dysfunction in patients with subclinical or prestupor stages of hepatic encephalopathy. The quantitiative number connection test is frequently applied, but allowance must be made for the effects of learning and age on test scores. Electroencephalographic abnormalities are non-specific. There is usualy a fairly good correlation between the clinical stage of encephalopathy and the degree of abnormality of the electroencephalogram. The electroencephalogram is of value in differential diagnosis; it can reveal focal lesions in the brain, seizure activity, and other findings that might suggest an alternative diagnosis. Visual event-related potentials that depend on cognitive function, such as P300 potentials, are sensitive in the detection of electrophysiological changes in the brain in patients with cirrhosis who do not have overt encephalopathy. Routine laboratory tests aid in the differential diagnosis of encephalopathies, and in the detection of factors that may precipitate hepatic encephalopathy (Table 2). Plasma ammonia concentrations are modestly increased in the majority of patients with hepatic encephalopathy, but correlate poorly with the clinical stage and are not useful in management. An elevated plasma ammonia may be helpful in suggesting a hepatic origin for an undiagnosed encephalopathy.

Haemorrhagic diathesis

The most important readily obtainable laboratory markers of this diathesis are the prothrombin time and the platelet count. Plasma activities of individual clotting factors that are synthesized in the liver are reduced (see Chapter 22.5.1).

Ascites

When the presence of ascites on physical examination is in doubt, the issue may be resolved by ultrasonography of the abdomen, which can detect as little as 100 to 200 ml of intraperitoneal fluid. Careful examination of the jugular veins is necessary in the exclusion of cardiac causes. On ultrasonography diffuse inhomogeneity of the liver suggests cirrhosis, and difficulty in visualizing major hepatic veins suggests the Budd–Chiari syndrome. A small diagnostic ascitic fluid tap is done routinely; analysis of the fluid includes determination of concentrations of leucocytes and protein, examination for malignant cells, and culture.

Hepatocellular jaundice

The conjugated hyperbilirubinaemia of hepatocellular failure has to be distinguished from acquired intrahepatic cholestatic disease, cholestasis due to large duct biliary obstruction, and rare congenital hyperbilirubinaemias in which other routine serum biochemical liver tests are normal. Recognition that conjugated hyperbilirubinaemia is attributable to hepatocellular failure is usually possible from clinical and routine haematological and serum biochemical data and an ultrasound showing no evidence of dilated bile ducts. Unconjugated hyperbilirubinaemia is not a feature of hepatocellular failure.

Acute hepatocellular failure

Acute hepatocellular disease associated with a conjugated hyperbilirubinaemia may be classified as acute liver failure when prolongation of the prothrombin time occurs. If acute liver failure is due to hypoxia, a cause is usually obvious, such as a hypotensive episode during surgery.

The diagnosis of fulminant hepatic failure requires the presence of encephalopathy, elevated serum alanine aminotransferase levels early in the course, and marked prolongation of the prothrombin time. Serum alanine aminotransferase concentrations exceeding 50 times the upper limit of normal are common in massive hepatocellular necrosis, but may be less than three times the upper limit of normal with minimal hyperbilirubinaemia when fulminant hepatic failure is associated with microvesicular hepatic steatosis (see Pathology). Abdominal pain may occur with poisoning. Rarely, hepatic encephalopathy precedes jaundice and abnormal behaviour may have to be distinguished from non-hepatogenous acute psychiatric disease. However, patients with fulminant hepatic failure due to massive hepatocellular necrosis, who survive more than a few days, develop deep jaundice. Lumbar puncture should usually be avoided, because of the coagulopathy and possible raised intracranial pressure. However, a baseline CT scan of the brain may be useful. Evidence for the presence of other types of encephalopathy is routinely sought. The syndrome of fulminant hepatic failure may occasionally be mimicked by severe sepsis or falciparum malaria. In subfulminant hepatic failure, ultrasonography may reveal inhomogeneity of the liver due to nodular transformation.

Chronic hepatocellular failure

The diagnosis of chronic hepatocellular failure requires the demonstration of an appropriate chronic liver disease and evidence of hepatocellular failure. Mild conjugated hyperbilirubinaemia and a modest prolongation of the prothrombin time tend to occur before the development of overt hepatic encephalopathy or ascites. In contrast to diseases that lead to sinusoidal portal hypertension (such as cirrhosis), those that cause presinusoidal portal hypertension (such as schistosomiasis) do not usually progress to hepatocellular failure.

Pathology

There is no single hepatic histological change that is pathognomonic of hepatocellular failure. Fulminant hepatic failure is usually associated with massive or

confluent hepatocellular necrosis. However, occasionally, when due, for example, to acute fatty liver of pregnancy, or hepatotoxicity caused by intravenous tetracycline, valproic acid, or antiretroviral drugs, liver histology reveals microvesicular hepatocellular steatosis, in which the nucleus retains its central location within hepatocytes. In an appreciable proportion of autopsies on patients who succumb to fulminant hepatic failure, there is evidence of cerebral oedema and raised intracranial pressure, such as increased brain weight, tense dura, flattened cortical gyri, dilated ventricles, and cingulate, uncal, or cerebellar herniation. The histological appearances of the brain in fulminant hepatic failure are essentially normal. In contrast, histology of the brain of patients who died from chronic liver failure typically shows an increase in the number and size of Alzheimer type 2 astrocytes. Functional renal failure is associated with no gross pathological changes in the kidney.

Course and prognosis

Acute hepatocellular failure

In patients with acute liver failure, who do not develop encephalopathy, such as the typical case of acute icteric viral hepatitis, complete recovery is the rule.

The course of fulminant hepatic failure is variable. There are no reliable criteria that enable prediction of whether an individual patient will die or regain consciousness and ultimately survive. Overall survival appears to have improved with advances in intensive supportive care, and may currently be about 40 per cent without liver transplantation. Mortality tends to be greater when the encephalopathy is severe and prolonged, and when coagulopathy is profound (prothrombin time greater than 100 s). Mortality also tends to be greater if the patient's age is below 5 or over 40 years, or if encephalopathy occurs more than 8 days after the onset of jaundice. The mortality is particularly high (more than 80 per cent) in cases caused by halothane, or drugs other than paracetamol, but is about 50 per cent when paracetamol is implicated. Major complications increase mortality. Small or decreasing liver size, convulsions, cardiac arrhythmias (other than sinus tachycardia), and marked fetor hepaticus are ominous signs. Serum concentrations of aminotransferases may decrease abruptly, but have no prognostic value. The course of fulminant hepatic failure can be divided into five phases.

Pre-encephalopathy

In acute liver failure a progressive increase in prothrombin time is ominous and often precedes the onset of hepatic encephalopathy. After paracetamol overdosage the onset of encephalopathy may be predicted from plasma concentrations of the drug.

Encephalopathy

About one-third of patients die within 2 days of the onset of stage IV encephalopathy. In about 20 per cent of cases, death appears to be due to acute liver failure with progressive encephalopathy. In other cases, death can be attributed to one or more complications of the syndrome, such as upper gastrointestinal haemorrhage, cerebral oedema and raised intracranial pressure, sepsis, and renal failure. In subfulminant hepatic failure, death due to raised intracranial pressure and/or sepsis is more common than in fulminant hepatic failure.

Hepatic regeneration

The key factor in determining the outcome of fulminant hepatic failure, in the absence of liver transplantation, is the ability of the liver to regenerate. Nodules of hyperplastic regenerating liver tissue may be found at autopsy in patients who survive more than 10 days after the onset of encephalopathy. In general, such patients have usually died of a complication of fulminant hepatic failure at a time when indices of hepatocellular function were improving. Serum concentrations of a-fetoprotein, which are regarded as an index of hepatic regeneration, do not usually become elevated until at least 10 days after the onset of encephalopathy. The concentrations tend to correlate fairly well with the amount of hepatic regeneration found at autopsy. Recovery is usually heralded by clinical improvement in encephalopathy, which may be preceded by a decreasing prothrombin time. The electroencephalogram may remain abnormal for several days after consciousness is regained.

Cholestasis

A phase of profound cholestasis often develops 2 to 3 weeks after patients regain consciousness. When death has occurred during this phase, large regenerative nodules and intense cholestasis in hepatocytes have been found at autopsy.

Long-term sequelae

Complete restoration of normal hepatic function and structure usually occurs in survivors of fulminant hepatic failure, even after cerebral oedema, decerebrate rigidity, and episodes of flattening of the electroencephalogram. Serum biochemical liver tests and hepatic histology typically return to normal 45 to 75 days after the onset of hepatic encephalopathy. Permanent neurological sequelae have been reported when recovery has occurred after respiratory arrest.

Chronic hepatocellular failure

In patients with chronic hepatocellular disease, hepatic encephalopathy is often reversible, particularly if a precipitating factor is identified. An MRI of the brain typically reveals symmetric pallidal hyperintensities, possibly due to increased deposition of manganese in the basal ganglia. These hyperintensities appear to correlate with the degree of impairment of hepatocellular function, but not with hepatic encephalopathy. Elevated serum conjugated bilirubin in cirrhosis or precirrhotic alcoholic liver disease is associated with a poor prognosis. An increasing serum conjugated bilirubin in a patient with a chronic cholestatic liver disease may reflect progression of the disease and/or the development of hepatocellular failure. The serum bilirubin is regarded as a good index of prognosis in primary biliary cirrhosis. When ascites first develops in a patient with cirrhosis, 1-year survival is about 50 per cent and 5-year survival about 20 per cent. Survival after the onset of the hepatorenal syndrome is usually only a few weeks or months.

Management

The first issue is whether there is any effective therapy for the underlying liver disease. A treatment that suppresses the pathological process responsible for impairing hepatocellular function may decrease or reverse manifestations of hepatocellular failure. For acute liver failure, corticosteroids are ineffective and may be harmful, except in uncommon patients in whom the underlying lesion is an autoimmune hepatitis, and in carriers of the hepatitis B or C virus in whom acute liver failure has been precipitated by the withdrawal of immunosuppressive chemotherapy. Antiviral therapy has not been shown to be efficacious for acute viral hepatitis. Acetylcysteine has been shown to improve survival in patients who have taken an overdose of paracetamol, and this may apply even when the antidote is given after hepatic encephalopathy has developed. When viral infections, other than viral hepatitis, are diagnosed, antiviral treatment is instituted. Interruption of pregnancy has been advocated to improve survival in patients with fulminant hepatic failure due to acute fatty liver of pregnancy. It is useful to consider management of acute and chronic hepatocellular failure separately. The chronic syndrome accounts for the great majority of cases of hepatocellular failure, whereas the acute syndrome, when severe, is one of the most challenging in clinical medicine, presenting the physician with a unique constellation of difficult problems. In addition to discontinuing drugs that might have contributed to the clinical condition, especially neuroactive, hepatotoxic, and nephrotoxic drugs, it is necessary to take into account hepatocellular disease-associated alterations in drug pharmacokinetics and pharmacodynamics when prescribing for the patient in hepatocellular failure. Drugs may modify the clinical manifestations of hepatocellular failure. For example, patients with cirrhosis exibit increased sensitivity to the central neuroinhibitory and muscle relaxant effects of benzodiazepines. Whether liver transplantation is an appropriate therapeutic option must be considered in all patients with hepatocellular failure (see Chapter 14.21.4).

Chronic hepatocellular failure

As the patient has irreversible architectural changes in the liver, there is no potential for complete recovery with medical treatment. In such cases, management consists of trying to reduce the manifestations of hepatocellular failure that are amenable to treatment, especially encephalopathy and ascites; optimizing nutritional status with a high protein diet, if tolerated; treating complicating infections; and assessing suitability for liver transplantation. Non-specific clinical deterioration raises the possibility of bacteraemia, spontaneous bacterial peritonitis, or hepatocellular carcinoma.

Hepatic encephalopathy

The following general principles are relevant in the management of hepatic encephalopathy: (i) removal or correction of any precipitating factor (Table 2); (ii) reduction of absorption of nitrogenous substances from the gut; (iii) reduction of increased portosystemic shunting; and (iv) reversal of contributing neuropathophysiological mechanisms with drugs that act directly on the brain (Table 3).

Acute hepatic encephalopathy

All drugs that might contribute to encephalopathy, including diuretics, are stopped, and consideration is given to administering an appropriate antidote, such an naloxone or flumazenil. Meticulous attention is paid to maintaining fluid and electrolyte balance, and an adequate urine flow. Dietary protein intake is restricted, and enemas, such as magnesium sulphate or phosphate, are given. Lactulose, or another disaccharide with similar properties, such as lactitol, is given routinely. There is no disaccharidase on the microvillus membrane of enterocytes that hydrolyses lactulose. Its metabolism by colonic bacteria leads to production of lactic acid and other organic acids, a fall in colonic pH, and increased ionization of nitrogenous compounds. These changes may lead to a decrease in the absorption of nitrogenous compounds, including ammonia. Lactulose is a cathartic and is widely believed to be efficacious in the management of hepatic encephalopathy. It may induce hypernatraemia due to increased faecal fluid loss. In addition, an enterically administered, broad-spectrum, poorly absorbed antibiotic may be given to reduce the enteric bacterial flora. Neomycin (up to 6 g daily) has been most extensively used; potent alternatives include kanamycin and paramomycin. Metronidazole, which is effective against anaerobes, may also be given. If improvement in consciousness occurs, dietary protein is increased incrementally.

Chronic portosystemic encephalopathy

In the absence of protein intolerance a nutritious diet that includes a high protein content (80 to 100 g/day) is encouraged to maintain a positive nitrogen balance and optimize liver function. Vitamins are given empirically and thiamine replacement may be indicated in malnourished patients who are alcoholic. Vegetable protein diets seem to be well tolerated and tend to be cathartic due to their fibre content. Oral branched-chain amino acids may decrease protein catabolism and facilitate maintenance of a positive nitrogen balance. When protein intolerance develops, management consists of reducing dietary protein intake to as low as 40 g/day. Lactulose or lactitol is given in doses sufficient to produce two or three semiformed bowel actions daily, and precipitating factors are carefully avoided. If disaccharide intolerance develops, a broad-spectrum antibiotic may be tried. However, long-term neomycin should be avoided because of the risk of ototoxicity and nephrotoxicity. Metronidazole may induce a peripheral neuropathy.

If intractable chronic portosystemic encephalopathy occurs in a patient with a large spontaneous or surgically-induced portosystemic shunt, the invasive technique of balloon occlusion, coupled with embolization of a collateral vein, may reverse portal blood flow from hepatofugal to hepatopetal, improve hepatocellular function, and ameliorate the encephalopathy. Similarly, in a patient with chronic portosystemic encephalopathy and a patent transjugular intrahepatic portosystemic stent (TIPSS) the shunt can be narrowed or closed.

A new approach

A new therapeutic approach is to give a drug that acts on the target organ of hepatic encephalopathy, the brain, by reversing contributory neuropathophysiological mechanisms. The benzodiazepine antagonist, flumazenil, is the first promising drug of this type. It competes with high specificity with other benzodiazepine receptor ligands for binding to central benzodiazepine receptors, and rapidly and completely reverses the sedative and other neurological effects of benzodiazepine agonists, such as diazepam. When given as a bolus intravenously, flumazenil induces transient, incomplete clinical and electrophysiological ameliorations of overt encephalopathy in an appreciable proportion of patients with encephalopathy complicating acute liver failure or cirrhosis.

Ascites

Treatment is discussed in Chapter 14.21.2.

Acute hepatocellular failure

Prevention

The incidence of fulminant hepatitis B should be substantially reduced by widespread vaccination. Fulminant hepatic failure can be prevented by avoiding re-exposure to an agent that has induced an idiosyncratic acute hepatitis (such as halothane), and may be prevented by giving *N*-acetylcysteine after paracetamol overdose.

Acute liver failure

Treatment of acute liver failure in the absence of encephalopathy is expectant, but frequent monitoring is necessary when the prothrombin time is prolonged and prompt admission to hospital is indicated at the first sign of encephalopathy. Referral to a specialized liver unit has been recommended before encephalopathy develops if levels of clotting factors fall to less than 50 per cent of normal.

Fulminant and subfulminant hepatic failure

Routine management for acute hepatic encephalopathy is instituted (by extrapolation from the management of hepatic encephalopathy complicating chronic liver disease). With the onset of stage II hepatic encephalopathy, intensive supportive care should be instituted and transfer of the patient to a unit with the potential of undertaking orthotopic liver transplantation is recommended. All patients are considered to have potentially reversible disease. Treatment is designed to buy time for hepatic regeneration to take place and to avoid iatrogenic deterioration. No factor reported to stimulate hepatic regeneration experimentally is of proven clinical benefit. Conventional intensive care for the unconscious patient is instituted. A fluid intake of 1 to 2 litres daily is usually adequate. A nasogastric tube is used to decompress the stomach and detect upper gastrointestinal haemorrhage. Despite the coagulopathy, an arterial catheter is useful for continuous blood-pressure monitoring, frequent blood sampling, and measurement of blood gases. Caloric intake is maintained by infusing hypertonic dextrose (10 to 50 per cent), usually 200 to 300 g/day into a central vein. Intravenous lipids and amino acids may also be given. Vitamins may be given empirically. Unless the aetiology is known to be non-infectious, blood and all secretions are considered to be infectious. In this circumstance, attending personnel should wear gowns, gloves, and masks. Enteric isolation procedures are enforced and all specimens from the patient are labelled as infectious.

Blood is withdrawn at the outset for serological markers (such as for hepatitis viruses, cytomegalovirus), screening for common drugs, and estimation of serum copper. Blood glucose is monitored as frequently as every 1 to 2 h. The following investigations are carried out every 12 h: haemoglobin, total and differential leucocyte count, platelet count, urea, creatinine, potassium, sodium, chloride, and bicarbonate. Daily investigations include prothrombin time, total and direct bilirubin, alkaline phosphatase, alanine and aspartate aminotransferases, albumin, amylase, calcium, phosphate, magnesium, fibrinogen, and fibrinogen split products. Chest radiographs are obtained daily. Serial ultrasonic determinations of liver size may be useful in following the course. Needle biopsy of the liver is contraindicated. Frequent semiquantitative assessment of neurological status (such as the Glasgow coma score) and continuous monitoring of the electrocardiogram and electoencephalogram should be instituted. Patients should be monitored frequently for complications, which must be treated promptly and vigorously. A major goal is the prevention of brain damage. If agitation, piercing cries, delirium, or seizures occur, the patient should be restrained in a dark quiet room and the temptation to administer sedatives should be resisted.

Specific problems

Susceptibility to infections

Intensive microbiological monitoring is necessary. In fulminant hepatic failure, daily cultures of blood, urine, sputum, and swabs of intravenous cannulas are recommended. For patients admitted to a liver failure unit, prophylactic antimicrobial therapy has been advocated, such as intravenous, broad-spectrum antibiotics, oral or nasogastric amphotericin B suspension, and in females, vaginal clotrimazole cream. Nephrotoxic aminoglycosides are avoided. Antibiotics are recommended

to cover invasive procedures. Potential sources of infection, such as intrauterine devices, are removed.

Acid–base and electrolyte disturbances

Alkalosis does not require treatment. Acidosis should be managed by specific treatment of the cause; intravenous sodium bicarbonate increases body sodium. Hypokalaemia (potassium less than 3.5 mmol/l) is corrected by adding potassium chloride to intravenous fluids. The serum potassium is not increased above 4.0 mmol/l if liver transplantation is an option, as graft reperfusion may precipitate hyperkalaemia. Addition of sodium chloride to intravenous fluids is not indicated in the presence of hyponatraemia unless there is clear evidence of excessive loss of sodium. Sudden changes in sodium concentration should be avoided; they have been causally related to central pontine myelinolysis.

Cerebral oedema and raised intracranial pressure

Hepatic encephalopathy in fulminant hepatic failure may be compounded by cerebral oedema and raised intracranial pressure, hypoglycaemia, hypoxia, renal failure, and acid–base/electrolyte changes. Cerebral oedema precedes raised intracranial pressure and is not always demonstrable on CT scan; it may be indicated by a loss of demarcation between grey and white matter. To avoid precipitating an increase in intracranial pressure, patients are nursed in a quiet room with the trunk and head elevated 40°; jugular venous compression is avoided. To measure intracranial pressure, direct monitoring is necessary. A parietal or temporal bur hole is required to place an extradural or subdural pressure transducer. This procedure is controversial—it is potentially hazardous due to the coagulopathy and should be undertaken by a neurosurgeon in an operating theatre. Epidural monitoring is safer, but less accurate, than subdural monitoring. The cerebral perfusion pressure (mean arterial pressure minus intracranial pressure) should be maintained at a minimum of 60 mmHg. The best time to introduce a transducer is uncertain, but may be when progression to stage III encephalopathy occurs or when the patient becomes a candidate for liver transplantation. Although monitoring intracranial pressure has not been associated with increased survival, it may facilitate optimal management before liver transplantation. Mannitol has been shown to reduce elevated pressures that are not greater than 60 mmHg. It is given as an intravenous bolus of a 20 per cent solution (1 g/kg), which can be repeated every 4 h (0.5 g/kg) if the previous infusion induced a diuresis, plasma osmolarity does not exceed 315 mosmol/l, and azotaemia is not present. Mannitol has variable and potentially deleterious effects on intracranial pressure when the initial pressure is over 60 mmHg, and should probably not be given without prior measurement of intracranial pressure. Thiopentone (185 to 500 mg intravenously over 15 min), indomethacin, or induced hypothermia may reduce intracranial pressure if mannitol is ineffective. Corticosteroids and controlled hyperventilation do not appear to be effective treatments.

Haemorrhagic diathesis

The haemorrhagic diathesis requires no treatment in the absence of overt bleeding. Vitamin K (10 mg) is usually given intravenously, in spite of the low risk of inducing anaphylaxis. Fresh frozen plasma is not given routinely, so that plasma levels of clotting factors can be used as indices of prognosis. Skin puncture sites may require protracted pressure to achieve haemostasis. Administration of an H_2-antagonist to maintain gastric pH above 5.0 decreases transfusion requirements in fulminant hepatic failure; dose reduction may be necessary in the presence of renal failure. Infusion of platelets and fresh frozen plasma may be indicated to cover invasive procedures. Clotting factor concentrates, which exacerbate disseminated intravascular coagulation, are contraindicated. Heparin is not indicated for mild disseminated intravascular coagulation. Standard regimens of endoscopic diagnosis and therapy are instituted when haemorrhage occurs from the gastrointestinal tract. A haematocrit of at least 30 to 35 per cent should be maintained. A substantial increase in intracranial pressure may be due to an intracranial haemorrhage and is an indication for a CT scan of the head.

Hypoglycaemia

Hypoglycaemia must be prevented. Dextrose is administered intravenously to maintain a plasma glucose of 60 to 200 mg/dl. Occasionally, massive amounts of dextrose are required (for example more than 2 kg).

Cardiovascular changes

Maintenance of a normal blood pressure may reduce the risk of cerebral oedema or lessen its severity. Ionotropes may increase tissue hypoxia and have not been shown to be beneficial. However, if sepsis is suspected as a cause of hypotension, an ionotrope infusion may be warranted. If hypertension occurs, hypotensive or vasodilator drugs, which might adversely affect intracranial pressure, are not given. Arrhythmias may subside with correction of hypoxia, or acid–base or electrolyte disturbances.

Hepatorenal syndrome

Optimization of blood volume by infusing 20 per cent albumin may transiently improve renal function by correcting haemodynamic disturbances. Care is taken not to overload the circulation to avoid an adverse effect on intracranial pressure. Any therapeutic agents that may contribute to impaired renal function, including diuretics, are avoided. Severe acid–base/electrolyte disturbances or fluid overload, and rarely azotaemia, may be an indication for ultrafiltration or renal dialysis. Such procedures, which must be undertaken carefully because of cardiovascular instability and coagulopathy, may be necessary to optimize a patient's condition before liver transplantation, but would not be expected to alter the course of the hepatic or renal dysfunction. In the presence of raised intracranial pressure, ultrafiltration is preferred. Continuous venous access may be obtained using a double-lumen tube. The left femoral vein may not be used to facilitate venovenous bypass during liver transplantation. Use of vasopressin analogues is experimental.

Hepatopulmonary syndrome

No attempt should be made to correct hyperventilation. Hypoxaemia is an indication for 100 per cent oxygen by face mask. Endotracheal intubation is recommended at the onset of stage III encephalopathy. A tube large enough to permit bronchoscopy should be used. The procedure may be facilitated by curarization. Assisted mechanical ventilation is indicated for patients with stage IV encephalopathy, respiratory failure (increasing PCO_2), or pulmonary oedema. Positive end-expiratory pressure, which may reduce hepatic blood flow and increase intracranial pressure, should be avoided.

Convalescence

Abstinence from alcohol for a period of 6 months is recommended after recovery from an episode of acute liver failure not precipitated by alcohol. If alcohol was implicated in such an episode, lifelong abstinence is advocated. Other identified precipitants, such as halothane, must be rigorously avoided.

Temporary hepatic support

The original rationale for providing temporary hepatic support was based on the assumption that the hepatic lesion in fulminant hepatic failure is potentially reversible, provided that the patient can be kept alive sufficiently long for hepatic regeneration to take place. Theoretically, the patient selected for treatment with temporary hepatic support would die if treated by conventional intensive supportive care alone and would survive if the functions of the liver could be provided artificially over a finite period (Fig. 7). Temporary hepatic support should not only maintain the general condition of the patient, but also prevent life-threatening complications of fulminant hepatic failure. As there is a lack of detailed understanding of the biochemical disturbances that need to be corrected in fulminant hepatic failure, the design of artificial liver support systems has been largely empirical. Attempts have been made to (i) remove substances that have accumulated in the body using non-biological systems, such as charcoal haemoperfusion; (ii) provide deficient factors normally synthesized by the liver as well as clear accumulated substances using biological systems, for example haemoperfusion using devices containing hepatocyte preparations; and (iii) combine both approaches (hybrid systems). It has not yet been established that the risk/benefit ratio associated with application of any liver support device favours the patient. The provision of temporary hepatic support in the management of chronic irreversible liver disease (such as cirrhosis) may be limited to preparing a patient for liver transplantation. When a patient with fulminant hepatic failure or cirrhosis is a candidate for liver transplantation, effective temporary hepatic support may not only reduce operative or perioperative mortality but may also beneficially increase the waiting time for a donor liver.

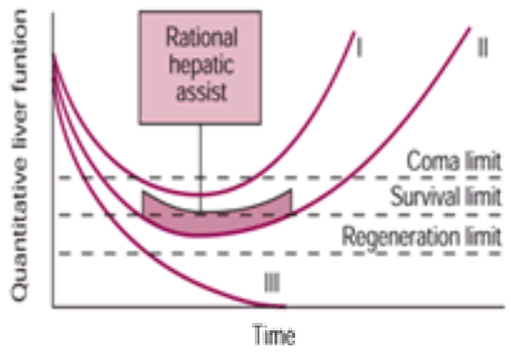

Fig. 7 Three hypothetical courses of fulminant hepatic failure (as envisaged by N. Tygstrup). In group I patients, liver function deteriorates below the coma limit, but does not fall below the survival limit; these patients should survive with intensive conventional medical supportive care alone. In group II patients, liver function deteriorates below the survival limit, but, if it can be maintained above this limit for a sufficient time by providing effective temporary hepatic support (rational hepatic assist), liver function would not fall below the regeneration limit and these patients should also survive. In group III patients, liver function deteriorates below the survival and regeneration limits irrespective of whether temporary hepatic support is provided. Liver transplantation offers the only hope of survival for group III patients. To facilitate optimal selection of patients for temporary hepatic support and liver transplantation, it is necessary to develop reliable criteria that indicate which course an individual patient will follow.

14.21.4 Liver transplantation

Graeme J. M. Alexander and M. Allison

Introduction

Pioneer work in the dog in the 1950s laid the basis for human liver transplantation, which was first undertaken in 1968 but liver transplantation was only established as a treatment for human therapy for liver failure in the mid 1980s. The number of centres and countries providing liver transplant services and the number of recipients continue to rise, accompanied by a combination of increased surgical and anaesthetic competence, more effective immune suppression, and improved organ preservation.

Liver transplantation services are now part of a sophisticated, multidisciplinary specialty. One-year survival of over 90 per cent should be achieved for low-risk elective cases. Successful liver transplantation enables most patients with severe liver disease to return to normal life.

The donor organ

Size match between donor and recipient is critical. Transplantation can be performed across the ABO barrier in exceptional circumstances but at the expense of long-term graft function. Matching for blood group is routine. Donor organ quality has a major impact on the immediate postoperative outcome and is influenced by many factors including experience of the surgical retrieving team, ensuring adequate, healthy artery, vein, and bile duct for the anastomoses. The introduction of cold University of Wisconsin solution *in situ* to the donor organ has prolonged the acceptable cold ischaemia time and transplantation can now be undertaken during working hours.

Fatty changes in the donor liver (the most common cause of primary graft non-function and the most frequent reason that a retrieval team refuse a liver) is important since such livers are less tolerant of cold and warm ischaemia. Relative donor shortage, increasing waiting lists, and prolonged waiting time compel the use of donors of marginal viability. Early postoperative graft function is likely to become more prevalent. Learning to use donor livers of impaired quality is a critical area for future research.

Surgical aspects

After recipient hepatectomy, the donor liver is implanted into the abdomen and anastomoses of the upper inferior vena cava, portal vein, lower inferior vena cava, and the hepatic artery are carried out. Surgeons may have to improvise the hepatic artery anastomosis, since about 20 per cent of donor hepatic arteries have anomalous anatomy. Venovenous bypass with extracorporeal circulation of blood via the portal vein back into the systemic circulation is associated with improved outcome in difficult cases and reduced rates of renal failure and sepsis.

Biliary anastomosis is carried out end-to-end, duct-to-duct unless there are doubts about the vascular supply to the biliary tree, with a second or subsequent transplant, or with biliary tract disease when a Roux loop is used. Whether this is appropriate in primary sclerosing cholangitis is contentious, since residual biliary tissue may retain a risk of future cholangiocarcinoma. In the past, the gall bladder was used as a conduit between recipient and donor ducts and was associated with a high rate of biliary strictures and gallstones.

Living-related donation has the advantages of a planned procedure, avoidance of cold ischaemia, minimal warm ischaemia time, and donor/recipient relatedness. However, the risk to such donors is not negligible. Auxiliary transplantation is one option for metabolic disease and acute liver failure but is not established because of difficulties in establishing an additional supply of blood. In an era of donor shortage, split livers are attractive, whereby the liver is divided and offered to two recipients, is an attractive option. Multiple organ transplantation is associated with reduced rates of rejection of organs transplanted with the liver, at the expense of prolonged delay waiting for a suitable donor.

Complication rates are higher in paediatric recipients because of size, the increased likelihood of in congenital anomalies and the use of 'cut-down' livers. Previous surgery is associated with an increased risk of haemorrhage. Established portal vein thrombosis is also a relative contraindication to transplantation.

Indications

There are no fixed rules for liver transplantation, which should be considered for patients with progressive disease where death is a likely end point (Table 1). It should be considered for patients with poor quality of life (a subjective assessment) who are able to withstand the procedure. For certain disorders guidelines are available to aid decisions.

Complications of liver disease

Liver transplantation may be used to treat the complications of liver disease: hepatic encephalopathy, ascites, subacute bacterial peritonitis, variceal haemorrhage (particularly gastric varices), jaundice, malnutrition, hepatic osteodystrophy, hepatopulmonary syndrome, hepatorenal syndrome, reversed portal vein flow, and superimposed hepatocellular carcinoma.

Early referral

Early referral allows time for the introduction of the patient to the concept of liver transplantation and improves outcome. Patients with a small body habitus and blood

group O have a prolonged wait and should be assessed early. Increasing age, renal dysfunction, poor nutritional status, high Child–Pugh score, and jaundice are associated with a poor outcome.

Assessment

As well as assessing the severity of their underlying liver disease, patients should be assessed for fitness for surgery. The presence of hepatopulmonary syndrome and pulmonary hypertension might complicate anaesthesia, but are not absolute contraindications. Some patients require psychiatric evaluation for alcohol or drug addiction. Early nutritional assessment is advised, to address weight loss in advance.

Accepted contraindications

Patients with AIDS and those with viraemia would not be considered without introduction of antiviral therapy. Extrahepatic malignancy is considered a contraindication, with the exceptions of neuroendocrine tumours and some cases of haemangioendothelioma. Metastatic disease involving liver is a contraindication.

Relative contraindications

The presence of HIV antibody may be regarded as a contraindication, despite an adequate CD4 count and absence of viraemia. Age alone is not a contraindication. Severe psychiatric disease requires psychiatric assessment. Continued alcohol or substance abuse, or a history of recidivism, are relative contraindications. Portal vein thrombosis in the absence of an adequate alternative vessel is a surgical contraindication. The likelihood of non-compliance with hospital attendances and immunosuppressive medication is difficult to assess but those deemed incapable of complying with these demands should not be considered.

Waiting list

Whilst waiting for transplantation, patients may develop new complications of their liver disease. Sepsis is common and requires suspension from the waiting list for treatment. Hyponatraemia (<125 mmol/l) is a risk factor and should be corrected in advance to avoid the risk of central pontine myelinolysis. Non-specific deterioration should prompt imaging of the portal vein and liver for new thrombosis or tumour respectively, and a search for sepsis. A proportion of patients develop the hepatorenal syndrome whilst under surveillance.

Specific disorders

Acute liver failure

Compared with chronic liver disease, the outcome for acute liver failure is less favourable (Table 2). However, the patients are often younger and may be cured by transplantation. For patients with paracetamol (acetoaminophen) poisoning, the decision to proceed to transplantation is made on the basis of prothrombin time, bilirubin, hepatic encephalopathy, renal failure, and acidosis; late rises in prothrombin time denote a grave prognosis and often indicate the presence of sepsis. Such patients require psychiatric assessment at the earliest opportunity to identify treatable conditions and to assess future compliance with medication and follow-up.

For patients with acute liver failure of other cause (drugs, hepatitis A, hepatitis B) the decision to proceed to transplantation is based on considerations of age, aetiology, jaundice to encephalopathy time, bilirubin, and prothrombin time.

Subacute hepatic failure

The prolonged period between onset of jaundice and encephalopathy allows patients with subacute hepatic failure to be identified. These are likely to survive long enough to be offered a liver and have an excellent outcome. Without transplantation, most patients with subacute hepatic failure die.

Chronic liver disease

Primary biliary cirrhosis

Several models have justified the introduction of transplantation for patients with primary biliary cirrhosis based on knowledge about life expectancy without liver transplantation. Such analyses are useful in decision making since definitive, controlled trials have never been done. A bilirubin in excess of 100 µmol/l predicts high mortality without transplantation. Some patients require transplantation because of extreme fatigue and pruritus prior to the onset of significant jaundice.

Primary sclerosing cholangitis

Patients suffering from primary sclerosing cholangitis are amongst the hardest to assess for liver transplantation. The presence of frequent episodes of jaundice, increasing jaundice, or cholangitis should prompt consideration of liver transplantation. There is a significant lifetime risk of cholangiocarcinoma (which would be a contraindication) and an ever-present concern that it may have evolved. Patients with primary sclerosing cholangitis should be considered for a transplant early in the course of their illness rather than late. Measurement of serum CA19.9 identifies patients with an evolving cholangiocarcinoma, but this value can rise very significantly in the presence of severe biliary disease and sepsis and should not be relied upon alone. Inflammatory bowel disease should be sought and treated before transplantation, even when asymptomatic.

Autoimmune hepatitis

Transplantation is indicated for complications of autoimmune hepatitis, poor control despite adequate therapy, or those patients who are slow to achieve control or escape control with immunosuppressant drugs.

Chronic viral hepatitis

Patients with chronic hepatitis B virus infection (HBV), chronic hepatitis C virus infection (HCV), and chronic hepatitis D virus infection (HDV) should be considered on merit according to the presence or absence of the complications of chronic liver disease and symptoms.

Alcohol

Patients with alcoholic liver disease undoubtedly constitute the most contentious group: liver transplantation is restricted largely to those with progressive disease despite abstinence. Most centres insist on complete abstinence from alcohol, first because the liver disease improves with prolonged abstinence and second because it is thought that patients who are able to maintain abstinence for six months have a lower risk of recidivism after transplantation. Assessment of abstinence is difficult and the ethics of random testing for alcohol abuse without consent are complex. It is important that details of any contract between patient and doctor are recorded accurately. In practice, those patients able to maintain a stable home life, job, and partner are more likely to be offered a liver transplant than those who are homeless, jobless, and isolated.

Tumours

For the treatment of hepatocellular carcinoma evolving on a background of cirrhosis, there are two options—resection and liver transplantation. Resection is unrealistic for most with cirrhosis and restricted to those with accessible tumours and Child–Pugh class A. Transplantation is indicated for those with a low risk of tumour recurrence. Accurate assessment of the extent of disease is therefore critical. Patients with tumours greater than 5 cm, or more than three nodules, or evidence of extrahepatic disease are likely to have recurrent disease after the transplant procedure. Radiological assessment of the extent of disease usually includes multiple modalities (hepatic angiogram, CT, MR, and ultrasound scans). Despite this, capsular or vascular invasion is often discovered at the time of transplantation.

The fibrolammellar variant of hepatocellular carcinoma usually occurs in young patients without cirrhosis and is probably more slow growing. However, resection is more appropriate for this group but although the 5-year survival figures for fibrolammellar disease are good, a significant risk of tumour recurrence remains.

Cholangiocarcinoma

The risk of postoperative recurrence is so high that this condition is regarded as a contraindication to hepatic transplantation.

Neuroendocrine tumour

P>Where disease is limited to the liver with a long lead-time, transplant offers reasonable 5-year survival. Recurrence after transplantation is frequent, although recurrent disease may be amenable to other strategies—chemotherapy, hormone modulation, radiotherapy, and direct tumour ablation.

Haemangioendothelioma

The reported prognosis after transplantation varies from early recurrence to none. A firm recommendation is impossible and the decision to go ahead with the procedure is often based on factors other than histology.

Budd–Chiari syndrome

Patients with acute liver failure in relation to the Budd-Chiari Syndrome should be managed as any other patient with acute liver failure. For chronic disease, there are alternative approaches, including surgical shunts and transplantation. One expressed view is that liver transplantation is the most reliable and effective shunt procedure. Most patients with Budd–Chiari syndrome have an underlying disorder predisposing to thrombosis, which should be thoroughly investigated and treated before the transplantation procedure is carried out.

Metabolic/genetic disease

Transplantation is successful in a number of metabolic/genetic disorders associated with liver disease, including Wilson's disease, a-1-antitrypsin deficiency (with maintained respiratory function), Gaucher's disease, glycogen storage disease, Crigler–Najar syndrome, and Bylers syndrome. Patients with haemochromatosis have increased morbidity, perhaps as a consequence of associated disorders (diabetes and cardiomyopathy), as well as an increased incidence of sepsis in the early postoperative stages that may be related to systemic iron overload.

Polycystic liver disease rarely requires liver transplantation but where associated with renal polycystic disease, combined liver/kidney transplantation is considered. The Rendu–Osler–Weber syndrome may be associated with hepatic haemangiomas causing portal hypertension or shunting that result in biliary ischaemia, and thus is best treated by liver transplantation.

Patients with cystic fibrosis represent a difficult group, presenting with portal hypertension and cardiorespiratory disease requiring heart/lung transplantation. Waiting for a triple organ donation for a recipient with a small body habitus may be futile, while proceeding with single organ transplantation in a patient with several diseased organs that will ultimately require transplantation procedures in their own right, may also be mistaken.

Metabolic disorder with a structurally normal liver

Patients with a structurally normal liver have undergone liver transplantation for hypercholesterolaemia and hyperoxaluria. In the former, it is essential to address the cardiovascular complications before transplantation. For the latter, it is important to recognize that the kidneys transplanted simultaneously remain at risk of oxalate-induced damage for several years after otherwise successful hepatic transplantation has been carried out.

Complications

Immediate

The most immediate, usual complication of transplantation is perioperative haemorrhage.

The presence of one or more of: coma following withdrawal of sedation, a rapidly rising prothrombin time, acidosis, high insulin requirement, thrombocytopenia, and hyperkalaemia, prompts consideration of three diagnoses—primary non-function of the graft, non-thrombotic graft infarction, or vascular thrombosis. Imaging of the hepatic artery and portal vein with ultrasound and angiography may greatly aid distinction between these possibilities. The patient may need a further hepatic graft as an emergency and delay in this situation can be catastrophic for survival.

Hyperacute rejection of the liver is rare (in contrast to the kidney) and liver transplantation can be undertaken successfully in the presence of a positive cross-match.

Early

Hepatic artery thrombosis may be identified by worsening liver function tests (confirmed by ultrasound and/or angiography), by ischaemia seen on liver biopsy, or biliary leak due to ischaemia of the bile duct. Portal vein thrombosis may present with either an ischaemic graft (less acute than that seen in the immediate postoperative phase) or the presence of ascites. Caval stricture might present with rapid accumulation of ascites and peripheral oedema. With an abdominal drain *in situ*, many litres of ascites might need to be removed daily. Cholangitis can be recognized by fever, neutrophilia, pain, and jaundice. A stricture should be sought by ultrasound.

Acute rejection

Acute rejection of the grafted organ may present with pain, fever and jaundice. Most often however, acute rejection is identified by noting a deterioration in liver biochemistry (particularly bilirubin) associated with peripheral blood eosinophilia. A liver biopsy is essential to determine severity and may confirm the presence of tissue eosinophils in association with lymphoblasts. The target tissues are bile duct and endothelial cells (hepatic artery, portal vein, and, less frequently, central vein). Not all acute rejection requires therapy but patients with acute rejection are prescribed supplemental high-dose corticosteroids. Severe rejection, steroid resistant rejection, and multiple episodes of acute rejection carry a poor long-term prognosis for the graft.

Graft-versus-host disease

Graft-versus-host disease is characterized by a skin eruption, gastrointestinal disturbance, and malnutrition. Often, patients with graft-versus-host disease are malnourished, have alcohol-related liver disease, are lymphopenic, and do not develop acute rejection. The diagnosis is confirmed by identification of host and recipient lymphocytes in the circulation. The best form of therapy is likely to be monoclonal antibody directed against activated T cells. Overall, the prognosis is poor.

Hepatic artery and portal vein strictures

These are identified usually as a consequence of abnormal liver biochemistry or a slow recovery following transplantation; occasionally, however, liver biochemistry may be normal. Ultrasound is unreliable for identification of vascular strictures and CT perfusion scanning or angiography are recommended.

Biliary strictures

Persistent elevation of the alkaline phosphatase and an ultrasound revealing intrahepatic duct dilatation reveal strictures of two types. The most common is

anastomotic and usually amenable to dilatation at ERCP. With recurrence, reconstruction should be considered. A hilar stricture should prompt a search for ischaemia. In these circumstances reconstruction and/or retransplantation are considered.

Bacterial infection

Bacterial sepsis is common in chest, urine, blood, abdomen, and intravascular cannulae. There is no universal recommendation for antibiotics although most physicians recommend the use of antimicrobial prophylaxis for up to 48 h. Thereafter, antimicrobial therapy is based on careful observation, clinical assessment, culture, and local knowledge of likely pathogens.

Viral infections

Herpes simplex virus infections are often clinically apparent and can be managed with topical acyclovir, unless there is a suspicion of systemic disease, requiring parenteral acyclovir. It seems probable that genital herpes will also be reactivated.

In the past, cytomegalovirus (CMV) infection has been the principal viral cause of infection in this period but there have been significant advances in the past decade. Prophylaxis with oral ganciclovir to prevent clinical expression of disease has proved effective but it may occur with reduced severity once ganciclovir is withdrawn at 3 months. For patients who have completed prophylaxis and recipients with antibody at transplantation, recrudescence or infection with a donor strain can be investigated by means of PCR for CMV DNA in serum. CMV viraemia is associated closely with clinical disease, affecting the gastrointestinal tract, central nervous system, respiratory system, the bone marrow, retina, and liver. Patients who become CMV PCR positive should receive systemic ganciclovir. Newer, quantitative assays might guide therapy more accurately. Ganciclovir resistance has been reported. Shingles is a common complication of the early postoperative period and should be treated with systemic antiviral therapy with acyclovir. Amitriptyline and carbamazepine reduce the risk of postneuralgic syndrome.

Fungal infections

Candidal species are isolated commonly and prophylaxis is in routine use. Fluconazole is effective, but drug interactions, particularly with immunosuppressive agents, may render its use problematic. Oral therapy with nystatin or amphotericin is recommended at a later stage, up to 3 months. Systemic candidal or *Aspergillus* infections are more likely in those with severe liver disease, ischaemic grafts, a poor postoperative course, and renal impairment.

Protozoal infections

Co-trimazole prophylaxis for lymphopenia has almost eradicated *Pneumocystis carinii* infection in many centres. Toxoplasmosis is rare since the introduction of prophylaxis with pyrimethamine or co-trimazole for 6 weeks for patients with prior serological evidence of infection.

Late

Multiple biliary strictures may present with recurrent cholangitis and may be a late expression of ischaemia. A proportion comes ultimately to retransplantation, usually after a period of years.

Lymphoproliferative disease

This affects 2 to 4 per cent of patients and is less common with liver than with other solid organ grafts. Usually the disorder is a B-cell lymphoma and most are Epstein–Barr virus related. The most frequent location for lymphoma is the liver. Management is by reducing immunosuppression to a minimum and chemotherapy according to conventional guidelines.

Carcinoma

There is a substantial increase in the incidence of almost all carcinomas, including squamous and other skin cancers.

Osteodystrophy

A large proportion of patients has severe bone disease at presentation, which then worsens so that there is an increased fracture rate in the postoperative period. The severity of bone disease has improved considerably over the past decade because of the reduced dose of corticosteroids used. Bone mass improves significantly over the first 2 to 3 years after transplantation but it is wise to use bisphosphonates (and sex hormones) for patients who show clear evidence of reduced bone density.

Chronic rejection

This is a devastating consequence of liver transplantation and is rarely reversible. It can be predicted on the basis of severe acute rejection, steroid-resistant acute rejection, or multiple episodes of acute rejection. It leads to graft loss and the requirement for a further transplant. It is uncertain what the main target for the process is and the precise immunological nature of the process remains to be determined. However, the main branches of the hepatic artery become obliterated with foamy macrophages and the histological pattern resembles chronic rejection of other solid organs. Bile ducts are lost (the vanishing bile duct syndrome), probably as a consequence of chronic ischaemia.

Cardiovascular disease

Patients who have undergone liver transplantation have a significant increase in their cardiovascular risk profile in the early postoperative phase, which extends long term. It is probable that this represents a consequence of immunosuppression, since hyperlipidaemia, hypertension, renal impairment, and weight gain are common features.

Recurrent disease

It is recognized that immunosuppressive regimes should be modified according to the primary indication for transplant, especially for prevention or treatment of recurrent graft disease.

Hepatitis B virus

Serum HBV DNA at the time of transplantation or the presence of HBcAg in host liver predicts accurately the likelihood that the graft will become infected with HBV. Graft infection without treatment is associated with a significant morbidity and mortality such that in the 1990s many patients with HBV were not considered.

The situation has been revolutionized. Hepatitis B immunoglobulin, although expensive, reduces the rate of graft infection, particularly in those HBV DNA negative in serum at the time of transplantation. Lamivudine prevents graft infection if given prior to transplantation and is effective therapy for graft infection. Regrettably, lamivudine resistance evolves rapidly and mutated virus can cause liver damage. Adefovir for patients with lamivudine resistant virus post-transplantation has been useful and resistance to the combination has not yet been reported. The role of adefovir in preventing graft infection has not been assessed. Corticosteroids should be withdrawn by week 6 and maintenance on single therapy with tacrolimus rather than cyclosporin is recommended.

Hepatitis C virus

HCV infects the graft inevitably, and is associated with a rapidly progressive fibrosis which is not usual in HCV-positive patients not treated by hepatic transplantation. A significant proportion of patients have cirrhosis by 5 to 10 years and a small proportion of patients lose the graft to HCV infection within 1 to 2 years of

transplantation. Trials of interferon-a and ribavirin in the transplant setting are underway but there is no evidence yet that this combination is able to prevent graft infection or to prevent liver damage once graft infection occurs. Most established transplant units recommend minimal immunosuppression for this group of patients.

Autoimmune hepatitis

Undoubtedly this can affect the graft and cause graft loss. It may be predicted in advance of significant deterioration by monitoring immunoglobulins. A small proportion of patients develops 'autoimmune hepatitis' *de novo*. Triple therapy with long-term azathioprine and long-term low dose prednisolone, tacrolimus, or cyclosporin is advised.

Primary sclerosing cholangitis

This may affect the graft and is associated with an increased incidence of biliary complications. Immunosuppression does not appear to prevent recurrence in the graft, which may be lost.

Primary biliary cirrhosis

This can affect the graft and cause graft loss. It appears that immunosuppression does not prevent recurrence. Indeed, cirrhosis with portal hypertension has occurred within 2 years of grafting for this indication.

Alcohol

Recidivism for alcoholism and the development of alcohol-related liver disease after transplantation for alcohol-related disease are well recognized but uncommon. Liver damage can lead to graft loss within a period of 12 months if the consumption of alcohol is resumed.

Immune regulation

Tolerance

Tolerance is probably rare and there are no adequate tests to identify tolerance in human grafts when it does occur. Studies of liver tissue in well patients with normal liver biochemistry have invariably shown many with abnormal liver histology; only a small minority are normal (and probably tolerant). It is recognized that calcineurin inhibitors prevent the development of tolerance, which is an active process. Nevertheless, these drugs are currently the best available for transplantation. Murine and other animal models indicate that a range of antibodies to T-cell markers can induce tolerance experimentally (including CD4, CD2, CD3, CTLA-4, CD45RB and CD40L).

Immunosuppression

Over the past decade the introduction of additional immunosuppressive agents has been a major therapeutic advance: individual disorders and individual patients can receive tailored therapy (Table 3). Maintenance in the early stages is based on triple therapy—cyclosporin or tacrolimus, which are prescribed indefinitely, azathioprine for 1 year, and prednisolone for a variable period. Our current practice is to stop prednisolone at 3months, adrenal function permitting. The daily dose of prednisolone used nowadays rarely exceeds 20 mg and the daily dose of azathioprine rarely exceeds 1 mg/kg. Large, parenteral doses of prednisolone are given for acute rejection.

Cyclosporin causes significant cardiovascular morbidity with hypertension, hyperlipidaemia, and weight gain. Neuropsychiatric illness is also reported. Peculiar to cyclosporin is the development of hirsutism and gum hypertrophy, making this particularly unsuitable for females. Renal impairment is a common problem which is probably under-reported and under-recognized. Renal grafting has been required for cyclosporin-induced renal failure.

Tacrolimus

Tacrolimus shares most of the side effect profile of cyclosporin, in particular the cardiovascular complications (hypertension, hyperlipidaemia, and weight gain) as well as neuropsychiatric disease and renal toxicity. The question of whether diabetes mellitus is induced by tacrolimus remains contentious.

Other immunosuppressive agents

Other agents used are unproven and at present lack clear clinical indications. These include rapamycin, which is associated with poor wound healing, bone pain, gastrointestinal upset, bone marrow suppression, and hypertriglyceridaemia. The absence of hypertension, weight gain, or renal toxicity may prove invaluable for those complications arising with calcineurin inhibitors. Mycophenolate mofetil is another unproven agent for liver transplant patients. It reduces cell proliferation in similar fashion to azathioprine but appears to be more lymphocyte-specific—gastrointestinal disturbances are common with this agent.

Antilymphocyte globulin and antithymocyte globulin are T-cell antibodies utilized in the treatment of steroid-resistant acute rejection. Some utilize one or other in the initial induction regime. They carry an increased risk of infection, long-term lymphopenia, and lymphoproliferative disease; the use of these compounds in routine immunosuppression is in decline.

A number of newer, monoclonal antibodies are in development or subject to evaluation in clinical trials. These are directed largely at activated T cells or adhesion molecules. Their clinical role remains to be defined.

Future

Three main areas can be identified for the future development of hepatic transplantation. First, increasing the number and quality of donor livers; at the same time research to improve rescue of damaged donor organs is critically important. Second, donor-specific tolerance remains a goal—in this respect, considerable encouragement has been gained by the successful induction of tolerance in experimental animals as a result of continued world-wide investment in basic transplantation research by immunologists. Finally, improved management of the long-term complications of transplantation, in particular cardiovascular and malignant disease, would greatly extend the duration and quality of life of the many patients who have received donor livers for otherwise fatal hepatic diseases.

14.21.5 Primary and secondary liver tumours

Iain M. Murray-Lyon

Benign and malignant tumours may arise in the liver from the hepatocytes, bile-duct epithelium, or supporting mesenchymal tissue. With the exception of hepatocellular carcinoma all the primary malignant tumours are rare, but the liver is frequently the site of secondary (metastatic) deposits of malignant tumours elsewhere in the body.

Hepatocellular carcinoma

This occurs either as a single mass or as scattered nodules of tumour, and in around 80 per cent of patients there is pre-existing cirrhosis. The tumour tends to invade the portal and hepatic veins, and spreads to the abdominal lymph nodes and bone. Histologically the tumour is typically composed of cells resembling hepatocytes, which are arranged in cords. A number of other distinct histological subtypes are now recognized, including the fibrolamellar variant in which clumps of eosinophilic carcinoma cells are surrounded by a characteristic fibrous stroma. This tumour occurs in young adults in a non-cirrhotic liver.

Epidemiology

Although this is a comparatively rare tumour in Western Europe and North America where the annual incidence is around 1 to 2 per 100 000 of the population, there is recent evidence that it is becoming more common, and in Africa and South-East Asia the incidence is 20 to 30 times higher. In patients with underlying cirrhosis, males greatly outnumber females but in non-cirrhotic cases this sex difference is less striking. In areas of high incidence the peak age is in the third and fourth decades of life but in Europe and North America most cases occur in the fifth and sixth decades.

Aetiology

In all countries in the world, cirrhosis, particularly the macronodular form, is present in about 80 per cent of cases. In Western Europe and the United States this is usually due to chronic alcoholism or chronic hepatitis B or C, and at least 10 per cent to 15 per cent of such patients will develop a hepatocellular carcinoma. In Africa and Asia, chronic liver disease is usually associated with hepatitis B or C virus infection. Rare cases may complicate cirrhosis due to other causes, and may follow prolonged use of the oral contraceptive pill or prior investigations using the radioactive contrast agent Thorotrast.

In parts of Africa and the Far East there is increasing evidence implicating aflatoxin. This is a potent carcinogen derived from the mould *Aspergillus flavus*, which often contaminates food.

The hepatitis B virus (**HBV**) is now recognized to have an important role in the development of hepatocellular carcinoma, particularly in areas of high incidence. Long-term, follow-up studies of large numbers of HBV carriers have confirmed that the risk of developing hepatocellular carcinoma is at least 100 times higher than in matched uninfected controls. The HBV can be identified in the tumour as well as the surrounding liver, and integration of viral DNA in the genome of hepatocellular carcinoma has been shown. This HBV DNA integration may result in major structural rearrangements in adjacent cellular DNA, and a range of deletions, duplications, and translocations between chromosomes has been reported. In geographical areas of high endemicity of HBV as well as exposure to aflatoxins, one of a variety of mutations of the *p53* gene on chromosome 17 is a frequent finding. How these molecular events are initiated and progress is still unclear.

The hepatitis C virus (**HCV**) is also closely linked with the development of hepatocellular carcinoma, especially in geographical areas such as North America, Western Europe, and Japan where HBV is not hyperendemic. Almost all cases are associated with cirrhosis. Prospective studies of patients with chronic post-transfusion HCV infection indicate the latent period before tumour development may be as long as 25 to 30 years.

Hepatocellular carcinoma is a largely preventable disease, and the extensive use of hepatitis B vaccination has already led to a reduction in the incidence of this tumour in Taiwan. Until such time as a vaccine against HCV is available, introduction of all possible measures to reduce transmission of this virus is important. Furthermore, there are indications that the successful treatment of chronic hepatitis B and C will reduce the cancer risk.

Clinical features

In Africa and other high-incidence areas, patients usually present with a short history of right upper abdominal pain, often associated with fever and weight loss. There may be considerable abdominal swelling due to liver enlargement, with or without ascites. Catastrophic intraperitoneal bleeding sometimes occurs due to tumour rupture. In low-incidence areas the disease is often more insidious and presents as a general deterioration in the health of a patient already known to have cirrhosis. There is usually hepatomegaly and a bruit may be heard over the liver. A number of non-metastatic systemic manifestations may also rarely occur, such as hypoglycaemia, hypercalcaemia, and porphyria cutanea tarda.

Because of the use of screening in high-risk groups, more small (less than 3-cm diameter), asymptomatic tumours are now being detected.

Investigations

Haematological and biochemical indices

The haematological and biochemical changes, apart from alpha-fetoprotein, are non-specific and reflect the space-occupying lesion as well as the underlying cirrhosis present in about 80 per cent of cases.

Alpha-fetoprotein is a glycoprotein synthesized by the fetal liver and its plasma concentrations reach their maximum at the end of the first trimester (3 to 4 mg/ml) and then decline. After birth, concentrations fall rapidly to adult levels (1 to 10 ng/ml). Raised levels are found in about 80 per cent of patients with hepatocellular carcinoma and tend to be higher in African and Far-Eastern populations than in those in low-incidence areas and in those patients with small tumours. Concentrations above 500 ng/ml in a patient with liver disease are highly suggestive of hepatocellular carcinoma. However, in interpreting alpha-fetoprotein levels it should be remembered that high plasma levels are found in some patients with germinal-cell tumours of the testis and ovary as well as occasional patients with carcinoma of the stomach or pancreas, usually with hepatic metastases. Below 500 ng/ml there is a diagnostic 'grey zone', for such levels may be found in patients with severe viral hepatitis and active cirrhosis. But subsequent readings tend to fall towards normal in patients with these conditions, whereas in patients with hepatocellular carcinoma the levels rise progressively. Sequential readings are therefore of great diagnostic value, and the measurement of hepatoma specific isoforms may improve diagnostic specificity and sensitivity.

Other tumour markers for hepatocellular carcinoma have been described in the serum, including an abnormal vitamin B_{12} binding protein which is usually present with the fibrolamellar histological variant.

Liver imaging

Real-time ultrasound

This is a sensitive and specific test and picks up hepatocellular carcinoma in 85 to 90 per cent of cases. False-negative results usually occur in patients with tumours of less than 2 cm in diameter.

Abdominal computed tomographic (CT) scanning

This technique is probably no more accurate in detecting hepatocellular carcinoma than ultrasound and should be reserved for cases in which doubt persists. Sensitivity can be increased by contrast enhancement. Dynamic spiral contrast-enhanced CT scanning is even more sensitive.

Magnetic resonance imaging (MRI)

This technique, particularly with the addition of a contrast agent, is proving useful in identifying and characterizing focal liver masses. Manganese dipyridoxyl diphosphate (**Mn-DPDP**) targets hepatocytes and super-paramagnetic iron oxide (**SPIO**) targets reticuloendothelial cells, resulting in increased prominence of the lesion with respect to normal liver tissue (Fig. 1). Lesions that do not contain reticuloendothelial cells or hepatocytes (haemangiomas and metastases) do not have their signal intensities altered.

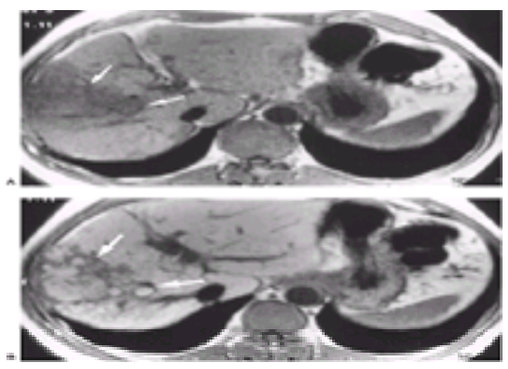

Fig. 1 (a) Axial T_1-weighted image through the liver in a patient with hepatitis C. An ill-defined area of reduced signal in the right lobe of the liver at the junction of segments 7 and 8 is suspicious for a liver tumour (arrowed). (b) Axial T_1-weighted image through the liver in the same patient following an infusion of Mn-DPDP, a hepatocyte specific contrast agent. There is a general increased signal in the normal liver and a heterogeneous increased signal in the liver tumour, characteristic of uptake by a hepatocellular carcinoma (arrowed).

Hepatic arteriography

Excellent visualization of the hepatic artery can usually be obtained by selective catheterization using the Seldinger technique. As the major vascular supply to a hepatocellular carcinoma is usually arterial, diagnostic changes are seen in a high proportion of cases. Information gained on the anatomical distribution of the tumour and the vascular anatomy is essential if surgical resection or transplantation is being contemplated, and consideration can also be given at the time of arteriography to intra-arterial chemotherapy and hepatic artery embolization. The sensitivity of arteriography can be increased by combining it with dynamic spiral CT scanning together with late films to show the portal venous system, as well as injection of the iodine-containing contrast medium Lipiodol. CT scanning 10 to 14 days later can visualize Lipiodol selectively retained in tumours as small as 2 to 3 mm in diameter.

Liver biopsy

For definitive diagnosis, liver biopsy is essential, although this is not always possible because of the prolongation of the prothrombin time. The diagnosis can be considered highly likely without liver biopsy proof if the alpha-fetoprotein level is greater that 500 ng/ml and the hepatic arteriogram shows a tumour circulation. Biopsy may be conveniently done at the time of laparoscopy or ultrasonography and suspicious areas can be sampled under direct vision. Because of the risk of tumour spread, biopsy is often avoided if curative resection or transplantation is planned.

Screening

Patients with an increased risk of developing hepatocellular carcinoma, such as those with cirrhosis or chronic HBV or HCV infection, should be considered for regular screening by alpha-fetoprotein assay and abdominal ultrasonography. While such a strategy has been shown to pick up early tumours, and there is evidence of improved survival figures for these patients in the Far East, the benefits of screening have so far proved disappointing in Europe.

Prognosis

This is a highly malignant tumour and the mean survival in most series is around 4 to 6 months. In Africa the disease tends to run a more malignant course. Patients with cirrhosis have a poorer prognosis than those without. Encapsulated tumours and the fibrolamellar histological variant, as well as small tumours picked-up at screening, have a better prognosis.

Treatment

Curative

Only complete resection or orthotopic transplantation hold out any chance of cure and these procedures should be considered in every case.

Resection

Resection is only possible in about 10 per cent of cases because of underlying cirrhosis or tumour in both lobes. Often a major resection is needed and the anatomical possibilities are illustrated in Fig. 2. In the presence of cirrhosis only a limited resection is possible as liver regeneration is defective, but this procedure may be curative if the tumour is small. In China, screening programmes to detect early hepatocellular carcinoma have led to higher rates of tumour resection in cirrhotic patients and improved long-term survival figures.

Fig. 2 Diagram to illustrate the main types of hepatic resection.

The best results are achieved in patients with well-compensated cirrhosis and small tumours (less than 3 cm), but 5-year survival rates of only 20 to 30 per cent are usually quoted due to progression of the underlying liver disease, tumour recurrence, and the development of new tumours.

Transplantation

This is an attractive option for patients with cirrhosis and a hepatocellular carcinoma and the procedure can cure both the tumour and the underlying cirrhosis. Long-term results are best with tumours less than 5 cm in diameter when survival figures up to 70 per cent at 5 years are recorded. The best results are obtained when a hepatocellular carcinoma is discovered incidentally in the resected liver when transplantation is performed for liver failure, and with the fibrolamellar histological variant.

Palliation

Radiotherapy

External-beam X-irradiation does not produce consistent improvement. Intra-arterial injection of Lipiodol mixed with iodine-131 has given some encouraging preliminary results.

Cytotoxic drugs

Doxorubicin (Adriamycin) is one of the few drugs that may produce worthwhile regression, but only 20 to 30 per cent of cases respond and no survival benefit has been established. Mitoxantrone (mitozantrone), which is structurally similar to doxorubicin, gives a similar response rate and has fewer toxic side-effects.

The presence of hormone receptors in hepatocytes has prompted attempts to modify tumour growth. Results are poor with tamoxifen but octreotide has been reported to be of value.

Targeted therapies

A wide variety of local targeted therapies have been developed and assessed in recent years. Very few, however, have yet been submitted to a prospective, randomized controlled trial.

Percutaneous ethanol injection

Sterile alcohol is injected directly into the tumour under ultrasound guidance causing tumour necrosis. Repeated injections may be given into more than one tumour mass. The best results are obtained with tumours less than 3 cm in diameter and the survival figures are comparable with those of limited surgical resection.

Lipiodol-targeted chemotherapy

Cytotoxic drugs may be emulsified with Lipiodol (see above) and delivered directly into the liver at selective hepatic arteriography. There are some data to show that the duration of action of the drugs is prolonged because of the retention of Lipiodol in the tumour. There is, however, no convincing evidence of benefit.

Transcatheter arterial embolization (TAE)

Embolization with foreign materials, such as gel foam, can be achieved at the time of hepatic arteriography and may result in substantial tumour necrosis, particularly in highly vascular tumours, which derive the bulk of their blood supply from the hepatic artery. In patients with decompensated cirrhosis and those with portal vein occlusion the procedure is contraindicated. Broad-spectrum antibiotics are given for some days because of the risk of anaerobic infection in the ischaemic liver. As tumour necrosis is never complete, embolization of the tumour should be combined with targeted chemotherapy (chemoembolization). The gel foam particles may be soaked in doxorubicin or cisplatin or the TAE may be immediately preceded by Lipiodol targeted chemotherapy. While such treatment may result in tumour necrosis, shrinkage, and symptomatic improvement, three controlled trials have not established survival benefit.

Cryoablation and thermal ablation

These techniques are intended to destroy tumour cells by physical means. No controlled trials have been reported. Cryotherapy probes are inserted into the tumour either at laparotomy or laparoscopy and liquid nitrogen is circulated through them. Thermal energy can be applied via probes placed percutaneously in the tumour using either laser, radiofrequency, or microwaves. All three techniques have proved safe, have few side-effects and can be repeated. Current data are insufficient to allow comparison of the efficacy of these ablative techniques.

Cholangiocarcinoma

Carcinoma may arise in any part of the biliary tree from the small intrahepatic bile ducts down to the lower end of the common bile duct. Two clinical varieties occur in the liver—a peripheral form, which consists of one single or multiple nodules; and the much commoner hilar form usually situated at the confluence of the right and left

hepatic duct. This invades locally and causes obstruction of the biliary tree. The histological appearances are identical whatever the site of origin. It is an adenocarcinoma with a simple ductular arrangement of columnar or cuboidal cells, usually with a prominent fibrous stroma.

Epidemiology

This tumour is much less common than hepatocellular carcinoma and accounts for about 7 to 10 per cent of primary malignant tumours, except in the Far East where it makes up about 20 per cent. The peak age is in the sixth and seventh decades and the sex incidence shows only a slight male predominance.

Aetiology

Thorium dioxide (Thorotrast) is a well-recognized but rare cause of the intrahepatic variety of the tumour. In the Far East, infestation of one of a variety of distomes (*Clonorchis sinensis*, *Opisthorchis viverrin*ı) is probably commonly related.

Patients with long-standing ulcerative colitis occasionally develop carcinoma in the biliary tree, and the risk is about 10 times greater than for the general population. Primary sclerosing cholangitis— whether or not associated with inflammatory bowel disease and various types of cystic disease of the biliary tree such an congenital hepatic fibrosis, polycystic disease of the liver, and Caroli's disease—may all be complicated by the development of malignant change. Unlike hepatocellular carcinoma neither long-standing HBV or HCV infection nor cirrhosis seem to predispose to cholangiocarcinoma.

Signs and symptoms

In the peripheral intrahepatic type, patients present with upper abdominal pain, anorexia, malaise, and weight loss. With hilar tumours, jaundice is an early feature. Hepatomegaly is usual and splenomegaly may be found if secondary biliary cirrhosis develops owing to prolonged biliary obstruction.

Diagnosis

The liver function tests show cholestatic features with elevation of bilirubin and alkaline phosphatase levels. Alpha-fetoprotein concentrations are usually normal or only slightly raised. Levels of Ca 19.9 and carcinoembryonic antigen (**CEA**) may also be raised, although sensitivity and specificity do not approach 100 per cent as raised levels are found in obstructive jaundice due to other causes.

Ultrasonography and CT scanning may demonstrate the tumour mass and with hilar tumours show dilatation of the intrahepatic biliary tree. On hepatic angiography the tumour tends to be avascular but encasement and occlusion of vessels occurs. Biliary tree obstruction in the hilum may be demonstrated on MRI cholangiography or by endoscopic retrograde cholangiography (**ERCP**) prior to insertion of a stent (see below).

Prognosis

Most patients deteriorate progressively, with an average survival from diagnosis around 12 to 18 months. If biliary drainage can be achieved in patients with hilar tumours, the prognosis may be better, for these tumours are often slow growing.

Treatment

For the peripheral tumours the principles of treatment are the same as for hepatocellular carcinoma (see above). The response to therapy is disappointing and no controlled trials have been reported. Hilar tumours may sometimes be suitable for curative resection with anastomosis of a Roux loop of jejunum to the biliary tree in the hilum. More usually curative excision is not possible, and the aim must be to establish biliary drainage. A stent can be placed through the growth at laparotomy, or at ERCP, or via the percutaneous transhepatic route thus avoiding surgery. The use of self-expanding metal stents is a recent advance.

Conventional radiotherapy and high-dose local irradiation within the biliary tree by means of iridium-192 wire may sometimes produce useful symptomatic relief. If biliary drainage can be achieved by these procedures, survival for 1 to 2 years is not unusual. Because of the high risk of tumour recurrence, liver transplantation is seldom indicated.

Angiosarcoma (Kupffer-cell sarcoma)

This is a rare tumour consisting of spindle-shaped malignant endothelial cells. It is often multifocal and may arise in a cirrhotic liver.

Considerable progress has been made in identifying aetiological agents. Like hepatocellular carcinoma and cholangiocarcinoma, it occurs in patients who were exposed to Thorotrast 15 to 25 years earlier, and chronic exposure to arsenic has also been implicated. More recently the tumour has been found in workers in the vinyl chloride industry, particularly those exposed to high concentrations of vinyl chloride monomer while cleaning the autoclaves. Since this discovery strict safety regulations have been introduced but because of the long latent period new cases continue to present. A few cases have occurred in long-term androgen takers, but no aetiological factor has yet been identified in the majority of cases. As with other liver tumours, patients present with abdominal pain and hepatic enlargement and blood-stained ascites is common.

This is a highly malignant tumour and curative resection is rarely possible. No form of palliative treatment has so far proved effective.

Epithelioid haemangioendothelioma

This is a rare malignant tumour of vascular endothelial origin with a characteristic histological appearance. It is usually multifocal. It occurs in younger patients than angiosarcoma and does not have the same aetiological associations. The tumour is usually slow growing and prolonged survival has been reported after resection and liver transplantation.

Other primary malignant tumours

These are extremely rare and include fibrosarcoma, leiomyosarcoma, and lymphoma. Children develop both hepatoblastoma and hepatocellular carcinoma.

Hepatic metastases

The liver is a favoured site for metastatic spread and about 50 per cent of malignant tumours in the portal venous drainage area eventually gives rise to hepatic metastases.

Diagnosis

The diagnosis is easy when physical examination reveals a large nodular liver but detection of small or solitary deposits is difficult. Liver function tests may be normal, but the alkaline phosphatase usually rises as the tumour mass enlarges. Ultrasound scanning should pick up tumours greater than 1 cm in diameter but accuracy is greatest when the metastases are large or numerous. The diagnosis can be confirmed by targeted liver biopsy at the time of laparoscopy or ultrasonography.

Prognosis

The prognosis is obviously worse when there is extensive liver replacement by tumour with severe disturbance in liver function tests or ascites. The site of the primary growth is also relevant and deposits from colorectal cancer have a better prognosis (untreated mean survival 9 to 12 months) than most other tumours.

Treatment

The range of possible treatments is the same as has been discussed for hepatocellular carcinoma. Partial hepatectomy to remove deposits may occasionally lead to prolonged survival or cure and, as mentioned above, the results are best in patients with colorectal cancer. A special situation exists with respect to hepatic metastases from the carcinoid tumour. This is often a slow-growing neoplasm and the main problem is the distress caused by flushing and diarrhoea. Resection of tumour bulk with no attempt at total removal often gives symptomatic relief for some years, as does embolization. Transplantation should be considered for slow-growing tumours.

The choice of chemotherapy will be determined by the origin of the primary tumour and this will not be discussed here. As with hepatocellular carcinoma the poor results with systemic chemotherapy led to trials with intra-arterial perfusion. Such treatment has been simplified by the development of implantable pumps, but while objective tumour regression may occur with improved quality of life, as yet there is little convincing evidence that survival is prolonged.

Benign tumours

Haemangioma

This is the most common benign tumour and is usually asymptomatic, being found incidentally either during ultrasonography or CT scanning. Occasionally when large it may cause abdominal pain or shock due to rupture leading to surgical excision.

Although the appearances with ultrasonography are usually diagnostic, it may be necessary to proceed to CT scanning with contrast, angiography, or MRI for diagnostic certainty.

Hepatic adenoma

The incidence of this tumour seems to have increased markedly since the introduction of the oral contraceptive pill, with most reported cases having occurred in females who have been on the pill for 5 years or more. It should be emphasized, however, that the risks for the individual woman is infinitesimal. Patients are often asymptomatic and a mass is discovered on physical examination or incidentally on ultrasound examination. Some patients complain of upper abdominal pain and others present acutely with shock due to intraperitoneal bleeding. The tumour is usually solitary but may be multiple. It consists of cords or acini of hepatocytes without bile ducts or portal tracts, and fibrous tissue septa are sparse. It may be encapsulated. There is little or no disturbance in liver function and alpha-fetoprotein concentrations are normal.

Ultrasonography shows a focal lesion of variable echogenicity, CT scanning shows marked arterial enhancement and sometimes areas of haemorrhage within the tumour which can be confirmed on MRI scanning.

In some cases the tumour has regressed after withdrawal of the contraceptive pill, but surgical resection is usually recommended because of the risk of intraperitoneal bleeding and the occasional development of malignant change.

Focal nodular hyperplasia

This is a benign condition of uncertain pathogenesis that is frequently confused with hepatic adenoma. The lesion is composed mainly of hepatocytes and Kupffer cells. Typically it has a central stellate scar with radiating septa containing arterial and venous channels and bile ductules. It is much more frequent in women than men, but no relationship to the oral contraceptive pill has been established. The mass is usually solitary and asymptomatic but rupture with intraperitoneal bleeding occasionally occurs. The findings on imaging are often different from those of hepatic adenoma and may allow definitive diagnosis. In particular Doppler ultrasound may show an arterial signal within the tumour, CT scanning or MRI scanning may demonstrate the central stellate scar and biliary scintiscanning may show a late hotspot in the tumour.

The prognosis is excellent and malignant change is not recorded. If the imaging techniques do not provide a definite diagnosis, however, surgical excision is often recommended.

Other benign tumours

These are very much rarer and include fibroma, lipoma, leiomyoma, and cystadenoma.

14.21.6 Hepatic granulomas

C. W. N. Spearman, P. de la Motte Hall, and S. J. Saunders

Introduction

Granulomas are localized collections of modified macrophages, known as 'epithelioid' cells, that have become transformed from a predominantly phagocytic cell to a more secretory cell in response to ingested antigens. The epithelioid cells, which are derived from blood monocytes, have abundant amounts of eosinophilic cytoplasm. Langhans' or foreign body-type giant cells, which form by fusion of the epithelioid cells, are often seen in granulomas. Granulomas are usually surrounded by a rim of mononuclear cells, predominantly lymphocytes. Granulomas may be progressively replaced by collagen.

The aetiology of hepatic granulomas varies with the patient population and geographical origin. In the developed world, sarcoidosis, primary biliary cirrhosis, and drug-induced hepatic granulomas probably account for most, whilst infectious causes such as mycobacterial infections, schistosomiasis, and AIDS-related infections predominate in the developing world.

The diagnosis of granulomatous hepatitis is usually made during the investigation of a systemic illness, frequently presenting as a pyrexia of unknown origin (**PUO**). However, granulomas are found in 10 to 15 per cent of all liver biopsies and may be an unexpected finding. The histomorphology of the granuloma, their distribution in the liver, and special stains, for example Ziehl–Neelsen for mycobacteria and a methenamine silver for fungi, may yield a definite diagnosis.

Pathogenesis

Granuloma formation represents a specialized cellular immune-mediated response involving the presentation of antigen, either endogenous or exogenous, by activated macrophages to CD4 lymphocytes, which are in turn activated by the secretion of macrophage-derived interleukin-1 (IL-2). The activated CD4 lymphocytes secrete interferon, resulting in the upregulation of MHC class II molecules on the surface of the activated macrophages. Upregulation of the HLA DR-positive macrophage and the resulting increased interaction with stimulated CD4 lymphocytes, is accompanied by the consequent increase in IL-2 receptor expression and IL-2 secretion. This results in a clonal increase in the CD4 lymphocytes, leading to the recruitment of B cells which are activated and produce immunoglobulins, antibodies, and autoantibodies. Persistent antigenaemia or poorly degradable antigens, such as chemicals or toxins, provide an ongoing stimulus for the cytokine cascade which results in the focal accumulation of activated lymphocytes and macrophages, with the macrophages undergoing epithelioid transformation.

In infections, the micro-organisms, together with their by-products, are the sensitizing exogenous antigens, whereas in malignancy, or immune complex disease, sensitizing endogenous antigens may trigger an interaction between the activated macrophages and lymphocytes.

Depending on the cause, differences are seen in the above-described structural/functional arrangement of the granuloma. The well-studied sarcoid granuloma has a central core of HLA DR-positive macrophages, epithelioid cells, and giant cells with a peripheral rim of CD4 lymphocytes. The macrophages surrounding the central core are distinguishable from those in the centre by their reactivity with the macrophage monoclonal antibody RFD-1 as opposed to RFD-2. CD8 suppresser cells, and some CD4 cells, may be found at the periphery but not in the centre of the granuloma. The epithelioid cells in sarcoid granuloma secrete a number of compounds, including angiotensin-converting enzyme, lysozyme, glucuronidase, collagenase, elastase, and calcitriol. In AIDS patients with *Mycobacterium avium intracellulare* (**MAI**) infection, there is a paucity of CD4 lymphocytes in the granulomas. While in granulomas infected with *Schistosoma mansoni*, the CD4 cells show increased Th2 co-operation. The granulomas in tuberculoid leprosy contain very few bacilli, while bacilli are profuse in lepromatous leprosy.

Aetiology

The many causes of hepatic granulomas are shown in Table 1. Granulomas are frequently non-specific in appearance and a clinicopathological correlation is essential for diagnosis. In 10 to 30 per cent of hepatic granulomas, the aetiology remains unknown. However, caseating granulomas (Fig. 1 and Plate 1) are characteristic of mycobacterium tuberculosis; the presence of ova and non-caseating granulomas permit the diagnosis of schistosomiasis; fat droplets are seen in the granuloma (lipogranuloma) that accompanies mineral oil ingestion; and fibrin-ring granulomas are highly suggestive of Q fever.

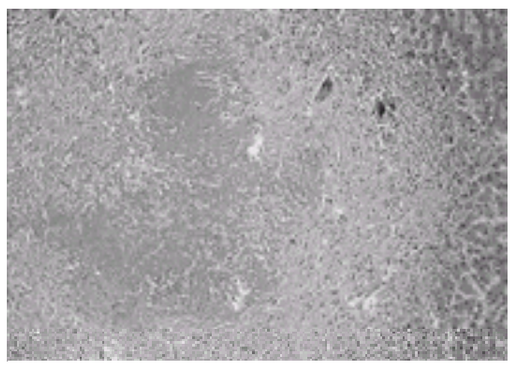

Fig. 1 Liver showing a portion of a large caseating granuloma from a patient with miliary mycobacterium tuberculosis. Several Langhans' giant cells are also seen. (Haematoxylin and eosin, total magnification 25.) (See also Plate 1.)

Clinical presentation

Fever (PUO) is the most common presenting symptom. The diverse clinical features, which include weight loss, anorexia, fatigue, hepatosplenomegaly, and abdominal pain, depend on the underlying aetiologies. Serum transaminase activities are frequently normal, but alkaline phosphatase activity may be elevated. Jaundice is uncommon unless there is bile-duct injury, for example primary biliary cirrhosis and sarcoidosis.

Infectious causes

Mycobacterium tuberculosis infection

Tuberculosis is a common cause of hepatic granuloma in the developing world. There may be evidence of pulmonary tuberculosis or of tuberculosis elsewhere, or the patient may present with a pyrexia of unknown origin. Hepatic granulomas are common in miliary tuberculosis. Caseation occurs in about one-third of cases but, while characteristic of tuberculosis, is not unique to it, occurring also in candidiasis, histoplasmosis, and cryptococcosis. Acid-fast bacilli are seen in 10 to 15 per cent of cases, and in 31 per cent of autopsy specimens, and therefore the biopsy must always be cultured. More recently, use of the polymerase chain reaction (**PCR**), based on amplification of IS6110 insertion sequences, was shown to have a sensitivity of 58 per cent in the diagnosis of hepatic granulomas of definitive tuberculosis origin and a specificity of 96 per cent, and is a useful test as it can be performed on paraffin-embedded tissue. BCG vaccination may also cause hepatic granulomas.

HIV/AIDS

Currently more than 30 million people worldwide test positive for the human immunodeficiency virus (**HIV**). Opportunistic infections, especially *Mycobacterium avium intracellulare* (**MAI**), are an important cause of hepatic granulomas in patients with AIDS. The MAI granulomas are composed of epitheliod cells with striated bluish cytoplasm, due to the presence of large numbers of micro-organisms (Fig. 2 and Plate 2).

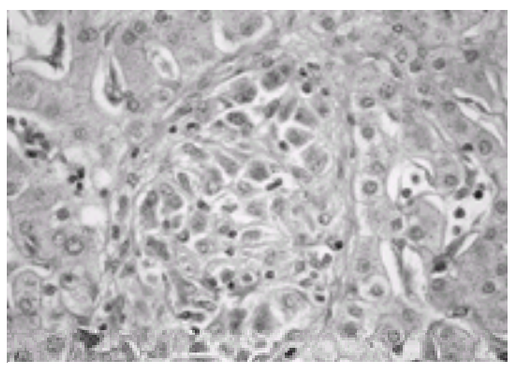

Fig. 2 Liver from an HIV/AIDS patient infected with *Mycobacterium avium intercellulare*, showing a granuloma composed of epithelioid cells which contain large numbers of micro-organisms. (Diastase/periodic acid–Schiff stain, total magnification 100.) (See also Plate 2.)

Histoplasmosis, cryptococcosis, toxoplasmosis, and cytomegalovirus may also cause granulomas in AIDS patients. However, an infectious cause is not always found, presumably there are as yet unidentifiable infections.

Drugs, Hodgkin's disease, and non-Hodgkin's lymphoma may also cause hepatic granulomas in AIDS patients.

Leprosy

Millions of people living in the Indian subcontinent have leprosy and this disease is also common in Africa. Hepatic granulomas are more common in lepromatous leprosy. The diagnosis is usually made from the characteristic skin and peripheral nerve lesions, and only occasionally, the physician is alerted to the diagnosis by the finding of an otherwise unexplained hepatic granuloma.

Histoplasmosis

Histoplasmosis is an important cause of hepatic granuloma in the United States. The fungus may be seen in the granulomas and may be cultured from liver biopsies, blood, or bone marrow. The chest radiograph is usually abnormal and the diagnosis is confirmed serologically.

Q fever

The patients usually present with a PUO or an illness resembling viral hepatitis. The typical granuloma contains inflammatory cells and fat droplets and has a fibrin ring within or at its margin. However, fibrin-ring granulomas may be seen in patients with cytomegalovirus infection, Hodgkin's disease, and leishmaniasis, and in drug reactions to, for example, allopurinol.

Schistosomiasis

Schistosoma japonicum and *Schistosoma mansoni* infestation occurs commonly in Africa, South America, and in the Far East. Ova are usually deposited in the portal tracts within the portal vein radicles where a granulomatous reaction occurs around the ova. Presinusoidal portal hypertension may occur with a 'pipe-stem' cirrhosis. Common presenting features are hepatomegaly and portal hypertension. Eosinophilia also occurs.

Hepatitis C virus (HCV)

Sparse non-caseating hepatic granulomas have been described in patients with chronic hepatitis C infection and in liver-transplanted patients who have subsequent recurrent HCV infections. There is controversy as to whether the presence of hepatic granulomas is predictive of a favourable response to interferon therapy.

Non-infective causes

Sarcoidosis

This is the most common non-infectious cause of hepatic granuloma formation. Although thought to be immunologically mediated, the triggering factor remains unknown. Hepatic granulomas are found in 60 per cent of liver biopsies performed on patients with sarcoidosis.

Well-formed, non-caseating granulomas occur in clusters in the parenchyma and the portal tracts. There may be associated portal fibrosis, which in some patients, progresses though bridging fibrosis to cirrhosis. Other features that are sometimes seen include bile duct damage and loss, which needs to be differentiated from primary biliary cirrhosis, other causes of ductopenia, and acute cholangitis associated with bile-duct obstruction. A lobular hepatitis, portal inflammation with interface hepatitis may also occur. The development of nodular regenerative hyperplasia as well as fibrosis and cirrhosis may be associated with granulomatous phlebitis of the portal and hepatic veins.

Hepatic sarcoidosis is frequently asymptomatic. While significant hepatomegaly is uncommon, splenomegaly is often present. The liver enzymes may be normal or

there may be elevated levels of alkaline phosphatase and aminotransaminases. Portal hypertension and cholestasis are rare complications occurring in only 1 in 300 European patients, but appear to be more common in the United States, and particularly in Black males. Patients may present with intrahepatic cholestasis and later cirrhosis. Differentiation from primary biliary cirrhosis is often difficult. The portal hypertension is presinusoidal and is thought to be due to granulomatous involvement of the portal venous radicals. These patients may present with variceal bleeds in the absence of cirrhosis.

Treatment with steroids often results in the reduction of the size of the hepatosplenomegaly and in improvement in liver enzymes. Steroids have little effect on portal hypertension but may benefit patients with intrahepatic cholestasis.

Primary biliary cirrhosis

Hepatic granulomas are found in approximately 25 per cent of patients with primary biliary cirrhosis (**PBC**). The granulomas are found in portal tracts and tend to surround damaged bile ducts. Occasionally, granulomas are seen in the parenchyma. The granulomas are seen in the early stages of PBC. PBC has a female to male ratio of 8:1, tends to present in the fifth decade of life, and usually has no extrahepatic systemic manifestations. Pruritis tends to be marked, clubbing and hepatomegaly is frequent. These clinical features help to differentiate PBC from sarcoidosis. The latter has an equal female to male ratio, occurs in the third and fourth decades of life, and frequently has extrahepatic manifestations such as erythema nodosa, uveitis, pulmonary involvement, hilar adenopathy, and abnormalities of calcium metabolism with hypercalcaemia and hypercalciurea. Antimitochondrial antibodies are positive in over 95 per cent of patients with PBC. The serum angiotensin-converting enzyme activity test may be elevated in both conditions.

Neoplasia

Non-caseating hepatic granulomas occur with a variety of neoplasms, including lymphoma and carcinoma. These granulomas may occur in the absence of tumour deposits and may represent an immune response to tumour antigens.

Lymphoma

Hepatic granulomas may occur in both Hodgkin's and non-Hodgkin's lymphoma. Granulomas may mask the infiltrates of malignant lymphoma and in Hodgkin's disease. Immunohistochemistry may demonstrate a clonal lymphocytic population in or around the granulomas associated with lymphoma.

Chronic granulomatous disease of childhood

This is a classical X-linked disorder, usually presenting at about 5 years of age with hepatosplenomegaly, generalized lymphadenopathy, granulomatous skin lesions, and diffuse miliary lung infiltration. The neutrophils of children with chronic granulomatous disease are unable to kill ingested bacteria, as they are deficient in those enzymes required for the superoxide respiratory burst. The diagnostic test for this condition is the inability of neutrophils to reduce nitroblue tetrazolium from colourless to blue-black formazan granules in their cytoplasm in the presence of a bacterial infection.

Crohn's disease

Non-caseating granulomas are found in the intestine, perineum, lip, and, occasionally, in the liver. The clinical manifestations are typical of Crohn's disease and diagnosis is not usually problematic.

Hepatic granulomatous disease

Hepatic granulomatous disease is a diagnosis of exclusion. The granulomas are seen in the portal tracts and lobules but there is no evidence of hepatitis. There appear to be two variants: one an acute febrile illness characterized by respiratory symptoms, a high white-cell count, and splenomegaly; and the other a more chronic condition presenting more frequently in middle-aged men with recurrent fevers, rigor, sweating, general malaise, and loss of weight. Neuralgia and arthralgia are common, there may be mild, tender hepatomegaly, and liver enzyme abnormalities are non-specific, including bilirubinaemia, mild elevation of transaminases, as well as elevated alkaline phosphatase levels. There is usually a good response to steroid therapy, with pyrexia resolving and liver enzymes improving. The cause is unknown.

Drugs and chemicals

Many drugs cause granulomatous hepatitis (Table 2). Drug-induced liver injury is frequently due to a hypersensitivity reaction. Although drug reactions may result in eosinophil-rich granulomas, in most cases the granulomas are non-specific.

Drug-induced hepatic granulomas may be completely asymptomatic or present with features suggestive of a drug allergy with a swinging fever, skin rash, eosinophilia, and abnormal liver enzymes. Although the diagnosis of drug-induced granulomatous hepatitis is one of exclusion, drugs should always be considered when granulomas are found in the liver.

Exposure to various chemicals such as beryllium, silicone, starch, talc, and suture material has also been associated with the development of hepatic granulomas.

Investigation and management of hepatic granulomas

To obtain the correct diagnosis and determine the appropriate therapy, it is important always to consider the epidemiological background of the patient. In the Western world, the common causes of granulomas in the liver are sarcoidosis, PBC, drugs, and neoplasms, whilst in patients in developing countries infectious causes must be considered first and excluded before considering others. However, the global problem of HIV/AIDS may well place mycobacterial and other infections as the most frequent causes of granulomatous hepatitis.

14.21.7 Drugs and liver damage

J. Neuberger

Introduction

Drug-induced liver injury is relatively uncommon, but unless it is recognized early and the drug discontinued it may cause death. Adverse drug reactions are responsible for between 0.1 and 3 per cent of all hospital admissions. Reliable data are difficult to come by: a relatively recent study has shown that in 1986 to 1987 about 1600 cases per year of adverse drug reactions were reported in England. Hepatic reactions accounted for 3.5 per cent of which 7 per cent were fatal. Similar figures were found by Pillans in New Zealand. A total of 205 drugs were associated with 943 reports of adverse liver injury between 1974 and 1994: 20 drugs accounted for nearly 60 per cent of reports. Most reactions are of jaundice and hepatitis; the more common are due to antibiotics and non-steroidal anti-inflammatory drugs. Halothane, perhexiline, and erythromycin were common causes of death and diclofenac, augmentin, and flucloxacillin were the most important causes of liver damage. In Denmark, Dossing and colleagues estimated that drug-induced liver injury accounts for between 1 in 600 and 1 in 3500 hospital admissions, amounting to 2 to 3 per cent of all hospital admissions due to adverse reactions and about 3 per cent of all jaundiced patients. In general practice, the spectrum of liver damage is slightly different: drugs associated with a high incidence of acute liver injury (greater than 100 per 100 000 users) were chlorpromazine and isoniazid; drugs with intermediate incidence of acute liver damage (more than 10 per 100 000 users) were amoxicillin/clavulanic acid and cimitedine.

Drug-induced liver damage may be caused by agents not considered as conventional drugs, such as herbal remedies, and by 'recreational drugs' such as ecstasy (methylenedioxymethampfetamine) and cocaine (see Box 1). The wide regional and individual variation in reporting rates and failure to report reactions after deliberate overdose combine to underestimate the frequency and severity of adverse drug reactions. Most adverse drug reactions are not fatal and withdrawal of the drug will usually lead to resolution of the liver damage. A study reporting the outcome of 110 cases of presumed drug-induced liver damage found a significant proportion of continuing liver damage, sometimes associated with continuing use of the hepatotoxic drug.

Box 1 The 'rules' of drug-induced liver disease

- Assume that all drugs may cause liver damage
- All patterns of liver damage have been associated with drug toxicity
- Some drugs may cause more than one pattern of liver damage
- Always take a full drug history
- Ask about other drugs—including herbal remedies, recreational drugs, vitamins
- The diagnosis of an adverse drug reaction is one of exclusion and temporal relationship
- Drug withdrawal is not always associated with improvement in liver function
- Reports of drug-associated liver damage do not necessarily mean causality
- Clinical challenge is rarely justified, may be fatal, and may be misleading

Almost all patterns of liver disease can be induced by drugs (Table 1) and some drugs may be associated with more than one type reaction. For example, oral contraceptives are associated not only with the development of cholestasis but also with adenoma, hepatocellular carcinoma, peliosis hepatis, and Budd–Chiari syndrome. It is important therefore to consider the possible contribution of drugs in a patient with any type of hepatic abnormality.

The diagnosis of drug-induced liver damage is largely circumstantial and by exclusion of other causes of liver disease. It must be remembered that the reporting of an associated drug reaction does not prove causality. The temporal association between the onset of damage and timing of drug exposure, and the response to drug withdrawal (Table 2) and the known patterns of drug reaction all help in establishing a drug as the cause of liver damage. Rarely, the presence of specific serological markers may help confirm the association between the drug and liver damage. For example, an antibody to tifluoroaceylated proteins is found in halothane-associated hepatitis, and antiliver–kidney microsomal antibodies occur in tienilic acid-associated hepatitis. Use of a clinical challenge is rarely justified, may be rnisleading, and may prove fatal.

Acute hepatitis

The severity of liver cell necrosis associated with drugs varies from a mild elevation of serum transaminases without symptoms to fulminant hepatic failure. Many drugs have been associated with acute liver failure (Table 3). Clinically, the picture may be indistinguishable from that of viral hepatitis. Occasionally, right upper quadrant pain may he so severe as to lead to the mistaken diagnosis of acute cholecystitis. The serological changes are those of acute hepatitis with initial elevations of serum aminotransferases. Prolongation of the prothrombin time and jaundice may occur in more severe cases. Histologically, the appearances vary from a mild focal necrosis to massive liver cell damage. In some cases, paracetamol for example, the damage is predominantly centrilobular, whereas in others, such as a-methyldopa, the whole lobule is affected. Steatosis, granulomas, and eosinophilia are variable features. The most common causes of drug-associated fulminant hepatic failure are paracetamol overdose and halothane hepatitis. Liver failure may also be associated with 'recreational' drugs.

The development of abnormalities of liver tests during prolonged drug use poses particular problems, as for example with antituberculous therapy. Derangement of serum aminotransferases occurs in approximately 10 per cent of patients and, if the noxious drug is continued, up to l0 per cent of these develop severe hepatic necrosis. Identification of those patients who will develop severe hepatic failure is difficult and the clinician has to decide whether the risks of continuing therapy outweigh the potential benefits. Drugs such as heparin are commonly associated with abnormal liver enzymes but very rarely with liver disease. The reason is not known but it may be due to loss of a few sensitive hepatocytes or to adaptation.

Conventionally, hepatic drug reactions are classified into predictable and idiosyncratic (Table 4). Predictable reactions are dose dependent; that is, the greater the amount of drug ingested, the greater the probability of developing liver damage. Because animal models can usually be developed, screening will detect many of these drug reactions and the drug withdrawn before reaching the market. Hence this type of drug reaction is relatively uncommon, except in overdose. The classic example is paracetamol toxicity, which is described in detail elsewhere.(Irene: cross reference?) None the less, between individuals there may exist great variability in the probability of developing predictable drug reactions.

With very few exceptions, drugs require metabolism before cytotoxicity develops. Variations in susceptibility may, therefore, be a consequence of genetic variations in drug metabolism. Well-recognized genetic polymorphisms include variations in the cytochrome P450 isoenzymes, drug oxidation, acetylation, and hydroxylation. Age, too, is associated with differences in susceptibility to toxicity. In general, younger children metabolize drugs differently from adults. Those taking enzyme inducers

such as alcohol, rifampicin, or phenobarbital are at a greater risk of increased metabolism of the drug and hence of forming toxic metabolites. Those with reduced glutathione stores, due to fasting, malnutrition, or associated disease for example, may be at greater risk of developing paracetamol toxicity because detoxification mechanisms are impaired. Other factors determining susceptibility include smoking and coexisting diseases, so that, for example, methotrexate toxicity is more common in those with diabetes. Finally, liver disease itself may alter susceptibilities to drug toxicity. However, because of potential alterations in absorption, volume of distribution, protein binding, detoxification, and excretion it is difficult to predict the effect of disease on susceptibility to drug toxicity. Many drugs induce hepatitis by apoptosis which may be accompanied by simultaneous or secondary necrosis.

In contrast, idiosyncratic drug reactions are dose independent and may be due either to metabolic idiosyncrasy or the involvement of immune mechanisms. Immune involvement rather than metabolic idiosyncrasy is suggested by a rapid onset after subsequent exposure and the appearance of markers such as peripheral and intrahepatic eosinophilia, granulomas, circulating immune complexes, autoantibodies, and other autoimmune phenomena, for example haemolytic anaemia. Two drugs in particular have been well studied with respect to immune-mediated hepatitis—halothane and tienilic acid. Halothane hepatitis occurs rarely and after multiple exposures. Risk factors include female sex, obesity, and repeated or subsequent exposure within 3 months. Immune involvement is suggested by an increased incidence of organ non-specific autoantibodies, peripheral eosinophilia, and circulating immune complexes, and the presence of antibodies reacting with a variety of halothane-associated liver cell macromolecules. In other examples. antibodies to drug-metabolizing enzymes are present in serum. Tienilic acid-associated hepatitis is associated with a circulating liver–kidney microsomal antibody that reacts with the cytochrome P450, CYP 2C9, associated with metabolism of the drug; antibodies to CYP 1A2 are associated with hydralazine and disulfiram hepatitis; alcohol and halothane hepatitis are associated with antibodies to CYP 2E1. Iproniazid hepatitis is associated with antibodies to MAO-B. Whether these antibodies are involved in the pathogenesis of the disease remains uncertain.

Cross-reaction between two drugs may occur. Thus, halothane sensitization may predispose to toxicity from other halogenated hydrocarbon anaesthetic agents such as isoflurane. This may be due to the two drugs inducing similar antigenic determinants, leading to cross-sensitization, or to a different mechanism of toxicity, as suggested for captopril and enalapril hepatotoxicity, where a similar metabolic pathway of toxicity has been postulated.

Acute cholestatic hepatitis

Acute cholestatic hepatitis is characterized by jaundice, pruritus, pale stools, and dark urine. There are usually few clinical findings, although the liver may be enlarged. Serologically, in the early stages there is elevation of the serum alkaline phosphatase and g-glutamyl transpeptidase; as the disease progresses, hepatocellular enzymes start to rise. Histologically, the liver shows dilated sinusoids with cholestasis often predominating in the centrilobular region. There may be an associated portal inflammation and liver cell necrosis. In the majority of cases there is rapid resolution following withdrawal of the drug, although with chlorpromazine and other phenothiazines the cholestasis may take up to 1 to 2 years to resolve. Many drugs cause a mixed hepatitis, where there are features both of cholestasis and liver cell damage (Table 5).

Bland cholestasis

Bland cholestasis is characterized by cholestasis in the absence of hepatitis and is due to specific interference with bile secretion. The two main groups of drugs associated with this condition are oral contraceptives and oestrogens and anabolic steroids. Cholestasis occurs in women taking oral contraceptives and in pregnancy. Prevalence varies, being low in southern Europe and North America (1 in 10 000) and high (1 in 4000) in parts of Chile and Scandinavia. Cholestasis associated with anabolic and contraceptive steroids is well recognized and may occur in association with virtually all the anabolic steroids with a C17 group; these drugs include norethandrolone, oxymethalone, danazol, stanozalol, and methyltestosterone. Other drugs are listed in Table 6. In some cases, drug induced cholestasis leads to a progressive, vanishing bile duct syndrome. Treatment is symptomatic: the itching may be intense and sometimes responds to cholestyramine or colestipol; other therapies include antihistamines, ursodeoxycholic acid, rifampicin, androgenic anabolic steroids, and opiate receptor antagonists.

Steatosis

Steatosis may be micro- or macrovesicular. Differentiation is important because the clinical features and outcomes are different. (Table 7).

Microvesicular steatosis

In microvesicular steatosis, the fat is distributed in small lipid droplets and the hepatocellular nucleus is not displaced. There may be an associated hepatitis. Extensive microvesicular steatosis, even in the absence of liver cell necrosis, may lead to a serious clinical syndrome with haemorrhage, syncope, hypotension, lethargy, coma, and hypoglycaemia. In some cases, renal failure and pancreatic inflammation may occur. Biochemically, serum aminotransferases and bilirubin are not greatly increased, although the prothrombin time may be greatly prolonged. Microvesicular steatosis is thought to be related to drug inhibition of mitochondrial oxidation of fatty acids.

Macrovesicular steatosis

In contrast, macrovesicular steatosis is usually far less serious. The hepatocyte contains a large droplet of fat, which displaces the nucleus to the periphery. Liver tests are usually only minimally deranged. Damage is thought to be related to impaired release of lipids from liver cells.

Granulomatous hepatitis

The spectrum of granulomatous hepatitis varies from an asymptomatic finding to a systemic illness characterized by generalized aches and pains, pruritus, jaundice, and hepatomegaly. Serologically. the main abnormality is an increase in serum alkaline phosphatase. Histologically the liver is infiltrated by granulomas—small, rounded foci of epithelioid cells with multinucleated giant cells. Drugs associated with granulomatous hepatitis are listed in Table 8.

Phospholipidosis

Phospholipidosis is characterized by the accumulation of phospholipids in liver cell lysosomes. The major drugs associated with this form of liver damage, perhexiline and amiodarone, are cationic, amphiphilic compounds that accumulate within the liver cell lysosomes where they form complexes with phospholipids. Accumulation can be detected by immunohistochemistry or electron microscopy. The compounds are stored in these complexes and may be released very slowly, even after ingestion has stopped. The extent to which these complexes accumulate in patients without toxicity remains uncertain.

Non-alcohol steatotic hepatitis

Long-term treatment with perhexiline and amiodarone may be associated with a syndrome that is clinically and histologically identical to alcoholic hepatitis. The disease develops insidiously and is characterized by hepatomegaly, jaundice, ascites, and encephalopathy. Other drugs implicated in this syndrome include diltiazem and nifedipine.

Fibrotic and vascular disease Table 9)

Perisinusoidal fibrosis

Perisinusoidal fibrosis is characterized by accumulation of collagen within the space of Disse. This may be asymptomatic or lead to hepatomegaly and portal hypertension. The most common causes of perisinusoidal fibrosis due to drugs are large doses of vitamin A given for prolonged periods, or methotrexate. Liver damage may be associated with alopecia. Characteristically the liver shows hyperplasia of the Ito cell as a consequence of vitamin A accumulation. Serum concentrations of vitamin A may he normal, even in the presence of marked liver damage. Patients with a high intake of alcohol are at greater risk of fibrosis.

Peliosis hepatis

Peliosis hepatis is a histological diagnosis and is characterized by blood-filled cavities, bordered by hepatocytes, which may be distributed throughout the liver.

Originally described in association with tuberculosis, it is now appreciated that peliosis hepatis may be drug induced and is often asymptomatic. The major drugs involved are the anabolic steroids, androgenic steroids, azathioprine, vinyl chloride, and pyrizolide derivatives.

Hepatic venous damage

Obstruction of the large hepatic veins results in the Budd–Chiari syndrome, characterized by the onset of abdominal pain and ascites, often with diarrhoea. In the acute form the patient may develop liver failure. Most cases of Budd–Chiari syndrome are due to myeloproliferative disorders, either clinically apparent or latent, but it may be associated with the use of oral contraceptives and some antineoplastic drugs such as dacarbazine, doxorubicin, and cyclophosphamide.

Obstruction of the small veins leads to hepatic veno-occlusive disease, characterized by non-thrombotic, concentric narrowing of the small centrilobular veins. Clinical presentation is often chronic but rarely may be acute. Veno-occlusive disease was initially described in association with ingestion of the pyrrolizidine alkaloids present in senecin plants but may be seen in patients treated with immunosuppressives, especially with organ transplantation.

Hepatic tumours

Hepatic tumours may be benign or malignant (Table 10). Hepatocellular adenoma has been associated with the use of oral contraceptives and anabolic steroids. These tumours have a potential for malignant transformation. Usually withdrawal of the steroid results in a reduction in the size of the tumour.

In contrast, hepatocellular carcinoma is also associated with the anabolic and androgenic steroids, oral contraceptives, and thorium dioxide. Although the risk of malignancy increases with the prolonged use of oral contraceptives, up to eightfold after 8 years, it must be emphasized that the overall risk of developing hepatocellular carcinoma with oral contraceptives is extremely small, and must be balanced against their beneficial, therapeutic effects. Angiosarcomas and cholangiosarcomas may also be related to drugs, although the association is less clear-cut.

Chronic disease

Cirrhosis and chronic hepatitis

Some drugs are associated with chronic liver disease. It may be that the initial lesions develop subclinically and that only prolonged use of the drug will result in cirrhosis. Rarely, a short-term exposure to a drug results in chronic liver disease. In some instances, there is a syndrome resembling autoimmune hepatitis: although corticosteroids may be given, withdrawal of the drug usually leads to resolution of the hepatic inflammation. Some of the drugs associated with the development of cirrhosis and chronic hepatitis are listed in Table 11.

Intrahepatic chronic cholestasis

In some instances of drug-related cholestasis, jaundice or cholestatic liver tests persist for 6 months or more (Table 12). In these cases it is important to exclude other causes of cholestatic disease, such as primary biliary cirrhosis or primary sclerosing cholangitis, which may have been brought to light by drug-induced disorders. However, some drugs may be associated with a chronic vanishing bile duct syndrome , which may be indistinguishable from primary biliary cirrhosis. A syndrome virtually identical to primary sclerosing cholangitis can be induced by infusion into the hepatic artery of floxuridine for the treatment of intrahepatic malignancy. Sclerosing cholangitis may develop several months after starting chemotherapy. The outcome is variable. A vanishing bile duct syndrome has been associated with carbamazepine, thiobendazole, flucloxacillin, haloperidol, ajmaline, cyproheptidine, and chlorpromazine. There has been a suggestion that primary biliary cirrhosis is associated with the use of benoxaprofen. The cause of the chronic cholestasis is uncertain; both immune mechanisms and the recirculation of toxic metabolites have been implicated.

14.21.8 The liver in systemic disease

J. Neuberger

The liver is affected in many systemic diseases. It most instances, disturbance of liver structure and/or function is a minor component of the illness, but in some cases abnormalities of liver function may be the presenting symptom. This chapter describes abnormalities of liver function that occur in systemic diseases.

Cardiovascular disease

Congestive cardiac fallure

Most patients with congestive cardiac failure have few symptoms related to hepatic congestion, although nausea, vomiting, and right upper quadrant pain may occasionally occur. Hepatomegaly is frequent in moderately severe heart failure. Rarely, cardiac cirrhosis develops and may be associated with splenomegaly and ascites. Jaundice occurs in about one-quarter of patients with persistent hepatic venous congestion.

The standard serum liver-related tests may show a rise in bilirubin, which rarely exceeds 50 µmol/litre. The level of unconjugated bilirubin usually exceeds that of conjugated bilirubin. The serum aminotransferases may also be elevated but rarely exceed twice the upper limit of normal. However, in severe, acute heart failure, concentrations in excess of 1000 IU/litre may be found. Serum alkaline phosphatase is rarely elevated. The prothrombin time is often prolonged by a few seconds. The liver is usually enlarged and a cut section shows the classical nutmeg appearance, with the pale periportal zones alternating with darker centrilobular zones. Microscopically there is congestion, with dilatation of the terminal hepatic venules and adjacent sinusoids, and areas of centrilobular necrosis due to hypoperfusion injury. With chronic heart failure centrilobular necrosis may be associated with fibrosis.

Constrictive pericarditis

Hepatic complications of constrictive pericarditis occur late in the course of the illness. Cardiovascular features of constrictive pericarditis are described elsewhere (see Section 15). The liver is enlarged and there may be associated splenomegaly. Jaundice and ascites may develop. Ultrasonography will show enlargement of the liver with dilated hepatic veins.

Tricuspid incompetence

Tricuspid incompetence most commonly occurs as a result of failure of right heart dilatation but may also result from congenital or acquired disease of the tricuspid valve. The liver is enlarged and pulsatile.

Tumours of the heart

Tumours of the right atrium, including myxoma and myosarcoma, may infiltrate he hepatic veins resulting in Budd–Chiari syndrome (a syndrome of hepatic venous thrombosis, characterized by abdominal pain, progressive ascites, and diarrhoea). Cardiac myxoma may be associated with abnormalities of liver function tests, including increased serum bilirubin and alkaline phosphatase and a reduction in serum albumin and total protein.

Drug reactions

As described elsewhere (see Section 15), many drugs used for the treatment of heart disease may be associated with adverse reactions that involve the liver. Thus, chronic active hepatitis may be associated with methyldopa, and granulomatous hepatitis with hydralazine. Quinidine, amiodarone, and perhexiline may cause phospholipidosis and a syndrome resembling alcoholic hepatitis.

Hypoxia

Hypoxic episodes, especially during surgery, may lead to an acute liver injury resulting from an ischaemic hepatitis. The clinical severity ranges from an asymptomatic elevation of serum aminotransferases to fulminant hepatic failure. The syndrome may be followed by a period of cholestasis. The aminotransferases may become greatly elevated (in excess of 10 000 IU/litre); histologically there is hepatocellular necrosis in the absence of inflammation, most marked in acinar zone 3 (the perivenular area). Similar changes occur in patients with heat stroke.

Syndromes affecting both the heart and the liver

Several conditions affect both the heart and the liver; these include Alagille syndrome (a multisystemic disorder, associated with a paucity of intrahepatic bile ducts, leading to a biliary cirrhosis with pulmonary stenosis and other cardiac abnormalities), biliary atresia (where up to 10 per cent of patients may have congenital heart disease), and cardiomyopathy which may be associated with a variety of inherited and acquired conditions affecting both organs, these include alcohol toxicity, haemochromatosis, tyrosinaemia, and mitochondrial cytopathy. Drugs, such as the immunosuppressive agent tacrolimus, may also cause cardiomyopathy.

Pulmonary disease

Cirrhosis

Lung disease may complicate cirrhosis; the hepatopulmonary syndrome, discussed elsewhere, may resolve after treatment of the underlying liver disease or after liver transplantation. In contrast, abnormalities of liver function in patients with pulmonary disease arise either as a consequence of that disease or of diseases affecting both lung and liver. In most patients with chronic lung disease, abnormalities of liver function are mild and may be manifest only by abnormalities of bromosulphophthalein clearance. In more advanced disease, associated with hypoxia, there may be more widespread disturbances of liver function, with elevation of serum aminotransferase, bilirubin, alkaline phosphatase, and g-glutamyltransferase. However, abnormality of liver function in patients with pulmonary disease is associated mainly with pulmonary hypertension rather than lung disease or hypoxia *per se.*

Pneumonia

Some patients with pneumococcal pneumonia may have jaundice. It usually occurs on the fourth or fifth day of the illness and is seen particularly in patients with consolidation of the right lower lobe. The serum bilirubin rarely exceeds 100 µmol/litre, and abnormalities of other liver tests are unusual. The cause of the jaundice is not known: factors that have been implicated are glucose-6-phosphatase deficiency, associated acute haemolysis, hypoxia, fever, and direct toxicity. The increased amounts of inflammatory cytokines seen in such patients may also contribute to the jaundice.

Abnormal liver function tests are also seen in patients with Legionnaire's disease and are characterized by elevation of aspartate aminotransferase and alkaline phosphatase. Jaundice is less common and tends to occur only in patients who are severely ill.

Diseases that involve lung and liver

a_1-Antitrypsin deficiency (see Chapter 11.13)

a_1-Antitrypsin deficiency was initially described in relation to pulmonary emphysema but it is now known that the liver, kidney, and pancreas can also be diseased. In children, a_1-antitrypsin deficiency often presents as neonatal hepatitis: in one-third it resolves, one-third develop fibrosis, and the remainder develop progressive cirrhosis, often requiring transplantation. In adults the disease often presents with cirrhosis or its complications. The liver shows the characteristic histological features of periodic acid-Schiff-positive, diastase-resistant globules in the liver. These globules are not diagnostic of the disease. Patients usually express the Pi zz phenotypic a_1-antitrypsin variant.

The course is unpredictable, but many patients develop progressive disease that requires liver transplantation. There is no other proven effective treatment. The onset of cholestasis often heralds liver failure. In cases where lung and liver disease coexist, the only effective therapy is transplantation of the heart, lung, and liver.

Cystic fibrosis

The increasing success in treating respiratory complications in children with cystic fibrosis has resulted in a greater number surviving to develop liver disease. Abnormal liver tests are found in up to half the children, and in adults up to a quarter of patients with cystic fibrosis develop a biliary cirrhosis. These patients present with cholestasis and jaundice. The pathogenesis and aetiology of this cholestasis are poorly understood. In most cases, liver disease is characterized by the development of a focal biliary cirrhosis that increases with time. Early involvement of the liver is characterized by the presence of eosinophilic granular material in the portal ducts. There is proliferation of bile ducts and portal fibrosis. This progresses to a focal biliary cirrhosis, which then develops into a multilobular cirrhosis with the onset of symptoms of cholestasis and jaundice. However, many patients have evidence of biliary obstruction shown by imaging the biliary tree by magnetic resonance cholepancreatography or endoscopic retrograde cholepancreatography. There is some evidence that infusion of *N*-acetyl cysteine into the biliary tree may relieve the obstruction in the extrahepatic biliary tree. The onset of jaundice and ascites is associated with a poor prognosis. Standard liver tests may underestimate the severity of the liver disease. Treatment with ursodeoxycholic acid will improve the liver tests and may improve liver function.

Other causes of cholestasis in patients with cystic fibrosis include gallstones and pancreatic insufficiency associated with increased loss of faecal bile salts, a consequent decrease in the size of the bile salt pool, and the development of lithogenic bile.

Treatment is uncertain. Open studies have suggested that ursodeoxycholic acid, 10 mg/kg/day, may result in biochemical improvement, weight gain, and improved nutrition. However, whether this agent has any long-term effect remains to be established.

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease of unknown aetiology. The liver is commonly affected with evidence of infiltration in up to 70 per cent of cases. However, symptoms and signs of hepatic disease are uncommon. Hepatomegaly and splenomegaly occur in about one-quarter of patients. While jaundice is rare, elevation of the serum alkaline phosphatase is frequently observed. Complications of granulomatous infiltration of the liver are unusual. Liver failure may supervene, but portal hypertension occurs more frequently and causes bleeding varices or ascites.

As with sarcoid elsewhere, the diagnosis is usually made by the finding of non-caseating granulomas around the portal tracts. These granulomas are usually large and consist of multinuclear giant cells with T lymphocytes. Most patients respond to corticosteroids, although the portal hypertension may persist, possibly due to established presinusoidal fibrosis.

Overlap syndromes with primary biliary cirrhosis are well recognized: in patients with typical sarcoid infiltration in lungs and liver in the presence of bile duct damage consistent with primary biliary cirrhosis (PBC) and with positive antimitochondrial antibody tests, treatment should be directed against the sarcoid because, as yet, there is no -treatment that improves survival in primary biliary cirrhosis. Other causes of granulomatous hepatitis are discussed elsewhere.

Drugs

As indicated elsewhere, many drugs used for the treatment of lung diseases may be associated with abnormal liver function. Inhaled disodium chromoglycate reportedly causes a syndrome that transiently resembles primary biliary cirrhosis. However, inhaled medications otherwise rarely cause significant abnormalities of liver-related tests.

Disorders of the gastrointestinal tract

Inflammatory bowel disease

The range of liver abnormality associated with inflammatory bowel disease includes fatty change, pericholangitis, sclerosing cholangitis, chronic active hepatitis, cirrhosis, and amyloidosis. The reported incidence of serum liver test abnormalities in inflammatory bowel disease varies from 3 to 10 per cent. In general, abnormalities of liver tests correlate poorly with the severity of liver disease determined histologically. Ulcerative colitis is more commonly associated with abnormal serum liver-related tests than is Crohn's disease.

There is no clear relation between the onset of symptoms of inflammatory bowel disease and liver abnormalities. In general, symptoms of ulcerative colitis precede changes in liver function tests by about 8 years, but liver disease may precede by many years the onset of clinically apparent inflammatory bowel disease. Conversely, liver disease may become manifest several years after colectomy. Furthermore, there is little correlation between the severity of inflammatory bowel disease and the incidence or severity of liver disease. Indeed, in many patients with sclerosing cholangitis the colitis tends to be a pancolitis but is often quiescent (Table 1). Fatty change is relatively common on histological examination of the liver in patients with inflammatory bowel disease and is probably multifactorial in origin, relating to the degree of ill health, poor nutrition, and use of corticosteroids. As a patient's condition improves, the fatty infiltration resolves. Primary sclerosing cholangitis is associated with inflammatory bowel disease in about 10 per cent of cases, whereas nearly 90 per cent patients with sclerosing cholangitis have inflammatory bowel disease. Primary sclerosing cholangitis is a premalignant condition, associated with bile duct carcinoma in 5 to 20 per cent of cases. In patients with primary sclerosing cholangitis and ulcerative colitis, there is an increased risk of colon cancer.

Cirrhosis occurs in up to 10 per cent of patients who die with ulcerative colitis. The cause of the cirrhosis is not known, but in some cases it may be caused by chronic hepatitis C infection from drug transfusions or by drug toxicity, rather than primary sclerosing cholangitis.

Although chronic active hepatitis in association with inflammatory bowel disease is rare, its recognition is important because it resembles autoimmune chronic active hepatitis and may respond well to corticosteroid treatment. Other hepatic complications of inflammatory bowel disease include granulomatous hepatitis, amyloid infiltration of the liver, bile duct carcinoma, gallbladder cancer, and gallstones.

Coeliac disease

In patients with coeliac disease there may be minor abnormalities of liver function tests, characterized by elevation of serum aminotransferases; they usually resolve with institution of a gluten-free diet. Coeliac disease may also be associated with autoimmune diseases affecting the liver, including primary biliary cirrhosis, cryptogenic cirrhosis, sclerosing cholangitis, and autoimmune hepatitis. Up to 4 per cent of patients with primary biliary cirrhosis may have coeliac disease and up to 3 per cent of patients with coeliac disease may have PBC.

Gastrointestinal bypass surgery

Jejunoileal bypass surgery may be associated with liver disease; the changes in the liver range from simple fatty infiltration to cirrhosis. In a few cases there may be features identical to those of alcoholic hepatitis. In those in whom liver function tests are deranged, progressive injury is likely; although treatment with metronidazole has been advocated, restoration of normal anatomy appears to be the only effective measure.

Total parenteral nutrition

The association of hepatobiliary disorders with total parenteral nutrition has been recognized over the last two decades. Although the pathogenesis remains obscure, most studies suggest that the incidence is now less than 5 per cent. Total parenteral nutrition-associated hepatobiliary disease varies from a mild, asymptomatic disease with acalculous cholecystitis, biliary sludge, or hepatomegaly to jaundice, cirrhosis, and liver failure. Biochemically, the severity of abnormalities will reflect the severity of the disease but elevations of serum liver enzymes such as aspartate and alanine transferases, lactate dehydrogenase, and alkaline phosphatase, and serum bilirubin, are common. The histological features vary from a mild fatty infiltrate or cholestasis to a more severe picture resembling alcoholic fatty liver. Cirrhosis will develop in chronic cases. The mechanism is uncertain but hypoxic enterocytes, nutritional depletion, sepsis, toxicity of certain unidentified amino acids, and even carnitine deficiency have been implicated (Table 2). Once a patient develops abnormal liver function, and provided that other causes have been excluded, there is little alternative other than to reduce or stop parenteral nutrition and find other ways of providing adequate nutrition.

Obesity

Obesity is occasionally associated with abnormalities of serum liver tests, especially of the serum aminotransferases. Cutaneous manifestations of chronic liver disease may develop. The liver ultrasound will show a fatty liver and liver histology a macrovesicular fatty infiltration. Rarely, a non-alcoholic steatohepatitis syndrome will develop.

The liver in endocrine disease

Autoimmune hepatitis may be associated with autoimmune endocrine disorders, such as thyroid disease, vitiligo, and diabetes mellitus.

In haemochromatosis, where both liver and pancreas are affected, diabetes itself is associated with liver abnormalities. The liver may be enlarged due to excess stores of fat and glycogen. In severe cases there may be a non-alcoholic steatohepatitis syndrome which can lead to hepatic fibrosis and cirrhosis. Liver abnormalities are seen much more commonly in non-insulin-dependent diabetes (20–75 per cent of patients) compared with well-controlled type I diabetes (< 1 per cent of patients).

Hypothyroidism may be associated with a mild hyperbilirubinaemia and elevated serum transaminases (which may be of muscular origin). Ascites occurs very rarely. Hyperthyroidism is also associated with mild abnormalities of liver function which resolve on treatment of the thyroid disorder; severe uncontrolled thyrotoxicosis is associated with cardiac failure, atrial fibrillation, and jaundice (Habershon's jaundice) in which hypoperfusion and the toxic effects of thyroid hormone lead to hepatocellular dysfunction —this syndrome carries a poor prognosis and requires urgent treatment for thyroid stores.

The liver in haematological diseases

In general, diseases of the blood do not affect the liver. However, diseases associated with abnormal blood clotting, such as protein C or S deficiency and paroxysmal nocturnal haemoglobulinuria, may lead to Budd–Chiari syndrome (hepatic vein thrombosis).

Haemolysis

Jaundice may accompany haemolysis and is principally associated with an increase in unconjugated bilirubin. In patients with underlying liver disease both conjugated and unconjugated bilirubin are elevated out of proportion to the degree of haemolysis. Patients with chronic haemolytic anaemia are at risk of developing haemosiderosis. Iron is deposited initially in the Kupffer cells, but spread to the parenchyma will subsequently occur. The identification of the gene for hereditary haemochromatosis has assisted in the distinction between primary and secondary iron overload. The haemolytic anaemias are associated with an increased risk of pigment gallstones, which may lead to liver and biliary tract disease.

Sickle cell disease

Most of the abnormalities of liver function in sickle cell disease are due to haemolysis or infections transmitted by blood transfusion. Kupffer cell hyperplasia, haemosiderosis, fibrosis, or cirrhosis may be due to iron overload following multiple transfusions. Sometimes, patients present with severe pain in the right upper quadrant and rapid enlargement of the liver is part of the hepatic sequestration syndrome. Liver histology may show clumps of sickled red cells in the sunusoids, erythrophagocytosis, and sinusoidal dilatation. There is an increased risk of gallstones.

Thalassaemia

As with sickle cell disease, there is an increase in haemolysis and the complications of blood transfusions. Gallstones are common.

Multiple transfusions

Patients who receive regular blood transfusions or blood products, those with thalassaemia or haemophilia for example, are at risk of developing viral hepatitis B or C. It is now clear that such patients are at an increased risk of hepatitis C which may lead to cirrhosis and liver cell cancer. With screening, the incidence of hepatitus C virus is likely to fall. Blood transfusion is also associated with secondary haemochromatosis since each unit of blood provides the equivalent of 225 mg of iron which ultimately causes iron storage disease in the liver and in other organs.

Lymphomatous disease

In patients with Hodgkin's disease, liver function tests are of limited value in predicting liver involvement, although jaundice is a recognized feature and may be due to a number of different causes. For example, haemolysis may complicate Hodgkin's disease, and occasionally there is a bland cholestasis in the absence of infiltration, which resolves when the disease is treated. The clinical manifestations of liver involvement in Hodgkin's disease relate to the degree of infiltration. In rare cases, patients with Hodgkin's disease develop fulminant hepatic failure: the clue to infiltration is a large liver, as most cases of viral or drug-related fulminant hepatic failure are associated with small livers. Liver biopsy may be diagnostic. Primary lymphoma of the liver has been described, but is rare. The liver may be involved in both non-Hodgkin's lymphoma and leukaemia and the diagnosis is usually made by biopsy. Some patients with non-Hodgkin's lymphoma have chronic hepatitis preceding diagnosis or treatment. A causal effect cannot be excluded. Hodgkin's disease and non-Hodgkin's lymphoma may be associated with obstructive jaundice due to invasion of the bile duct by invasive nodal disease in the hilum.

The liver and infections

Abnormal liver function may occur during systemic infections but it is rare for patients with sepsis to present primarily with liver symptoms (Table 3). However, jaundice, abnormal liver function tests, or even, occasionally, fulminant hepatic failure may be the principal presenting feature.

Bacterial infections

Pneumococcal infections are discussed above. Meningococcal infections are occasionally associated with features suggestive of viral hepatitis. Jaundice may be associated with the toxic shock syndrome associated with *Staphyloccus aureus*. Gonococcal infection is a well-recognized cause of liver disease. The classical Fitzhugh–Curtis syndrome, perihepatitis, is characterized by sudden onset of severe pain in the right upper quadrant, occurring classically in a woman with a previous history of pelvic inflammatory disease. On examination there may be little to find, although tender hepatomegaly and a hepatic rub may be present. Where laparotomy has been performed in the mistaken diagnosis of cholecystitis, perihepatitis with adhesions and pus around the liver may give the clue to the diagnosis. In chronic infection, adhesions develop between the surface of the liver and the anterior abdominal wall. The condition usually resolves without treatment, although the use of penicillin promotes more rapid resolution. Abnormalities of liver function may occur in gonococcal bacteraemia, peritonitis, and endocarditis. Perihepatitis is also reported in association with syphilis and chlamydial infections. Chlamydial infection is today the most frequent cause of chronic perihepatic adhesions.

In childhood, some infections with *Escherichia coli* may be associated with hepatitis and jaundice. Jaundice is rare in older patients, although pregnant women seem more susceptible. Abnormalities of liver function occur in systemic streptococcal and staphylococcal infection and in enteric fevers, paratyphoid, and typhoid. Hepatomegaly is common in typhoid infection and jaundice occurs in about 10 per cent of patients, although up to a third have abnormal liver function tests with increased levels of aminotransferase and normal values for alkaline phosphatase. The hepatomegaly rapidly responds with treatment. In gas gangrene, deep jaundice may occur may occur in up to a fifth of patients. The liver may be infected and a plain radiograph of the abdomen may show gas within the liver. Liver damage and jaundice are associated with *Listeria monocytogenes* and *Legionella pneumophila* infections

Brucellosis may also be associated with jaundice and abnormal liver function tests. All three species of *Brucella* have been associated with abnormal liver function. Characteristically, the liver biopsy shows a marked inflammatory infiltrate and fibrosis with multiple large or small granulomas scattered throughout the parenchyma. Some reports have suggested that granulomatous hepatitis due to *Brucella* may cause cirrhosis, but this is questionable. The common causes of liver granulomas, including infections, are listed in Table 4. The liver damage asociated with leptospirosis (Weil's disease) is described elsewhere (Section 7).

Actinomyces spp. are commensal organisms that rarely cause disease. Actinomycotic infection of the liver may occur, the patient presenting with abdominal pain, anorexia, and fever. In one case report the liver was found to have small, multilocular abscesses.

Tuberculosis may present with granulomatous hepatitis, biliary tuberculosis, a solitary tuberculoma, or tuberculosis of the biliary tract. The liver is involved in up to 85 per cent of patients with tuberculosis, especially in those with miliary disease. The presence of multiple granulomas in the liver should raise the possibility of tuberculosis, although the differential diagnosis of granulomatous hepatitis is long (see Table 4). With the increasing incidence of atypical mycobacterial infections, lesions similar to tuberculosis can be found. In those infected with *Mycobacterium avium intracellulare* there are numerous acid-fast bacilli, often in the absence of granulomas.

Leptospirosis

Leptospiral infections are described in Section 7. Acute leptospirosis is frequently accompanied by jaundice, although frank liver failure is uncommon. The jaundice is mainly cholestatic, although there may be liver cell injury.

Rickettsial infection

Liver injury in Q fever (*Coxiella burnetti*) is recognized, although symptoms of liver disease are uncommon. Hepatomegaly is frequent and liver function tests may show an elevation of serum alkaline phosphatase and, rarely, a picture resembling viral hepatitis. Histologically, the liver has areas of focal necrosis, Kupffer cell proliferation, lipogranuloma formation, and mononuclear cell infiltration in the portal tracts. The characteristic histological feature of Q fever is eosinophiliic fibrinoid necrosis but this is not specific. Treatment is with chloramphenicol or tetracycline. Liver disease is much more frequent in Rocky Mountain spotted fever (*Rickettsia rickettsia*).

Fungal infections

The liver may be involved in fungal infection, often in patients with immunodeficiency such as with AIDS, following chemotherapy, and after organ transplantation. Histoplasmosis, cryptococcosis, aspergillosis, blastomycosis, and candidiasis are all causes of liver damage. The liver is usually involved in disseminated fungal infections. Cryptococcal infection has also been associated with a primary biliary cirrhosis-like condition.

Protozoal infections

Protozoal infections are described in detail in Section 7.13 many of them involve the liver. In toxoplasmosis, while most patients are asymptomatic and liver involvement is mild, hepatitis may occur and *Toxoplasma gondii* may be found in liver biopsy samples. In malaria, due to either *Plasmodium falcipartun* or *P. vivax*,

abnormalities of liver tests may be observed. Hepatomegaly is common and is often associated with jaundice. The jaundice is in part due to haemolysis but liver tests may provide a picture suggestive of viral hepatitis. Histological examination may show characteristic features of Kupffer cell proliferation with black malarial pigment and mononuclear cell infiltrate. Frank hepatic failure is extremely rare.

Schistosomiasis is one of the most common causes of liver disease worldwide. A heavy infection of fertile schistosomes in the portal system results in deposition of eggs that induce an immune response, leading to portal fibrosis and granuloma formation, portal hypertension with consequent splenomegaly, ascites, and variceal haemorrbage. Hepatocyte function is well preserved. There is a complex interaction between schistosomal eggs and the immune system; the degree of fibrosis is directly related to the number of eggs and the duration of infection. The diagnosis is made on stool examination or finding schistosomes in the liver. Serological tests are unreliable at present. Treatment is described in Chapter 7.16.1. Successful treatment is associated with a significant but variable improvement in the degree of portal hypertension. Treatment of the portal hypertension is dependent on the medical facilities available. As parenchymal function is well preserved, these patients usually tolerate a portosystemic shunt.

Coinfection of patients with schistosomiasis and hepatitis B or C virus is associated with an aggressive progression.

Viral infections

Hepatitis may be a significant feature of viral infection other than with the classical hepatitis viruses. Thus, infection with cytomegalovirus, Epstein–Barr virus, herpesviruses, measles, rubella, coxsackievirus, adenoviruses, and echoviruses may all cause a significant hepatitis. Such viral infections (especially cytomegalovirus) are more common in immunosuppressed patients. The diagnosis is made serologically, but in some cases, such as with cytomegalovirus, herpes, and adenoviral infections, the liver histology may show characteristic features.

Pyogenic liver abscess

Pyogenic liver abscesses may occur as part of a systemic illness, or as a consequence of portal phlebitis. Abscesses are often associated with bowel sepsis, biliary tract disease, direct trauma, septicaemia, and in association with carcinoma of the colon or bacterial endocarditis. They most commonly arise out of portal phlebitis, with the primary focus being the appendix, colon, diverticular disease, or in the pelvis (Table 5). Although abscesses may occur in patients with inflammatory bowel disease, this is relatively rare. The patient presents with abdominal pain, pyrexia, nausea, and weight loss. However, fever is less common in children. Hepatomegaly may be present and the liver is sometimes tender. The serum albumin is often reduced and alkaline phosphatase elevated. There is usually marked neutrophil leucocytosis, but this is not invariable. The diagnosis is made on imaging of the liver. A chest radiograph may show elevation of the right hemidiaphragm with an associated pleural effusion or even lung consolidation. Ultrasound, computed tomography, and magnetic resonance imaging may define a hepatic abscess. With the increasing sensitivity of these techniques, radio-isotope scanning is now less important.

Treatment of a solitary abscess is by percutaneous drainage in the first instance. Under the guidance of ultrasound or computed tomography, a percutaneous drain should be established for single abscesses, and even in some cases of multiple abscesses. The abscesses should be drained to dryness, and antibiotics should be given according to the sensitivities of the organisms isolated. Pathogens are usually anaerobic or aerobic gut coliforms, especially *Streptococcus milleri*, but in children *Staphylococcus aureus* is common. The success rate of treatment with drainage and systemic antibiotics is 80 to 90 per cent. Fatality is high in children and the elderly, in those with coexisting disease such as diabetes mellitus, and in those with delayed diagnosis. Once the abscess has been drained, the primary source of infection must be sought and appropriate management instituted. Surgery may be required for patients with multiple abscesses or for those with abscesses that do not respond to simple drainage and antibiotic therapy. Liver abscess due to hydatid and amoebal infection is discussed elsewhere.

AIDS and liver disease

Liver disease in patients with human immunodeficiency virus (HIV) infection may be due to pre-existing hepatitis virus, opportunistic infections, or neoplasms. In some cases the abnormality of liver function may be due to virus itself. Such patients have non-tender hepatomegaly with anorexia, weight loss, and low-grade fever. Liver function tests show slight derangement with cholestasis. The liver biopsy shows non-specific features including Kupffer-cell hyperplasia, fat infiltration, non-caseating granulomas, and portal-tract inflammation; Mallory hyaline bodies may occasionally be present.

Other causes of hepatobiliary abnormality in patients with HIV include primary hepatic infection due to viral hepatitis.

Other causes of liver damage in AIDS

Many patients with AIDS are also at risk from hepatitis B, C, and D. As discussed elsewhere, these patients respond less well to interferon than do those who are HIV negative. Other infections that are more common in HIV-positive patients include cytomegalovirus, herpesvirus, cryptosporidiosis, and mycobacterial infections including tuberculosis and *Mycobacterium avium intracellurare*. Drug-induced liver damage must always be considered in HIV patients with abnormal liver tests, and it has been suggested that such patients are more susceptible to drug hepatotoxicity. Thus, many of the anticonvulsants, analgesics, and antimicrobials are associated with hepatocellular damage, and antibiotics may also be associated with cholestasis. Other abnormalities that may be of less significance clinically include peliosis hepatis and fatty infiltration.

The biliary tree may also be affected in HIV infection inducing a syndrome superficially resembling primary sclerosing cholangitis. This is characterized by a rapid elevation of the serum alkaline phosphatase, which may be associated with pain in the right upper quadrant and, later, jaundice. Ultrasonography may be unhelpful, although dilated and thickened walls of the bile duct may be seen. Otherwise, endoscopic retrograde cholepancreatography will show the characteristic changes of sclerosing cholangitis with bleeding, dilatation, and stricture. Both cryptosporidial and cytomegaloviral infections have been associated with this form of sclerosing cholangitis.

The liver may be affected by HIV in other ways. There is an association between AIDS and lymphomas, be they Burkitt's, large cell, or immunoblastic lymphomas. The liver and/or spleen may be the site of these tumours and hepatic infiltration may be present in up to a third of those with gastrointestinal lymphomas. Tumours may be microscopic or macroscopic. The hepatic masses are often asymptomatic but if large they may cause pain in the right upper quadrant, fever, jaundice, and abnormalities of serum liver tests, especially of the serum alkaline phosphatase. Kaposi's sarcoma may affect the liver and biliary tree but is often asymptomatic.

Liver and rheumatological disease

Liver abnormalities occur in patients with rheumatological disorders, although they rarely prove to be clinically significant. Hepatic disease may either be a consequence of treatment or occur in association with other autoimmune diseases. For example, those diseases assumed to have an autoimmune basis, such as autoimmune hepatitis or primary biliary cirrhosis, may be associated with extrahepatic rheumatological diseases such as the sicca syndrome.

Rheumatoid arthritis

Abnormalities of liver structure and function are uncommon in patients with rheumatoid arthritis, although minor abnormalities of liver function tests occur in 20 to 50 per cent of cases. Nodular regenerative hyperplasia may cause complications of portal hypertension.

Felty's syndrome

Felty's syndrome is characterized by the triad of splenomegaly, hypersplenism, and seropositive rheumatoid arthritis. Liver function tests tend to be more commonly deranged than in uncomplicated rheumatoid arthritis. Anti-inflammatory therapy may contribute to the abnormal liver tests. Histological examination of the liver shows lymphocytic infiltration and, rarely, an established cirrhosis. Nodular regenerative hyperplasia occurs in patients with Felty's syndrome, as with rheumatoid arthritis. Although portal hypertension and variceal haemorrhage may occur, jaundice is unusual.

Connective tissue disease

Systemic lupus erythematosus

Usually only minor abnormalities of liver function occur in patients with systemic lupus erythematosus, although spontaneous rupture of the liver has been described. The pattern of liver disease in patients with systemic lupus erythematosus varies from minimal change to chronic persistent hepatitis, chronic active hepatitis, and cirrhosis. In others, a granulomatous hepatitis has been identified.

Polyarteritis nodosa

In contrast to rheumatoid arthritis, liver injury in polyarteritis nodosa is relatively uncommon, although a hepatic arteritis may occur, leading to aneurysm. Rupture of an aneurysm is rare and is characterized by fever, pain in the right upper quadrant, and jaundice. In most cases, abnormalities of liver function are due to an associated hepatitis C virus infection.

Polymyalgia rheumatica

Abnormalities of liver function are well recognized in patients with polymyalgia rheumatica. These abnormalities (of elevation of serum alkaline phosphatase and aminotransferase activity) usually resolve with effective treatment. Histologically, the liver shows mild portal inflammation with occasional liver cell necrosis. Granulomas and steatosis may also be seen.

Sjögren's syndrome

Symptoms of sicca syndrome are common in patients with liver disease, particularly primary biliary cirrhosis, and abnormalities of salivary gland function have been described in all patients in some series. Sicca syndrome is also found in patients with cryptogenic cirrhosis and autoimmune chronic active hepatitis. In patients with Sjögren's syndrome there is often hepatomegaly and minor derangement of liver function tests, particularly serum alkaline phosphatase, in 25 per cent of cases. The liver may show non-specific inflammatory infiltration.

Amyloid (see Chapter 11.12.4)

The liver is infiltrated in both primary and secondary amyloidosis; liver disease is found in over 80 per cent of patients with either form. In general, however, liver amyloidosis has few significant clinical consequences, although jaundice, hepatitis, portal hypertension, and spontaneous hepatic rupture occur. Clinically, the liver is enlarged; the serum alkaline phosphatase is usually greatly elevated and jaundice is uncommon. It is believed that liver biopsy may be particularly hazardous in patients with amyloid because there may be an increased risk of bleeding after biopsy. There is no treatment other than that which addresses the underlying cause.

Cryoglobulinaemia

The reported incidence of liver disease in essential, mixed cryoglobulinaemia varies greatly. In 20 to 50 per cent of patients there is an association with hepatitis C viral infection. Up to half of patients have evidence of infection with hepatitis B virus, and up to 10 per cent have chronic active hepatitis or cirrhosis with jaundice.

The liver in malignancy

Although the liver may become infiltrated by metastatic cancer, abnormalities of liver tests can be seen in the absence of infiltration. This may be due to a systemic effect of tumour-derived cytokines, to the hepatotoxic effects of drugs, or to the effects of irradiation.

The liver in the sick patient

Abnormalities of serum liver tests are frequent in patients who are critically sick, and are associated with a poor prognosis. There are many causes of abnormal liver tests in this situation (Table 6). 'Intensive therapy unit' jaundice occurs in up to 10 per cent of patients so treated, usually in the context of sepsis or abdominal trauma. Hepatomegaly is often present, but the cutaneous features of chronic liver disease are absent. Encephalopathy is uncommon. The liver tests show a rise in serum bilirubin with a smaller and less consistent rise in serum alkaline phosphatase and aminotransferase levels. Blood coagulation tests are mildly deranged and blood sugar levels tend to be high rather than low. The cause of intensive therapy unit jaundice is unclear but factors such as ischaemia, hypoxia, and hepatocyte necrosis may occur.

Liver disease in pregnancy

Liver disease in pregnancy is discussed in Chapter 13.9.

14.22 Miscellaneous disorders of the gastrointestinal tract and liver

D. P. Jewell

This chapter describes conditions that do not fall naturally into any of the other major sections which deal with disorders of the gastrointestinal tract and liver.

Cystic disorders of the bowel

Diverse disorders of the small and large bowel are associated with cyst formation. All are rare but present major diagnostic and therapeutic problems.

Colitis cystica

There are several varieties of benign cystic lesions involving the colonic mucosa. Colitis cystica superficialis occurs in patients with pellagra and has also been reported in adult coeliac disease. The presenting feature is usually diarrhoea and the condition is characterized by the presence of small mucus-filled cysts that lie superficially to the muscular layer of the colon. The disease seems to respond to therapy for pellagra. In colitis cystica profunda the cysts occur below the muscular layer of the colon. The pathogenesis and aetiology of this condition are unknown. It is usually characterized by cramping lower abdominal pain, tenesmus, and diarrhoea associated with blood and mucus in the stools. The diagnosis is made by sigmoidoscopy, rectal biopsy, and barium enema examinations. Treatment consists of local surgical excision.

Pneumatosis cystoides intestinalis

This disorder is characterized by the presence of multiple, gas-filled cysts in the wall of the colon and, less frequently, the small intestine. The stomach and mesentery may also rarely be affected. The condition is usually seen in middle-aged patients and may be associated with obstructive airways disease or pyloric obstruction. It has also been found in association with a variety of other conditions, including mesenteric vascular disease, small-bowel tumours, and Whipple's disease, and after small-bowel surgery. It can also occur after sigmoidoscopy or colonoscopy.

The pathogenesis of the condition is unknown. The composition of the gas within the cysts is similar to atmospheric air with the addition of small quantities of methane and a higher concentration of hydrogen. Thus, the gas may diffuse into the lamina propria from the intestinal lumen. Suggestions that the gas is formed by excessive bacterial fermentation of carbohydrate or that, in patients with obstructive airways disease, alveolar air tracks down through the muscle planes of the posterior abdominal wall and out into the mesentery lack firm evidence.

Pneumatosis cystoides can be an incidental finding during radiological examination of the abdomen. It can present with symptoms that include lower abdominal pain, recurrent diarrhoea, rectal bleeding, and tenesmus. Obstructive symptoms can occur. The cysts can frequently be detected at sigmoidoscopy and rectal biopsy specimens may show the characteristic giant cells that frequently line the cyst walls. Double-contrast radiology is the best method to establish the diagnosis but computed tomographic scans may detect serosal or mesenteric cysts.

If the disease is detected incidentally and the patient has no abdominal symptoms, no treatment is necessary. However, treatment is indicated for symptomatic patients, especially those with severe obstructive symptoms. The most effective therapy is oxygen in high concentration. Most patients will benefit from a concentration of 60 to 70 per cent given by a face mask or a nasal catheter. Hyperbaric oxygen may rarely be indicated for resistant pneumatosis. The aim of oxygen therapy is to wash out the nitrogen from the cysts and replace it with oxygen, which can be resorbed, with collapse of the cysts. Other treatments that have been tried are antibiotics (metronidazole), a low-carbohydrate diet, and an elemental diet. Surgical resection may be necessary for patients who do not respond and for those with severe obstructive symptoms, especially if there is a suspicion of volvulus.

Lymphocytic and collagenous colitis

These two disorders are principally seen in middle-aged women presenting with a watery diarrhoea. Although claims have been made that lymphocytic colitis progresses to a collagenous colitis, this has not been universal experience; here the disorders will be described separately.

Collagenous colitis was first recognized by Lindstrom in 1976. Patients usually present in the fifth and sixth decade; mostly women, but the disorder can occur in young adults as well as in the elderly. A watery diarrhoea accompanied by abdominal cramps, wind, distension, and nausea are the usual symptoms. The diarrhoea can be severe and is often secretory in nature. There may be some mucus but bleeding is not a feature. Despite severe symptoms, these patients are usually well, with a good appetite, and do not lose weight. There are no abnormal physical signs on examination and, on sigmoidoscopy, the rectal mucosa can be normal but may be hyperaemic with some oedema and granularity. These endoscopic changes occur throughout the colon but are usually patchy and never severe. The diagnosis is made on the appearance of colonic biopsies. There is a thickened band of subepithelial collagen exceeding 15 μm compared with the normal thickness of 2 to 6 μm. The collagen band is of maximal thickness in the right colon and tends to become thinner more distally—there may rectal sparing, which may lead to misdiagnosis if the only histological material available is from the rectum. Immunohistochemical studies have shown that the abnormal tissue consists predominantly of collagen type III, but why the pericryptal fibroblasts synthesize abnormal collagen in this disorder but not in other inflammatory disorders is not understood. There is a patchy and variable inflammatory infiltrate in the lamina propria consisting of lymphocytes, plasma cells, and some neutrophils. The disease is confined to the colon and does not extend into the ileum. It is therefore distinct from collagenous sprue.

Lymphocytic colitis shares the same clinical features as collagenous colitis but the colonic mucosa always looks normal at colonoscopy. Nevertheless, histological examination of biopsy specimens shows a diffuse inflammatory infiltrate throughout the lamina propria with no architectural changes of the glands. The infiltrate is predominantly lymphocytic but there are also plasma cells and eosinophils. A characteristic feature is the marked increase in intraepithelial lymphocytes, which clearly separates this disease from ulcerative colitis in which the intraepithelial lymphocyte counts are normal or reduced. A lymphocytic colitis can be seen in some patients with untreated coeliac disease and in some patients receiving non-steroidal anti-inflammatory drugs. These possibilities need to be excluded before the diagnosis of lymphocytic colitis can be made.

Both of these disorders have a variable clinical course and the symptoms can spontaneously remit and relapse. However, in general, treatment is difficult, especially if a large-volume secretory diarrhoea occurs. Antidiarrhoeal agents, such as loperamide, should be used initially, but if no response is seen, then 5-aminosalicylic acid compounds or oral corticosteroids can be tried. If symptoms persist, dietary exclusion and even an elemental diet are sometimes helpful. Other treatments that have had some anecdotal benefit are metronidazole, cholestyramine, and mepacrine.

Patients may have intermittent symptoms over many years and, unless a rectal biopsy is obtained and correctly interpreted, the true diagnosis is not made. Many of these patients are thus labelled as having an irritable bowel syndrome. A few cases of lymphocytic colitis have been reported as progressing to a collagenous colitis, but this outcome appears to be infrequent. Neither disease progresses to a frank ulcerative colitis.

Miscellaneous vascular disorders of the bowel

Intramural bleeding

The most common cause of bleeding into the wall of the bowel is anticoagulant therapy. Occasionally, intramural haematomas form in patients with congenital coagulation defects such as haemophilia or in conditions such as vasculitis. The usual presentation is with abdominal pain and symptoms of intestinal obstruction and bleeding. The diagnosis is made by barium follow-through or enema examination and the condition can usually be treated conservatively with blood replacement and, if necessary, nasogastric suction.

Aortic aneurysm

Aneurysmal dilatation of the aorta is relatively common in elderly patients, the usual site being the segment distal to the origin of the renal arteries. Aneurysms larger than 6 to 7 cm or those that show increasing enlargement are probably best resected. Rarely, a spontaneous fistula into the duodenum may develop with catastrophic gastrointestinal haemorrhage. This condition is considered in more detail in Section 15.

In patients who have had prostheses inserted into the abdominal aorta or into other retroperitoneal arteries the complication of paraprosthetic-enteric fistula may occur. This is characterized by the abrupt onset of abdominal pain and shock. Treatment is surgical and the prognosis is extremely poor.

Vascular malformations

The vascular ectasias of the colon are described in Chapter 14.16. Haemangiomas of the small intestine are rare. They usually present as recurrent anaemia due to gastrointestinal bleeding. They are best diagnosed by angiography or, occasionally, by enteroscopy. Telangiectasia may also occur throughout the stomach and bowel as part of the Osler–Rendu–Weber syndrome.

Endometriosis

The term endometriosis describes the presence of extrauterine endometrial tissue and its clinical manifestations. The disorder occurs most frequently between the ages of 30 and 40 years and is rare below the age of 20. Intestinal involvement is most common in those parts of the bowel adjacent to the uterus and fallopian tubes, particularly the rectosigmoid colon. It is not certain how heterotopic endometrial tissue reaches the bowel and spread may be direct, by the bloodstream, or by means of the lymphatics. The mucosa of the bowel is seldom penetrated by ectopic endometrial tissue and therefore gastrointestinal bleeding is an unusual accompaniment of endometriosis of the bowel.

The usual symptoms of endometriosis include dysmenorrhoea, menorrhagia, sterility, and intermenstrual pelvic pain and backache. If the rectosigmoid region is involved, there may be cyclic pains in the rectum and, occasionally, mild diarrhoea and tenesmus. Implants in the small intestine may produce symptoms of obstruction or volvulus. However, endometriosis affecting the intestine is frequently asymptomatic and much of the pain and altered bowel habit attributed to this condition is more often caused by an irritable bowel syndrome.

The diagnosis of endometriosis requires a thorough pelvic examination to demonstrate tender nodules in the rectosigmoid region or in the rectovaginal area. The diagnosis may be suggested by radiological evidence of the presence of lesions in the rectosigmoid region, but ultimately depends on biopsy of these lesions. Laparoscopy is often helpful in making the diagnosis. The differentiation from carcinoma may be difficult and when in doubt surgical exploration should be carried out.

The management of this condition requires expert gynaecological assistance. Mildly symptomatic cases are probably best managed by analgesics and sedation. More severe cases may require hormonal therapy with danazole, gestrinone, or gonadorelin analogues. These drugs inhibit gonadotrophin release from the pituitary.

Malakoplakia

This is a rare granulomatous disease involving the urinary tract and occasionally the colon or stomach. Histologically the condition is characterized by the presence of histiocytes containing dark inclusions that stain positive with periodic acid–Schiff and seem to contain both calcium and iron. There appears to be an acquired abnormality of macrophage function associated with defective digestion of phagocytosed bacteria.

Colonic malakoplakia is usually discovered as an incidental finding in elderly debilitated individuals, quite often in association with a malignant disease of the colon. Occasionally it presents as a systemic illness characterized by fever, diarrhoea, and other gastrointestinal symptoms. It can only be diagnosed by histological examination of the bowel. There is no effective treatment, although there has been a recent report of improvement in otherwise unresponsive cases by the use of cholinergic drugs.

Isolated ulcers of the large intestine

Caecal ulcers

These occasionally occur but their aetiology is unknown. They can present with abdominal pain, either acute or chronic, and may be a cause of an acute abdomen. Laparotomy may show perforation or local abscess formation. More commonly, they present with bleeding. Similar ulcers may occur elsewhere in the colon, especially at the flexures.

Solitary rectal ulcer syndrome

This refers to the occurrence of an ulcer in the rectum, usually 4 to 10 cm from the anal verge. It is usually found in young adults, mostly in women, but can arise at any age. The ulcers are most commonly on the anterior wall, but they can be multiple and can be sufficiently extensive to encircle most of the rectum. There may be an associated anterior-mucosal prolapse. Symptoms include rectal bleeding, which is the most common mode of presentation, tenesmus, and abdominal and rectal pain. The bowel habit may be normal, but many of these patients have a history of constipation and straining. At sigmoidoscopy the ulcer is readily seen and usually has a greyish base. However, there may be just an area of inflamed mucosa or the ulcer can be a polypoid lesion simulating a carcinoma. In either case, a biopsy specimen should allow the correct diagnosis to be made. Histologically, there is often evidence of ischaemia, but the characteristic feature is hypertrophy of the muscularis mucosae with smooth-muscle fibres extending between the crypts towards the epithelium. There may be considerable fibrosis. Treatment is often difficult.

Correction of constipation with bulking agents (with or without lactulose) is important and patients should be warned not to strain. Topical treatment with 5-aminosalicylic acid or corticosteroids may be helpful, but there are no controlled data to confirm their efficacy. As these ulcers can remit spontaneously, it is difficult to be sure whether treatment has been effective in an individual patient. For patients with continuing and disabling symptoms, anorectal physiological measurements should be made because there may be evidence of denervation of the pelvic floor muscles. A defaecating proctogram should also be obtained to demonstrate whether the anorectal angle changes when the patient attempts to empty the rectum and to record the degree of mucosal prolapse. Surgical therapy such as an anterior and posterior rectopexy may be helpful in some patients.

Stercoral ulcers

These occur in association with faecal impaction and are most commonly found in the sigmoid–rectal area. Most patients are elderly but they can occur in any patient who is severely constipated, including patients with neurological causes of constipation (for example paraplegia or multiple sclerosis). The common symptoms are those associated with the constipation—nausea, abdominal distension and pain, and anorexia—and there may be overflow incontinence. The ulcers are frequently asymptomatic but may be a cause of anaemia from chronic blood loss. They are normally revealed because of an acute bleed or a perforation. Treatment of these acute complications requires surgery, but otherwise, the ulcers are treated by relieving the faecal impaction.

Acute colonic pseudo-obstruction (Ogilvie's syndrome)

This syndrome describes a massive and acute dilatation of the caecum and right colon in the absence of organic obstruction or inflammatory disease of the colon. It may occur following intra-abdominal surgery, including urological or gynaecological surgery, but can also happen in any sick patient. Hence, it can occur in association with severe systemic sepsis, or respiratory or cardiac disease. Most patients have a constant, rather dull pain with marked abdominal distension and they frequently vomit. There is constipation but usually patients continue to pass wind and some may actually have diarrhoea. On examination, there is a distended and tympanitic abdomen that is tender to the point of mild rebound tenderness. Bowel sounds are variable in pitch and frequency but are rarely absent. The diagnosis is made on a plain radiograph of the abdomen. The danger is that of a colonic perforation if treatment is not instituted immediately. Intravenous fluids and electrolytes are given together with nasogastric suction. Any drugs that might be implicated (such as tricyclic antidepressants, anticholinergics) are stopped. Rectal tubes and enemas are often used but there value is dubious. It is usually recommended that the patient is turned from side to side at regular intervals. Theoretically this should distribute the intracolonic gas and hence reduce a continuous high pressure in the right colon—again, evidence that this is effective in reducing the incidence of perforation is not clear-cut. If the dilatation does not resolve, decompression can sometimes be achieved by colonoscopy, but as it is dangerous to prepare the colon the procedure is difficult. Surgical decompression with a caecostomy may be needed, which may be accompanied by resection if there is an obviously ischaemic segment of colon.

Melanosis coli and related disorders

The term melanosis coli is used to describe black or brown discoloration of the mucosa of the colon. It results from the presence of dark pigment in large mononuclear cells or macrophages in the lamina propria of the mucosa. The coloration is usually most intense just inside the anal sphincter and is less dark higher up in the sigmoid colon. Similar pigment has been found in the appendix and mesenteric nodes. The condition is thought to result from faecal stasis and the use of anthraquinone cathartics such as cascara or senna. Chronic cathartic abuse may also cause radiological changes of the colon that go under the general heading of cathartic colon. The changes are characterized by loss of haustral markings and appearances resembling multiple strictures, although in fact these areas are capable of distension. These changes may involve all parts of the colon and the terminal ileum, and have to be distinguished from those of ulcerative colitis, Crohn's disease, and other inflammatory bowel diseases.

Miscellaneous vascular disorders of the liver

The important vascular disorders of the liver include underperfusion in conditions of shock and left ventricular failure, the wide variety of diseases that give rise to portal hypertension, and acute and chronic venous congestion due to cardiac failure, diseases of the pericardium, or rarely, primary obstruction of the hepatic veins. Portal hypertension is considered in Chapter 14.21.2.

Acute cardiac failure and shock

Reduced hepatic blood flow primarily causes ischaemia in Rappaport zone III, which leads to centrilobular necrosis. This occurs frequently in acute congestive heart failure or in severe hypotension from any cause.

In acute congestive cardiac failure, the liver may be enlarged and tender if the central venous pressure is elevated. There may be biochemical features of liver cell damage or intrahepatic cholestasis. Liver function may be interfered with sufficiently to cause a reduction of prothrombin synthesis and hence increased sensitivity to anticoagulant drugs.

In patients with severe hypovolaemic shock there may be marked biochemical changes of deranged liver function and, in severe cases, jaundice. These changes are transient and revert rapidly to normal following restoration of a normal blood pressure and perfusion.

Chronic venous congestion

A persistently elevated central venous pressure due to right-sided heart failure or constrictive pericarditis results in hepatic venous congestion and hepatomegaly. The associated histological changes are characterized by centrilobular congestion with surrounding fatty change (the typical 'nutmeg liver'). If the disorder is of long standing, there may be progressive fibrosis extending peripherally from centrilobular to portal areas, although regenerative nodules are not prominent.

Apart from the underlying cardiac lesion, this disorder is characterized by hepatic enlargement and signs of congestive cardiac failure. The serum bilirubin level is usually increased and there may be a slight elevation in the serum alkaline phosphatase and in the transaminases.

It should be emphasized that, although the changes outlined above are relatively common in patients with long-standing heart failure, true cirrhosis of the liver with regenerative nodules is very rare, as is the clinical picture of portal hypertension that accompanies other forms of cirrhosis of the liver; it is very unusual to find oesophageal varices in patients with cardiac cirrhosis.

Hepatic arterial occlusion

This is a rare condition. It usually follows surgical trauma but has been found in association with arteritis and bacterial endocarditis.

The condition is characterized by an acute onset of pain in the upper abdomen, tenderness over the liver, and progressive shock and liver failure. Most cases have a fatal outcome.

Hepatic arterial aneurysm

This condition is recognized by the triad of upper abdominal pain, jaundice, and haematemesis following rupture of the aneurysm into the stomach or duodenum. The diagnosis is made by hepatic angiography. Treatment is by surgical resection.

Septic venous thrombosis of the portal system

This condition results from infection anywhere in the abdominal cavity leading to pylephlebitis of the portal venous system. It may occasionally result from a systemic septicaemia or from inflammatory disorders of the bowel, such as ulcerative colitis.

The acute phase of the disorder is usually characterized by features related to the underlying abdominal sepsis. This is followed by an episode of high fever, worsening abdominal pain, and rigors. There may be obvious evidence of septic embolization to the liver. This may lead to abdominal pain and hepatic tenderness

with mild jaundice. All the systemic features of a severe infection develop and there is usually a polymorphonuclear leucocytosis and abnormal liver tests. Occasionally, multiple large intrahepatic abscesses may develop.

The condition should be suspected in any patient with abdominal sepsis who develops an acute systemic illness with abdominal pain and deranged liver tests. Management consists of intensive antibiotic treatment directed particularly towards Gram-negative organisms and micro-aerophilic streptococci. In some patients the clinical picture associated with portal venous thrombosis may develop after the acute phase has settled.

Protein-losing enteropathy

Rarely, hypoproteinaemia may result from excessive loss of plasma proteins into the gastrointestinal tract. All plasma proteins are affected; those showing the greatest reduction in concentration are the ones with the longest half-lives, including albumin. The resulting oedema is largely due to the low level of albumin, this being the main molecule responsible for the plasma colloid osmotic pressure. Although uncommon, this is an important condition to recognize because the resulting oedema or ascites may overshadow the intestinal symptoms and hence the underlying condition is easily missed.

This condition has been found in association with a wide variety of inflammatory or neoplastic disorders of the small bowel and abdominal lymphatic system. It is an almost inevitable consequence of intestinal lymphangiectasia, an inherited or congenital disorder caused by maldevelopment of the lymphatic system. It is also associated with allergic disorders involving the small bowel. n most of these conditions protein loss is mild and incidental. Severe protein loss occurs mainly in lymphatic disorders and in Ménétrier's disease, a curious condition characterized by the presence of giant gastric rugae.

Clinical features

When severe, the condition is characterized by peripheral oedema and occasionally by ascites and pleural effusions. There is marked hypoalbuminaemia in the absence of liver or renal disease. There may be associated steatorrhoea, particularly if the condition occurs in association with lymphoma of the bowel.

Diagnosis

The diagnosis is made by determining the rate of loss of protein into the intestine using a radioactive label, usually chromium(III) chloride ($^{51}CrCl_3$), which attaches to all plasma proteins, or as chromium-51 albumin, which redistributes the label, to some extent, to other proteins. ^{67}Copper-labelled caeruloplasmin is theoretically a better marker but has a short half-life. The proportion of radioactivity in the stool is measured during the succeeding 4 days; 0.7 per cent is taken as the upper limit of normal. In comparison with plasma radioactivity, more sophisticated measures of plasma clearance can be derived to give quantitative data. Alternatively, measurement of a_1-antitrypsin in the stool has been shown to be a useful marker of protein-losing enteropathy, without necessitating radioactive labelling.

The further diagnosis of the condition is directed towards determining the underlying cause.

Treatment

Treatment is directed towards raising the plasma albumin and correction of the underlying disorder. For example, cases associated with neoplasm of the stomach or colon require surgical resection. Those secondary to coeliac disease, sprue, Whipple's disease, or allergic gastroenteropathies should be treated appropriately.

Jejunoileal bypass

Most patients with massive obesity have fatty infiltration of the liver. After jejunoileal bypass, 55 per cent of them show further fatty change, although this is usually asymptomatic. The increase in fat is due entirely to an accumulation of triglyceride. There is frequently a mild elevation of liver enzymes in serum but this returns to normal once weight reduction has been achieved. The mechanism for the increased fatty change is unknown but it may be a result of protein–calorie malnutrition. An alternative possibility is that the steatosis may be secondary to bacterial overgrowth in the excluded loop of small intestine, as steatosis may diminish with metronidazole therapy.

Acute liver failure may develop in a few patients and is associated with considerable mortality. It is thought to be due to bacterial colonization of the included and excluded small intestine with the production of 'hepatotoxins', which are then absorbed. Treatment consists of intravenous amino acids and broad-spectrum antibiotics. If the condition recurs, further treatment should be given and the ileal bypass reversed.

A micronodular cirrhosis may develop 1 to 6 years after a bypass operation. Histologically, the liver often shows appearances similar to those induced by alcohol. If liver function deteriorates, small-bowel continuity should be restored. Patients may still progress to liver failure and death, but there are reports of the cirrhosis arresting or even reversing with complete recovery of the histology.

Parenteral nutrition and the liver

Abnormalities of serum liver enzymes and bilirubin are commonly seen in patients receiving total parenteral nutrition. Thirty to 60 per cent of patients will show a rise in at least one liver test of greater than 50 per cent of baseline, a rise in alkaline phosphatase being the most frequent abnormality. The changes occur towards the end of the first week and peak between 9 and 12 days. Patients receiving intravenous lipid are particularly at risk, but biochemical cholestasis can occur when no fat is given. Liver histology shows steatosis, mild portal inflammation and fibrosis, bile-duct proliferation, and bile plugs. The changes in serum liver tests and in liver histology are reversible once parenteral nutrition is discontinued, although persistent histological changes have been reported. The abnormal concentrations of liver enzymes may also return to normal if the calorie–nitrogen ratio is lowered by reducing the amount of dextrose given, or may even settle spontaneously if parenteral nutrition is continued without change.

The cause of the intrahepatic cholestasis is unknown. Direct toxicity of the intravenous solutions (especially those containing tryptophan), calorie excess, or a deficiency of essential fatty acids have been proposed as possible mechanisms. A more likely explanation is the possibility of an overgrowth of anaerobic bacteria in the intestine with subsequent production of endotoxin and lithocholic acid, both of which induce liver damage in animals with similar histological features to those seen in humans receiving total parenteral nutrition. Patients who develop a rise in serum transaminases and alkaline phosphatase have a high concentration of lithocholic acid in the bile compared with patients being parenterally fed who do not have abnormal liver tests. Furthermore, metronidazole has been shown to prevent cholestasis developing in these patients. Hence, the situation may be analogous to the cholestasis associated with a jejunolileal bypass (see above).

Peliosis hepatitis

This consists of venous lakes within the liver, which probably occur as a result of sinusoidal ectasia. It may be seen in association with oral contraceptive usage, terminal cachexia from carcinoma, and with androgenic steroid therapy. Clinically there are usually few symptoms, although hepatomegaly may be present. Mild to moderate increases in transaminases may occur. Diagnosis is usually made coincidentally on liver biopsy and the prognosis is that of the underlying condition.

15.1.1.1

Introduction

Peter L. Weissberg

The scale of the problem

All organs require an adequate blood supply to survive and function normally, yet in the Western world we are in the midst of an epidemic of disease caused by atherosclerosis in which lipids are deposited in the subendothelial space of major arteries initiating a process that results in narrowing and occlusion of vessels and consequent ischaemia and necrosis of organs and limbs. Although atherosclerosis is manifested most dramatically as acute myocardial and cerebral infarction (heart attack and stroke), it also has a substantial impact on limb, gut, and renal function. Indeed, there is no other single disease that has such a potent and diverse impact on health. Coronary, cerebrovascular, and peripheral vascular disease together account for approximately 40 per cent of male and 30 per cent of female deaths in the United Kingdom in those under 75 years of age. In recent years there has been a gratifying fall in the incidence of deaths from cardiovascular causes in middle-aged adults in the so-called developed world. However, since most heart attacks and strokes occur in the elderly and life expectancy is increasing, the prevalence of cardiovascular disease is bound to increase. Also, there is clear evidence that the epidemic of cardiovascular disease is spreading rapidly, particularly in former Eastern Block countries and, alarmingly, in the Third World. It therefore follows that if atherosclerosis could be understood and overcome, the impact on world health would be substantial.

The atherosclerotic plaque

An atherosclerotic plaque comprises a subendothelial accumulation of oxidized lipid at its core with an inflammatory cell infiltrate covered by a fibrous cap consisting of modified vascular smooth muscle cells and their extracellular matrix. Plaques begin in early life as asymptomatic fatty streaks. Symptoms arise later on, either because a plaque has grown large enough to limit flow, or because a plaque erodes or ruptures causing platelet aggregation and evolution of an occlusive thrombosis within the vessel lumen.

Large plaques eventually declare themselves through the emergence of inducible ischaemia, manifested as angina pectoris (coronary disease, Fig. 1) or intermittent claudication (peripheral vascular disease), which resolves when oxygen demand is reduced, either by stopping the triggering activity or by drug therapy. Plaque erosion or rupture is sudden and usually precipitates an acute ischaemic event such as unstable angina (Fig. 1), myocardial infarction, transient cerebral ischaemia, or stroke depending on the vascular bed involved. Tissue viability then depends on whether or not flow can be restored and how quickly. In the coronary circulation removal of the offending thrombus is achieved either with drug therapy or by angioplasty. Pharmacological and mechanical strategies for restoring cerebral blood flow after ischaemic stroke are less well established.

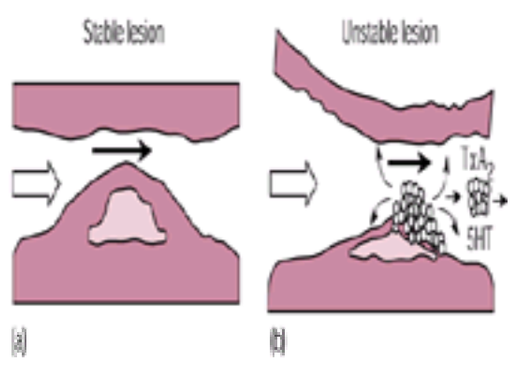

Fig. 1 Mechanisms by which atherosclerotic plaques induce symptoms. (a) Large stable atherosclerotic plaque limits blood flow in response to increased demand causing stable angina. (b) Platelet aggregation and thrombus formation on an unstable atherosclerotic plaque limit blood flow and cause vasoconstriction and embolization at rest, leading to unstable angina (TxA_2 thromboxane A_2, 5HT, 5-hydroxytryptamine). (Redrawn from Weinberg PL (1999). In: *Angina in clinical practice* (ed. P. Schofield). Martin Dunitz Ltd.)

The inflammatory basis of atherosclerosis

It is now recognized that atherosclerosis is a destructive inflammatory process, probably initiated and maintained by modified (oxidized) lipids, involving endothelial dysfunction, and mediated by activated macrophages, T cells, and possibly also mast cells. The inflammatory process is isolated from the circulation by a protective fibrous cap synthesized by intimal vascular smooth muscle cells. If the inflammatory process predominates, then plaque rupture and thrombosis results (Fig. 2). The inflammatory basis of atherosclerosis is reflected in a close correlation between circulating markers of inflammation, for example fibrinogen, C-reactive protein, serum amyloid A, and serum albumen (inverse) and clinical outcome in patients with known disease.

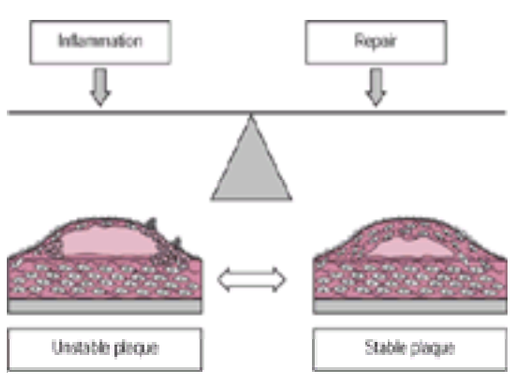

Fig. 2 The balance of atherosclerosis. The stability of atherosclerotic plaque is determined by the net effect of the destructive inflammatory process tending to plaque rupture and thrombosis balanced by the stabilizing influence of the fibrous cap synthesized by intimal smooth muscle cells. (Redrawn from Weinberg PL (1999). *Atherosclerosis*, **147** (suppl. 1), S3–S10.)

The changing treatment of atherosclerosis

Atherosclerosis has traditionally been regarded as a collection of end-stage organ-based diseases such as myocardial infarction, stroke, and limb ischaemia, treated by specialists from a variety of disciplines concerned more with its consequences than its cause. Therapy has therefore relied largely on mechanical procedures such

as bypass surgery, endarterectomy, and balloon angioplasty to relieve obstruction and improve blood flow. However, whilst these procedures have been very successful at relieving symptoms, they have had little impact on survival, except in a few specific patient groups. The main impact on survival has come from advances in drug therapy.

Since thrombosis is the commonest terminal event in atherosclerosis it is not surprising that fibrinolytic, antithrombotic, and antiplatelet drugs are all effective in acute events caused by plaque rupture, such as myocardial infarction, unstable angina, and transient ischaemic attacks. However, the most important recent therapeutic development has been the introduction of inhibitors of HMG Co-A reductase (the statins), which reduce low-density lipoprotein cholesterol and triglycerides, increase high-density lipoprotein cholesterol, and improve endothelial function. Treatment with statins reduces the risk of a vascular event (both heart attack and stroke) by about 30 per cent in patients with and without symptoms of atherosclerosis (secondary and primary prevention) and with high or 'normal' cholesterol levels, yet they produce little, if any, haemodynamically meaningful plaque regression. The optimistic message from these observations is that statins have a greater effect on plaque stability than on plaque size and that atherosclerosis is therefore a dynamic process that can be modified, even in advanced disease.

In the twenty-first century atherosclerosis is best viewed as a single dynamic disease in which complex interactions between endothelial cells, smooth muscle cells, inflammatory cells, and platelets dictate its course. The development of effective medical therapies for atherosclerosis argues for a common approach to its management regardless of its presentation. Thus all patients with established atherosclerotic disease should have the opportunity to benefit from treatment with lipid-lowering and antiplatelet therapies. Since it is now possible to prevent clinical events in asymptomatic patients with occult vascular disease, the challenge is to target expensive therapies to those at highest risk. In the future this is likely to include assessment of 'classical' risk factors (family history, smoking, diabetes, cholesterol levels) but also possibly indices of inflammation and measures of genetic variations (polymorphisms) in molecules known to play a central role in plaque progression and stability.

15.1.1.2Vascular endothelium: its physiology and pathophysiology

P. Vallance

A monolayer of endothelial cells lines the intimal surface of the entire vascular tree (Fig. 1) to form the largest endocrine/paracrine organ in the body. These cells are metabolically very active and exert a profound influence on vascular reactivity, thrombogenesis, and the behaviour of circulating cells. Abnormalities of endothelial function have been implicated in a wide variety of diseases ranging from atheroma and hypertension to acute inflammation and septic shock (Table 1). Recent advances in endothelial research have led to the development of new therapies and re-evaluation of those that exist. This section provides an introduction to the biology of the vascular endothelium and describes how endothelial dysfunction may contribute to cardiovascular disease.

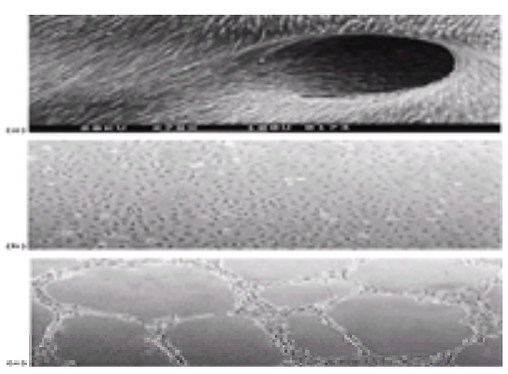

Fig. 1 Panel (a) shows a scanning electron micrograph of the endothelium of a human coronary vessel at a branch area (supplied by P. M. Rowles). Panel (b) shows endothelial cells grown in culture in the absence of angiogenic factors. With stimulation by the correct angiogenic factors, endothelial cells form a tube-like structure (Panel (c)).

Development of endothelium

During early development the endothelium forms the first layer of the circulatory system and extends to produce a network of interconnecting tubes; this ability of endothelial cells to form tube-like structures is retained even when they are grown *in vitro* (Fig. 1). *In vivo*, the endothelial tubes differentiate into arteries, arterioles, capillaries, veins, and lymph vessels, and regional differences in function and structure evolve such that the properties of endothelial cells vary between arterial and venous beds, between micro- and macrovasculature, between organs, and between different parts of individual organs—perhaps the most striking example being the specialized layer of endothelial cells that forms the blood–brain barrier. Heterogeneity of endothelial cell function undoubtedly has implications for physiology, pathophysiology, and therapeutics. However, endothelial cells from different vessels also have many features in common and a number of pathologies, including those causing premature vascular disease, are associated with widespread changes in the behaviour of endothelial cells.

Anatomy of endothelium

Each endothelial cell is between 25 and 50 μm long, 10 and 15 μm wide, and up to 5 μm deep, and lies with its long axis aligned in the direction of the blood flow (Fig. 1). The underlying smooth muscle cells lie radially, are about 5 to 10 μm wide, and taper at either end so that a single endothelial cell can communicate with many smooth muscle cells, and vice versa. The endothelium also comes into intimate contact with circulating cells, and the total area of the luminal surface of endothelium is in excess of 500 m^2. This thin layer of cells is particularly susceptible to injury, and changes in endothelial cell morphology and turnover occur in experimental hypertension, diabetes, and atheroma. Antibodies directed against endothelium can be found in a number of inflammatory and immune conditions.

Signal detection by endothelial cells

The endothelial cell membrane expresses a large number of receptors for circulating hormones, local mediators, and vasoactive factors released from blood cells. It can also sense local changes in pressure and flow; stretch of the cell membrane leads directly to opening of a cation channel permeable to calcium, and flow across the cell surface leads to opening of a potassium channel, which hyperpolarizes the cell. The precise mechanisms linking the various stimuli received to the response of the endothelial cell have yet to be determined, but calcium is undoubtedly important. Receptor occupation, stretch, or shear stress all lead to changes in the concentration of intracellular free calcium, and the profile of change influences which endothelial functions are activated and therefore which message is produced by the cell. In addition, it is clear that the endothelial cell can adjust both the expression and localization of certain key enzymes in response to physical or chemical stimuli. Translocation of enzymes from cytosol to cell surface or to specialized invaginations in the cell surface (caveolae) in response to stimuli can greatly alter the metabolic activity of the endothelial cell. The endothelium acts as a signal transducer and exerts a profound influence on the cardiovascular system by virtue of the way in which it alters its phenotype in response to signals.

Control of vascular tone

Endothelium extracts and inactivates circulating hormones, converts inactive precursors into active products, and synthesizes and releases a variety of vasoactive mediators (Fig. 2). Vasoconstrictor and vasodilator mediators are produced and allow the vessel to respond to changes in the local milieu, but the predominant background influence of the endothelium is dilator, with removal of the endothelium leading to vasoconstriction. Basal endothelium-dependent dilator tone seems to provide a physiological counterbalance to the continuous constrictor tone of the sympathetic nervous system.

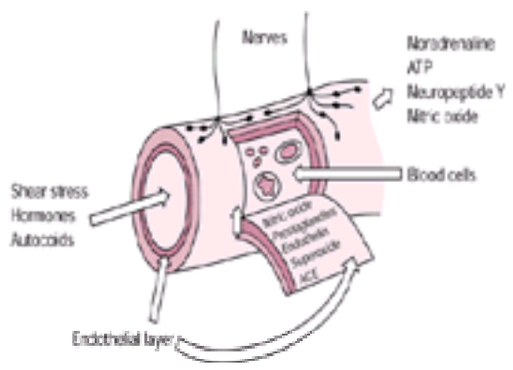

Fig. 2 Vascular endothelial cells lie at the interface between blood and the smooth muscle cells. They detect chemical and physical signals in the lumen of the blood vessel and adjust their output of biologically active mediators accordingly. This provides a mechanism of local regulation of vascular function. Rapid adjustment of vascular tone is probably achieved through a balance of endothelium-derived nitric oxide and neuronally derived noradrenaline. Endothelin provides a slowly modulating constrictor tone and angiotensin II has the capacity to fine-tune neuronal, endothelial, and smooth muscle function. Abbreviations: ACE (angiotensin converting enzyme), ATP (adenosine triphosphate).

Vasodilators

The endothelium produces at least three vasodilator mediators (Fig. 2): nitric oxide, prostanoids, and hyperpolarizing factor.

Nitric oxide

Physiology

The production of nitric oxide is responsible for basal endothelium-dependent dilator tone. This simple gas is a potent vasodilator: its synthesis and main actions through the second messenger cyclic GMP are described in Fig. 3. In addition, nitric oxide inhibits cytochrome c oxidase, initially in a reversible manner, but irreversibly under certain conditions. Inhibition of this enzyme decreases oxygen utilization, and the release of nitric oxide by endothelial cells appears to be an important determinant of oxygen consumption in the vasculature. It is possible that there are additional important targets for nitric oxide, including ion channels and other enzymes, but the physiological significance of these effects is not yet clear. Nitric oxide modifies the adhesiveness of the endothelial cell for circulating white cells, but rapid inactivation by haemoglobin prevents any significant downstream effect.

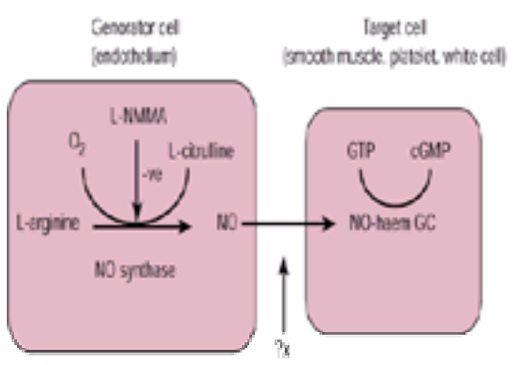

Fig. 3 Nitric oxide (NO) is synthesized from L-arginine by the action of nitric oxide synthase. Citrulline is the byproduct of the reaction. Nitric oxide, which has a half-life of only a few seconds, diffuses from the endothelial cell to reach a target cell—this may be vascular smooth muscle, a platelet, or a white cell. In the process of diffusion nitric oxide may interact with other molecules (X) which may stabilize or destroy the mediator. A major physiological target for nitric oxide is guanylyl cyclase (GC). Nitric oxide binds to the haem moiety of this enzyme and this leads to enzyme activation and generation of cyclic guanosine monophosphate (cGMP). Elevation of cGMP relaxes smooth muscle and inhibits platelet aggregation and adhesion. The platelet-derived mediators adenosine diphosphate (ADP) and 5-hydroxytryptamine (5-HT; serotonin) stimulate endothelial cells to synthesize nitric oxide and this provides a negative-feedback system to prevent activated platelets from causing vasospasm and further platelet adhesion and aggregation. The synthesis of nitric oxide can be inhibited by certain guanidino-substituted analogues of L-arginine such as N^G-monomethyl-L-arginine (L-NMMA) and this substance as well as asymmetric dimethylarginine (ADMA) occurs naturally and may contribute to nitric oxide deficiency in disease states. Nitric oxide synthase activity can be stimulated by calcium, provision of co-factors, phosphorylation of the enzyme, and by altered intracellular localization

Nitric oxide is a free radical (it has an unpaired electron in its outer orbit) and as such reacts readily with other free radicals and reactive oxygen species. The reaction between nitric oxide and superoxide anion (O_2^-) is extremely fast and can result in the formation of either the toxic product peroxynitrite ($ONOO^-$) or the inactive breakdown product nitrate (NO_3^-). Such interactions between radicals can greatly influence the overall behaviour of the wall of the blood vessel and can lead to an apparent defect in endothelial function even when the output of endothelial mediators is normal.

The arterial circulation of animals and humans is vasodilated continuously and actively by endothelium-derived nitric oxide, and inhibition of the synthesis of nitric oxide with certain guanidino-substituted analogues of L-arginine, including N^G-monomethyl-L-arginine, leads to vasoconstriction, hypertension, and sodium retention. Shear stress—the force caused by the viscous drag of flowing blood—is probably an important physiological stimulus for the continuous production of nitric oxide. As shear stress increases more nitric oxide is produced and the blood vessel relaxes, reducing the stress. This process of flow-mediated dilatation appears to be a homeostatic mechanism to prevent shear stress from increasing to levels that might initiate activation of platelets or other cells and may also help co-ordinate tissue perfusion. Flow-mediated dilatation is an autoregulatory property of blood vessels that tends to oppose classical myogenic autoregulation—the process by which a blood vessel constricts in response to an increase in intraluminal pressure.

Synthesis of nitric oxide is stimulated by acetylcholine, bradykinin, and substance P, and in many vessels release of nitric oxide accounts for the vasodilator actions of these mediators, which are known as 'endothelium-dependent vasodilators'. Circulating hormones, including insulin and oestrogens, may also act on receptors on or within the endothelial cell to stimulate the release of nitric oxide acutely or to alter the expression of endothelial nitric oxide synthase chronically.

Veins differ from arteries and arterioles, and do not seem to be actively dilated by continuous release of nitric oxide. Venous endothelium releases nitric oxide when stimulated by acetylcholine or bradykinin, but not under basal conditions. Furthermore, human veins do not release much nitric oxide in response to platelet-derived mediators. Indeed, aggregating platelets constrict veins, due to the unopposed action of the platelet-derived mediators on vascular smooth muscle. The reasons for the arteriovenous difference in nitric oxide production are not fully understood, but one consequence is that the guanylyl cyclase in venous smooth muscle is relatively upregulated and veins respond to maller amounts of nitric oxide than do arteries or arterioles. This is of therapeutic relevance; nitric oxide is the active moiety of glyceryl trinitrate and other nitrovasodilators, and the low basal synthesis of endogenous nitric oxide by venous endothelium accounts, in part, for the venoselective action of these drugs.

Pathophysiology

Loss of nitric oxide leads to arterial vasoconstriction, has the potential to enhance platelet and white cell adhesion, and in experimental models may enhance atherogenesis. Several clinical conditions, including atherosclerosis, hypertension, hypercholesterolaemia, and diabetes, are associated with a functional loss of nitric

oxide-mediated effects.

In the coronary vasculature, loss of nitric oxide predisposes to vasospasm and may contribute to the onset of anginal symptoms. Atherosclerotic coronary arteries constrict in response to the platelet-derived mediator serotonin (5-hydroxytryptamine), whereas healthy vessels are stimulated to produce more nitric oxide and dilate (Fig. 3). Flow-dependent dilatation is also lost in such vessels, and the response to sympathetic stimulation is converted from dilatation to unopposed constriction. Endothelial dysfunction precedes the development of overt atheroma and there is a relationship between risk factors for ischaemic heart disease and impaired responsiveness of coronary arteries to endothelium-dependent vasodilators. Furthermore, hypercholesterolaemia, even in the absence of angiographic evidence of atheroma in large vessels, is associated with abnormal endothelium-dependent vasodilatation in coronary and peripheral arterioles. Modified low-density lipoproteins appear to inhibit nitric oxide synthesis or speed its destruction, possibly by enhancing production of superoxide anion.

Basal endothelium-dependent dilatation is also impaired in patients with essential hypertension and the degree of impairment increases with increasing blood pressure. It is not known whether the defect is a consequence or a cause of the raised pressure, but the fact that endothelial function appears to be restored by antihypertensive therapy argues in favour of dysfunction being a response to raised pressure. Patients with diabetes show diminished endothelium-dependent dilatation, and this defect does not reverse with treatment. Thus patients with uncontrolled hypertension, diabetes, and hypercholesterolaemia all display defects of nitric-oxide-mediated vasodilatation and this could provide a common mechanism of vascular dysfunction in these diseases. Impaired endothelium-dependent dilatation associated with hypercholesterolaemia is partially reversed by supplementation with L-arginine (see below).

In addition to the effects of disease states on nitric oxide, genetic variation in endothelial nitric oxide synthase may predispose to cardiovascular disease. Common variations occur in promoter and coding regions of the gene encoding endothelial nitric oxide synthase and certain variants appear to be associated with excess cardiovascular risk, but the data are not yet conclusive. Nor is it clear how the genetic variations alter nitric oxide synthesis or endothelial cell function.

Overproduction of nitric oxide may also contribute to disease. Bacterial endotoxin, and certain cytokines, including interleukin 1 and interferon-g, induce expression of a second nitric oxide synthesizing enzyme which appears in the endothelium, vascular smooth muscle, and inflammatory cells invading the vessel wall. Unlike the constitutive enzyme present in healthy endothelium (endothelial nitric oxide synthase), this inducible isoform of nitric oxide synthase is not regulated by calcium and produces large amounts of nitric oxide. In these quantities nitric oxide, either alone or in combination with superoxide, may contribute to tissue damage in addition to causing profound vasodilatation and hypotension. Excess production of nitric oxide from endothelial nitric oxide synthase due to stimulation of certain essential cofactors including tetrahydrobiopterin may also contribute to these effects. The therapeutic potential of specific inhibitors of nitric oxide synthase as anti-inflammatory agents has not yet been established. In contrast to the general increase in nitric oxide seen in response to inflammation, certain proinflammatory cytokines (particularly tumour necrosis factor-a) may impair normal endothelium-dependent relaxation and nitric oxide synthesis. This might be an important mechanism linking infection or inflammation to increased risk of cardiovascular events including arterial or venous thrombosis.

Prostanoids

Nitric oxide appears to be the dominant vasoactive factor released from endothelial cells under basal conditions, but it is by no means the only mediator produced. The endothelium is a rich source of prostanoids, including the vasodilators prostacyclin and the prostaglandins E_2 and D_2. However, whereas inhibition of nitric oxide leads to profound and widespread changes in vascular tone, inhibition of prostanoid synthesis with aspirin, or other non-steroidal anti-inflammatory drugs, does not. Renal vasculature is an exception, and dilator prostanoids do appear to be important in the regulation of basal renal blood flow; aspirin and other non-steroidal anti-inflammatory drugs lead to vasoconstriction in the kidney, indicating tonic release of vasodilator prostanoids in this vascular bed. Furthermore, in the fetus and newborn, indomethacin leads to closure of the ductus arteriosus and a fall in cerebral blood flow suggesting a significant contribution of endothelium-derived prostanoids to tonic vasodilatation in these beds, at least during development. Cerebral blood flow in adults also falls in response to indomethacin, but not to aspirin and other cyclo-oxygenase inhibitors, and so the role of prostanoids is unclear. Vasodilator prostanoids are important in the vascular changes of inflammation, although whether the prostanoids derive exclusively from the endothelium is not known. A cytokine-inducible isoform of cyclo-oxygenase (cyclo-oxygenase II) has been identified and this probably contributes to the increased synthesis of vascular prostaglandins in inflammation.

Hyperpolarizing factor

An endothelium-derived hyperpolarizing factor has been identified in certain animal and human blood vessels. Hyperpolarization of vascular smooth muscle cells leads to a fall in calcium entry and vascular relaxation. Increasing evidence suggests that endothelium-dependent hyperpolarization may be particularly important in small arteries and arterioles. The chemical identity of endothelium-derived hyperpolarizing factor has not been clearly established, but products of activity of cytochrome P450, the cannabinoid anandamide, and the potassium ion have all been suggested as possible candidates. Only when a clear identify for endothelium-derived hyperpolarizing factor has been established, or a specific inhibitor produced, will it be possible to determine the precise role of this mediator in vascular physiology and pathophysiology.

Vasoconstrictors

Although the predominant background influence of the endothelium is dilator, important vasoconstrictor factors are also synthesized and released.

Endothelin

The endothelins are a family of potent vasoconstrictor peptides containing 21 amino acids that are closely related to the snake venom toxin of the Israeli burrowing asp. Three types of endothelin have been described, endothelin 1, 2, and 3, and there are at least two endothelin receptors in human blood vessels: endothelin A receptor and endothelin B receptor. Endothelins vasoconstrict and can promote the growth of vascular smooth muscle cells. Effects are mediated in part through stimulation of increases in calcium and in part through calcium-independent mechanisms including activation of protein kinases.

Endothelin 1 is synthesized from 'big endothelin' within human endothelial cells (Fig. 4). It is a potent and long-lasting constrictor of human blood vessels, and causes widespread vasoconstriction, hypertension, and sodium retention when infused into healthy volunteers. Antagonists of the endothelin A receptor cause vasodilatation when infused locally, and mixed endothelin A/B antagonists lower blood pressure in normotensive and hypertensive individuals. These findings indicate that there is a tonic synthesis and release of endothelin. A number of studies suggest that there may be important interactions between the sympathetic nervous system, the renin–angiotensin system, and the endothelin system and that these may act in concert to control constrictor tone, with the endothelin system providing a slowly modulating background constrictor tone.

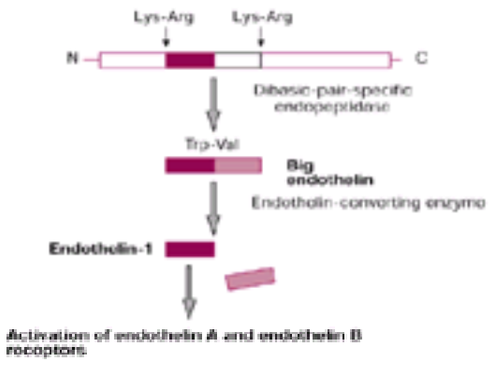

Fig. 4 Biosynthesis of the vasoconstrictor peptide endothelin 1. Endothelin 1 produces profound vasoconstriction, through activation of endothelin A receptors. Activation of endothelin B receptors on smooth muscle also causes vasoconstriction, but stimulation of endothelin B receptors on the endothelium stimulates nitric oxide and prostacyclin production.

Paradoxically, endothelin can also produce transient vasodilatation. This seems to be mediated by activation of endothelin B receptors. Although activation of

endothelin B receptors on vascular smooth muscle causes constriction, activation of endothelial endothelin B receptors leads to the generation of vasodilator prostanoids and/or nitric oxide. Binding of endothelin to endothelin B receptors also seems to be important to clear the peptide from the circulation. Stimuli for endothelin production include thrombin, insulin, cyclosporine, adrenaline, angiotensin II, cortisol, various proinflammatory cytokines, hypoxia, and shear stress.

The concentrations of endothelins circulating in plasma are low and may not reflect local concentrations achieved within the vessel wall. It is difficult to interpret the elevated values reported in many conditons. A role for endothelin in the pathogenesis of vasospasm associated with subarachnoid haemorrhage and some types of renal ischaemia is suggested by results from experiments in animals, and endothelin A/B antagonists produce short-term changes in haemodynamics in patients with heart failure that suggest a possible beneficial therapeutic effect. It seems likely that the precise role of endothelin in these diseases, and other vasospastic conditions, will become apparent as inhibitors of endothelin synthesis, and specific endothelin receptor blockers become more widely used in clinical trials.

Increased production of endothelin has been clearly implicated in the pathogenesis of a very rare form of secondary hypertension caused by malignant haemangioendothelioma, a vascular tumour characterized by intravascular proliferation of atypical endothelial cells. In this condition the degree of hypertension correlates with plasma levels of endothelin and when the tumour is removed blood pressure and plasma endothelin levels fall.

Angiotensin converting enzyme

Angiotensin converting enzyme is located primarily on the luminal surface of the endothelium. This enzyme converts angiotensin I to angiotensin II and also metabolizes bradykinin to inactive products (see Fig. 2). The pulmonary vasculature provides the largest area of endothelium, and is important in the regulation of circulating levels of angiotensin II, but activity of endothelial angiotensin converting enzyme in systemic vessels may be more important in determining the final concentrations of angiotensin II and bradykinin reaching the blood vessel wall. Furthermore, endothelial cells also have the ability to synthesize renin and its substrate. It therefore seems as though the enzymatic machinery for a complete renin–angiotensin system is present within the vessel wall.

The activity of the renin–angiotensin system is clearly important in cardiovascular diseases including hypertension and heart failure, but the relative importance of local compared with systemic regulation of angiotensin II production is not yet clear. Furthermore, the full clinical significance of bradykinin metabolism by endothelial angiotensin converting enzyme (see Fig. 2) has yet to be determined. It has been demonstrated that at least part of the vasodilator action of angiotensin converting enzyme inhibitors in certain isolated blood vessels is due to accumulation of bradykinin which stimulates nitric oxide synthesis.

Prostanoids

The endothelium synthesizes thromboxane and the unstable prostaglandin endoperoxides prostaglandin G_2 and prostaglandin H_2. Overproduction of constrictor prostanoids by the endothelium has been implicated in animal models of diabetes and hypertension, but the significance of these findings for human disease remains uncertain.

Superoxide

The superoxide anion (O_2^-) is synthesized within endothelial cells. There are several possible enzymatic sources including co-factor deplete nitric oxide synthase and cyclo-oxygenase. In neutrophils, NADH/NADPH oxidase is the major source of superoxide. Components of this system have been detected in endothelial cells and they are now assumed to be the major site of superoxide generation. Superoxide is usually destroyed by superoxide dismutase, but under certain conditions it seems as though it may act as an endothelium-derived contracting factor or interact with nitric oxide as described above.

Regulation of platelet function and haemostasis

The endothelium synthesizes and releases prothrombotic and antithrombotic factors. However, healthy endothelium presents a thromboresistant surface, indicating that the antithrombotic factors predominate under basal conditions.

Platelets

Endothelial cells inhibit the aggregation and adhesion of platelets, and disaggregate aggregating platelets. Two mediators are of particular importance: nitric oxide and prostacyclin (or prostaglandin E_2 in microvascular endothelium). They act synergistically through different second messenger systems: cyclic guanosine monophosphate for nitric oxide and cyclic adenosine monophosphate for prostacyclin.

Thiols and sulphydryl-containing molecules react with nitric oxide to produce more stable adducts, including nitrosocysteine, nitrosoglutathione, nitrosoalbumin, and even nitrosohaemoglobin. Some of these compounds are formed *in vivo* and may enhance the antiplatelet effects of endothelium-derived nitric oxide. Furthermore, interaction between nitric oxide and tissue plasminogen activator leads to the formation of nitrosotissue plasminogen activator, a molecule with fibrinolytic, antiplatelet, and vasorelaxant properties. It is not yet clear how important these nitric oxide adducts are in human physiology or pathophysiology.

Deficient production of nitric oxide has been implicated in a wide variety of cardiovascular diseases (see above) and abnormalities of prostanoid synthesis occur in experimental models of atherosclerosis and diabetes. In the presence of a quiescent healthy endothelium, loss of basal nitric oxide alone does not lead to significant systemic platelet activation. However, loss of nitric oxide and prostacyclin at sites of endothelial damage, dysfunction, or activation promotes the formation of platelet aggregates and may contribute to thrombosis and vessel occlusion. In animals, stenosed endothelium-denuded vessels lead to cyclical variations in flow as platelets stick to the vessel wall and release vasoactive and proaggregant mediators. If this also occurs in human vessels *in vivo*, it might be an important mechanism of vasospasm and thrombosis.

Under basal conditions the endothelium inhibits platelet activation, but in response to certain stimuli, proaggregant, proadhesive mediators may be synthesized and released. Unstable prostaglandin endoperoxides activate platelets, platelet activating factor may be produced, and von Willebrand factor, which is synthesized and stored within endothelial cells, increases platelet adhesion. These changes occur in response to inflammatory mediators and may also result from repeated endothelial 'injury'.

Coagulation

Heparan sulphate is a glycosaminoglycan closely related to heparin, but less potent, which is found on the surface of endothelial cells. Antithrombin III is also expressed on the endothelial cell surface and together with heparan sulphate provides a mechanism for binding and inactivating thrombin. In addition, endothelial cells participate in the activation of the anticoagulant protein C; protein S is secreted and thrombomodulin is found on the cell surface.

In the quiescent state, expression of anticoagulant factors predominates, but when activated the endothelium may promote coagulation. Receptors for clotting factors appear on the endothelial surface, von Willebrand factor is secreted, and tissue factor—the principal cellular initiator of coagulation—is expressed. Bacterial endotoxin, inflammatory cytokines, and glycosylated proteins activate the endothelium and shift the balance in favour of coagulation. This may occur in response to infection, inflammation, or endothelial injury. Circulating levels of von Willebrand factor are increased in certain patients with diabetes or hypertension.

Fibrinolysis

The endothelial cell surface has a fibrinolytic pathway. Urokinase and tissue plasminogen activator are secreted and there are specific binding sites for plasminogen activators and plasminogen. Thrombin, adrenaline, vasopressin, and stasis of blood may be physiological stimuli for the release of tissue plasminogen activator from human endothelium.

Plasminogen activator inhibitor 1 is also synthesized and bound by endothelium, providing a pathway for local inhibition of the fibrinolytic system. Under basal conditions fibrinolysis is dominant, but the balance may be altered by a variety of local and circulating factors, including inflammatory cytokines and the atherogenic particle lipoprotein (a), which inhibits plasminogen binding and hence plasmin generation. In the presence of atherosclerosis the fibrinolytic properties of endothelium are diminished.

Cellular adhesion

The resting endothelium prevents cells from adhering fully to the vessel wall but allows leucocytes to roll along its surface. The regulation of 'rolling', adhesion, and migration is governed largely by specialized glycoproteins known as cell adhesion molecules, which are expressed in varying amounts on the endothelial cell surface and interact with complementary adhesion molecules on circulating cells. Endothelial-leukocyte adhesion molecule 1 (also known as E-selectin), vascular adhesion molecule 1, intercellular adhesion molecule 1, and P-selectin (also known as GMP 140) are all expressed on cytokine-activated endothelium. The degree of expression and the type of adhesion molecules expressed determines the 'stickiness' of the endothelium for different cell types.

Expression of adhesion molecules is an important mechanism of cellular adhesion during inflammation and is also important in recruitment of T cells and monocytes in atherosclerosis. Increased expression of endothelial-leukocyte adhesion molecule 1 is seen in the coronary arteries of transplanted hearts and has been implicated in the rapid development of atherosclerosis in these vessels. Nitric oxide and prostacyclin inhibit the adhesion of white cells to endothelium and this effect may be mediated by changes in the expression or configuration of adhesion molecules. Certain endothelial cell adhesion molecules are shed into the plasma: changes in their concentration have been detected in a variety of cardiovascular diseases, but the significance of this is uncertain.

Proinflammatory cytokines

Cytokines are released from activated leucocytes in response to infection and immunological stimulation and are also produced by the vessel wall itself; interleukins 1, 6, and 8, and colony stimulating factors are synthesized by endotoxin-stimulated endothelial cells, and tumour necrosis factor by human smooth muscle cells. A large number of cytokines alter endothelial functions, upsetting the balance of vasoactive mediators, altering thrombotic activity and the expression of adhesion molecules, or initiating apoptosis (programmed cell death). Interleukin 1 and certain other proinflammatory cytokines alter the synthesis of nitric oxide (see above) and a variety of prostaglandins, enhance the generation of thrombin, platelet activating factor, von Willebrand factor, and plasminogen activator inhibitor, alter endothelial permeability, increase expression of intercellular adhesion molecule 1 and vascular adhesion molecule 1, and may also cause endothelial cell damage and death. These findings are of direct relevance to the vascular changes occurring in inflammation and sepsis, but might also provide a link between acute or chronic immunological stimulation (for example infection) and the development of cardiovascular disease including atherosclerosis or acute cardiovascular events.

Cell growth and angiogenesis

The endothelium of healthy differentiated vessels inhibits proliferation of the underlying smooth muscle. Endothelium-derived vasodilator, antiplatelet, and antithrombotic mediators (nitric oxide, prostacyclin) tend to inhibit the growth of vascular smooth muscle cells whereas vasoconstrictor and prothrombotic mediators (endothelin, angiotensin) tend to promote it. Thus the basal state of the endothelium, in which dilatation and thromboresistance predominates, also prevents the growth of smooth muscle. The heparin-like molecules prevent cell growth and molecules similar or identical to platelet-derived growth factor and fibroblast growth factor are endothelium-derived growth promoters. Others such as transforming growth factor-b produced by endothelial cells may either inhibit or promote cell growth, and the precise role of this molecule *in vivc* is unclear. The basal antiproliferative effects of the endothelium may retard the development of atherosclerosis and intimal proliferation.

In addition to affecting the growth of underlying smooth muscle, endothelial cells are essential for the formation of new blood vessels. The ability of endothelial cells to initiate the formation of new vessels (angiogenesis and vasculogenesis) is retained in adults, but the only place this occurs physiologically is in the female reproductive tract. However, angiogenesis occurs in a wide range of disease states including atherosclerosis, rheumatoid arthritis, and tumour growth and during wound healing or in response to ischaemia. Positive and negative regulators of angiogenesis have been identified and a wide variety of cytokines, growth factors, and local autacoids can act alone or in concert to promote endothelial cell growth, migration, and tube formation. Of particular interest is vascular endothelial growth factor, a growth factor produced by smooth muscle cells in response to hypoxia, inflammatory cytokines, and certain other growth factors. There is good evidence that vascular endothelial growth factor can promote angiogenesis in a variety of animal models and in humans. Intriguingly, it appears as though vascular endothelial growth factor can increase the production of nitric oxide by endothelial cells and this may be one of the effector molecules mediating some of the actions of this growth factor. In order to form tubes through tissues, endothelial cells must degrade matrix and they are capable of synthesizing and releasing a variety of matrix metalloproteinases. Some of these matrix metalloproteinases may in turn affect endothelial function by regulating cell attachment, proliferation, and migration. Failure of endothelial cells to initiate appropriate angiogenesis in response to ischaemia may lead to tissue hypoxia, whilst excessive or inappropriate angiogenesis may contribute to a sustained inflammatory response in the vessel wall, disrupt vessel wall architecture, or lead to haemorrhage into atherosclerotic plaques.

Transport and metabolism

The endothelium presents a permeability barrier for molecules in the bloodstream. Transfer of molecules from the bloodstream into the vessel wall across the endothelium can occur by transport through the endothelial cells or between them. The junctions between endothelial cells are maintained by specialized molecules, including cadherins, and are actively regulated. Transport between cells occurs when endothelial cells contract to leave intercellular gaps. This is an important mechanism for formation of localized oedema. Transport through cells occurs by transcytosis and is an important mechanism for the passage of certain macromolecules, including insulin. In addition, specialized channels for transport of water have been identified—the aquaporins.

The endothelium is intimately involved in lipid metabolism. Lipoprotein lipase is located on the endothelial cell surface and receptors for low-density lipoproteins are present in varying amounts. In quiescent endothelium lipoprotein lipase is active but there are few low-density lipoprotein receptors, indicating that healthy endothelium provides a barrier for entry of low-density lipoprotein into the vessel wall. However, under conditions in which low-density lipoprotein is taken into the endothelium, modification by oxidation occurs and this step may stimulate atherogenesis.

Therapeutic implications

The balance of mediators produced by quiescent healthy endothelium promotes vasodilatation, inhibits activation of platelets and white cells, prevents thrombosis, prevents the growth of smooth muscle cells, and does not support angiogenesis. However, the endothelium also has the capacity to constrict blood vessels, promote cellular adhesion, initiate thrombosis, stimulate the growth of smooth muscle cells, and initiate the formation of new vessels. Whilst all of these properties of the endothelium may be considered as appropriate in the correct physiological context, the term 'endothelial dysfunction' is usually taken to mean impairment of the usual vasodilator and thromboresistant properties of the endothelium and this seems to be a marker of enhanced atherogenesis and increased cardiovascular risk. Therapeutic implications of endothelial dysfunction are now emerging.

Certain therapeutic interventions cause endothelial damage. Antibodies directed against the endothelium are found after heart transplantation and endothelial dysfunction may contribute to the rapid development of coronary artery disease seen in transplant recipients. Balloon angioplasty leads directly to severe disruption of the endothelium and this has been implicated in the development of postangioplasty vasospasm, thrombosis, and restenosis due to the growth of smooth muscle. Venous coronary artery bypass grafts are more prone to occlusion than arterial grafts, and this may reflect differences between arterial and venous endothelium including reduced basal release of nitric oxide by venous endothelium or differential production of growth factors. Acute disruption of endothelial function may promote vasospasm, thrombosis and occlusion, while chronic changes enhance atherogenesis.

Drugs also affect endothelial function. Nitrovasodilators mimic endogenous nitric oxide: glyceryl trinitrate is metabolized to nitric oxide within the vessel wall while sodium nitroprusside liberates nitric oxide spontaneously. Like the endogenous mediator, certain nitrovasodilators inhibit platelet activation and this may provide an additional mechanism to explain the beneficial effects of these drugs in coronary artery disease. Other drugs of benefit in acute coronary artery disease may also replace endothelial mediators, or restore a healthy balance of mediators released by endothelium and blood-borne cells; heparin mimics heparan sulphate proteoglycans on the cell surface, plasminogen activators replace the endogenous molecule, and low-dose intermittent aspirin preferentially inhibits thromboxane synthesis in platelets while sparing endothelial prostanoid production. Furthermore, angiotensin converting enzyme inhibitors block the breakdown of bradykinin and this mediator stimulates the release of nitric oxide from endothelial cells. Recently it has been demonstrated that oestrogens modify endothelial function and enhance endothelium-dependent vasodilatation. Antioxidants may restore a redox balance within the vessel wall which reduces superoxide levels and protects and stabilizes nitric oxide. In experimental systems fish oils may enhance the generation of antiplatelet prostanoids and increase the generation of nitric oxide. Thus all of these interventions appear to work in part by affecting endothelial function and restoring the usual vasculoprotective balance.

There has been considerable interest in the possibility that the amino acid arginine might have therapeutic utility. Theoretically giving extra arginine should have no effect on the synthesis of nitric oxide since the intracellular concentrations of arginine are far in excess of the amounts needed for nitric oxide synthesis. However, in

practice several studies have shown that arginine supplementation restores endothelium-dependent relaxation towards normal in patients with certain conditions including hypercholesterolaemia and some types of renal failure. The discrepancy between biochemical theory and experimental observation is known as the 'arginine paradox'. Improvement of endothelium-dependent relaxation is a surrogate end-point of uncertain significance and clinical trials of the effects of arginine on clinically relevant end-points are currently under way.

A greater understanding of the normal protective functions of vascular endothelium and how these are altered by disease is bound to lead to therapies designed to modify endothelial function. New drugs based on nitric oxide, endothelin, adhesion molecules, and growth factors are in development and likely to enter clinical practice, and seeding of genetically altered endothelial cells on to blood vessels or genetic manipulation of the expression of enzymes that generate key endothelial mediators is a possibility. Indeed gene transfer experiments with endothelial nitric oxide synthase and vascular endothelial growth factor have already shown promise in studies in animals and appear to be technically feasible in humans.

15.1.1.3 Vascular smooth muscle cells

Peter L. Weissberg

Introduction

Normal human arteries comprise an intima made up of a single layer of endothelial cells and a few underlying vascular smooth muscle cells, separated from the tunica media by an internal elastic lamina. The media comprises only vascular smooth muscle cells and elastic lamellae arranged circumferentially. The number of layers of vascular smooth muscle cells varies, being fewest in small arterioles and greatest in large arteries like the aorta. On the outer boundary of the media is the external elastic lamina that separates the medial vascular smooth muscle cells from the adventitia containing connective tissue, small blood vessels (the vasa vasora), nerves, and adventitial myofibroblasts. The main function of the medial vascular smooth muscle cells is to contract and relax in response to exogenous stimuli, thereby altering the calibre of the arterial lumen and regulating vascular tone. However, unlike cardiac and skeletal myocytes, which are terminally differentiated and can only perform a contractile role, mature vascular smooth muscle cells are highly reactive and can respond to changes in their extracellular environment by dramatic alterations in gene expression, a process often referred to as phenotypic modulation. Thus vascular smooth muscle cells have the ability to migrate and proliferate and to change from a contractile cell to one that produces large quantities of extracellular matrix and other proteins (Fig. 1). This phenotypic plasticity means that vascular smooth muscle cells can play multiple roles in the pathogenesis and progression of vascular disease.

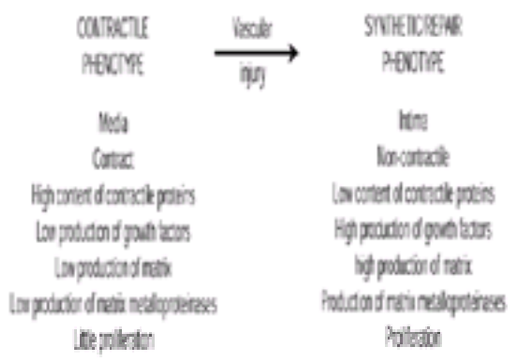

Fig. 1 Characteristics of vascular smooth muscle cell phenotypes.

Vascular development

The versatility of the vascular smooth muscle cell is best exemplified during vascular development. Most of what is understood about this process comes from observations in developing rodents, in particular rats and mice, where the vascular smooth muscle cell is the main cell responsible for vessel growth and development. Blood vessels begin to develop in very early fetal life as endothelial tubes that recruit cells from the surrounding tissues to form the vascular smooth muscle cells of the vessel media. Vascular smooth muscle cells in some vessels are derived from mesoderm and in others from neural crest tissue or both under the influence of local morphogens. It still remains to be determined whether the heterogeneous origin of vascular smooth muscle cells in different arteries has any influence upon development of disease, and in particular the propensity of some, particularly the coronary arteries, to develop atherosclerosis.

Expression of smooth muscle specific genes is first detectable in early fetal development, implying an early commitment to muscle development, but expression of contractile proteins remains low until well after birth. During late fetal and very early neonatal development vascular smooth muscle cells proliferate in the media as the vessels grow. However, shortly after birth, the proliferation of vascular smooth muscle cells decreases rapidly and thereafter vessel growth is achieved by a combination of vascular smooth muscle cell hypertrophy (enlargement) and, particularly, accumulation of extracellular matrix. As blood pressure increases after birth there is an increase in expression of the contractile proteins required to regulate vascular tone, such as smooth muscle myosin heavy chain and actin, and a corresponding decrease in production of matrix and basement membrane proteins. Thus, mature vascular smooth muscle cells in the adult vascular wall undergo little if any proliferation, contain abundant myofilaments, and produce only small amounts of extracellular matrix proteins. This 'contractile' phenotype is maintained thereafter by the combined influences of mechanical forces and extracellular matrix components, particularly sulphated proteoglycans and basement membrane proteins, which signal into the cell and dictate gene expression via receptors on the vascular smooth muscle cell surface.

Vascular smooth muscle cell phenotype

When adult vascular smooth muscle cells are removed from their extracellular environment and placed in cell culture, they immediately reduce production of contractile proteins and increase production of matrix proteins, in particular collagen and elastin. This change from a contractile phenotype to what has been called a 'synthetic' phenotype is characterized ultrastructurally by loss of contractile myofilaments and a dramatic increase in synthetic organelles. The cells also become more responsive to growth factors and gain the ability to take up lipids and to elaborate matrix-degrading enzymes (Fig. 1). This phenotypic change does not occur if the cells are maintained in a medium containing proteoglycans and basement membrane proteins that mimic their natural extracellular environment in the vessel wall, indicating that vascular smooth muscle cells posses an inherent tendency to 'default' to a phenotype resembling that of the developing vessel if not actively stimulated to do otherwise.

Electron microscopic studies have shown that intimal vascular smooth muscle cells in atherosclerosis contain a higher proportion of synthetic organelles and fewer myofilaments than medial vascular smooth muscle cells and therefore resemble the synthetic phenotype observed in cell culture. These observations contributed to the emergence of the 'response to injury' hypothesis of atherosclerosis, initially proposed in the 1960s and still widely quoted today. This hypothesis proposed that the initiating event in atherosclerosis was endothelial cell loss or injury leading to local platelet aggregation and recruitment of vascular smooth muscle cells into the intima where a switch to the synthetic phenotype facilitated proliferation and accumulation of lipids to form the atherosclerotic lesion. This paradigm therefore portrayed the vascular smooth muscle cell as being central to the initiation and maintenance of the atherogenic process, a view reinforced by the contemporaneous suggestion that restenosis after angioplasty was due to excessive proliferation of intimal vascular smooth muscle cells. However, over the past 20 years this view of the role of vascular smooth muscle cells has changed completely, such that vascular smooth muscle cells are now considered to be the main cell type in the plaque protecting against the thrombotic complications of atherosclerosis.

The response of the vascular smooth muscle cell to injury

When the intima of an artery is damaged, for example by a balloon catheter, there is a wave of DNA synthesis in medial vascular smooth muscle cells which is quickly followed by migration of vascular smooth muscle cells into the intima where they change phenotype to form a neo-intima comprising vascular smooth muscle cells and their extracellular matrix (Fig. 2). It remains unclear whether the neo-intimal population of vascular smooth muscle cells is derived directly from contractile medial vascular smooth muscle cells or arises from a clonal expansion of a small subpopulation of vascular smooth muscle cells with inherently different properties from normal adult medial cells. It is also possible that adventitial myofibroblasts may also migrate into the intima to contribute to neo-intima formation. The resulting endothelialized neo-intima 'heals' the damage and may be sufficiently large to narrow the vessel lumen, as occurs in restenosis following therapeutic balloon

angioplasty.

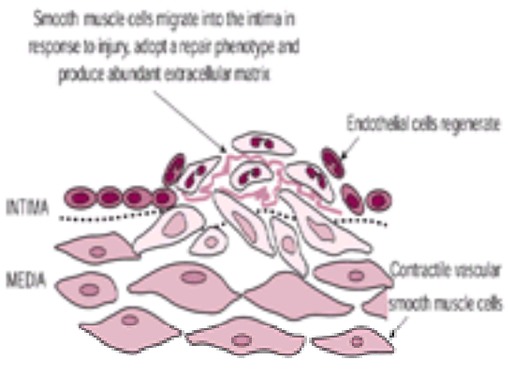

Fig. 2 The response of vascular smooth muscle cells to mechanical intimal damage.

Vascular smooth muscle cells in atherosclerosis

The recent recognition that atherosclerosis is an inflammatory process driven by the interaction between oxidized lipids and reactive inflammatory cells has brought about a complete re-evaluation of the role of vascular smooth muscle cells in its pathogenesis. Intimal vascular smooth muscle cells protect against plaque rupture and therefore the thrombotic consequences of atherosclerosis by migrating into the intima and changing phenotype to elaborate the matrix components of the all-important fibrous cap. Indeed, vascular smooth muscle cells are the only cells capable of making the fibrous cap, such that loss of vascular smooth muscle cells from the cap is one of the major determinants of plaque rupture. By reverting to a phenotype very similar to that of vascular smooth muscle cells in the neonatal blood vessel, they are adopting a beneficial 'repair' phenotype, in which the genes they express facilitate their reparative role. When reacting to either mechanical injury or the chemotactic influence of inflammatory cells they synthesize plasminogen activators and matrix metalloproteinases. These interact to digest the basement membrane of the vascular smooth muscle cells and thereby allow the vascular smooth muscle cells to migrate into the intima to form the fibrous cap by a combination of proliferation and matrix production, the latter being predominant (Fig. 3).

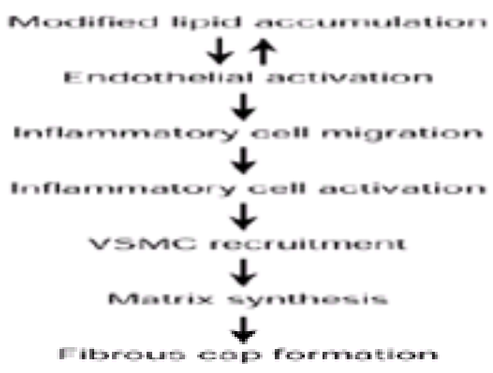

Fig. 3 Events leading to formation of the protective fibrous cap in atherosclerosis.

A paucity of vascular smooth muscle cells in the fibrous cap predisposes the lesion to plaque rupture. Vascular smooth muscle cells can be destroyed by inflammatory cells within the lesion, as discussed later in this chapter. Also, intimal vascular smooth muscle cells lose their capacity to regenerate and become highly susceptible to spontaneous 'suicide' by apoptosis (programmed cell death). Unless senescent vascular smooth muscle cells are replaced by those that are active, the capacity to repair and maintain the fibrous cap is lost, thereby tipping the balance in favour of plaque rupture. Indeed, senescence could be a feature of all vascular smooth muscle cells as they get older, possibly explaining why plaque rupture, leading to heart attacks and strokes, occurs increasingly frequently with age.

Atherosclerosis does, therefore, involve the response of vascular smooth muscle cells to injury, but it is not an initiating event, rather it is secondary to, and protective against, the destructive lipid-driven inflammatory process that leads to plaque instability, thrombosis, and patient death. However, vascular smooth muscle cells do contribute to some extent to plaque progression in as much as the formation of a new fibrous cap over a subclinical erosion or rupture necessarily increases the size of the lesion.

The role of vascular smooth muscle cells in restenosis

In approximately 30 to 40 per cent of patients undergoing successful balloon angioplasty for symptomatic coronary disease, symptoms will return because of restenosis at the site of the procedure. Initially this was thought simply to be due to excessive proliferation of intimal vascular smooth muscle cells in response to the injury. However, it has now become apparent that several factors in addition to the proliferation of vascular smooth muscle cells contribute to restenosis in man. Firstly, there is the early elastic recoil of the vessel wall that occurs soon after the balloon has been removed. Secondly, there is less vascular smooth muscle cell proliferation than anticipated from animal models and the bulk of the neo-intima comprises relatively few vascular smooth muscle cells scattered throughout an abundant extracellular matrix. Thus the production of vascular smooth muscle cell matrix is probably more important than the proliferation of vascular smooth muscle cells in determining neo-intimal bulk. Thirdly, eventual lumen diameter is determined by the capacity of the vessel to remodel. Angioplasty induces a vigorous adventitial response characterized by proliferation of adventitial myofibroblasts: these also express smooth muscle cell genes and synthesize a dense extracellular matrix that splints the vessel and prevents outward remodelling. As mentioned above, these cells may also migrate through the damaged media and contribute to the formation of neo-intima. Most of these consequences of balloon angioplasty can be abrogated by the deployment of an intravascular stent that prevents elastic recoil and negative remodelling. Although proliferation of intimal vascular smooth muscle cells and matrix synthesis still occur in stented vessels, their impact on the final diameter of the lumen is offset by the initial gain in diameter achieved by balloon dilatation and maintained by the stent (Fig. 4).

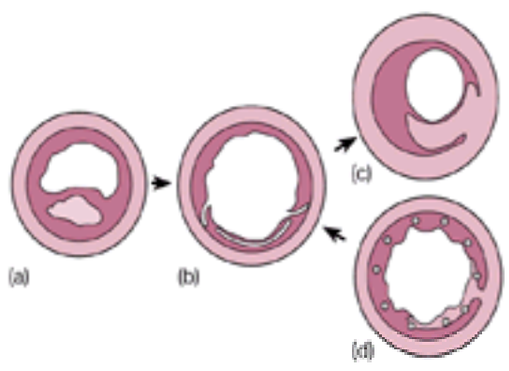

Fig. 4 Restenosis after balloon angioplasty. (a) Stenotic atherosclerotic lesion before angioplasty. (b) Lesion immediately after angioplasty showing expansion of the whole artery with fissuring through the media into the adventitia. (c) Restenosis occurs because of formation of neo-intima in response to balloon injury. The neo-intima arises in part through medial smooth muscle cell proliferation and matrix synthesis and invasion of adventital myofibroblasts. Note also that the adventitia has thickened and in effect 'splints' the vessel, preventing outward remodelling to compensate for the formation of neo-intima. The net result is lumen narrowing and restenosis. (d) Stent deployment after balloon dilatation prevents elastic recoil and negative remodelling induced by the adventitial response. Although there is still

neo-intima formation it is insufficient to induce significant lumen narrowing.

Summary

The vascular smooth muscle cell is highly adaptable and can serve multiple roles. In the normal vessel wall it acts principally as a contractile cell. However, in response to any form of vascular insult it rapidly assumes a wound-healing role and expresses the repertoire of genes necessary to repair the vessel wall. In the context of the chronic inflammatory stimulus of atherosclerosis, this response creates the protective fibrous cap responsible for conferring stability to the plaque and preventing plaque rupture. Following balloon angioplasty the reactive vascular smooth muscle cells act primarily to 'heal' the damage caused by the balloon. In so doing, they create a neo-intima that stabilizes the lesion but which may also cause restenosis if adequate compensatory remodelling does not occur.

15.1.2.1 The pathogenesis of atherosclerosis

R. P. Naoumova and J. Scott

Introduction

Atherosclerosis, the underlying cause of heart attacks, strokes, and peripheral vascular disease, is one of the major killers in the world. The disease develops slowly over many years in the innermost layer of large and medium-sized arteries. It does not usually manifest before the fourth or fifth decade of life, but may strike with devastating suddenness. At least 30 per cent of individuals die from their first heart attack. In England and Wales coronary heart disease accounts for 31 per cent of all deaths in men and 23 per cent of all deaths in women, and morbidity from the disease is significant, with a profound impact on health-care services and on the industrial economy.

Epidemiology

The demonstration of coronary heart disease in an individual is taken as a reliable index of the presence of more general atherosclerosis. The highest death rates from coronary heart disease are found in Britain, northern Europe, the United States, Australia, and New Zealand. Deaths from coronary disease rose dramatically after the First World War, peaked in the late 1960s in the United States, and have since declined. In western Europe this peak and decline lagged behind the United States by some 10 years. Changes in diet, exercise, smoking, and affluence account for much of this decline. Better medical and surgical interventions have also been important. By contrast, the countries of eastern Europe and the former Soviet Union are showing a marked increase in the prevalence of coronary heart disease. This can be attributed to the influence of the risk factors that operate in the industrialized West (Table 1). Substantially lower death rates are found in southern Europe, Latin America, Japan, and China. For further discussion see Chapter 15.4.1.2.

The lesions of atherosclerosis

Autopsy studies show that in humans atherosclerosis begins in early life and develops slowly over many years (Fig. 1) before becoming symptomatic. Atherosclerosis is a focal intimal disease of arteries ranging in size from the aorta down to those of approximately 3 mm external diameter. The arteries most commonly involved with atherosclerosis include the aorta, coronaries, carotid, cerebral, and femoral. Branch points and curvatures, the sites of blood turbulence, favour the development of atherosclerotic lesions.

The earliest lesions of atherosclerosis are fatty streaks. These consist of an accumulation of lipid-engorged macrophages (foam cells), and T lymphocytes in the arterial intima. The fatty streaks progress to intermediate lesions (or transitional plaque), composed mainly of macrophage foam cells and smooth muscle cells which migrate into the intima from the media. With time these develop into raised fibrous (advanced) plaques, characterized by a dense fibrous cap of connective tissue and smooth muscle cells overlying a core containing necrotic material and lipid, mainly cholesteryl esters, which may form cholesterol crystals on histological section. The necrotic core is a result of apoptosis and necrosis, increased proteolytic activity and lipid accumulation. Fibrous plaques also contain a large number of macrophage foam cells, T cells, and smooth muscle cells. This collection of cells, surrounding the necrotic core, promotes plaque growth. The plaque undergoes vascularization and microvessels develop in connection with the artery's vasa vasorum. The new vessels provide a channel for the access of inflammatory cells and may also lead to intraplaque haemorrhage and thus weaken the plaque. Advanced atherosclerotic plaques frequently accumulate calcium, due to the presence of proteins specialized in binding calcium (osteocalcin, osteopontin, bone morphogenic proteins).

The advanced plaque is the substrate from which the complicated plaque develops, leading almost inevitably to clinical symptoms. The complicated plaque has a thin cap, especially at the shoulders or margins of the lesion, and may contain ulcerations, fissures, erosions, or cracks. These provide sites of platelet adherence, aggregation, and thrombosis. The thin fibrous cap may break or tear leading to haemorrhage into the necrotic core and thrombosis.

Arterial remodelling and clinical syndromes associated with atherosclerosis

Arterial remodelling is a clinically important feature in the evolution of the atherosclerotic lesion. It delays the development of significant luminal narrowing and is a compensatory process in human atherogenesis. During early phases of plaque formation the lesion grows away from the lumen, so affected vessels increase in diameter (compensatory enlargement) and the plaque will not cause flow-limiting stenosis. Most plaques of this type will not be visible angiographically.

When the plaque covers more than 40 per cent of the elastic lamina, the artery cannot compensate by dilatation and the lesion begins to intrude into the arterial lumen, becoming angiographically detectable. It may impede the blood flow to an organ, giving rise to ischaemia, the symptoms of stable angina, and intermittent claudication. If the atherosclerotic lesion undergoes superficial erosion of the endothelium with limited thrombosis, this may result in unstable angina or myocardial infarction, even when the lesion is not flow limiting. Deep fissuring or frank rupture of the plaque with complete sudden occlusion of coronary arteries may cause myocardial infarction or sudden death. In the cerebral circulation, the same process causes transient ischaemic attacks and completed stroke. In arteries weakened by the ageing process and complicated by atherosclerosis, aneurysmal dilatation and rupture may occur.

Plaque stability and plaque rupture

Rupture of atherosclerotic lesions can trigger the thrombosis that precipitates clinical events. However, plaques have different propensities to rupture. Plaques with dense extracellular matrix, relatively thick fibrous caps, and limited lipid cores are generally unlikely to initiate thrombosis followed by an acute vascular event.

Culprit lesions, causing myocardial infarction or unstable angina, characteristically have thin fibrous caps, large cores of extracellular lipids, and an abundance of macrophages and T lymphocytes at the site of plaque rupture. Plaques usually contain limited numbers of smooth muscle cells, leading to decreased synthesis of extracellular matrix and weakening of the plaque's fibrous cap. The integrity of the fibrous cap is also attacked by cytokines derived from activated macrophages, which can promote the expression of proteinases that can degrade the extracellular matrix. Plaque rupture usually occurs at the 'shoulders' of the plaque.

Angiography cannot accurately predict the stability of a lesion.

The pathogenesis of atherosclerotic lesions

Atherosclerosis develops as a healing response of the intima to repeated vascular wall injury, where risk factors (Table 1) operate by promoting chronic cycles of damage and repair. In the broadest terms, atherosclerosis is now recognized to be a chronic inflammatory process.

Endothelial dysfunction is the first step in the development of atherosclerosis. Modified low-density lipoprotein, toxins in tobacco smoke, the shear stress of hypertension, elevated plasma homocysteine concentrations, diabetes mellitus, and infectious micro-organisms can all cause dysfunction of endothelial cells. The dysfunctional endothelium undergoes a protective response that alters normal homeostatic properties due to expression of adhesion molecules, growth-promoting substances, and activation of the blood coagulation cascade. Monocytes and T lymphocytes adhere to the activated endothelium, become activated, and produce growth factors, cytokines, and chemoattractants. Adherent white blood cells migrate into the arterial intima and smooth muscle cells are recruited from the media into the intima. With repeated rounds of injury and repair, palisades of smooth muscle cells, matrix proteins, lipid-laden macrophages, and T lymphocytes accumulate to form atherosclerotic plaques (Fig. 1).

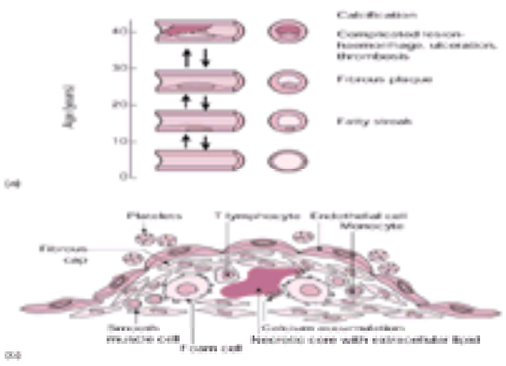

Fig. 1 (a) Natural history of atherosclerosis. (Reprinted with permission from McGill HC Jr, *et al.* In: Sandler S and Bourne N, eds. *Atherosclerosis and its origin*, Academic Press, New York, 1963). (b) Schematic diagram of an advanced atherosclerotic lesion. As fatty streaks progress to advanced lesions, they form a fibrous cap due to migration and proliferation of smooth muscle cells. This represents a type of healing response to injury. The cap covers a mixture of foam cells, T lymphocytes, lipids, and debris, forming a necrotic core—the result of apoptosis and necrosis.

Low-density lipoprotein has a central role in the pathogenesis of atherosclerosis. It may enter the intima through the damaged endothelium or, more commonly, by transcytosis across the intact endothelium, becoming 'trapped' in the subendothelial space. There, low-density lipoprotein undergoes low-grade modification by oxidative free radicals, secreted by cells of the artery wall, forming minimally modified low-density lipoprotein (Fig. 2). Although still recognized by the low-density lipoprotein receptor, minimally modified low-density lipoprotein can stimulate the release of macrophage colony-stimulating factor and monocyte chemoattractant protein 1 from endothelial cells: these facilitate monocyte recruitment and their differentiation into tissue macrophages. Minimally modified low-density lipoprotein adheres to matrix proteins of the arterial wall, where it undergoes more extensive oxidation. Free radicals are produced from macrophages and from nitric oxide derived from endothelial cells. This is compounded by the products of tobacco smoke and by homocysteine. Highly oxidized/modified low-density lipoprotein is characterized by changes not only of the lipid but also of the protein portion of low-density lipoprotein, leading to loss of recognition by the low-density lipoprotein receptor. Thus oxidized low-density lipoprotein becomes the major ligand for the scavenger receptor family (scavenger receptor A, scavenger receptor B, and others), expressed in the macrophages accumulating at the site of the injury to the vessel wall. This shift in receptor recognition leads to uptake of oxidized low-density lipoprotein by receptors, not regulated by the cholesterol content of the cell. The result is massive accumulation of cholesteryl esters in the macrophages, giving the cytoplasm its characteristic foamy appearance and transforming the macrophage into a foam cell.

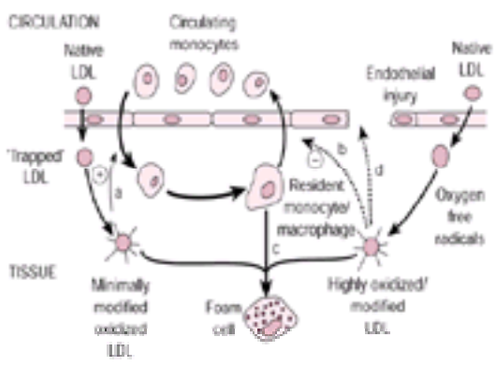

Fig. 2 Oxidation of low-density lipoprotein. The figure shows the mechanisms by which oxidized low-density lipoprotein contributes to atherosclerosis. (a) Oxidized low-density lipoprotein is chemotactic for circulating monocytes. (b) Oxidized low-density lipoprotein inhibits the movement of resident macrophages out of the arterial intima. (c) Resident macrophages generate free radicals and contribute to production of oxidized low-density lipoprotein, leading to the generation of foam cells. (d) Oxidized low-density lipoprotein is cytotoxic and this leads to endothelial cell damage and loss of integrity. (Reproduced from Quinn MT *et al*. (1987). Oxidatively modified low density lipoproteins: a potential role in recruitment and retention of monocyte/macrophages during atherogenesis. *Proceedings of the National Academy of Sciences of the United States of America* **84**, 2995–8, with permission.)

Hypertension accelerates atherogenesis by activating genes in response to increased sheer stress, the products of which perturb vascular tone and promote the accumulation of smooth muscle cells. Hypertension also increases the formation of hydrogen peroxide and free radicals that worsen oxidative damage, reduces the formation of nitric oxide by the endothelium, and increases leucocyte adhesion. In diabetes mellitus hyperglycaemia may promote non-enzymatic glycation of low-density lipoprotein, which may initiate atherosclerosis in the same way as oxidatively modified low-density lipoprotein. A high plasma homocysteine concentration is toxic to endothelium, decreases the availability of nitric oxide, and has prothrombotic activity.

The cells of the atherosclerotic plaque

Endothelial cells

In the earliest stages of atherogenesis, damaged endothelial cells become dysfunctional. Sloughing of the endothelium occurs at a later stage, when plaques become complicated and split or fissure. Dysfunctional endothelial cells produce growth factors, cytokines, chemoattractants, clotting factors, and adhesion molecules. The result is recruitment and transformation of monocytes into macrophages, and recruitment and proliferation of smooth muscle cells and T cells. Thrombotic processes are activated. There is chronic alteration of vascular tone as a result of disordered nitric oxide production and signalling.

Monocyte/macrophages

The lipid-laden macrophage is the hallmark of atherosclerosis and is instrumental in its development. Monocyte conversion from a quiescent cell to a phagocytically active macrophage is associated with expression of scavenger receptors and oxidized low-density lipoprotein receptors which avidly take up highly oxidized low-density lipoprotein, the latter no longer being recognized by the low-density lipoprotein receptor. The cholesteryl ester released from low-density lipoprotein is

broken down in lysosomes and re-esterified in the cytoplasm.

Activated macrophages secrete a wide variety of growth-modulating substances and chemoattractants. Phagocytic macrophages produce free radicals and are induced to produce nitric oxide, which generates free radicals, promoting further oxidative damage to low-density lipoproteins (Fig. 2). Macrophages also secrete proteolytic enzymes (collagenase, elastase, stromelysin, and gelatinases): these contribute to the necrosis and liquefaction of the core of advanced fatty plaques and also render the plaque prone to rupture by thinning the fibrous cap.

Vascular smooth muscle cells

Smooth muscle cells in the walls of normal arteries mainly contain contractile proteins, such as actin and myosin, and are said to display a contractile phenotype. They respond to vasoregulatory substances—catecholamines, angiotensin II, prostaglandins, leukotrienes, endothelin, nitric oxide, and other regulatory compounds. However, under the influence of proinflammatory cytokines and growth factors, smooth muscle cells in the atherosclerotic plaque switch from a contractile to a secretory phenotype and produce extracellular matrix. In the media of normal arteries, the matrix consists of types I and III collagen, whereas in the atherosclerotic lesion it comprises largely proteoglycans, intermixed with loosely scattered collagen fibrils. The local release of growth factors, cytokines, and chemoattractants leads to autocrine and paracrine effects on growth and cell recruitment. Smooth muscle cells also express scavenger receptors and they, too, become lipid-loaded.

T lymphocytes

T cells (both CD4 and CD8) are present in the atherosclerotic lesion in all stages of the process. These are activated when they bind antigen processed and presented by macrophages, resulting in the secretion of proinflammatory cytokines, including interleukin 1, interferon-g, and tumour necrosis factor a and b, which amplify the inflammatory response and compound the atherosclerotic process by attracting further macrophages and T lymphocytes and perpetuating endothelial cell activation. T cells in the plaque become sensitized to new antigens in the lesion, such as modified low-density lipoprotein.

Platelets

Platelets undergo activation in response to agonists such as thrombin, ADP, adrenaline, and platelet activating factor. When activated, platelets release their granules, containing cytokines and growth factors. The activation is also triggered when peripheral blood is exposed to thrombogenic agents at the site of blood vessel damage. Here agonists such as collagen present in the extracellular matrix, exposed in the subendothelium along with von Willebrand factor and fibrinogen produced at the wound site, initiate the cascade of events that leads to platelet aggregation and the formation of a platelet plug. In this process platelet-specific integrins act as receptor tyrosine kinases (glycoprotein, GP IIb/IIIa), initiating the intracellular changes that mediate platelet activation and aggregation, and later the binding to fibrin and clot retraction.

Molecular and cell interactions

The formation of the atherosclerotic plaque is brought about by a complex series of cellular and molecular interactions. Substances expressed at the cell surface and secreted in response to cellular activation bring about these events. Intracellular co-ordinating mechanisms, such as the NF_B system, operate at the site of the lesion. NF_B is a ubiquitous transcription factor that can be activated by diverse proatherogenic stimuli and provides a potential common link to co-ordinate the expression of series of genes involved in atherogenesis.

Growth factors

Molecules controlling the proliferation of smooth muscle cells include platelet-derived growth factor, fibroblast growth factor, heparin-binding epidermal growth factor, insulin-like growth factor I, interleukin 1, tumour necrosis factor-a, transforming growth factors a and b, thrombin, and angiotensin II.

Platelets contain platelet-derived growth factor and other growth regulatory substances, such as epidermal growth factor, transforming growth factors a and b, insulin-like growth factor I, and thromboxane, which are released during platelet aggregation and activation. Platelet-derived growth factor is also produced from activated endothelial cells and secretory smooth muscle cells in response to the macrophage cytokines interleukin 1, tumour necrosis factor-a, and transforming growth factor-b. Fibroblast growth factor, the other potent mitogen for vascular smooth muscle cells, also has mitogenic activity for endothelial cells. Heparin-binding epidermal growth factor is a potent growth factor and chemoattractant for smooth muscle cells only. Transforming growth factor-b is a multifunctional cytokine, expressed with its receptor system on smooth muscle cells. It is a potent inhibitor of mitosis of smooth muscle cells and also stimulates elaboration of matrix proteins such as fibronectin and vascular collagen.

Vascular endothelial cell growth factor is a potent and specific mitogen for endothelial cells and also promotes permeability of small veins and venules. It is produced by endothelial cells and macrophages in response to ischaemia and acts as a potent chemoattractant for macrophages, also inducing endothelial cells to produce collagenase as well as urokinase-type plasminogen activator, tissue plasminogen activator, and their inhibitor plasminogen activator inhibitor 1.

Cytokines

Cytokines are multipotent mediators of inflammation and immunity with generalized action in host defence and pathology. They can affect key functions of vascular wall cells and may participate as autocrine and paracrine mediators in atherogenesis.

The cytokines interleukin 1, interleukin 2, tumour necrosis factor-a, g-interferon, and granulocyte–macrophage and macrophage colony stimulating factors are secreted from macrophages, T lymphocytes, activated endothelial cells, and secretory smooth muscle cells. Interleukin 1, tumour necrosis factor-a, and transforming growth factor-b induce endothelial cell activation, with the release of mitogens and chemoattractants for smooth muscle cells, and activate the coagulation cascade. Colony stimulating factors attract further inflammatory cells. Cytokines can also inhibit the proliferation of smooth muscle cells, and thus may either promote or retard atherogenesis.

Chemokines (chemoattractants)

Chemokines are members of a superfamily of small polypeptides that share the ability to induce migration, growth, and activation of subsets of leucocytes and other cells present in atherosclerotic lesions. They are also involved in regulating angiogenesis at inflammatory sites of the atherosclerotic plaque. More than 30 human chemokines have been identified. Interleukin 8 acts predominantly on neutrophils; monocyte chemoattractic protein 1 acts on lymphocytes, monocytes, mast cells, and eosinophils; whereas lymphotactin acts solely on lymphocytes. Chemokines mediate their actions via specific cell surface receptors, members of the seven transmembrane-spanning G-protein-linked molecules.

Adhesion molecules

Dysfunctional endothelial cells undergo activation, with the production of cell surface proteins that mediate the adherence of inflammatory cells. This inductive process is mediated by cytokines. The adhesion molecules induced include E-selectin, which is a membrane glycoprotein specific to endothelial cells that mediates the adhesion of neutrophils. It is a member of the selectin gene family, which also includes L-selectin and P-selectin. These molecules are implicated in the initial 'rolling step' of leucocyte extravasation.

Vascular cell adhesion molecule 1 is induced on endothelial cells by interleukin 1, tumour necrosis factor-a, lipopolysaccharide, and oxidized low-density lipoprotein. Vascular cell adhesion molecule 1 binds cells expressing integrins a4b1 (VLA4), such as monocytes and lymphocytes, but not neutrophils. Another adhesion molecule is intercellular adhesion molecule 1, a receptor for integrins, which binds all leucocytes. Thus vascular cell adhesion molecule 1 and intercellular adhesion molecule 1 serve to anchor activated leucocytes after the initial 'rolling step'.

Platelet endothelial cell adhesion molecule exists at the tight junctions of endothelial cells and is required for the transmigration of neutrophils and monocytes and for platelet adhesion.

Matrix proteins

Smooth muscle cells that have taken on a secretory phenotype are the primary source of extracellular matrix. Matrix proteins comprise collagens, elastin, proteoglycans, and microfibrillar protein. Their production is controlled by interleukin 1, tumour necrosis factor-a, and transforming growth factor-b, which mediate the switch between proliferative and secretory smooth muscle cell phenotypes, whereas g-interferon suppresses collagen expression.

In the normal artery both synthesis and degradation of matrix are very slow, whereas atherosclerosis and injury lead to increased synthesis of many matrix proteins. The degree of ongoing matrix degradation is a highly controlled and essential component of the homeostasis of the normal artery. Increased matrix degradation, due to high activity of proteases in the plaque, is common in unstable atherosclerotic lesions. Ageing is associated with a reduction of elastin in the extracellular matrix, leading to hardening of the arteries.

Cellular death

Advanced fibrous caps that have ruptured have twice as many macrophages, but only half as many smooth muscle cells, as unruptured fibrous caps. The relative decrease in the number of smooth muscle cells may result from growth inhibition due to g-interferon or cellular death from lytic injury and necrosis. Recent studies show that smooth muscle cells of the atheromatous plaque undergo programmed cell death, apoptosis.

Coagulation factors

The activation of endothelial cells initiates cell-surface assembly of the prothrombinase complex and subsequent deposition of fibrin and platelet activation. The process is initiated by plasma membrane expression of tissue factor, which activates factor VIIa and, in turn, factors IX and X. Thrombin is generated in the presence of endothelial cell factor V. Thrombin contributes to the inflammatory response by induction of the adhesion molecule P-selectin and platelet activating factor. Platelet arachidonic acid is released by activity of phospholipase C and phospholipase A2. The enzyme cyclo-oxygenase generates platelet endoperoxides, and the enzyme thromboxane synthase generates thromboxane, which in turn increases phospholipase C activity, stimulating platelet activation and degranulation. Together these substances promote neutrophil and platelet adhesion. Thrombin also induces plasminogen activator inhibitor 1, and increases tissue factor synthesis and expression of platelet-derived growth factor. E-selectin is induced and serves as a site for leucocyte attachment. Thus the control of coagulation by cytokines closely mimics that of the inflammatory response, indicating the interdependence of the two processes.

Restenosis

Surgical treatment of arteries narrowed by atherosclerosis is by arterial or venous bypass grafting or endarterectomy. Medical treatment is by percutaneous transluminal balloon angioplasty. Immediate complications of this procedure are thrombosis and arterial wall dissection. There is also a high failure rate due to restenosis of the arterial lumen (30–40 per cent within 3–6 months).

Restenosis is a complex reparative process involving the following sequence of events after angioplasty: recoil, remodelling, mural thrombus formation with subsequent organization by connective tissue, followed by smooth muscle cell activation, migration, proliferation, and increased synthesis of extracellular matrix. Growth factors originating from the thrombus, vessel wall, and circulating cells contribute to these events. After 2 to 6 months the stenotic region becomes organized and consists of a maturing scar, but little thrombus or lipid. The NF_B pathway plays a central role in triggering the transcription of genes encoding leucocyte adhesion molecules, chemokines, and enzymes that can influence extracellular martix metabolism, leading to restenosis. Satisfactory regimens for the prevention of restenosis have yet to be established.

Transplant atherosclerosis

Cardiovascular disease is emerging as the major cause of late morbidity and mortality in transplant patients, accounting for 45 per cent of deaths in renal transplant recipients and being the major factor limiting survival of cardiac allografts.

Recipients of organ transplant often have multiple classical risk factors before transplantation and contributing to accelerated atherosclerosis afterwards (Table 1). Immunosuppressive agents such as prednisolone and cyclosporine have adverse effects on lipid metabolism, whereas tacrolimus (FK506) affects lipid metabolism to a lesser extent. Cytomegalovirus infection and abnormal platelet aggregation also contribute to accelerated atherogenesis.

Specific immunological factors contribute to the development and progression of transplant atherosclerosis, especially in the accelerated form of coronary arteriopathy that plagues heart transplant recipients.

Future perspectives

Despite changes in lifestyle and the use of potent lipid-lowering agents, cardiovascular disease continues to be the major cause of death in western Europe and North America. Furthermore, end-point clinical trials using statins show at best a 30 per cent decrease in total mortality, with a 42 per cent decrease in coronary deaths. Clearly new therapeutic targets need to be pursued.

Serum levels of high-density lipoprotein cholesterol are inversely related to coronary heart disease. Reduced levels of high-density lipoprotein are found in half of the patients with coronary heart disease. The discovery of the pivotal role of the *ABC1* transporter gene, encoding the cholesterol-efflux regulatory protein, in the generation of high-density lipoprotein provides opportunities for new drug targets.

Better understanding of the pathogenesis of the initiation, progression, and complications of atherosclerotic lesions will provide new potential therapeutic approaches, different from plasma lipids. An understanding of the central role of oxidized low-density lipoproteins and of the macrophage in the pathogenesis of atherosclerotic lesions points to a new direction for prevention and treatment—antioxidants.

Since atherosclerosis is a multigenic disease, understanding the patterns of gene expression will shed light on differences in susceptibility to agents causing disease, on genetic variability in prediction of risk and response to therapy, and may provide clues for designing new therapeutic approaches.

15.1.2.2 The haemostatic system in arterial disease

T. W. Meade, P. K. MacCallum, and G. J. Miller

Introduction

General recognition of the thrombotic component in arterial disease, particularly coronary heart disease, is comparatively recent. The term 'coronary thrombosis' appears to have first been used by Herrick very early in the 1900s and it continued to be used until coronary heart disease became the preferred terminology after the Second World War, when the condition had reached epidemic proportions.

Epidemiological studies which started in the late 1940s—the work in the community of Framingham being the best known—began to establish the characteristics of those at particular risk of heart attacks. The main emphasis, however, was on the part played by lipid infiltration, which has tended to dominate thinking in North America ever since in comparison with a readier acceptance in Europe of a thrombotic component (as well as of atherogenesis). There was good reason for supposing that lipids play a major part: it was easy to demonstrate lipid-rich material, including cholesterol crystals, in the coronary arteries and it seemed logical to suggest that high-fat diets and blood cholesterol levels might contribute to atheroma. In the 1950s, however, J. N. Morris and his colleagues at the (now Royal) London Hospital showed very clearly that while advanced atheroma obviously contributed, it could not explain the whole of the coronary heart disease epidemic, although the implication that there must be another process involved—almost certainly thrombosis—was not fully recognized for another 20 years.

Interest in a thrombotic component to coronary heart disease started to re-emerge in the 1970s but was initially characterized by a rather sterile debate as to whether thrombosis causes or is a consequence of myocardial infarction. Evidence for the role of thrombosis in myocardial infarction was provided in convincing form when angiographic monitoring of the early use of thrombolytic therapy showed the development of occlusive thrombi preceding full manifestation of the clinical event. As for sudden coronary death, one reason for doubting the involvement of thrombosis had been the failure to demonstrate thrombi at autopsy in many cases. Apart from limitations in methods for detecting thrombi, the very striking increase in fibrinolytic activity associated with the agonal process of dying from a heart attack is likely to result in the dissolution of some thrombi that were nevertheless responsible for the event. In 1984, a particularly careful study comparing the prevalence of thrombosis in sudden death from coronary heart disease with sudden death from other causes gave the results summarized in Table 1, indicating that a degree of thrombosis is demonstrable in nearly all sudden coronary deaths. Other studies have generally confirmed this. It is now also recognized that the pathology of unstable angina pectoris is similar to that of myocardial infarction and of sudden coronary death in consisting of a significant thrombotic component and in responding to antithrombotic treatment (see Chapter 15.4.2.1).

Further evidence for the role of thrombosis in coronary heart disease came with recognition of the effects of aspirin in modifying the aggregation of platelets and with the results of observational studies and early trials showing the reduction in coronary heart disease attributable to aspirin. Morphological observations and striking cine film pictures of platelet aggregation at sites of vascular injury have put the role of platelets in the thrombotic process beyond any doubt for many years now. However, no tests of platelet behaviour have convincingly been shown to be associated with the subsequent risk of first events of coronary heart disease, although spontaneous platelet aggregation and increased platelet volume may help predict those at risk of recurrent episodes.

Until fairly recently, the contribution of the coagulation system to arterial thrombosis through fibrin formation was not considered to be of clinical significance. This was partly because platelet aggregation in response to vascular injury is very rapid, and hence possibly more relevant than the allegedly slower-acting coagulation system, and also because of the value of aspirin in reducing coronary heart disease. However, epidemiological studies of the coagulation system in thrombosis and coronary heart disease have now demonstrated its involvement and implications for the management and prevention of coronary heart disease. This section summarizes, first, the mainly epidemiological evidence regarding coagulability and coronary heart disease (also arterial disease at other sites), and secondly, implications for long-term management and prevention (the treatment of acute events being described in Chapter 15.4.2.3).

Epidemiological evidence

Population-based studies started from the general proposition that high levels of procoagulatory clotting factors and low levels of anticoagulatory factors would predispose to coronary heart disease. Sceptics argued that (other than in obvious deficiency conditions such as haemophilia) clotting factors circulate well in excess of concentrations required for haemostasis under normal conditions and that no associations with coronary heart disease would therefore be demonstrable. However, requirements for haemostasis may not be a reliable guide to the influence of different levels of clotting factors on thrombosis, where a high level of a procoagulatory factor might facilitate thrombosis and a major coronary heart disease event. By analogy with blood pressure, a certain level of pressure is necessary to maintain normal circulatory function while raised levels predispose to the pathological processes involved in coronary heart disease and stroke.

Studies that demonstrate associations between different characteristics and the risk of coronary heart disease have two main purposes. One is to contribute to our understanding of the pathogenesis of the condition. The other is to identify characteristics with reasonably clear implications either for screening purposes and/or for treatment and prevention.

Figure 1 shows the main features of the coagulation system. Here and in the text the letter 'a' signifies the activated form of the clotting factor. The coagulation process, resulting in the generation of thrombin, can be initiated either through the extrinsic system, so called because it depends on the availability of tissue factor which has not generally been considered a component of the circulating blood, or through the contact system which is not dependent on biochemical properties outside the circulating blood. Tissue factor becomes available when atheromatous lesions leak or rupture, and other evidence strengthens the conclusion that the extrinsic system predominates in coronary heart disease, though not to the exclusion of an influence of factors XII and VIIIa on the intrinsic system (see below). As well as its well-known function in converting soluble fibrinogen into insoluble fibrin, thrombin has numerous other properties, of which the principal ones are shown in Table 2. It is a potent platelet-aggregating agent and may exert this action at least as soon as (if not before) its action on fibrinogen, so that the coagulation system has a strong influence on platelet behaviour as well as on the deposition of fibrin. Other actions of thrombin include the activation of protein C, which together with protein S inhibits the coagulation process; it also has both activating and inhibiting effects on the fibrinolytic system (see Fig. 1 and Table 2).

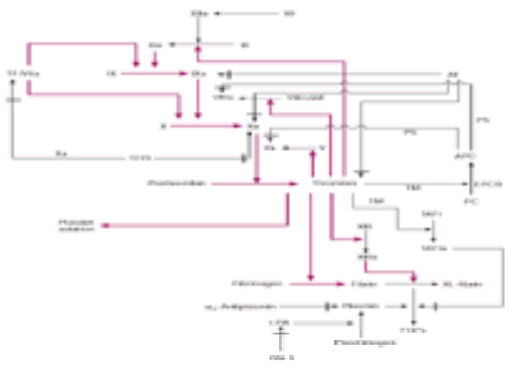

Fig. 1 Outline of the coagulation system and its regulation. The bold arrows represent the main pathways of generation of thrombin and thrombin's key role in fibrin formation and platelet activation: – reflects inhibitory activities; TF = tissue factor; TFPI = tissue factor pathway inhibitor; AT = antithrombin; PC = protein C; APC = activated protein C; PS = protein S; TAFI = thrombin activatable fibrinolysis inhibitor; XL-fibrin = cross-linked fibrin; FDPs = fibrin degradation products; t-PA = tissue-type plasminogen activator; PAI-1 = plasminogen activator inhibitor type 1; vWF = von Willebrand factor; EPCr = endothelial protein C receptor.

There have now been numerous cohort (prospective) and case-control or case-comparison studies of associations between different components of the coagulation system and the risk of coronary heart disease.

Fibrinogen

A recent overview of 18 cohort studies based on 4018 cases of coronary heart disease demonstrated that those in the top third of the fibrinogen distribution are at 1.8 times the risk of coronary heart disease compared with those in the bottom third, the findings being similar in the 12 studies concerned with first events and the other six with individuals known to have had previous episodes and followed for recurrences. The association of fibrinogen with the incidence of coronary heart disease is independent of other risk factors, is of a similar magnitude to the risk due to raised cholesterol, and is probably the same in women as in men. Besides first and recurrent events of coronary heart disease, high fibrinogen levels are also associated with the onset, recurrence, and progression of cerebrovascular and lower extremity arterial disease, with the incidence of graft occlusion following bypass surgery, and possibly with an increased risk of restenosis following coronary or lower limb angioplasty.

Factor VII

The possible involvement of factor VII activity in coronary heart disease is of theoretical as well as practical interest: when tissue factor is exposed it binds with factor VII, such that high levels of the latter might affect the amount of thrombin produced. However, the evidence is equivocal. Two cohort studies suggest that high levels increase risk, whilst others do not. Case-control and cross-sectional studies have also given conflicting results. Several assay techniques have been used and it has been established that these may vary in their sensitivity to factor VII activity, which might partly account for the differing results.

Factor VIII and von Willebrand factor

Factor VIII circulates in a complex with von Willebrand factor. The two proteins serve different haemostatic functions and have different sites of production, but they are closely correlated in a statistical sense so that independent contributions of the two proteins cannot easily be demonstrated, if at all. Four cohort studies have shown high levels of factor VIII to confer an increased risk of coronary heart disease. Haemophiliac patients appear to have a lower than expected incidence of coronary heart disease (though a considerable excess of cerebrovascular disease because of bleeding) and carriers of haemophilia have a reduced standardized mortality rate from coronary heart disease. Autopsy data show that haemophilia does not prevent the development of atheroma, suggesting that the decreased risk of coronary heart disease in patients with haemophilia is due to the effect of low levels of factor VIII on fibrin formation and thrombogenic potential. Case-control data show that elevated levels of factor VIII are associated with an increased relative risk of venous thrombosis, which also supports a prothrombotic role for factor VIII since vessel wall disease is not a consideration on the venous side. The association of factor VIII with coronary heart disease therefore appears to be due to a direct contribution of the level of factor VIII in circulating blood and not to a chronic phase response to atheromatous vessel wall changes.

Fibrinolytic activity

Several cohort studies, whether concerned with first events or in patients with previous episodes of coronary heart disease, have led to the conclusion that impaired fibrinolytic activity is an independent risk factor for coronary heart disease or its recurrence. Different studies have used different methods. These have included global tests of fibrinolytic activity such as the dilute clot lysis time, which takes account of both activators and inhibitors, and assays of specific components of the fibrinolytic system, principally plasminogen activator inhibitor type 1 and of D-dimer, the main degradation product of fibrinolysis. The principal determinants of the dilute clot lysis time are plasminogen activator inhibitor type 1 and, in men, activity of tissue-type plasminogen activator. Several studies have shown that fibrinogen does not make an independent contribution to measures of fibrinolytic activity so that the latter is not simply a reflection of the fibrinogen level. Fairly consistently, high levels of tissue-type plasminogen activator antigen have been associated with both coronary heart disease and stroke, which seems counterintuitive since high levels of tissue-type plasminogen activator would be expected to confer protection. The explanation may be that tissue-type plasminogen activator antigen, which is what the studies in question have measured, complexes with plasminogen activator inhibitor type 1 that is present in higher concentration and for which tissue-type plasminogen activator antigen is a surrogate marker. Raised levels of D-dimer, indicating increased fibrin turnover, have been found to be predictive of future cardiovascular events—again, independent of fibrinogen. The association of activity of plasminogen activator inhibitor type 1 with coronary heart disease is not seen after adjustment for the features of insulin resistance (body mass index, triglyceride, high-density lipoprotein cholesterol, blood pressure, and diabetes) so that the prognostic value of plasminogen activator inhibitor type 1 may be related chiefly to this syndrome.

Other factors

Whereas inherited deficiencies of the naturally occurring inhibitors of coagulation such as antithrombin, protein C, and protein S clearly increase the risk of venous thromboembolism, the contribution that alterations in the levels of these proteins makes to arterial thrombosis is unclear. Anecdotally, case reports and case series have described deficiencies of these inhibitors in patients who have sustained arterial events. More formal studies have given conflicting and inconclusive results. What evidence there is suggests that low antithrombin levels may predispose to coronary heart disease.

Controversy surrounds the role in arterial disease of two recently recognized clotting factor polymorphisms, the factor V Leiden mutation and the prothrombin G20210A mutation (a polymorphism in the 3' untranslated region of the gene associated with higher prothrombin levels), in contrast to their generally accepted role in venous thromboembolism (see Chapter 15.15.3.1). Resistance to activated protein C, the laboratory phenotypic abnormality which led to discovery of the factor V Leiden mutation at one of the activated protein C cleavage sites on factor Va, has been described in patients with arterial disease. The roles in coronary heart disease of particular polymorphisms of platelet surface glycoprotein receptors and circulating levels of thrombomodulin, an endothelial receptor that binds thrombin, thereby leading to activation of protein C (anticoagulant effect) and thrombin-activatable fibrinolysis inhibitor (antifibrinolytic effect), are also uncertain. The antiphospholipid syndrome, which is characterized by both venous and arterial thrombosis together with laboratory evidence of anticardiolipin antibodies and/or the lupus anticoagulant, is discussed in Chapter 13.14 and Chapter 18.10.2.

The contact system consists of factor XII, factor XI, prekallikrein, and high molecular weight kininogen. Regulation of the system is provided in part by the multifunctional inhibitor, C1 inhibitor. The step which initiates activity is the conversion of factor XII to its derivative enzyme, factor XIIa, in response to exposure to biological substances with a negatively charged surface, for example lipopolysaccharide and phosphotidylinositol. The generation of factor XIIa triggers several activating reactions along pathways concerned with the response to injury, including activation of factor XI (which activates factor IX in the intrinsic pathway of coagulation), the production of kallikrein (which cleaves high molecular weight kininogen to bradykinin), the production of plasmin and renin, degranulation of neutrophils, activation of collagenase, and activation of the first component of complement. This range of activities raises the possibility that the contact system plays a co-ordinating role in the response to injury. A high level of factor XIIa is associated with raised levels of a number of familiar risk factors for coronary heart disease,

including plasma triglyceride and systolic blood pressure, and it is an independent predictor of coronary heart disease.

Overall, the evidence shows that predisposition to thrombosis and coronary heart disease is associated with changes in several components of the coagulation system, as well as with platelet behaviour, and the question arises as to whether they represent causality. If so, what are the pathways involved and what are the implications for management and prevention through measures affecting the haemostatic system? There are three main ways in which these questions can be approached: first, detailed laboratory studies; secondly, the extent to which the associations of clotting factor with coronary heart disease are consistent with the effects of known risk factors such as smoking; and thirdly, the ability of agents used in randomized controlled trials (for whatever reason and with whatever clinical outcome) to affect particular pathways.

Laboratory studies

The effects of fibrinogen have been extensively studied and are summarized in Fig. 2. High fibrinogen levels make a substantial contribution to the viscosity of whole blood and plasma and to the amount of fibrin deposited when coagulation is initiated, they increase platelet aggregability, enhance the binding of leucocytes to platelets and endothelial cells, decrease clot deformability, and contribute to the atheromatous process—all of which have been shown to, or are likely to, increase the risk of thrombosis and thus of clinical events. The fibrinogen level itself is influenced by a range of characteristics, including smoking (increase), moderate alcohol consumption (decrease), and genetic characteristics. As an acute and chronic phase protein, fibrinogen levels also rise in response to inflammatory stimuli, of which underlying vessel wall pathology may be an example. This has sometimes led to the view that fibrinogen is no more than a marker of the risk of coronary heart disease, whereas the likelihood seems to be that, whatever the original explanations for raised fibrinogen levels may be, these will increase risk. If so, fibrinogen may be considered to be both a marker and a causal feature.

Fig. 2 Summary of determinants and thrombogenic pathways of fibrinogen in the pathogenesis of coronary heart disease.

A number of metabolic studies have shown associations of factor VII with dietary fat intake and with serum triglyceride concentrations. Factor VIIa is also associated with plasma levels of the activation peptide fragment 1 + 2, an indicator of thrombin generation that is released from prothrombin upon its conversion to thrombin. Dietary and other studies have shown a pivotal role for factor IXa on the level of blood coagulability. Binding of factor VIIa to tissue factor may also lead to intracellular signalling, the consequences of which may include augmented macrophage activation. Factor VIII has been shown to increase the rate of activation of factor X by factor IXa in a dose-dependent manner.

Consistency with known risk factors

Very generally, associations of haemostatic variables with coronary heart disease are similar to the effects of more familiar risk factors. This is best illustrated for fibrinogen in Fig. 2 in which many of the personal or lifestyle characteristics apparently influencing fibrinogen levels are known to be associated with the risk of coronary heart disease itself—for example the increased risk due to smoking and the protective effect of a moderate intake of alcohol. Indeed, the associations of smoking and alcohol with fibrinogen are likely to explain, at least in part, how these aspects of lifestyle affect coronary heart disease itself.

One feature absent from Fig. 2 is dietary intake, particularly of saturated fat, but diet undoubtedly exerts a major effect on factor VII activity. Obesity and the other features of the insulin resistance syndrome impair fibrinolytic activity, as does smoking. The general conclusion, therefore, is that the personal and lifestyle influences on the risk of coronary heart disease operate through effects on the haemostatic system and thrombotic tendency as well as through more familiar lipid pathways. The implications for pharmacological intervention are considerable (see below).

Other effects of haemostatic variables in arterial disease

Response to injury

It is becoming increasingly clear that besides coagulability the haemostatic system plays a major role in the response to injury (although in evolutionary terms these two functions serve the same common purpose of repair of injury). Fibrinogen, for example, serves as a cell–cell adhesion protein for binding between platelets, monocytes, neutrophils, and endothelial cells. Fibrin forms a temporary matrix at sites of vessel wall injury, providing a framework for infiltration of smooth muscle cells and fibroblasts. Factor Xa stimulates proliferation of smooth muscle cells, and by limited proteolysis of protease-activated receptors, thrombin induces many cellular inflammatory responses including the expression of cytokines and adhesion molecules. Factor XIIa and kallikrein activate neutrophils and trigger the degranulation reaction. Inflammatory products have actions on components of the haemostatic system. For example, leucocytosis with neutrophil activation is a feature of atherosclerotic disease. Neutrophil elastase and cathepsin-G have diverse actions (at least *in vitro*) on the haemostatic pathway including limited proteolytic cleavage of factor IX, factor VII, factor VIII, factor V, and of platelets, and degradation of fibrinogen, fibrin, antithrombin, and tissue factor pathway inhibitor. The significance of interactions such as these between the haemostatic system and the inflammatory/immune mechanism is poorly understood, but they are likely to be pivotal in ensuring an integrated response to injury and tissue defence and repair. In summary, the original hypothesis that the haemostatic system contributes to coronary heart disease simply by a direct effect on thrombogenic potential, and thus through 'hypercoagulability', probably now requires modification. Account must also be taken of other processes involved in the pathogenesis of coronary heart disease to which changes in the coagulation system may be a secondary response, although some of these changes may then contribute to thrombotic potential.

Inflammatory markers and arterial disease

Recent years have seen the widespread recognition that atherosclerosis is an inflammatory process and the emegence of evidence that circulating markers of inflammation might be used to predict the risk of coronary events.The most consistently observed association has been that of the acute-phase reactant, C-reactive protein (CRP), with coronary risk. In healthy, asymptomatic adults, a single CRP measurement (using a sensitive assay) in the high normal range is associated with an increased risk of angina, acute myocardial infarction and death. The association is independent of lipids and its strength is similar to that observed with other risk factors including cholesterol and fibrinogen. CRP is also associated with the risk of recurrent events in those with established coronary heart disease.

CRP is synthesized in the liver and, stimulated by cytokines (particularly interleukin 6) , its level rises more than 100-fold in response to severe infection. In this setting, it binds to phosphocholine on the surface of invading microbes and assists their killing by complement and phagocytes. It also diminishes adherence of leucocytes to the vascular endothelium, releasing marginated neutrophils to infected sites while preventing the accumulation of leucocytes in uninflamed tissues. By these and other mechanisms, CRP (together with other inflammatory markers) provides an important survival function.

By contrast with this beneficial effect, repeated or prolonged low-grade stimulation of the acute phase response might have harmful consequences (see below). In the context of arterial disease, debate continues as to whether CRP is merely a marker of the inflammation that characterizes atheroma or is directly involved in the pathogenesis of atherothrombosis. In support of the latter view, CRP is deposited in human atherosclerotic lesions and is capable of binding to both enzymatically-degraded, non-oxidized low-density lipoprotein and to the terminal complement complex, C5b-9, thereby promoting inflammation. It is chemotactic for

monocytes and may play a role in the recruitment of monocytes during atherogenesis. It may contribute to the expression on the endothelium of adhesion molecules such as intercellular adhesion molecule I (ICAM-I), vascular-cell adhesion molecule I (VCAM-I), and E-selectin, further enhancing the local inflammatory response within atheromatous plaques. CRP may also promote thrombosis by enhancing tissue factor expression by monocytes. Therefore, like fibrinogen, CRP may be both a marker of the underlying pathological process and a direct contributor to the development of atherothrombosis.

It is uncertain whether the acute phase stimulus for increased CRP levels comes from the atheromatous plaques themselves, from arterial infection, or from chronic extravascular stimuli. Causes of the latter may include smoking, chronic mucosal infections such as bronchitis, gastritis and periodontitis, and obesity, with strong associations having been made between the levels of body fat and inflammatory markers with adipose tissue increasingly recognized as a source of cytokines including interlukin 6. Indeed different mechanisms might operate within one individual. As yet little is know about the genetic determinants of CRP.

Statin therapy, administered to lower cholesterol levels in those at risk of coronary events, also lowers levels of CRP, an effect which appears to be independent of their effect on lipid levels. The possibility has therefore been raised that CRP might be added to an individual's risk factor profile when deciding whether or not to use a statin for the primary prevention of coronary heart disease but this requires confirmation in prospective trials.

Associations between many other inflammatory markers and coronary heart disease risk have been reported. Inflammatory markers are synthesized in a number of different sites including the liver (CRP, serum amyloid A), macrophages (lipoprotein-associated phospholipase A_2, soluble phospholipase A_2), the vessel wall (ICAM-I, VCAM-I, E-selectin), and adipocytes (cytokines including interleukin-lb, interleukin 6, tumour necrosis factor a). It is possible that each makes a contribution to the chronic process of atherosclerosis, although in prospective studies they have generally been less clearly associated independently with coronary heart disease than has CRP. However, this may be for assay-related rather than biological reasons and independent associations of soluble ICAM, interleukin 6, and lipoprotein-associated phospholipase A_2 with coronary disease have been reported.

Homocysteine

Although not itself a component of the haemostatic system, the sulphur-containing amino acid homocysteine has emerged in recent years as a potentially important risk factor for arterial disease (and also for venous thromboembolism), with postulated mechanisms of effect that may be mediated in part through components of the haemostatic system.

It was first recognized in the 1960s that premature atherothrombosis was often seen in individuals with the rare inherited metabolic disorder homocystinuria, in which the plasma level of homocyteine is very high. Within the past decade evidence has emerged from observational studies showing an association between homocysteine levels and the risk of vascular disease within the general population, although the causal nature of this association remains to be established.

Homocysteine is a byproduct derived from the metabolic demethylation of dietary methionine. Study of the metabolic pathway of homocysteine metabolism (Fig. 3) shows that it can be metabolized either by trans-sulphuration, with vitamin B_6 (pyridoxine) as a cofactor, or by remethyl-ation to methionine, with vitamin B_{12} as a cofactor and N^5-methyl-tetrahydrofolate (derived from dietary folate) as the methyl donor. In the liver, betaine can act as an alternative methyl donor.

Fig. 3 Homocysteine metabolism. MTHFR, methylenetetrahydrofolate reductase; CbS, cystathionine b synthase

Homocysteine is present in plasma in several forms: 70 to 80 per cent is disulphide-bound to plasma proteins, 20 to30 per cent combines either with itself to form the disulphide homocystine or with other thiols such as cysteine to form mixed disulphides, and about 1 per cent circulates as the free thiol. Homocysteine (usually as the combined total of the different forms) can be measured either in the fasting state or post- methionine-loading with a standard amount of methionine. The latter estimate may be particularly sensitive to disturbances in the trans-sulphuration pathway, thereby enabling additional cases of hyperhomocysteinaemia to be detected, but it is inconvenient for patients. Blood samples should ideally be centrifuged immediately because homocysteine is progressively released from blood cells with the passage of time. If this is not possible, samples should be placed on ice following collection and centrifuged as soon as possible. The fasting reference range in Western populations is approximately 5 to 15 µmol/1, reflecting levels 2 standard deviations above and below the mean, and higher levels are arbitrarily categorized as moderate (16–30 µmol/l), intermediate (31–100 µmo/l), and severe (>100 µmol/l) hyperhomocysteinaemia. However, although such a range can be defined statistically, there is no clear threshold effect in studies that have reported positive associations between homocysteine levels and atherothrombotic disease, an analogous situation to that observed with other CHD risk factors such as cholesterol and blood pressure where risk rises even within the 'normal range'.

Plasma homocysteine levels are influenced by a number of factors, both genetic and environmental. Nutritional deficiency of folate is the most common cause of hyperhomocysteinaemia and deficiencies of vitamin B_{12} and vitamin B_6 also contribute. Other acquired causes of hyperhomocysteinaemia include renal impairment, hypothyroidism, malignancy, severe psoriasis and drugs that interfere with folate or B6 metabolism. Levels rise with age and are higher in males than females and in smokers compared to non-smokers. The combined oral contraceptive pill and hormone replacement therapy appear to lower the concentration. Homocysteine should probably not be measured immediately after an occlusive vascular event as levels may be transiently depressed.

The most common genetic cause of moderate hyperhomocysteinaemia is a point mutation (C-to-T substitution at nucleotide 677) in the coding region of the gene for N^5, N^{10}-methylenetetrahydrofolate reductase (MTHFR) that results in a thermolabile variant of the enzyme with about half normal activity. The homozygous MTHFR polymorphism is present in 10 to 15 per cent of Caucasians and is associated with an increase in homocysteine levels particularly if folate status is suboptimal. Rarer inherited causes are covered in Chapter 11.1

The data linking homocysteine and atherothrombotic disease are somewhat inconsistent, perhaps inevitable given that the relationship has been examined in over12 000 patients in more than 100 observational studies. Data from case-control studies have mostly reported a positive association between homocysteine and arterial disease. Data from prospective cohort studies have been less consistent, although the association has been in a positive direction, even if not significantly so, in the majority. Moreover, the association appears to be independent of traditional CHD risk factors such as age, sex, smoking, blood pressure, and cholesterol. Critics of the association of homocysteine and atherothrombosis point to the lack of consistent findings in the prospective studies, the lack (so far) of an association between the common genetic marker of raised homocysteine (the thermolabile MTHFR genotype), and vascular disease despite the association of genotype with homocysteine level, and the possibility that homocysteine may be simply a marker of another causal risk factor. Overall, it seems probable that homocysteine is an independent risk factor and the results of further genetic analyses and intervention trials will hopefully resolve this uncertainty.

The mechanism(s) by which homocysteine might promote atherothrombosis remains speculative. A number of possible explanations have been put forward but have often been based on *in vitro* studies that have used higher levels of homocysteine than those typically found clinically and therefore should be interpreted with caution. They include effects on platelet adhesiveness or activation, activation of clotting factors V and X, and inhibition of fibrinolysis through enhanced binding of lipoprotein(a) to fibrin. Possible effects on the endothelium may result from oxidative damage and include increased tissue factor and decreased thrombomodulin expression, and inhibition of nitric oxide. Proliferation of smooth muscle may be enhanced.

Folic acid (pteroylmonoglutamic acid) is the single most effective treatment for hyperhomocysteinaemia. It is the synthetic version of dietary folate with twice the

bioavailability and it lowers homocysteine levels even in those who are not folate deficient. For most people the maximum reduction of about 25 per cent is seen with a dose of 0.8 mg daily although patients with renal impairment need much higher doses. Vitamin B_{12} produces a smaller 7 per cent decrease in homocysteine. Dietary sources of folate include green vegetables and fortified breakfast cereals. In the United States flour has been fortified with folic acid since 1998 in order to reduce the risk of neural tube defect by ensuring improved folate status in women of child-bearing age. The level of fortification is likely to produce an extra 0.1 mg at least of folic acid per day in the diet and therefore lead to a partial lowering of homocysteine in the general population. Discussions are ongoing as to whether similar measures should be adopted in the United Kingdom. Concerns have been expressed about increasing the risk of subacute combined degeneration of the cord in patients with undiagnosed B_{12} deficiency through correction of the haematological manifestations by administration of folic acid potentially masking development of the neurological condition. The extent of this theoretical risk is uncertain and is probably extremely small but no consensus has yet been reached on whether B_{12} deficiency should be excluded before starting higher doses of folic acid or whether vitamin B_{12} should be administered in conjunction with folic acid.

A number of clinical trials with therapy that lowers homocysteine (with folic acid alone or in combination with vitamin B_6 or B_{12}) are under way in an effort to prevent coronary and cerebrovascular disease and venous thromboembolism and the results should become available within the next few years.

Implications for clinical practice

Screening and diagnosis

Recent work on the haemostatic system has certainly led to improved understanding of the pathogenesis of coronary heart disease, but only some of the information gained so far has implications for clinical practice—in particular, attempting to identify those at increased risk of first or recurrent events. Measuring fibrinogen and assessing fibrinolytic activity are the two investigations that may be helpful. A high fibrinogen level is sometimes the only identifiable risk factor in a patient referred for investigation because of a strong family history of coronary heart disease, for example, or in some patients who have recovered from myocardial infarction and in whom there are no other obvious risk factors. It may also, of course, be an additional finding in those with other risk factors. Although there is only limited evidence on the value of lowering fibrinogen levels (see below), information about these may be useful in deciding whether, for example, to recommend low-dose aspirin for primary prevention—a measure that should almost certainly be taken only after much more careful consideration than is often the case—even though aspirin does not lower fibrinogen. Measuring the euglobulin lysis time and the activity of plasminogen activator inhibitor type 1 can also be helpful, though they are often to be explained by obesity and other features of the insulin resistance syndrome.

Fibrinogen and fibrinolytic activity should only be measured some time after an acute episode of coronary heart disease and in the absence of recent infection. As for other risk factors such as cholesterol and blood pressure, they should be measured several times before an individual's habitual level can be established with any certainty. There is now a World Health Organization standard for fibrinogen, which means that ranges and values can be much more confidently compared between different centres than previously. Assays of factor VII activity are difficult to perform and the interpretation of results is uncertain. There are no established interventions for lowering levels of activity of factor VIII. While there is some evidence that low levels of antithrombin increase the risk of coronary heart disease, there are no specific agents for raising them.

Prevention

Primary prevention

In contrast to the value of aspirin in reducing recurrent major vascular events and mortality after a first attack (secondary prevention, see below), its value in primary prevention seems on present evidence to be confined mainly to reducing non-fatal myocardial infarction. There is no evidence for a reduction in fatal episodes of coronary heart disease and it is possible that the risk of cerebral haemorrhage is actually increased. It is also possible that the reduction in non-fatal events is mainly confined to those who are normotensive. Thus, those with raised blood pressure may not only experience more cerebral haemorrhage but also be exposed to the risk of gastrointestinal haemorrhage while deriving no protection against coronary heart disease. These conclusions need to be strengthened or refuted by results from further studies, but they do justify considerably more thought than is commonly given to the use of aspirin in primary prevention: many middle-aged men take aspirin indiscriminately and not necessarily beneficially and safely.

One trial has evaluated low-dose aspirin (75 mg daily) and low-intensity oral anticoagulation with warfarin (aiming at an international normalized ratio of 1.5) either singly or in combination in men at increased risk of coronary heart disease. Both agents reduced the incidence of major coronary heart disease by about 20 per cent. However, in common with other evidence in primary prevention, aspirin achieved this as a result of reducing non-fatal events by just over 30 per cent (and, if anything, slightly increasing the risk of fatal episodes). Warfarin reduced fatal episodes by 39 per cent but had little effect on non-fatal events. The combination of both agents reduced events, whether fatal or non-fatal, by 34 per cent. Warfarin may also have reduced the onset of angina pectoris slightly. There was no demonstrable difference in serious bleeding between the three active treatment groups (warfarin and aspirin together, warfarin alone, and aspirin alone) or between them and the placebo group (although minor bleeding was clearly more frequent in those on active treatment regimens). The assumption that warfarin is intrinsically more dangerous than aspirin was therefore not supported. The disadvantage of the need for international normalized ratio and dose monitoring when using warfarin is balanced by the possibility of a substantial reduction in fatal events which needs to be considered alongside the inability to predict which first major events of coronary heart disease will be fatal and the high proportion of those experiencing their first major event who die.

There is still only limited agreement about the optimal dose of aspirin: the evidence mostly points to the need for no more than 75 mg and certainly no more than 300 mg daily, both for antithrombotic effect and safety.

Secondary prevention

Antithrombotic treatment in the early stages of myocardial infarction, in which a combination of aspirin and thrombolytic treatment is used, merges into the longer-term secondary prevention of further episodes. Aspirin in the early stages reduces further major vascular events (myocardial infarction, stroke, or vascular death) by some 25 per cent, the reduction in non-fatal episodes of coronary heart disease being somewhat more than for fatal outcomes. The proportional benefits of aspirin are similar in older and younger patients, in men and women, in normotensive and hypertensive patients (which contrasts with the possible difference in primary prevention), and in non-diabetic and diabetic patients. Absolute reductions, however, are greater in the higher-risk groups (for example older, hypertensive, or diabetic patients) because of their higher event rates. There is little or no formal evidence on how long aspirin should be taken after an initial event, but since those who have already experienced episodes of arterial disease are likely to remain at high risk indefinitely, antithrombotic treatment should probably also be continued long term.

Despite the clear value of aspirin in secondary prevention, the benefits of oral anticoagulation should not be overlooked. First, it is possible that anticoagulation confers slightly greater protection against recurrence than aspirin, perhaps because of the effect of thrombin, which is reduced by warfarin, on platelets as well as fibrinogen. Despite the disadvantages of anticoagulation, this extra benefit (if real) may still be worthwhile for a common condition with a high risk of recurrence. Secondly, the value of oral anticoagulants in modifying fibrin production may add to the value of aspirin in reducing platelet aggregability. The value of combined antithrombotic regimens has been well illustrated through the concurrent use of aspirin and thrombolytic therapy in early myocardial infarction and in the postoperative treatment with aspirin and warfarin of patients undergoing heart valve surgery. Aspirin with heparin followed by warfarin is also beneficial in the setting of acute coronary syndromes. Other trials have cast doubt on the possible benefit of combined antithrombotic therapy for recurrent coronary heart disease, but they used fixed or capped low-dose warfarin, whereas it is almost certainly necessary to give warfarin in a dose-adjusted manner, i.e. to achieve a target international normalized ratio. Combined regimens of agents modifying different aspects of platelet function such as aspirin and dipyridamole in the secondary prevention of stroke further illustrate the potential value of modifying more than one pathway at a time, provided the risk of serious bleeding is not unacceptably increased. An obvious question not so far tested in randomized trials is the potential value of the simultaneous use of antithrombotic and lipid-modifying agents. While intravenous antagonists of the platelet glycoprotein IIb/IIIa receptor are effective in the early postacute management of acute coronary syndromes, oral therapy does not appear to confer benefit.

15.1.3.1 Physiological considerations: biochemistry and cellular physiology of heart muscle

P. H. Sugden, N. J. Severs, K. T. MacLeod, and P. A. Poole-Wilson

Introduction

The heart of a normal human weighs 250 to 300 g, contracts at a rate of 70 to 75 beats/min at rest, and pumps approximately 5 litres of blood/min. The cardiac content of the energy transducing molecule ATP is only sufficient to support contraction for a few beats (about five to ten) and the supply of endogenous fuels (for example glycogen, endogenous triglyceride) is limited given the amount of work the heart has to perform. In order to maintain fuel oxidation, ATP regeneration, and cardiac contraction, a highly developed coronary circulation and a maintained coronary blood flow are necessary to ensure adequate delivery of O_2 and fuels, and to remove the major product of fuel oxidation (CO_2). Thus, about 5 per cent of the cardiac output is used to perfuse the heart itself (about 1 ml/min/g of myocardium). On maximal exercise both heart rate and cardiac output can increase substantially—to 200 beats/min and 20 litres/min respectively—and these changes are accompanied by an almost immediate increase of coronary blood flow to about four times its normal amount. The magnitude of the potential increase is known as the coronary reserve.

The heart is made up of many different cell types. Cardiac myocytes (the contractile cells of the heart) constitute about 75 per cent of the ventricular mass but, as they are large cells, they account for only about 25 per cent of the cell number. Other types of myocytes are specialized for the initiation of the cardiac action potential (sinoatrial nodal cells) and its transmission in a regular and co-ordinated manner to the working ventricular myocardium (conduction myocytes of the atrioventricular node, the bundle of His, and the Purkinje fibres). In addition, the heart is innervated by neurones of the autonomic nervous system. Cardiac fibroblasts synthesize and maintain the extracellular matrix. The extensive vasculature contains smooth muscle cells and pericytes, and is lined by a monolayer of endothelial cells. The endothelium is more than simply a barrier lining the blood vessels and heart chambers. Release of signalling molecules such as endothelin and nitric oxide from the endothelial cells regulates vascular smooth muscle tone and the biological properties of the myocytes themselves (see Chapter 15.1.1.2).

Interrelationships between structure and function in the ventricular myocyte and myocardium

The adult ventricular myocyte is a large cell, approximately 100 to 120 µm long and 20 to 35 µm wide (Fig. 1). Each is physically joined to approximately 10 adjacent myocytes and lies close to an extensive capillary network. The ventricular myocyte contains a highly developed contractile apparatus and a large complement of mitochondria. These fit it for its major role *in vivo*, namely the rhythmic contraction that provides the force needed for the ejection of blood from the ventricles. Atrial myocytes have a less well developed myofibrillar apparatus than ventricular myocytes, in accordance with the lesser contractile demand on the atria compared with the ventricles.

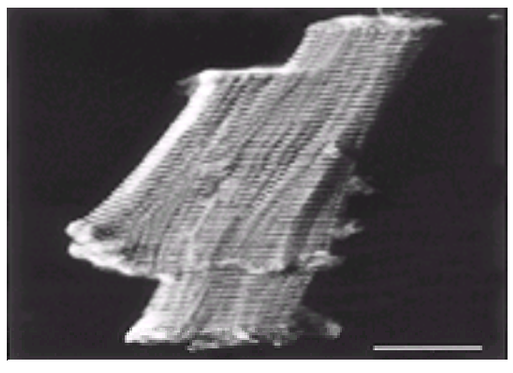

Fig. 1 Ventricular myocyte viewed by confocal microscopy. The image was prepared by combining a stack of serial optical sections through the cell. The striated myofibrils are visualized by the immunostaining of a-actinin, a component of the Z bands. The bar is 10 µm. (From Severs NJ (2000) *BioEssays* **22**, 188–99, with permission.)

Intercommunication between the myocytes and extracellular matrix

The myocardial cell is surrounded by the sarcolemma which comprises the plasma membrane (about 10 nm thick) and an outer layer (70 nm thick) called the surface coat or glycocalyx (Fig. 2). As with all biological membranes, the plasma membrane consists of a phospholipid bilayer with numerous intercalated and associated proteins. Transmembrane proteins include the channels, transporters, and pumps that allow passage of ions through the membrane, and receptor sites for hormones, pharmacologically active substances, and components of the extracellular matrix. The glycocalyx lies outside the plasma membrane (but is attached to it) and is made up of polysaccharides conjugated to protein or lipid.

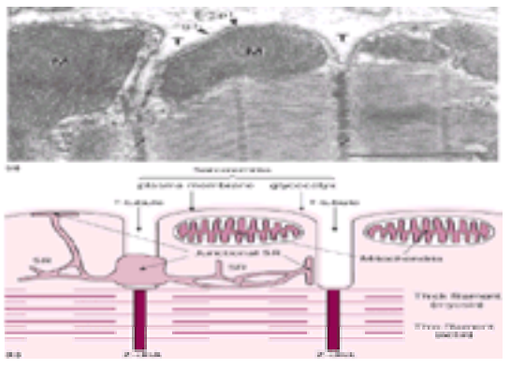

Fig. 2 Electron micrograph (a) and explanatory diagram (b) illustrating the organization of T tubules and sarcoplasmic reticulum. Labels on the micrograph as follows: T, T tubule; Z, Z disc of myofibril; M, mitochondrion; pl, plasma membrane; gl, glycocalyx. The bar is 1 µm.

At the ends of its long axis and at branches along its length, each myocyte makes contact with neighbouring myocytes through a characteristic area of plasma membrane called the intercalated disc. The intercalated disc contains three types of cell junction: the fascia adherens, the desmosome, and the gap junction. The fasciae adherentes link adjacent myocytes mechanically so that force can be transmitted between them. The contractile apparatus is anchored to the fascia adherens by a series of linking proteins such as a-actinin, filamin, and vinculin; these bind to adhesive proteins (cadherins) which are transmembrane proteins that bond across the extracellular space. The desmosomes form sites at which the intermediate filaments of the cytoskeleton attach to the plasma membrane, the cytoskeleton being important in the establishment and maintenance of myocyte shape as it provides an intracellular supporting lattice structure. As with the fasciae adherentes, bonding at the desmosome is mediated by proteins of the cadherin superfamily. The gap junctions are the sites in the intercalated disc where the membranes of adjacent myocytes come into intimate contact. Here, clusters of channels, each made of dodecamers of the protein connexin surrounding a central pore, permit myocyte-to-myocyte communication. The permeability of these pores to ions allows electrical impulses to pass easily between myocytes. The gap junctions also allow the passage of other small molecules (< 1 kDa) between the cytoplasmic compartments of adjacent cells.

The lateral (non-intercalated disc) plasma membrane is strengthened on its cytoplasmic aspect by a net-like skeleton composed of the structural proteins dystrophin and spectrin. As well as being responsible for the skeletal muscle abnormalities of Duchenne and Becker muscular dystrophy, mutations in dystrophin are responsible for the cardiomyopathy associated with these syndromes. The skeletal structure of the membrane is further reinforced by rib-like transverse bands of vinculin, termed costameres, which contain transmembrane proteins (for example integrins) that bind to components of the extracellular matrix, thereby allowing lateral transmission of the mechanical force of contraction from the cell to the matrix.

The extracellular matrix is important for the overall morphology of the heart and provides an anchoring structure against which the myocytes contract. It is made principally of collagen and fibronectin. Fibronectin fills the spaces between the cells and possesses binding sites for the integrins of the plasma membrane and for collagen. Collagen types I and III form a fibrous network that weaves around the myocytes, maintaining their alignment, preventing overstretching, and transmitting force. This network preserves the overall shape and architecture of the heart, and acts as a spring to store energy during systole. The normal heart contains about 5 per cent collagen but, in pathological conditions, this can increase to 25 per cent. This increases myocardial 'stiffness' and can impede contraction.

Contraction

The contractile apparatus is highly ordered, consisting of bundles of striated myofibrils (approximately 1 µm in diameter with around 150 per cell) running the length of the cell (Fig. 3). As in skeletal muscle, myofibrils (which are responsible for contraction) are made up of a repeating sarcomeric unit that is about 2 µm in length in the relaxed state. Each sarcomere consists of thick filaments that interdigitate with thin filaments (Fig. 4). The thick filament is a polymer of the protein myosin, a hexamer of two myosin heavy chains and four myosin light chains. The myosin heavy chain has an elongated rod-like domain and a globular head, to each of which two light chains are bound (Fig. 5). The rod-like regions of two myosin heavy chains intertwine to form the hexamer. The thin filaments consist of a double-beaded strand of the globular protein actin with which the rod-like protein tropomyosin and members of the troponin family (troponin I, troponin C, and troponin T) are associated (Fig. 5). The thin filaments within adjacent sarcomeres are linked at the Z line. The alignment and the overlapping of thick and thin filaments gives the myofibril its striated appearance in micrographs (Fig. 3 and Fig. 4).

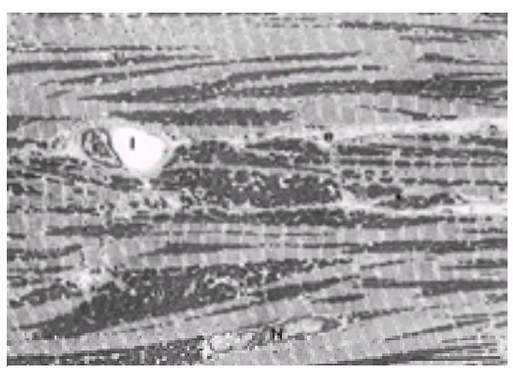

Fig. 3 Structure of ventricular myocardium by thin-section electron microscopy. The major components of the myocytes, the striated myofibrils and the mitochondria (m, seen as abundant dark-stained rounded objects), dominate the view. N, nucleus of myocyte; n, nucleus of endothelial cell; l, lumen of capillary; e, extracellular matrix. The bar is 10 µm.

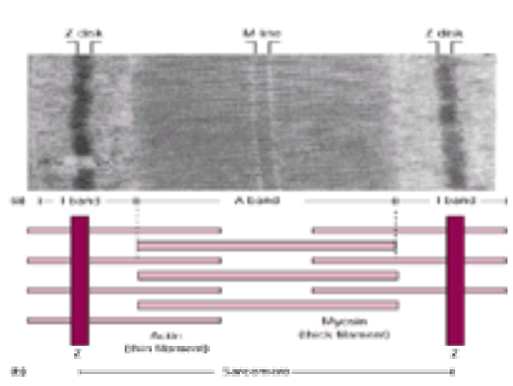

Fig. 4 High-power electron micrograph of a single sarcomere (a), the basic contractile unit of heart muscle, with explanatory diagram (b) of the organization of the thick and thin filaments, Z discs, and bands.

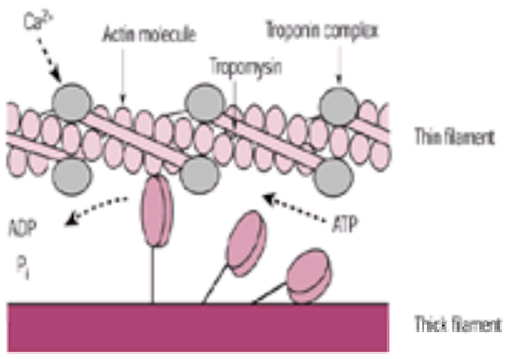

Fig. 5 Diagrammatic representation of myofilament structure and contraction. The thick filament is a polymer of myosin, the double beaded helix of the thin filament is a polymer of actin. Increases in intracellular Ca^{2+} ion concentrations are detected by troponin C of the troponin complex and this relieves the inhibition of the actomyosin ATPase by troponin I. The hydrolysis of ATP by the ATPase provides the energy for contraction. The globular myosin heads, which form crossbridges with the thin filaments, move as shown causing shortening of the sarcomere.

Myofibrillar contraction in the heart is essentially similar to that in skeletal muscle. The globular heads of myosin interact with actin, and the myofibrillar actomyosin adenosine triphosphatase (**ATPase**) transduces the chemical energy released by ATP hydrolysis into external mechanical work (Fig. 5). In the absence of Ca^{2+}, troponin I maintains the actomyosin ATPase in an inactive state. Binding of cytoplasmic Ca^{2+} ions to troponin C removes this restraint and contraction occurs by the movement of the myosin heads in the thick filaments along the actin beads in the thin filaments, with concomitant hydrolysis of ATP. Mutation of specific amino acid residues in the myosin heavy chain in particular (but also in other myofibrillar proteins) can give rise to an inheritable disease known generically as hypertrophic cardiomyopathy (see Chapter 15.8.2).

Since Ca^{2+} is intimately involved in the regulation of contractile activity, a well-developed apparatus controls the intracellular (subscript 'i') concentration of Ca^{2+} ions. The ventricular myocyte possesses an array of T tubules and an extensive sarcoplasmic reticulum, a specialized form of endoplasmic reticulum. The T tubules are finger-like invaginations from the cell surface with openings of up to 200 nm in diameter, spaced so that a T tubule lies alongside each Z disc of most (or even all) of the myofibrils (Fig. 2). Both the T tubule and the sarcoplasmic reticulum are involved in regulation of the movement of Ca^{2+}. The T tubules regulate the entry of extracellular (subscript 'o') Ca^{2+} into the myocyte, and the sarcoplasmic reticulum 'stores' Ca^{2+}_i during diastole. The regulation of movement of Ca^{2+} in the myocyte is described in more detail below.

Although much of the intracellular volume of the ventricular myocyte is occupied by myofibrils, about 30 per cent is taken up by mitochondria (Fig. 3). As in other oxidative tissues, these subcellular organelles oxidize metabolic fuels and convert the energy released by this oxidation to drive regeneration of ATP (from ADP and inorganic phosphate). In the myocyte, the majority of the energy released by ATP hydrolysis is used to power myofibrillar contraction, but there are also other essential processes that require energy (for example macromolecule synthesis and other biosynthetic pathways, ion transport, etc.).

The nucleus and the cell cycle

The mammalian ventricular myocyte is believed to lose its ability to divide during the perinatal period, hence most maturational growth occurs through cellular enlargement. However, complicating factors are that the myocyte may be multinucleate, and its nucleus may possess more that two chromosome pairs (polyploidy). Thus the arrest in the cell cycle appears to reside at the stage of cell division (cytokinesis) rather than nuclear division (karyokinesis). The reasons for the withdrawal of the myocyte from the cell cycle are not understood, and although some molecules which regulate the cell cycle are present in the ventricular myocyte, it has not yet been experimentally possible to drive the cell into division. This means that the myocardium cannot regenerate, and the loss of myocytes following, for example, an ischaemic insult is potentially disastrous. An ability to restore entry of ventricular myocytes into the cell cycle in a controlled manner might well have considerable clinical significance as it would be one step towards allowing the damaged heart to regenerate its contractile capacity. As it is, the myocyte can only increase its contractile capacity by cell enlargement (hypertrophy), and this leads to the clinical entity of cardiac hypertrophy.

Cardiac electrophysiology

Each heartbeat is initiated by a spontaneous electrical discharge in the sinoatrial node. The electrical signal passes across the atrium to the atrioventricular node, through the bundle of His, and down the Purkinje fibres to the ventricular myocardium. This incremental excitation of the heart provides a means of co-ordinating the contractile activities of the four chambers and is the basis for the electrocardiogram (see Chapter 15.3.2).

Electrical excitation of each myocyte involves the movement of ions through ion channels. These are 'excitable' macromolecules embedded in the plasma membrane which contain pores that open or close in response to a stimulus. This stimulus could be a change in membrane potential, a neurotransmitter or hormone, an intracellular second messenger or ion, or mechanical stretch of the membrane. When a channel opens, it becomes selectively permeable to a restricted series of ions, selectivity being determined by the interaction of the various ions with the channel pore. There are a large number of different types of channel, often named after the most important permeant ion they pass, for example the Na^+, Ca^{2+}, and K^+ channels. The groups of channels are functionally distinct and can be further divided into subgroups on the basis of amino acid sequence and tertiary structure. Ions move down their electrochemical gradients through the channels at high rates (> 10^6 ions/s), which distinguishes them from other ion transport proteins (for example, the Na^+,K^+-ATPase or pump, and the Na^+,Ca^{2+} exchanger, see below) which move ions across plasma membranes several orders of magnitude more slowly.

When a ventricular myocyte is at rest (diastole), there is a potential difference of – 80 mV across the plasma membrane, the inside of the cell being negative with respect to the outside. This is due to K^+ channels being open, making the plasma membrane more permeable to K^+ than any other ion. The concentration of K^+ is about 4 mmol/litre outside the cell and about 140 mmol/litre inside, so K^+ tends to leave the cell by diffusing down its concentration gradient, which results in the inside becoming negatively charged since there is no movement of anions to balance the K^+ loss. An equilibrium is established where the electronegative force retaining K^+ inside the cell balances its tendency to diffuse out of the cell down its concentration gradient. This is termed the equilibrium potential (E), and can be calculated from the Nernst equation. The calculated equilibrium potentials for important ions are shown in Table 1.

The actual transmembrane potential difference at rest and the calculated equilibrium potential for K^+ are rarely the same owing to a small leakage of other ions (mainly Na^+) into the cell. To counteract this leak of Na^+ down its concentration gradient and to maintain the concentration gradients of Na^+ and K^+ upon which the generation of the membrane potential depends, the sarcolemmal Na^+,K^+-ATPase uses energy derived from the hydrolysis of ATP to pump these ions against their concentration gradients. This process is electrogenic (three Na^+ are extruded for two K^+ entering) and generates 3 to 10 mV of the membrane potential.

When a myocyte is electrically excited, Na^+ channels open and allow Na^+ ions to enter the cell. Positive charge is taken into the cell, the membrane potential increases towards the equilibrium potential for Na^+ (Table 1), and the cell depolarizes (Fig. 6). This causes the rapid upstroke (phase 0) of the action potential. The rate of change of the potential is related to the propagation velocity of the action potential across the heart. The current (I) generated by the inward movement of Na^+ (I_{Na}), like the same current in nerve tissue, is inhibited by tetrodotoxin, lidocaine, and quinidine. Na^+ channels close very rapidly and so I_{Na} almost entirely inactivates within the first 4 ms of the action potential. A small proportion of Na^+ channels do not inactivate as rapidly and allow a small inward current to persist for up to 100 ms, i.e. during the plateau phase of the action potential (phase 2).

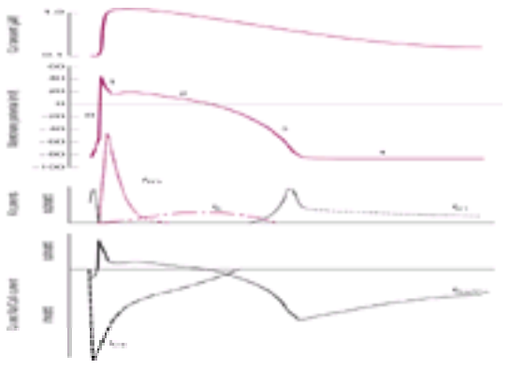

Fig. 6 Major ionic currents flowing during a ventricular myocyte action potential. Top trace: changes in cytoplasmic Ca^{2+} concentration during the action potential (Ca^{2+} transient). Second trace: the action potential recorded from a ventricular myocyte. Third and fourth traces: time courses and relative sizes of current flows during one beat. All K^+ currents (I_{TO}, I_K, and I_{K1}, seen in the third trace) repolarize the cell because of outward K^+ movement. Because of the inward movement of Ca^{2+}, Ca^{2+} current (I_{Ca}, seen in the fourth trace) is depolarizing. The Na^+,Ca^{2+} exchanger (Na/CaX, fourth trace) produces both outward and inward current ($I_{Na,Ca}$). Note that the inward Na^+ current that produces the rapid upstroke of the action potential is not shown: it is roughly eight to ten times the size of the Ca^{2+} current and has largely inactivated by the time the peak of the Ca^{2+} current is reached.

The characteristic notch observed in phase 1 of the action potential in ventricular myocytes (Fig. 6) (the notch is also particularly apparent in the Purkinje cell action potential; see Fig. 7) is caused by a transient outward current (I_{TO}), mainly carried by K^+ ions, that partially repolarizes the membrane. A number of different currents flow during phase 2 (the action potential plateau): the most important, from the point of view of the generation of contraction, is I_{Ca}. Ca^{2+} channels, which take longer to activate and inactivate than Na^+ channels, open within 3 ms of the start of the upstroke. The inward flow of Ca^{2+}, mainly through the L-type Ca^{2+} channel, maintains depolarization (Table 1 and Table 2) and can be inhibited by 'Ca^{2+} antagonists' such as verapamil and the dihydropyridines. The influx of Ca^{2+} initiate Ca^{2+}-induced Ca^{2+} release from the sarcoplasmic reticulum through the sarcoplasmic reticulum Ca^{2+}-release channels, and the increase in cytoplasmic Ca^{2+} concentration causes the myocyte to contract (see below).

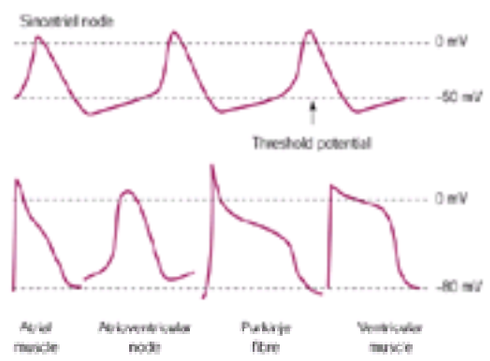

Fig. 7 Regional configuration of the action potential. In the sinoatrial and atrioventricular nodes, the cells spontaneously depolarize during diastole (phase 4 depolarization). When the membrane potential reaches a threshold value, the complete action potential is initiated. Because the sinoatrial nodal cells have the fastest phase 4 depolarization, they act as the cardiac pacemaker.

The plateau phase (phase 2) of the action potential (Fig. 6) is prolonged in ventricular myocytes because of the properties of several types of K^+ channel. The repolarizing current I_K flows through a channel that opens at positive membrane potentials and closes at negative potentials, akin to its counterpart in nerve. However, the kinetics of this channel are much slower than in nerve so that a much longer time is taken for it to start to repolarize, this being one of the reasons that a cardiac action potential is so much longer than a nerve action potential. In addition, ventricular myocytes possess another K^+ channel with peculiar characteristics. The current I_{K1} flows through a channel that first increases its conductance but then decreases it as the cell depolarizes away from E_K (anomalous rectification). The combined effect of these K^+ currents is that, despite the membrane potential approaching 0 mV during the plateau phase, a large outward K^+ current does not occur and the action potential is prolonged.

Repolarization (phase 3) starts to occur because of an increase in K^+ conductance via I_K and the termination of I_{Ca} (Fig. 6). As repolarization proceeds, the Na^+,Ca^{2+} exchanger responds to the increase in cytoplasmic Ca^{2+} concentration and produces an inward current ($I_{Na,Ca}$) through the exchange of three Na^+ entering the cell for one Ca^{2+} expelled. By producing an inward current, the Na^+,Ca^{2+} exchanger helps to prolong the plateau and slows repolarization. In ventricular myocytes, complete repolarization and a return to a negative membrane potential is eventually achieved by the current I_{K1}. The clinical consequences of the presence of I_{K1} are profound and result from this channel being acutely sensitive to the extracellular concentration of K^+. For example, shortly after myocardial infarction there is a loss of K^+ from cells and local K^+_o concentrations increase. Because K^+_o increases channel conductance and outward movement of K^+_i, I_{K1} increases accordingly. Thus, more outward current flows and the action potential duration shortens, which may lead to arrhythmia.

The configuration of the cardiac action potential differs regionally (Fig. 7) because of the presence or absence of different ionic currents. In the sinoatrial node (the pacemaker), I_{Na} is very small and the main current responsible for the depolarizing upstroke is I_{Ca}. The only repolarizing current is I_K. I_{K1} is absent and this partially explains why sinoatrial node cells have a more depolarized diastolic potential than ventricular myocytes. Sinoatrial node cells also depolarize spontaneously (phase 4), probably owing to the absence of I_{K1} and the presence of a current activated on hyperpolarization called I_f. Phase 4 is often termed the 'pre- or pacemaker potential' and is caused by the gradual decrease in I_K and increase in I_f (Fig. 6 and Fig. 7). Once the cell has depolarized to the point where Ca^{2+} channels open (the threshold), a more rapid depolarization takes place forming the upstroke of the sinoatrial node action potential. Atrial and ventricular myocytes do not have pacemaker potentials and spontaneously discharge only when injured or when there is abnormal intracellular Ca^{2+} balance. The longest action potential is in Purkinje fibres; this acts as a gate preventing retrograde activation by depolarization of adjacent ventricular myocytes. The action potential is longer in the epicardium than in the endocardium, and in the apex than in the base of the heart: the reason for this is not clear, but the discrepancy is the probable explanation for the upright T wave on the electrocardiogram.

When the cholinergic drive from autonomic neurones to the nodal cells is increased, the slope of the pacemaker potential is decreased (Fig. 8). Acetylcholine (**ACh**) opens another group of K^+ channels and activates $I_{K,ACh}$, which counters the decline in I_K and slows the rate of depolarization. I_f and I_{Ca} are also reduced and the overall effect is a reduction in the rate of production of action potentials. Conversely, upon stimulation of the sympathetic cardiac nerves, noradrenaline activates I_f and facilitates the opening of L-type Ca^{2+} channels, so increasing I_{Ca}. The net effect is to depolarize the membrane to the threshold level more quickly and increase the rate of production of action potentials. A summary of the ionic currents flowing during the cardiac action potential is given in Table 2.

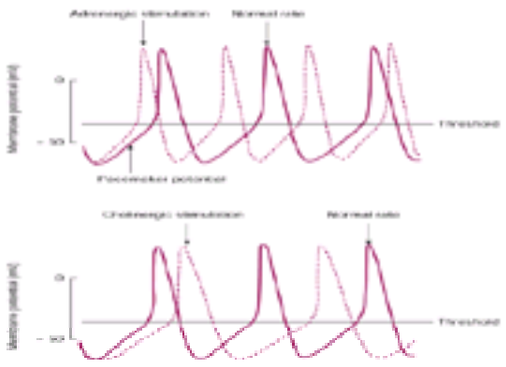

Fig. 8 Change in heart rate produced by altering the phase-4 slope of the pacemaker potential. Adrenergic stimulation increases and cholinergic stimulation decreases the slope, affecting the time taken to reach threshold.

Intracellular calcium ions—regulators of contraction

The electrical events throughout the heart initiate and regulate contraction (Fig. 9). The coupling of the electrical excitation of the heart to the production of contraction (called EC coupling) by Ca^{2+} ions involves the interaction of a number of cellular proteins involved in Ca^{2+} homeostasis. The T tubules allow the wave of depolarization of the action potential to reach deeply into the cell. The sarcoplasmic reticulum is an intracellular membranous lace-like structure surrounding the myofibrils, with swellings called junctional sarcoplasmic reticulum where the membrane of the sarcoplasmic reticulum comes close to the T tubules, (Fig. 2 and Fig. 10). During diastole, when cytoplasmic Ca^{2+} concentrations are low (around 0.1 µmol/litre), Ca^{2+} is sequestered by the Ca^{2+} buffering protein calsequestrin within the junctional sarcoplasmic reticulum. When opened, the L-type Ca^{2+} channels (also known as dihydropyridine receptors because of their sensitivity to the dihydropyridine Ca^{2+} channel antagonists) allow influx of Ca^{2+} across the sarcolemma (Fig. 10). This influx increases the local Ca^{2+} concentration around clusters of Ca^{2+} release channels in the sarcoplasmic reticulum (the ryanodine receptors, so-called because of their sensitivity to interference by the plant alkaloid ryanodine) sufficiently to open them, the number of channels activated in this way being mainly, though not exclusively, determined by the size of the Ca^{2+} current. This allows Ca^{2+} stored by the sarcoplasmic reticulum to be released into the cytoplasm (Ca^{2+}-induced Ca^{2+} release). The fluxes of Ca^{2+} combine to raise the cytoplasmic concentration of Ca^{2+} to between 5 and 10 µmol/litre, when contraction is initiated by the binding of Ca^{2+} to troponin C, relieving the inhibition of the actomyosin ATPase by troponin I.

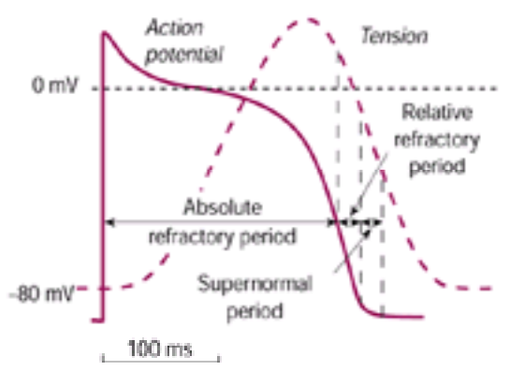

Fig. 9 The relationship between the action potential and the generation of force. The peak of force production is not achieved until near the end of the plateau phase of the action potential. This reflects the time required for Ca^{2+}-induced Ca^{2+} release. For a period between phase 0 and about halfway through phase 3, cardiac muscle cannot be excited with another stimulus no matter how strong. The muscle is in its absolute refractory period. Thus, tetanic contraction of the type seen in skeletal muscle cannot occur. When cardiac muscle is in its relative refractory period, an abnormally strong stimulus can initiate an action potential. In the supernormal period that follows, a slightly weaker stimulus that would normally fail to reach threshold can also initiate an action potential. The states of refractoriness are related to the ability of ion channels to recover from a stimulus. This recovery is both voltage- and time-dependent.

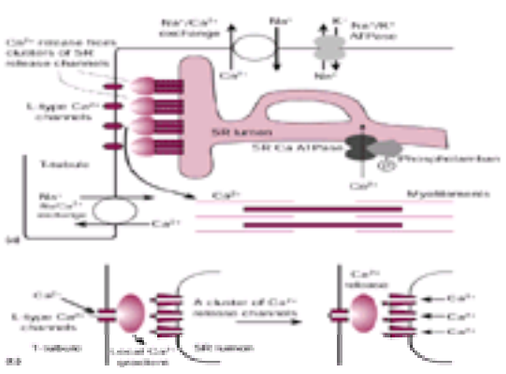

Fig. 10 EC coupling in the heart. Panel A: L-type Ca^{2+} channels allow Ca^{2+} influx across the sarcolemma and this creates I_{Ca}. This influx increases the local Ca^{2+} concentration around a cluster of Ca^{2+} release channels in the sarcoplasmic reticulum (SR) in sufficient amounts to open them (Ca^{2+}-induced Ca^{2+} release). Panel B: The opening of clusters of Ca^{2+} release channels in the sarcoplasmic reticulum allows Ca^{2+} stored by the sarcoplasmic reticulum to be released into the cytoplasm. The fluxes of Ca^{2+} combine to initiate contraction. The process is terminated by the sarcoplasmic reticulum Ca^{2+} ATPase (regulated by phospholamban) which removes Ca^{2+} from the cytoplasm and pumps it into the sarcoplasmic reticulum, and by the sarcolemmal Na^+,Ca^{2+} exchanger which expels Ca^{2+} from the cell. In steady-state conditions, the amount of Ca^{2+} leaving the cell (via the Na^+,Ca^{2+} exchanger) balances the amount entering (via the L-type Ca^{2+} channel).

Contraction is terminated by two principal mechanisms:

- By the activation of an ATP-requiring Ca^{2+} pump present in the sarcoplasmic reticulum membrane (the sarcoplasmic (endoplasmic) reticulum ATPase type 2 (**SERCA2**)), which catalyses ATP-dependent reuptake of Ca^{2+} into the sarcoplasmic reticulum.
- By the response of the sarcolemmal Na^+,Ca^{2+} exchanger to the increase in cytoplasmic Ca^{2+} (Fig. 10).

On a beat-to-beat basis, these are the main systems involved in removing Ca^{2+} from the cytoplasm and so inducing relaxation. Ca^{2+} is pumped back into the sarcoplasmic reticulum by SERCA2, which is regulated by the extent of phosphorylation of the SERCA2-associated protein, phospholamban. Hypophosphorylated phospholamban tonically inhibits SERCA2; as more phospholamban is phosphorylated (see below) the inhibition is removed and more Ca^{2+} is pumped into the sarcoplasmic reticulum. This, along with increased troponin I phosphorylation (see below), accounts for the more rapid relaxation of myocytes when the intracellular concentration of cyclic adenosine 3_,5_-monophosphate (**cAMP**) and the activity of cAMP-dependent protein kinase (see below) are increased by, for example, heightened sympathoadrenal tone.

Ca^{2+} is extruded from the cell by the sarcolemmal Na^+,Ca^{2+} exchanger that utilizes the energy associated with the concentration and electrical gradients for Na^+ to expel Ca^{2+} from the cell. It couples the transport of three Na^+ into the cell with the expulsion of one Ca^{2+}. It is thus electrogenic, and for every Ca^{2+} removed from the

cell, one positive charge enters. It can be predicted thermodynamically that the direction of ion movement mediated by the exchange can vary according to the membrane potential and the intracellular and extracellular concentrations of Na^+ and Ca^{2+}. The exchange is sensitive to the intracellular Na^+ concentration (normally about 7 to 10 mmol/litre in ventricular myocytes). When membrane potential is near diastolic levels and intracellular Na^+ concentration at normal physiological levels, the Na^+,Ca^{2+} exchanger will eject Ca^{2+} from the cell. However, if the intracellular Na^+ concentration increases by a few mmol/litre and the membrane potential becomes depolarized, the exchanger can reverse and mediate Ca^{2+} entry. Although ventricular myocytes possess other systems to decrease cytoplasmic Ca^{2+} concentrations (namely the sarcolemmal Ca^{2+} ATPase and mitochondrial Ca^{2+} uptake), these contribute less than 5 per cent towards relaxation of a normal twitch. SERCA2 and Na^+,Ca^{2+} exchange contribute about 70 and 25 per cent respectively towards relaxation, though these figures vary greatly between animal species. In steady-state conditions, the amount of Ca^{2+} leaving the cell via the Na^+,Ca^{2+} exchanger is the same as the amount entering (via I_{Ca}) to evoke Ca^{2+}-induced Ca^{2+} release, hence precise Ca^{2+} homeostasis is achieved.

Cardiac mechanics

Four key factors determine the contraction of isolated cardiac muscle preparations; these are also applicable to the intact heart. The first factor is the relationship between the initial fibre length and the force it produces: initial 'preload' stretches the sarcomeres, increasing the sensitivity of the myofilaments to Ca^{2+} and allowing them to produce force that is directly proportional to the preload (i.e. resting length). The second factor determining contraction is termed the 'afterload': if a mass is attached to a muscle just before it contracts isotonically, it represents a constant force (afterload) against which the muscle must work during contraction, and the amount and speed of contraction are inversely proportional to this. If preload and afterload are held constant, the maximum force and speed of contraction can be altered by changing the inotropic state of the muscle, which is generally brought about by chemical or hormonal influences (for example, increasing concentrations of catecholamines). In the whole heart, these three factors (preload, afterload, and inotropic state) influence the stroke volume (the volume of blood ejected by the ventricle during each systole), which, along with heart rate (the fourth factor), determines the cardiac output. These issues are discussed in Chapter 15.1.3.2.

Energy for contraction

As mentioned earlier, the heart is principally reliant on aerobic metabolism for its energy supply. In normal humans at rest, the heart extracts 60 to 65 per cent of O_2 passing through it. This corresponds to a rate of O_2 utilization of about 4.5 µmol/min/g wet weight (0.1 ml/min/g wet weight), which may increase by three- to fourfold during exercise. The comparable rates (in µmol/min/g wet weight) in other organs are: brain, 1.7; kidney, 7.1; liver 1.6; skeletal muscle at rest, 0.08; and skeletal muscle during exercise, 6.4. Thus, the maximal physiological O_2 uptake of the heart is higher than that of any other tissue.

In terms of metabolic fuels, the heart utilizes any fuel presented to it, within the constraints of metabolic regulation. Furthermore, because the heart is contracting continuously, an uninterrupted exogenous provision of fuels through the coronary circulation is essential. The major substrates for oxidation in man are lipid-derived fuels (long-chain fatty acids, principally palmitate, triglycerides, and ketone bodies (acetoacetate and 3-hydroxybutyrate)) and the carbohydrate-derived fuels (glucose, lactate, and pyruvate) (Fig. 11). Although the heart can oxidize amino acids, these probably represent a relatively minor fuel. The relative contribution of each substrate to cardiac fuel supply depends principally on the individual concentrations of substrates in the plasma (which are largely hormonally regulated).

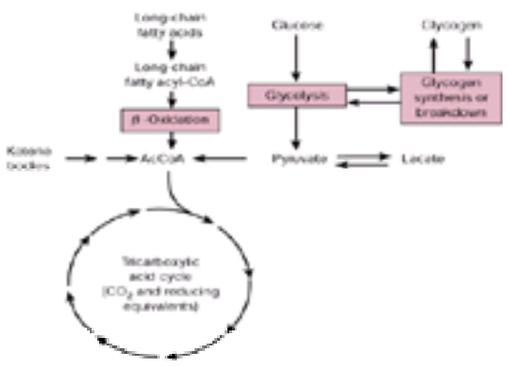

Fig. 11 Fuel utilization. Multistep processes are shown in boxes. In aerobic metabolism, the key intermediate acetyl CoA (AcCoA) is oxidized to CO_2 and water. Reducing equivalents produced mainly in the mitochondria by the tricarboxylic acid cycle and b-oxidation are passed between a series of carriers (the electron transport chain), the chemical energy released at each transfer step being used to drive regeneration of ATP from ADP and inorganic phosphate (oxidative phosphorylation). The ultimate electron acceptor for the reducing equivalents is O_2, which is reduced to water.

Carbohydrate metabolism

Glucose crosses the myocardial plasma membrane by two carrier-mediated mechanisms (the type 1 and the type 4 glucose transporters). The activity of the type 1 glucose transporter is largely independent of insulin but is controlled by the intra- and extracellular concentrations of glucose. Insulin can increase glucose uptake by recruiting intracellular type 4 glucose transporter to the plasma membrane. The principal use of intracellular glucose is to provide energy for contraction. In addition, the heart has a limited capacity to store carbohydrate as the polysaccharide glycogen. Whilst glycogen breakdown may not be quantitatively significant under normal conditions, it represents a fuel that can be used for a limited period in pathological conditions (e.g. during myocardial infarction, when the supply of fuels and O_2 is disrupted).

Each molecule of glucose is degraded through the exclusively cytoplasmic glycolytic pathway to pyruvate, the chemical energy released allowing the regeneration of two molecules of ATP (from ADP) per glucose molecule utilized and the concomitant reduction of the electron carrier nicotinamide adenine dinucleotide (**NAD+**) to NADH (Fig. 11). This pathway occurs anaerobically but is inefficient in terms of the quantity of ATP regenerated per glucose utilized. Under the aerobic conditions that normally exist in the heart, pyruvate is transported into the mitochondria and the glycolytically derived reducing equivalents enter on a shuttle mechanism (the malate/aspartate shuttle) regenerating cytoplasmic NAD^+. The remaining steps of carbohydrate metabolism take place in the mitochondria: pyruvate is oxidized to acetyl CoA and NADH (NAD^+ accepting the reducing equivalents) by the pyruvate dehydrogenase multienzyme complex, and acetyl-CoA then enters the tricarboxylic acid cycle, with the net result being the complete oxidation of the glucose molecule (glucose + $6O_2$ ® $6CO_2$ + $6H_2O$). The bulk of the mitochondrially generated ATP is then exchanged with cytoplasmic ADP, making it available for myofibrillar contraction and other processes.

In some pathological circumstances (for example in coronary artery disease), the heart may become intermittently hypoxic. When this happens, glucose is increasingly metabolized anaerobically (glucose ® 2 lactate + $2H^+$), and lactate and protons are released into the circulation. By contrast, under aerobic conditions exogenous lactate or pyruvate can also be utilized by the heart, entering oxidative metabolism in the same way as glycolytically derived pyruvate and NADH.

Metabolism of fatty fuels

Long-chain fatty acids, triglycerides, and ketone bodies are all capable of providing energy for the heart. Long-chain fatty acids (principally palmitate) are present in the plasma either non-covalently bound to albumin or covalently bound as triglycerides, which are in turn complexed with apolipoproteins. The albumin-bound long-chain fatty acids enter the ventricular myocyte by a carrier-mediated process that is still relatively ill-defined. Triglycerides are hydrolysed by the ectoenzyme lipoprotein lipase on the capillary wall to form long-chain fatty acids (and glycerol). Ketone bodies are synthesized hepatically from long-chain fatty acids and are (compared with long-chain fatty acids) a relatively soluble, readily diffusible, non-toxic fuel.

Long-chain fatty acids and ketone bodies can only be metabolized aerobically, and their catabolism takes place exclusively in the mitochondria (Fig. 11). Two-carbon fragments are successively removed from long-chain fatty acids (as long-chain fatty acid CoA) in a series of reactions known generically as b-oxidation to form acetyl CoA. Each turn of b-oxidation generates sufficient reducing equivalents to regenerate five ATP molecules. Acetyl CoA is then oxidized through the tricarboxylic acid cycle to regenerate more ATP, hence the energy yield from long-chain fatty acid oxidation is considerable. Lipid-derived fuels are preferentially used by the heart and their utilization diminishes the use of carbohydrate, thereby conserving glucose for tissues that are obligatorily dependent on carbohydrate as an energy source. This

is achieved by the inhibitory phosphorylation of pyruvate dehydrogenase multienzyme complex, which is stimulated by increased acetyl CoA and NADH concentrations, and by inhibition of the glycolytic pathway by intermediates of the tricarboxylic acid cycle, such as citrate.

Transmembrane and intracellular signalling pathways in the heart

Systemic stimuli in the form of neuroendocrine factors (for example catecholamines and insulin) impinge on the extracellular face of the sarcolemma of the myocyte. These molecules bind to transmembrane receptors that transfer information carried by the stimuli into the inside of the cell. Intracellular signalling pathways then transmit information from one part of the cell to another. Many of these pathways involve reversible protein phosphorylation (catalysed by protein kinases) and dephosphorylation (catalysed by protein phosphatases). Some hormones (for example thyroid hormone and oestrogen) interact directly with intracellular receptors. This group is mainly concerned with signalling at the level of transcription, which is achieved by the formation/presence of the signal–receptor complex in the nucleus.

Extraneous signals that utilize transmembrane receptors mediate their intracellular responses through signalling pathways that, although limited in number compared with the variety of receptors, produce diverse intracellular responses in different cellular contexts. End responses are cell specific because of the variety of proteins expressed in a given cell and the wide range of cell structures.

Intracellular signalling processes are discussed elsewhere. Those relevant to the heart are shown in Fig. 12.

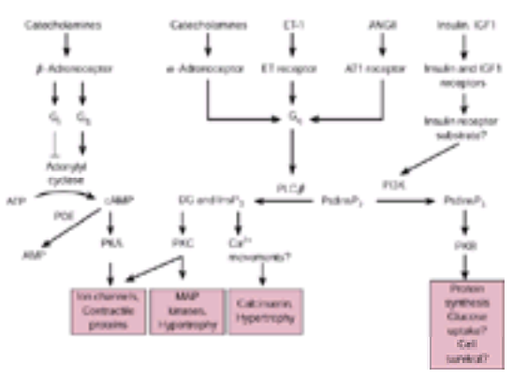

Fig. 12 Intracellular signalling pathways. Neurohumoral agonists bind to their transmembrane receptors and stimulate the formation of a variety of small molecule second messengers (cAMP, diacylglycerol (DG), inositol 1,4,5-trisphosphate ($InsP_3$), phosphatidylinositol 3,4,5,-trisphosphate ($PtdInsP_3$)). These then often activate enzymes, many of which catalyse reversible protein phosphorylation (protein kinases) or dephosphorylation (protein phosphatases) and alter the phosphorylation states of proteins which regulate biological processes, thereby modulating the rates of those processes. With the exception of the effect of the G_i protein on adenylyl cyclase, all stages shown are stimulatory. Other abbreviations: ANGII, angiotensin II; ET-1, endothelin-1; G_i, G_q, and G_s, heterotrimeric G_i, G_q, and G_s proteins; IGF 1, insulin-like growth factor 1; MAP kinases, mitogen-activated protein kinases; PDE, cyclic nucleotide phosphodiesterase; PI3K, phosphatidylinositol 3-kinase; PKA, PKB, and PKC, protein kinase A, B, and C, respectively.

G protein-coupled receptors

The ventricular myocyte is heavily dependent on signalling through transmembrane G protein-coupled receptors. The intracellular domains of these receptors interact with one or more of the large family of heterotrimeric (abg) guanine nucleotide-binding proteins (G proteins). In their inactive state, guanosine diphosphate (GDP) is bound to the G protein a subunit (a.GDP). The binding of agonists to the extracellular domain of their individual receptors and the receptor-G protein interaction that follows stimulates exchange of GDP for guanosine triphosphate (GTP) on the a subunit and dissociation of abg into a.GTP and bg. This dissociation is reversed by the innate GTPase activity of the a subunit and a(GDP). bg is reformed. a.GTP (and possibly bg) are effectors of membrane-bound enzymes that produce so-called 'second messengers'.

The archetypal second messenger is cAMP, which is formed from ATP by the membrane enzyme adenylyl cyclase following b-adrenergic receptor activation (Fig. 12). The interaction of the b-adrenergic receptor with the G_s protein causes formation of a_s.GTP which stimulates adenylyl cyclase and the cAMP formed activates cAMP-dependent protein kinase. The activation of this protein kinase is terminated by hydrolysis of cAMP to AMP by a group of phosphodiesterases. The b-adrenoceptor also activates G_i proteins (a_i.bg) which counteract the effects of a_s on adenylyl cyclase and act as a negative feed-back mechanism. In the heart, b-adrenergic agonists are positively inotropic, positively lusitropic (i.e. they increase the rate of relaxation), and positively chronotropic. The positive inotropism is the result of a cAMP-dependent protein kinase-catalysed phosphorylation of the L-type Ca^{2+} channel which enhances Ca^{2+} entry into the cell, and the direct activation of the L-type Ca^{2+} channel by a_s.GTP. The positive lusitropism involves increased phosphorylation of the sarcoplasmic protein phospholamban and the myofibrillar protein troponin-I. In its hypophosphorylated state, phospholamban is an inhibitor of SERCA2. Phosphorylation removes this inhibition and thus activates SERCA2, stimulating re-uptake of Ca^{2+} ions into the sarcoplasmic reticulum and increasing the rate of myofibrillar relaxation. Phosphorylation of troponin I stimulates dissociation of Ca^{2+} from troponin C, again increasing the rate of relaxation. The positive chronotropic effect of catecholamines is probably exerted at the level of the pacemaker and presumably also involves cAMP. The loss of b-adrenoceptor responsiveness in heart failure is due to increased inhibition of adenylyl cyclase by G_i and loss of cell surface b-adrenoceptors by an internalization pathway involving heightened activity of a b-adrenoceptor kinase and arrestin.

Receptor protein tyrosine kinases

Receptor protein tyrosine kinases (which include the insulin and the insulin-like growth factor 1 receptors) are a second group of transmembrane receptors. These possess an intracellular domain with a protein tyrosine kinase activity essential for signalling. The ventricular myocyte possesses receptors for both insulin and insulin-like growth factor 1 which mediate the stimulatory effects of these hormones on glucose uptake, protein synthesis and cell survival (Fig. 12). Activation of the insulin or insulin-like growth factor 1 receptor stimulates formation of another signalling molecule, phosphatidylinositol 3,4,5,-trisphosphate (**PtdInsP3**), which is formed in the membrane by phosphorylation of $PtdInsP_2$ by phosphatidylinositol 3-kinase (Fig. 12). This leads to the activation of the recently-identified protein kinase B (or Akt), which is intimately concerned with regulation of cell growth, protein synthesis, and cell survival (although its role in the ventricular myocyte has not yet been extensively investigated). However, activation of protein kinase B may account for the observed amelioration of heart failure by insulin-like growth factor 1.

Other signalling pathways

In addition to endothelin, the endothelial cells that line the coronary circulation and the endocardium produce nitric oxide, which induces the relaxation of smooth muscle (thus causing vasodilatation and increasing coronary blood flow) and is negatively inotropic. There is immense current interest in nitric oxide: see Chapter 15.1.1.2 for further information.

Positive and negative inotropes

The action of drugs on the myocardium can be due to an effect on the Ca^{2+} transient (upstream regulation) or on the sensitivity of the contractile proteins to Ca^{2+} (downstream regulation). No inotrope in general use in clinical practice increases the force of contraction by a direct effect on the myofibrils.

Upstream Ca^{2+} regulation—positive effects

The importance of increases in cytoplasmic Ca^{2+} concentrations and of b-adrenoceptor-mediated increases in cAMP concentrations in regulating myocardial contractility were described earlier. These two processes are the points of action of many useful drugs. Catecholamines (adrenaline and the pharmacological b-agonist isoprenaline) raise cAMP and protein kinase activity and are powerful positive inotropic drugs. Cyclic nucleotide phosphodiesterase inhibitors (for example caffeine, amrinone, and milrinone) raise cAMP concentrations by inhibiting its breakdown and thereby also activate protein kinase. Increased concentrations of cAMP

and increased protein kinase activity increase Ca^{2+} entry through L-type Ca^{2+} channels; relaxation is also augmented by phosphorylation of phospholamban and the ensuing activation of SERCA2, as described previously. The positive chronotropicity of these agents probably results from cAMP facilitating the opening of L-type Ca^{2+} channels and augmenting I_f in the conduction tissue.

Cardiac glycosides (for example digoxin) inhibit the Na^+,K^+-ATPase, preventing the extrusion of Na^+_i. This in turn inhibits Ca^{2+}_i extrusion through the Na^+,Ca^{2+} exchanger and may, when the cell is depolarized, augment Ca^{2+} entry by reversing the direction of the exchanger. Ca^{2+} may also be taken up in increased amounts by the sarcoplasmic reticulum, thereby increasing the cardiac Ca^{2+} pool and facilitating Ca^{2+}-induced Ca^{2+} release. The net effect is to increase the cytoplasmic concentration and availability of Ca^{2+} resulting in an increased force of contraction.

Upstream Ca^{2+} regulation—negative effects

In some circumstances, a decrease in myocardial contractility is desirable. This can be achieved with b-blockers that compete with catecholamines for occupancy of b-adrenoceptors. These lower cAMP and can exert an anti-ischaemic effect by lowering heart rate, increasing diastolic blood flow, and reducing myocardial contractility, thereby diminishing O_2 demand and improving O_2 delivery.

The 'calcium antagonists' (verapamil, nifedipine, diltiazem) inhibit Ca^{2+} entry through the L-type Ca^{2+} channel in both cardiac myocytes and vascular smooth muscle cells. They reduce myocardial contractility, relax smooth muscle, and reduce conduction in the sinoatrial and atrioventricular nodes. Therapeutically, their major effects are through their vasodilator activity (which increases blood flow and O_2 delivery to the myocardium).

Downstream Ca^{2+} regulation—positive effects

A group of drugs known as Ca^{2+}-sensitizing agents was initially believed to provide a fresh approach to the treatment of chronic/congestive heart failure. This heterogeneous group of positive inotropic agents mediate their effects by increasing the sensitivity of the contractile elements to Ca^{2+}, either by increasing the affinity of troponin C for Ca^{2+} or by direct effects on the actin–myosin complex. They were envisaged as being able to enhance myocardial contractility without changing the cytosolic Ca^{2+} concentration. Pimobendan, levosimendan, MCI-154, EMD-53998, and CGP-48506 have been studied as possible therapies for chronic/congestive heart failure: all have positive inotropic effects on isolated cardiac tissue, but their clinical usefulness has not yet been established.

Myocardial ischaemia

The three important consequences of myocardial ischaemia are failure of contraction, increased frequency of arrhythmias, and cell death. The general pathophysiology of this condition is discussed in Chapter 15.1.1.3 and the clinical aspects in Chapter 15.4.2.2 and Chapter 15.4.2.3: the following discussion is limited to the biochemical consequences of ischaemia for heart muscle.

Regulation of cardiac fuel and adenine nucleotide metabolism during hypoxia

In myocardial ischaemia the coronary blood flow to the affected area is insufficient to meet the demands for O_2 and fuels and to remove the products of metabolism. Maintenance of ATP regeneration is impossible, given the lack of O_2 supply and the fact that, given its high work output, the heart contains relatively little of the endogenous fuel polysaccharide glycogen. Anaerobic carbohydrate metabolism would have to increase about tenfold (not possible given the activity of the glycolytic pathway) and lactate would have to be removed (not possible in ischaemia). ATP concentrations eventually fall and contractile activity decreases. Two mechanisms operate in the short term to maintain ATP. First, ATP is buffered by the operation of the creatine phosphokinase equilibrium (phosphocreatine + ADP + H^+ ?2; creatine+ATP) which is driven to the right by proton production from glycolytic lactate. Second, the small amount of glycogen present is broken down (glycogenolysis) and glycolysis is increased.

In partial ischaemia, changes similar to those described above are also observed. Additionally, these hearts show increased accumulation of endogenous triglyceride droplets. These probably arise because, during ischaemia, the intermediates of fatty acid metabolism accumulate (for example long-chain fatty acid CoA and long-chain fatty acid carnitine, the long-chain fatty acid derivative which actually traverses the inner mitochondrial membrane). Combined with accumulation of glycerol-3-phosphate (formed from the reduction of the glycolytic intermediate 3-phosphoglyceraldehyde by accumulating NADH), this leads to synthesis of triglycerides. Long-chain fatty acid CoA and long-chain fatty acid carnitine are also powerful detergents. Their accumulation may therefore lead to disruption of membrane systems within the myocyte, to the detriment of cellular integrity.

Metabolic and mechanical consequences of ischaemia

Total ischaemia results in cessation of contraction within 60 s. Two important causes of the decline in contractility are the rapid development of intracellular acidosis through production of lactate and protons (see above), and an increase in intracellular concentrations of inorganic phosphate. The latter is caused by an inability to regenerate ATP from ADP and inorganic phosphate by fuel utilization. ATP concentrations are maintained in the short term (~ 60 s) because they are 'buffered' by creatine phosphate (see above). Thus, the inability to regenerate ATP by fuel utilization is reflected in a rapid decline in concentration of creatine phosphate. Both the fall in pH and the rise in inorganic phosphate decrease the maximum force that the myofilaments can produce, by shifting the Ca^{2+} sensitivity of the myofilaments to the right. The result is that higher concentrations of Ca^{2+} are required to produce the equivalent amount of force (Fig. 13). During ischaemia there is also a gradual increase in the resting (diastolic) level of cytoplasmic Ca^{2+}, probably because of a progressive failure of Ca^{2+} sequestration and efflux mechanisms. The effects of inorganic phosphate and acidosis would be larger if it were not for this increase in Ca^{2+} concentration. If ischaemia is prolonged, the sequestration and efflux mechanisms fail completely and this accounts for the cessation of the Ca^{2+} transient.

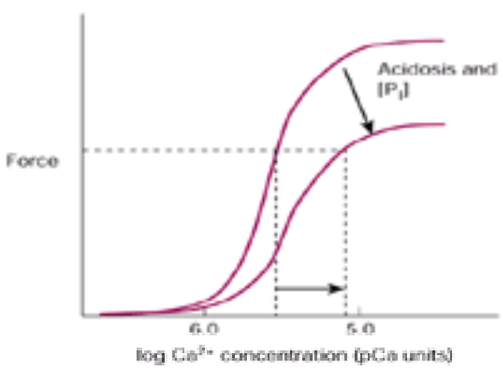

Fig. 13 Intracellular pH, inorganic phosphate, and myofilament Ca^{2+} sensitivity. The normal sigmoidal force/Ca^{2+} concentration relationship is shown by the line on the left. Acidosis or an increase in increased intracellular inorganic phosphate (P_i) decrease the sensitivity of myofilaments to Ca^{2+} and shift the relationship downwards and to the right. The maximum force produced is reduced.

In addition to intracellular buffering, there are other mechanisms to protect myocytes against acidosis. Two systems in the sarcolemma (the Na^+,H^+ exchanger and the Na^+,HCO_3^- symport) are activated by intracellular acidosis (Fig. 14). The Na^+,H^+ exchanger expels intracellular protons in exchange for extracellular Na^+ and is inhibited by the amiloride group of compounds. The Na^+,HCO_3^- symport transports HCO_3^- and Na^+ into the cell to buffer H^+.

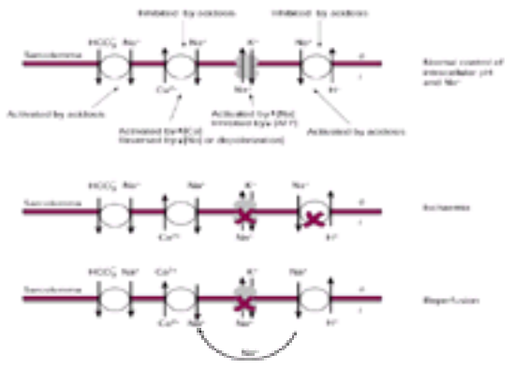

Fig. 14 Control of intracellular pH and Na^+ concentration. The membrane Na^+,H^+ exchanger and the Na^+,HCO_3^- symport counteract a fall in pH_i. Intracellular Na^+ concentration is controlled by the Na^+,K^+-ATPase and influences the direction of Ca^{2+} transport by the Na^+,Ca^{2+} exchanger. If ischaemia is prolonged, the decrease in extracellular pH inhibits the Na^+,H^+ exchanger and a decrease in intracellular ATP inhibits the Na^+,K^+-ATPase. On reperfusion, rapid normalization of extracellular pH reactivates the Na^+,H^+ exchanger and results in a large influx of Na^+ which cannot be expelled quickly owing to inhibition of the Na^+,K^+-ATPase. The increase in intracellular Na^+ concentration coupled with a depolarized membrane potential reverses the normal direction of the Na^+,Ca^{2+} exchange and mediates Ca^{2+} entry. Abbreviations: *o*, extracellular; *i*, intracellular.

Under normal resting conditions, the myocardium will recover almost completely after 10 to 15 min of ischaemia if adequate flow is restored. More prolonged periods of ischaemia cause the plasma membrane to become permeable to cations and recovery is reduced. If limited blood flow is present from collateral coronary arteries or from 'stuttering ischaemia' (periodic opening and closing of the native coronary artery), the onset of necrosis is delayed. After 60 to 90 min of ischaemia, the plasma membrane is destroyed. This may be attributable to low ATP concentrations, acidosis, activation of phospholipases, and lysosomal activity.

Reperfusion of ischaemic heart muscle results in further damage (reperfusion injury). This is characterized by an immediate swelling of the cell, release of intracellular enzymes (creatine phosphokinase, lactate dehydrogenase) and a large influx of Ca^{2+}. Ca^{2+} is taken up by the mitochondria and can be detected by electron microscopy as deposits of insoluble calcium phosphate. A large gain of Ca^{2+} is indicative of cell damage since it prevents the normal functioning of mitochondria and the regeneration of ATP. Many theories exist to explain the sudden influx of Ca^{2+}. A popular hypothesis is that the reintroduction of O_2 causes increased generation of reactive oxygen species, normal 'byproducts' of electron transport, which damage the plasma membrane through lipid peroxidation and render it permeable to Ca^{2+} in particular. The normal mechanisms within the cell for the removal of reactive oxygen species may be insufficient to protect against the sudden increased production of reactive oxygen species. Another hypothesis involves the Na^+,H^+ exchanger. If ischaemia is prolonged, there is a fall in extracellular pH that can often exceed the intracellular decline. Na^+,H^+ exchange is activated by intracellular acidosis, but is inhibited by extracellular acidosis. Thus, in prolonged ischaemia, the initial stimulation of the exchange will be followed by inhibition. On postischaemic reperfusion, there will be a rapid washout of extracellular protons that will reactivate the exchanger and result in a large influx of Na^+. The preceding ischaemia will have caused a decline in intracellular ATP so the Na^+,K^+ pump will be inhibited and thus the influx of Na^+ will lead to an increase in intracellular Na^+ concentration. As described earlier, the increase in intracellular Na^+ concentration coupled with a depolarized membrane potential reverses the normal direction of the Na^+,Ca^{2+} exchange and mediates excessive Ca^{2+} entry (Fig. 14).

Recovery from a period of ischaemia is slow. This is partly because the myocyte loses nucleotides. ATP is hydrolysed to ADP and operation of the adenylate kinase equilibrium (2ADP ?2; ATP + AMP) leads to AMP production. AMP is hydrolysed to adenosine (a vasodilator in its own right), but adenosine is rapidly broken down to inosine, thence oxidized to hypoxanthine and xanthine by xanthine oxidase, producing reactive oxygen species. Regeneration of nucleotides is slow and is the probable reason why, even if a cell does not die, total recovery is prolonged.

At present, treatments which are used in an attempt to reduce the size of a myocardial infarction act either by reducing ATP consumption (cardioplegic solutions, hypothermia, afterload reduction, negative inotropic agents) or by increasing coronary flow (afterload reduction, coronary vasodilators) through collaterals or the native coronary. The use of thrombolytic therapy in many patients with myocardial infarction reduces infarct size if the occlusion is due to thrombus, if the thrombus can be dissolved, and if the occlusion has not been present for more than 6 to 12 h. The only treatments that may benefit the ischaemic myocyte by mechanisms that act directly on the cell metabolism or cell structure are insulin, glucose and K^+ therapy, corticosteroids, and hyaluronidase.

15.1.3.2Clinical physiology of the normal heart

D. E. L. Wilcken

Introduction

The function of the heart is to pump sufficient oxygenated blood containing nutrients, metabolites, and hormones to meet moment to moment metabolic needs and preserve a constant internal environment. The heart has two essential characteristics, contractility and rhythmicity. The nervous system and neurohumoral agents modulate relationships between the venous return to the heart, the outflow resistance against which it contracts, the frequency of contraction, and its inotropic state; there are also intrinsic cardiac autoregulatory mechanisms. This section describes normal cardiac function and discusses the principal mechanisms contributing to its regulation.

The cardiac cycle

Electrical events initiate the cardiac cycle with depolarization of the sinoatrial node in the upper right atrium near the orifice of the superior vena cava (Fig. 1). Cardiac muscle acts as a functional syncytium. Cell to cell conduction is possible because the intercalated discs offer a low electrical resistance. The action potential in an active cell causes current flow, which depolarizes the adjacent cells. The generated action potential spreads from the sinoatrial node across the functional syncytium at a speed of 1.0 to 1.2 m/s. The first mechanical response is atrial systole.

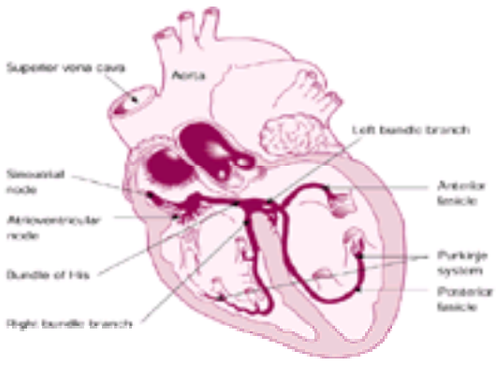

Fig. 1 Diagram of the heart showing the impulse-generating and impulse-conducting system. (Reproduced with permission from Junqueira LC, Carneiro J, Kelley RO (1998). *Basic histology*, 7th edn. Appleton and Lange, Norwalk, CT.)

The valvular attachments and connective tissue in the atrioventricular groove normally prevent cell to cell conduction of the electrical impulse from atrium to ventricle. This conduction occurs only through the specialized cells of the atrioventricular node (Fig. 1). The atrioventricular node is a region of slow conductance, from 0.02 to 0.1 m/s. This delays activation of the cells of the bundle of His and allows time for completion of ventricular filling. The conduction velocity in the bundle of His is from 1.2 to 2.0 m/s. The impulse passes via the right bundle branch and the two branches of the left bundle, and spreads rapidly (2.0 to 4.0 m/s) through the Purkinje fibres and each muscle cell to produce an orderly sequence of ventricular contraction (Fig. 1). Atrial and ventricular depolarization (P wave and a QRS complex) and repolarization (T wave) can be recorded on the electrocardiogram as the summation of the spread of the electrical potentials over all the cells of the heart (Fig. 2). Electrocardiography is considered in Chapter 15.3.2.

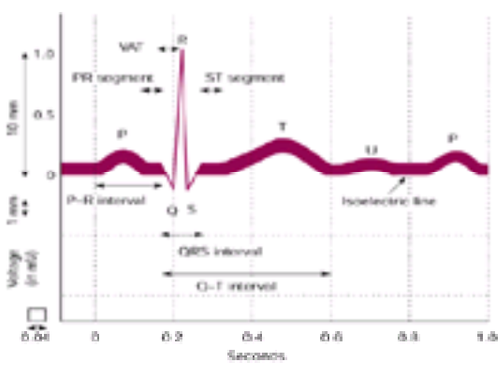

Fig. 2 Diagram of electrocardiographic complexes, intervals, and segments. VAT, ventricular activation time. (Reproduced with permission from Goldman MJ (1986). *Principles of clinical electrocardiography*, 12th edn. Lange, Los Altos, CA.)

The specialized cells of pacemaker tissue have an inherent rhythmicity which is shared by the sinoatrial node, the atrioventricular node, and Purkinje tissue. Unlike other myocardial cells these cells do not maintain a diastolic intracellular potential of about –90 mV but tend to depolarize spontaneously. Because the sinoatrial node has the fastest inherent discharge (depolarization) rate, and because there is a brief period after depolarization of the whole heart during which a further stimulus is ineffective—the absolute refractory period—the sinoatrial node is normally the pacesetter for the heart. However, if this does not occur, pacemaker tissue in the atrioventricular node, the bundle of His, or the Purkinje system, will assume this role. The heart rate is then considerably slower.

Mechanical events

The mechanical events following depolarization of the atrial and ventricular muscle and their timing in relation to the electrocardiogram, to pressure and flow changes, and to heart sounds are shown in five phases in Fig. 3. After the P wave, and coinciding with atrial systole, 'a' waves appear in left atrial and right atrial pressure tracings due to atrial contraction, and an 'a' wave can be seen in the jugular venous pulse. Atrial contraction increases ventricular filling by about 10 per cent (phase 1).

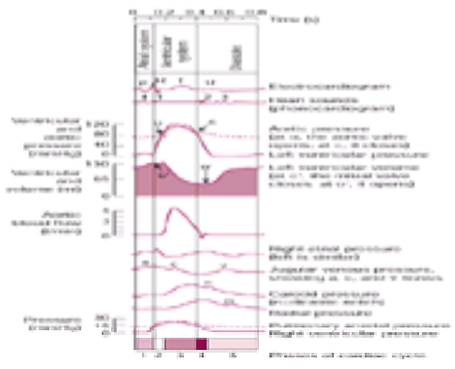

Fig. 3 Events of the cardiac cycle at a heart rate of 75 beats/min. The phases of the cardiac cycle identified by the numbers at the bottom are: (1) atrial systole; (2) isovolumetric ventricular contraction; (3) ventricular ejection; (4) isovolumetric ventricular relaxation; and (5) ventricular filling. Note that late in systole, aortic pressure actually exceeds left ventricular pressure. However, the momentum of the blood keeps it flowing out of the ventricle for a short time. The pressure relationships in the right ventricle and pulmonary artery are similar. The jugular venous pulse is similar in form to that seen in the right atrial pressure tracing. The 'c' wave interrupts the 'x' descent of the 'a' wave. The decline in pressure from the peak of the 'v' is the 'y' descent; the rate of decline reflects speed of ventricular filling. Atr. syst, atrial systole; ventric. syst, ventricular systole. (Modified with permission from Ganong WF (2001). *Review of medical physiology*, 20th edn. Appleton and Lange, Norwalk, CT.)

The onset of ventricular contraction coincides with the peak of the R wave of the electrocardiogram and there is a rapid rise in intraventricular pressure, which closes the mitral and tricuspid valves. The first heart sound is heard at the time of maximum displacement of these valves as they reach their closing positions. During this short isovolumetric period (phase 2 of Fig. 3) the pressure rises rapidly in the ventricle. When ventricular pressures exceed those in the pulmonary artery and aorta, the outflow valves open and ventricular ejection follows, with the highest flow rate occurring in early systole, and pressures in the aorta and pulmonary artery rise. Normally between 50 and 70 per cent of the ventricular volume is ejected during systole, and this can be seen in the volume curve included in Fig. 3 (phase 3).

The jugular venous pulse during ventricular contraction has a positive deflection in early systole, the 'c' wave, due to right ventricular contraction and bulging of the tricuspid valve into the right atrium. Descent of the tricuspid ring caused by ventricular contraction then produces a negative 'x' descent, but as atrial inflow continues the pressure rises in the atria and great veins, producing the 'v' wave. This reaches its peak just before the opening of the tricuspid valve, declining during early ventricular filling as the negative 'y' descent. The changes in the pulmonary veins and left atrium are similar.

As the strength of ventricular contraction declines, and coinciding with the end of the T wave of the electrocardiogram, the aortic and pulmonary valves close, producing the dicrotic notch seen on both aortic and pulmonary artery pressure tracings in Fig. 3. Aortic closure slightly precedes pulmonary closure, and together these are responsible for the two components of the second heart sound. A short period of further rapid decline in ventricular pressure ensues without change in the ventricular volume (the period of isovolumetric ventricular relaxation, phase 4) and at the end of this the mitral and tricuspid valves open. There is a pressure gradient from atrium to ventricle so that a period of rapid ventricular filling follows, which coincides with the timing of the third heart sound. The rapid ventricular filling is reflected in the shape of the ventricular volume curve, and is followed by a period of slower filling (phase 5) with a final sudden small increment from the next atrial contraction as diastole ends (phase 1).

Third heart sounds are audible with the stethoscope in normal children and young adults, but over the age of about 40 years this usually indicates elevation of ventricular end-diastolic pressure (most frequently in the left ventricle). This is probably because the myocardium and valvular structures become stiffer with ageing, and large increases in ventricular end-diastolic pressure are then required to tense valvular structures and generate audible vibrations. The hearing of a fourth heart sound almost always indicates abnormal ventricular function. The end-diastolic pressure in the affected ventricle (usually the left) is increased, and the already stretched inflow valve responds to atrial systole and further filling with oscillations, producing a low-pitched sound that is often palpable as well as audible at the cardiac apex. A fourth heart sound precedes the Q wave of the electrocardiogram and must be distinguished from a normal splitting of the two components of the first heart sound. The latter occurs after the Q wave (Fig. 2 and Fig. 3).

Normal volumes, pressures, and flows

The blood volume in normal adults is about 5 litres (haematocrit 45 per cent), and of this about 1.5 litres are in the heart and lungs—the central blood volume. The pulmonary arteries, capillaries, and veins contain about 0.9 litres, with only about 75 ml being in the pulmonary capillaries at any one instant. The volume of blood in the heart is about 0.6 litres. Left ventricular end-diastolic volume is about 140 ml, the stroke volume about 90 ml, so that the end-systolic volume is around 50 ml, and the ejection fraction (stroke volume/end-diastolic volume) is between 50 and 70 per cent. The right ventricular ejection fraction is similar.

Of the 3.5 litres in the systemic circulation most, at least 60 per cent of the total blood volume is in the veins. The term 'mean circulatory pressure' introduced by Guyton is useful and refers to the equilibrium pressure measured in the entire circulation within a few seconds of stopping the heart; in dogs this is about 7 mmHg. The systemic veins containing most of the blood volume are easily distensible, and input of blood into the contracting heart is associated with only small changes in venous pressure. By contrast, ejection of blood into the much less distensible arterial tree produces large pressure changes.

The normal values for pressures generated in the heart and great vessels during the cardiac cycle are shown in Table 1. Pressures are measured with reference to a zero pressure arbitrarily set at 5 cm below the sternal angle with the patient recumbent. 'Normal' arterial blood pressure is considered later (see below).

P>Cardiac output is the product of stroke volume and heart rate. It is related to body size and is best expressed as litre/min/m ^{2} of body surface area: the 'cardiac index'. The mean cardiac index under resting and relaxed conditions is 3.5 litre/min/m ^{2}, and values below 2 and above 5 are abnormal. The cardiac index declines with age. In persons of average size, resting oxygen consumption is about 240 ml/min, and the difference in oxygen content between arterial and mixed venous blood is about 40 ml/litre (arteriovenous oxygen difference), giving a basal cardiac output of 6 litre/min from the direct Fick equation. In normal subjects the arteriovenous difference in oxygen content at rest is maintained within narrow limits, from 35 to 45 ml/litre; values of 55 ml/litre and above are always abnormal.

Pulmonary or systemic vascular resistance is estimated by dividing the difference between mean inflow pressure (pulmonary artery or aortic) and mean outflow pressure (left atrial or right atrial) in mmHg by the flow in litre/min through the respective circulations. In normal subjects and patients without intracardiac shunts this flow is the cardiac output. Normal pulmonary vascular resistance is less than 2 mmHg/litre/min (160 dyn/s/cm ^{5}). Arterial blood pressure is the product of cardiac output and total peripheral resistance.

Stroke work is the integral of instantaneous ventricular pressure with respect to stroke volume, but is usually estimated as the product of stroke volume and mean ejection pressure. The orderly sequence of contraction in the normal cardiac cycle co-ordinates changes in instantaneous pressure and flow, so maximizing the transfer of energy to the circulation. Normal left ventricular work output at rest is about 6 kg/m ^{2}/min.

Myocardial mechanics

A more rational approach to the understanding of cardiac muscle contraction and altered performance in disease states has come from renewed interest in the results of classic experiments in skeletal muscle physiology. The three-component model for muscular contraction proposed by Hill in 1938 (Fig. 4) comprises, first, a contractile element which, when activated, develops force and shortens; second, a series elastic element that is stretched passively during shortening and produces a

dampening effect; and, third, a parallel elastic element which supports resting tension. The latter, together with the series elastic element, is responsible for the extensibility or compliance of relaxed muscle. It is not known which precise structures are responsible for the series elastic and parallel elastic components, but there is no doubt about their functional significance.

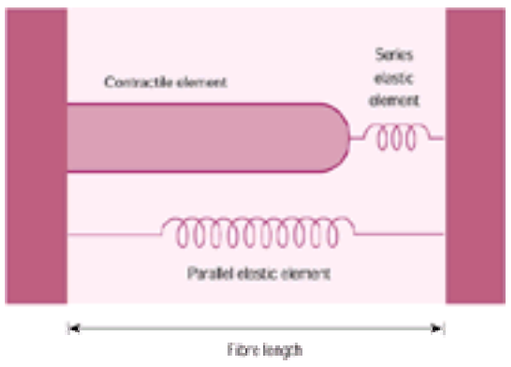

Fig. 4 A representation of the model used by A. V. Hill to illustrate the three mechanical components of functioning muscle.

When a muscle is activated to contract, it develops a potential for doing work. In isolated skeletal and heart muscle preparations the stretching force applied to the muscle, and therefore the length of the muscle, can be varied before contraction; this is the preload. The activated muscle will begin to shorten when it has generated a force sufficient to overcome that exerted by the attached weight or load against which it contracts. When the force exerted by the load is so arranged that it is not applied to the relaxed muscle and is applied only after the muscle has begun to develop tension it is termed the afterload. If this load is so large that the activated muscle is unable to overcome it, and so cannot shorten, the contraction produces tension only, and the contraction is isometric. When shortening does occur, external work is done. If the load is constant during the shortening, the contraction is said to be isotonic; if it changes it is auxotonic.

The tension produced by both skeletal and cardiac muscle during contraction depends on initial fibre length; during afterloaded isotonic contractions from a particular length, the amount and the speed of fibre shortening and the tension developed all depend upon the afterload. Over a range of loads the initial velocity of muscle shortening is most rapid and the most extensive shortening occurs when the load is smallest.

The inverse relationship between initial velocity of fibre shortening and load in an isotonic contraction is a fundamental one for both skeletal and cardiac muscle (Fig. 5). There is, however, a major difference between the two types of muscle in that the relationship at any one length is constant in a skeletal muscle, whereas in cardiac muscle there are variations in inotropic state that are accompanied by considerable changes in the relationship between force and velocity. A positive inotropic effect produces a more extensive contraction from the same initial length and afterload, and a faster maximum velocity of shortening (V_{max}). An increase in initial fibre length with no increase in inotropic state increases the force of contraction but does not, however, change the maximum velocity of shortening. This is illustrated in Fig. 5.

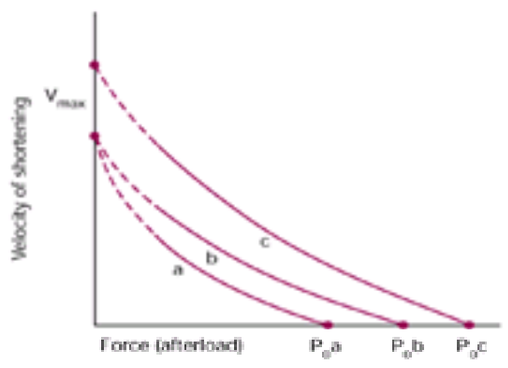

Fig. 5 Idealized relationships between velocity of fibre shortening and afterload or force developed during contraction of a strip of cardiac muscle under three different conditions. Curves a and b were obtained with the muscle in the same inotropic state but with a longer initial fibre length (greater preload) for curve b. Curves b and c were obtained with initial fibre length the same but with contractility increased in c by the addition of a drug producing a positive inotropic effect. The terms V_{max} and P_0 were used by Hill to describe, respectively, a hypothetical maximum shortening velocity in the absence of any load (hence the broken lines), and the force developed in an isometric contraction. An increase in initial fibre length increases P_0 but not V_{max}; a positive inotropic change increases both P_0 and V_{max}.

The contraction of the intact heart can be visualized as being similar mechanically to the afterloaded contraction of an isolated muscle strip. For the left ventricle, the preload is the distending force which stretches the muscle fibres in end-diastole, and the initial afterload is the force the ventricle must generate in order to open the aortic valve and eject blood. At the end of ejection, the ventricular muscle is isolated from the peripheral circulation, with the afterload then supported by the competent aortic valve, and the muscle relaxes against a comparatively small force. Relaxation of the heart is an active process due to withdrawal of calcium ions from the cytoplasm surrounding the myofibrils. 'Active' relaxation is still proceeding in the ventricular wall when the atrioventricular valves open, and, if it is delayed, as in the hypoxic heart, the slower relaxation increases the stiffness of the ventricular wall and reduces filling. Wall thickness is also a determinant of relaxation rate and compliance. For this reason filling pressures are higher for the thicker and stiffer left ventricle than for the thinner and more distensible right ventricle (Table 1). When the left ventricle is hypertrophied due to chronic pressure overload, as in systemic hypertension or aortic stenosis, it becomes stiffer and filling pressures may then be abnormally high.

Regulation of cardiac function

Four essential factors determine the performance of the heart:

1. venous return;
2. outflow resistance (afterload);
3. inotropic state or contractility;
4. heart rate.

Changes in cardiac performance are accomplished by mechanisms that alter these four determinants.

Venous return, preload, and the Frank–Starling relationship

The relationship described independently by Frank and Starling between end-diastolic fibre length and force of contraction is shown in Fig. 6. When the right or left ventricle ejects against a constant pressure, variations in venous return alter the degree of stretch of the muscle fibres in diastole, and this determines contraction strength and work output. The number of active force-generating sites in each fibre increases as it lengthens so that, within limits, the force of contraction and stroke work are positively related to end-diastolic fibre length. The relationship is curvilinear when stroke work is plotted against end-diastolic pressure as an index of preload, reflecting the exponential relationship between end-diastolic pressure and end-diastolic volume. When stroke work is plotted against end-diastolic volume the relationship between stroke work and preload is linear.

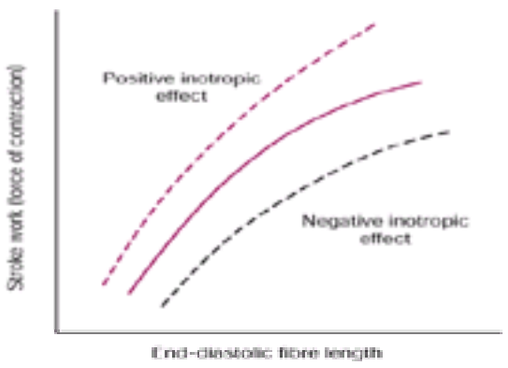

Fig. 6 The relation between left ventricular end diastolic fibre length and left ventricular stroke work showing displacement upward and to the left with an increase in contractility and downward and to the right with a reduction in contractility. Similar but not identical curves are obtained by plotting left ventricular stroke work as one measure of the force of contraction against ventricular end-diastolic pressure or volume (see text). Similar function curves may be obtained from both ventricles and both atria.

The response of the heart at any particular time depends upon:

1. The intrinsic state of the muscle, i.e. the nature of its own biochemistry and contractile machinery.
2. The prevailing neurohumoral state, i.e. increased sympathetic outflow produces a more forceful contraction at any end-diastolic fibre length and shifts the curve upward and to the left.
3. Extrinsic inotropic influences; drugs which have a positive inotropic effect also shift the curve upward and to the left, whereas myocardial depressants have a negative inotropic effect and shift the curve downward and to the right.

End-diastolic fibre length is determined by the force distending the ventricle at end-diastole, and end-diastolic pressure provides a reasonable indication of this force when the ventricle has normal distensibility or compliance; this is the preload. The systemic venous return and the elastic properties of the myocardium produce the end-diastolic distending pressure for the right ventricle, and the pulmonary venous return and myocardial elasticity that for the left ventricle. For clinical purposes it is convenient to equate venous return with preload because, as it changes from beat to beat, it adjusts the strength of the subsequent ventricular (and atrial) contraction by varying the force stretching the relaxed cardiac muscle and changing end-diastolic fibre length.

Outflow resistance or afterload

The pressure which the ventricle must develop to exceed that in the pulmonary artery and the aorta and open the pulmonary and aortic valves is determined largely by the pulmonary and systemic vascular resistances, as shown for the latter in Fig. 7. These resistances, together with an inertial component dependent upon the mass of blood within the vessels, the compliance (stiffness) of the vessels, and the physical characteristics of each vascular tree combined with the pulsatile nature of the flow, constitute the impedance to ventricular outflow. This is the load against which the ventricle must contract and shorten. As this load is not applied in diastole to the relaxed muscle, it then being supported by competent aortic and pulmonary valves, it is usefully described clinically as the afterload; it becomes applied to the muscle only after the ventricle has begun to develop tension.

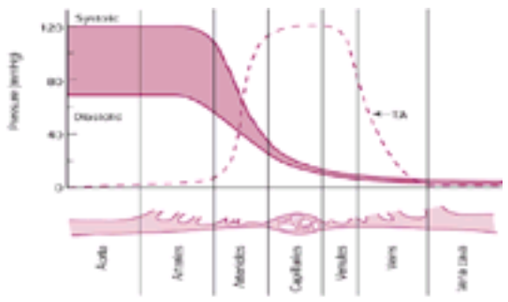

Fig. 7 Diagram of the changes in pressure as blood flows through the systemic circulation. TA, total cross-sectional area of the vessels. This increases from 4.5 cm ^{2} to 4500 cm^2 in the capillaries. The major resistance to flow is at the arteriolar level. (Modified and reproduced with permission from Ganong WF (2001). *Review of medical physiology*, 20th edn. Appleton and Lange, Norwalk, CT.)

Regulation of systemic arterial blood pressure

The regulation of the systemic circulation is well adapted to the vital function of maintaining constant, adequate cerebral perfusion. There is a need to maintain a relatively constant arterial blood pressure when there are changes in posture and circulating blood volume. The baroreceptors mediate rapid responses to alterations in aortic pressure, whilst a variety of hormonal and physical factors regulate the circulating blood volume.

Baroreceptors

The baroreceptor regulatory system comprises two groups of stretch receptors: one group in the carotid sinuses near the bifurcations of the common carotid arteries in the neck and a second group in the arch of the aorta. These respond to an increase in central arterial pressure by the firing of impulses, which pass by the glossopharyngeal and vagus nerves to the solitary tract nucleus in the medulla and inhibit sympathetic outflow. Efferent impulses from these central connections pass via the right vagus nerve mainly to the sinoatrial node, and via the left vagus mainly to the atrioventricular node. The effect is to decrease the heart rate and the force of atrial contraction. There is also attenuation of sympathetic discharge via the thororacolumbar sympathetic outflow to arteriolar smooth muscle in the limbs and visceral circulation, resulting in a release of peripheral arteriolar constriction and therefore peripheral vasodilatation. Thus the immediate response to a rise in arterial pressure is slowing of the heart rate, reduced force of atrial contraction, and reduced vascular resistance. The net effect of this negative feedback system is to offset the elevation in blood pressure. Conversely a lowering of blood pressure diminishes stimulation of the stretch receptors and reduces afferent traffic to the solitary tract nucleus resulting in reduced inhibition of sympathetic outflow. As a consequence there is a quickening of the heart rate and peripheral vasoconstriction so that the blood pressure increases. The changes in heart rate take place within 1 to 2 s and changes in vasomotor control within 5 or 6 s.

Baroreceptor mechanisms effectively modulate the responses of blood pressure to postural change. Additionally they adapt to maintain the normal circadian variation in blood pressure (see below). They also maintain elevated arterial blood pressure in systemic hypertension. Sensory input to the reflex is reduced in disorders of the autonomic nervous system, and in the prolonged weightlessness of space flight.

Blood volume

The circulating blood volume is relatively small and a large proportion is contained in the veins (Fig. 7) so that any change in blood volume will affect venous return and therefore cardiac output and blood pressure. When blood volume is large and the veins full there is little reduction in venous return on standing and cardiac output is maintained. However, when effective blood volume is reduced and the veins are relatively empty, on standing there is pooling of blood in the veins of the legs and a reduction in venous return and cardiac output so that arterial blood pressure falls. Baroreceptor responses become evident within a couple of beats, the

heart rate increases, and cardiac output and blood pressure are restored. Circulating blood volume is kept relatively constant by a combination of mechanisms which involve the actions of natriuretic peptides, the renin–angiotensin–aldosterone system, vasopressin, and osmolality.

The natriuretic peptides

The discovery of secretory granules in the atria of the heart and the demonstration in 1981 that they produce a natriuretic factor that inhibits the reabsorption of sodium in the distal tubule of the kidney enhanced understanding of the regulation of blood volume and cardiac performance. Three natriuretic peptides have subsequently been identified.

Atrial natriuretic peptide is present in the circulation and concentrations increase during volume expansion. The right atrium contains about two to four times as much activity as the left, and release of the hormone is mediated largely by atrial distension. The effect is to produce a diuresis and to reduce cardiac and circulating blood volume. Atrial natriuretic peptide also has a vasodilator action and opposes the vasoconstricting effects of noradrenaline and angiotension II.

The second natriuretic peptide was identified in brain tissue, and is referred to as brain natriuretic peptide. Large amounts were later shown to be in the ventricles of the heart and circulating levels are increased in venticular hypertrophy and cardiac failure. Brain and atrial natriuretic peptides have similar actions. The third to be identified was C-type natriuretic peptide. It is distributed widely in tissues, circulating concentrations are low, and it appears also to have actions similar to the other two peptides, but with a greater vasodilator effect on veins.

Thus these three peptides contribute to the regulation of cardiac and circulating blood volume and of blood pressure. The therapeutic potential of manipulating the effects of these peptides is currently being assessed.

The renin–angiotensin system

This system, which is both local and systemic, is of major importance in the regulation of circulating blood volume and the maintenance of normal blood pressure. Enhanced activity of systemic renin and angiotensin increases the production of aldosterone, which promotes reabsorption of sodium by the kidney and expansion of circulating blood volume. All components of the renin–angiotensin system are distributed widely throughout tissues, including the brain and the heart, and increased activation of the system increases the risk of cardiovascular events. Angiotensin II is a potent vasoconstrictor that also enhances the proliferation of smooth muscle cells. The angiotensin converting enzyme inhibitors in clinical use diminish angiotension II production locally and in the circulating blood. Both local and general effects appear important in mediating the benefits that accrue from the use of these drugs in the management of hypertension and congestive cardiac failure, and in the reduction in rates of recurrence of coronary events in ischaemic heart disease. The mechanisms mediating this latter effect in particular await clarification. It is yet to be determined whether the use of the more recently developed angiotensin II receptor blocking drugs will result in similar outcomes.

Ventricular volume and afterload

Ventricular volume also has a major effect on afterload, as pressure is equal to force per unit area. The force acting radially on the inner surface of the whole ventricle at any time during systole is the product of the intraventricular pressure and ventricular surface area at that time. If the left ventricle is assumed to be a sphere (surface area = pd^2), the force opposing ejection at any time during contraction is the product of the intracavity pressure and p d^2 at that time. Thus, a change in left ventricular diameter from a normal value of 5 cm to one of 10 cm would result in a fourfold increase in the force opposing ejection for the same intracavity systolic pressure; the ventricle would need to develop greatly increased wall tension to overcome that force. Because wall tension developed during systole is the major determinant of myocardial oxygen consumption, the contraction will clearly be much less efficient in the larger heart for the same stroke volume and ejection pressure (stroke work).

During a normal heartbeat the afterload is greatest at the beginning of ejection (rapid rise in pressure and maximum volume; Fig. 3), but thereafter decreases as the pressure reaches a plateau and then declines as the ventricle becomes smaller. There is therefore a matching of the afterload to the declining intensity of the contraction as it proceeds to completion, and fibres shorten at a relatively constant rate. This is less obvious in a large heart where the volume change during ejection is a smaller proportion of the total ventricular volume.

The end-diastolic volume is influenced by preload, afterload, circulating blood volume, the inotropic state of the ventricle, heart rate, and neurohumoral influences. For example, it is smaller in the erect than in the horizontal position because of reduced venous return, and it decreases with a moderate increase in heart rate because of an associated positive inotropic effect. The proportion of end-diastolic volume ejected during systole, the ejection fraction (normal 50 to 70 per cent), is a useful index of overall left ventricular function and is easily measured non-invasively by gated blood pool scanning and two-dimensional echocardiographic techniques. The ejection fraction increases with exercise and with positive inotropic interventions. Values for right ventricular ejection fraction are of the same order as those for the left side of the heart.

Myocardial contractility and inotropic state

Myocardial function is greatly altered by changes in inotropic state or contractility. Positive inotropic effects are thought to be mediated by activation of excitation–contraction coupling mechanisms and are associated with an increased influx of calcium ions into myocardial cells and a more powerful contraction. Changes in the intensity of excitation–contraction coupling are independent of the Frank–Starling mechanism. Increases in the intensity shift the curve upwards and to the left and decreases shift it downwards and to the right (Fig. 6). With a positive inotropic effect, the force of contraction, however measured, is increased for a given end-diastolic fibre length and, if the afterload is the same, the initial velocity of fibre shortening is also increased (Fig. 5); in the intact heart, there is more complete emptying during systole. Increased sympathetic stimulation, some drugs, and an increase in heart rate itself (the staircase or Bowditch phenomenon; postectopic potentiation, see below) have positive inotropic effects. Myocardial depressants, such as hypoxia and most anaesthetic drugs, have negative inotropic effects. Increased parasympathetic stimulation produces acetylcholine-mediated negative inotropic effects that are confined almost entirely to the atria because of the anatomical distribution of vagal endings in the myocardium.

It is difficult to measure inotropic changes accurately in the human heart because changes in the intensity of excitation–contraction coupling and changes in the Frank–Starling relationship, though separate, are nevertheless closely linked. Whilst Hill's classic model (Fig. 4) has been important conceptually, attempts to define contractility as predicted by the model—by deriving an extrapolated maximum velocity of fibre shortening which would obtain with the muscle contracting against zero load—have not been rewarding. The peak rate of change of intraventricular pressure (peak d *p*/d*t*) is a useful index of change in contractility provided that preload, afterload, and heart rate remain constant.

An approach that appears relatively insensitive to changes in both preload and afterload is that of Suga and Sagawa, using the ventricular pressure–volume loop diagram. There is an approximately linear relationship between end-systolic pressure (or wall stress) and end-systolic volume when measured over a narrow physiological range in the human left ventricle. Increased contractility shifts the relationship upward and to the left, as illustrated in Fig. 8, allowing the separation of enhanced from reduced contractility in the same heart, and poorly contracting from normally contracting ventricles. Stroke volume is shown on the abscissa as the difference between end-diastolic and end-systolic volumes. The efficacy of reduction in afterload in assisting reduced ventricular function is also easily explained from the diagram. With a reduced afterload, the aortic valve opens at a lower pressure and a greater stroke volume is ejected; a new end-systolic pressure–volume point is reached, which is shifted downwards on the same linear relationship. There has been no change in contractile state.

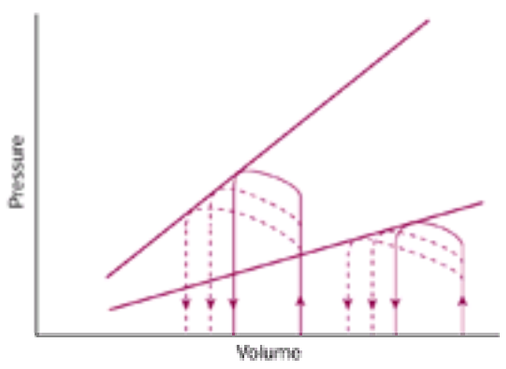

Fig. 8 Diagrammatic representation of intraventricular pressure and volume relationships during the cardiac cycle at two levels of myocardial contractility; three separate beats with the same end-diastolic volume are shown for each. The loops on the left of the diagram were obtained when contractility is increased and those on the right when it is reduced. There is a linear end-systolic pressure–volume relationship with different afterloads (pressures) for each level of contractility. The slope of the end-systolic pressure–volume relationship for any inotropic state is relatively insensitive (see text) to changes within physiological ranges in afterload and preload, although changes in preload are not shown in this diagram. The volume change seen on the horizontal axis for each beat is the stroke volume. This increases with reduction in pressure (afterload).

Heart rate

Frequency of contraction is the fourth essential determinant of cardiac performance. Heart rate during rest and exertion may vary from 45 to 200 beats/min in the healthy young adult. As changes can occur within seconds, an increase in heart rate is the usual and most effective way of producing a rapid increase in cardiac output. It plays the major role in the response to exercise, during which stroke volume does increase (more so in athletes and when in the erect rather than the supine position) but the changes are less marked than those of rate. In addition, an increase in contraction frequency itself produces a positive inotropic effect, whereby the force of contraction increases and reaches a new steady state within a few beats. This is termed the 'positive staircase', Treppe, or Bowditch effect. It may be a consequence of an augmented movement of calcium ions into myocardial cells with increased frequency of action potentials, combined with diminished time for outward movement of calcium between beats. More forceful contractions also follow premature beats—the phenomenon of postextrasystolic potentiation—and the mechanism is probably the same. The extrasystole occurring prematurely is a weak contraction because of decreased filling time and an unco-ordinated activation of the ventricle when the ectopic focus is within the ventricle. The next beat is delayed because of the refractory period of the extrasystolic beat, but is a more powerful contraction because of increased filling time and ventricular volume, and increased contractility. Calcium-dependent changes similar to those of the Bowditch effect are probably responsible for the latter.

Coronary blood flow

Coronary blood flow accounts for about 4 per cent of the cardiac output. The heart extracts most (70 per cent) of the oxygen carried in the coronary circulation; the arteriovenous difference for oxygen across the heart being about 110 ml/litre, whilst that for the whole body is only about 40 ml/litre under resting conditions. Therefore, large increases in myocardial oxygen requirements must be met largely by increases in coronary blood flow, and this may increase five- or sixfold during strenuous exercise. The greater part of this flow is to the left ventricle, of which at least two-thirds occurs during diastole because of the throttling effect systole has on myocardial perfusion. The main coronary arteries are on the superficial surface of the heart, and because of this, and the hindrance to coronary flow during systole, the subendocardial region of the left ventricle is more vulnerable to perfusion deficits in relation to oxygen need than the outer two-thirds of the muscle wall. Despite these mechanical problems, flow is normally evenly distributed throughout the myocardium so that, when regional coronary blood flow is measured using injected radioactive microspheres (in dogs), the ratio of endocardial to epicardial flow is approximately unity. In fact the inner layers of the heart probably receive slightly more blood (up to 10 per cent) than the outer layers. This is consistent with the subendocardium developing more tension than the subepicardium, and is evidence for a greater rate of myocardial oxygen consumption in the inner layers.

Myocardial oxygen requirements and coronary blood flow are finely adjusted. The regulation of coronary blood flow is described elsewhere.

The nervous system and the heart

The heart is richly supplied with adrenergic nerves. Terminals reach atrial and ventricular muscle fibres and impinge upon all pacemaker tissue including the sinoatrial and atrioventricular nodes and Purkinje fibres. Sympathetic stimulation leads to an increase in myocardial contractility and heart rate, and in the rate of spread of the activation wave through the atrioventricular node and the Purkinje system. This is mediated by local noradrenaline release, which interacts with b-adrenergic receptors. The key elements in these regulatory mechanisms are calcium ions and cyclic AMP. The activated b-receptor increases adenylcyclase activity and the conversion of ATP to cyclic AMP. Peptide cotransmitters released with noradrenaline and acetylcholine have recently been isolated and also influence autonomic function. Neuropeptide Y is a peptide of 36 amino acids that is collocated with noradrenaline in most sympathetic nerves and is released with sympathetic stimulation. It is a powerful pressor agent with direct arteriolar vasoconstrictor action and also potentiates the pressor action of noradrenaline.

The distribution of parasympathetic fibres is much more limited, being confined to the sinoatrial and atrioventricular nodes and the atria, with few if any fibres reaching the ventricles in humans, except perhaps in relation to coronary arteries and Purkinje tissue. The effects of parasympathetic nerve stimulation are mediated by local acetylcholine release, which slows the heart rate and speed of conduction through the atrioventricular node and Purkinje tissue, and depresses atrial contractility. The negative inotropic effects are associated with a lowering of the concentration of intracellular cyclic AMP.

The effect of the nervous system on the heart at any one time is the sum of the activities of these two opposing control systems. They usually vary reciprocally. Under resting conditions, vagal inhibitory effects predominate, maintaining a slow heart rate, there being virtually no sympathetic outflow. With exercise, there is withdrawal of vagal activity and an increase in sympathetic outflow. Afferents from stretch receptors in the carotid sinus and aortic arch—the baroreceptors—also have a considerable effect on cardiac performance, this effect being mediated via the adrenergic nervous system and vagal withdrawal. A fall in blood pressure reduces stretching in the carotid sinus and inhibitory afferent traffic so that the sympathetic outflow increases. As a consequence of this combined vagal and adrenergic effect there is a quickening of the heart rate within one or two beats, a positive inotropic effect, and also a constriction of veins and arterioles that increases preload and afterload. Elevation of pressure in the carotid sinus has the reverse effects. In cardiac failure there is a reduced variability in heart rate due to these autonomic mechanisms as there is then a predominance of adrenergic activity.

There are also mechanoreceptors in all four chambers of the heart (in dogs) and in the coronary vessels, which give rise to depressor reflexes. Their clinical relevance is uncertain, but they may contribute, for example, to the bradycardia and hypotension occurring in some patients with acute myocardial infarction and to the syncope that patients with critical aortic stenosis may experience with the onset of exercise when there is sudden left ventricular distension. Vagal afferents from reflexogenic areas in the infarcting left ventricle may be responsible for the bradycardia, gastric distension, nausea, and vomiting which frequently occur with the onset of inferior or posterior myocardial infarction, but not usually of anterior infarction, which is generally associated with a marked increase in sympathetic activity. The cardiac receptors connected to afferent fibres running in cardiac sympathetic nerves, however, are very important because they are responsible for the perception of cardiac pain. Receptors have also been identified (in animals) at the junction of pulmonary veins with the atrial wall. These respond to mechanical distension with increased sympathetic outflow to the sinus node and inhibition of secretion of antidiuretic hormone from the posterior lobe of the pituitary gland. The result is a quickening of the heart rate and diuresis, effects that could contribute to the regulation of cardiac volume.

Autonomic efferent activity

The autonomic outflow to the heart is controlled by multiple integrative sites within the central nervous system, with complex interactions between afferent and central inputs. Autonomic responses are mediated through the suprapontine and bulbospinal pathways, both those arising 'reflexly' and those arising from various types of volitional or central 'command'. Nevertheless, intrinsic mechanisms are sufficient for adequate cardiac function in the absence of autonomic control, as prolonged survival after cardiac transplantation has shown. But in the denervated heart there is blunting of the normally rapid physiological adjustments mediated by the autonomic nervous system.

Diurnal variation in autonomic function

Variations in vascular tone and control of blood pressure and of hormone secretion and platelet function occur in a predictable way throughout the 24-h cycle. In normal subjects there is a circadian rhythm of blood pressure changes that is not seen in patients after cardiac transplantation who have denervated hearts. There is a decline in blood pressure at night and an increase soon after wakening. This is due to a normal adrenergic surge in the early morning, which results in increased vascular tone and blood pressure. Increased forearm vascular resistance in the morning with a reduction in the afternoon and evening can be clearly identified in humans by assessing responses to a-adrenergic blockade. It is presumed that this occurs in coronary vessels as well. Measurable early morning increases in circulating catecholamines and in the propensity for platelets to aggregate can also be documented.

The circadian rhythm of autonomic function is correlated with a significant tendency for myocardial infarction and sudden cardiac death to occur more frequently in the morning soon after wakening. There is also an increase in the occurrence of angina pectoris in the early morning, independent of the level of physical activity.

Exercise and the heart: cardiac reserve

The heart responds to exercise with an increase in cardiac output, and values of 30 litre/min may be achieved in a trained athlete. Exercising muscles extract more oxygen from the blood perfusing them, but the response of the cardiac output is the ultimate determinant of delivery of oxygen to tissues and is the limiting factor for aerobic exercise.

The cardiac response to exercise involves all the mechanisms already discussed. Interaction within the central nervous system between higher and autonomic centres augments sympathetic discharge and there is a withdrawal of parasympathetic outflow. The heart rate increases immediately, and redistribution of peripheral flow increases venous return and preload. There is venoconstriction, particularly in the large-volume splanchnic circulation, and vasoconstriction and increased oxygen extraction in non-active parts. In active parts there is vasodilation. This is most evident in the vascular beds of the exercising skeletal muscles and of the heart. The overall effect is a marked lowering of total peripheral vascular resistance, which reduces afterload and encourages greater systolic emptying of the left ventricle. Stroke volume increases during exercise in the upright position. During light to moderate exercise (running or cycling), up to about 80 per cent of maximum exercise capacity, there is an almost linear relationship between work intensity and heart rate response, cardiac output, and oxygen uptake. With further exercise the heart rate and cardiac output responses level off whilst additional increases in oxygen consumption (about 500 ml) occur by increased oxygen extraction and a greater widening of the arteriovenous difference for oxygen.

The venous return increases in relation to the elevated cardiac output. Vasodilation in the working muscles that receive the bulk of the redirected blood permits high flow rates into the capacitance vessels. Because of adrenergically mediated venoconstriction the capacity of this system is reduced, so that blood moves rapidly into the right atrium. Venous return is also enhanced by the pumping action of the rhythmically contracting working muscles, by a decrease in intrathoracic pressure with forced inspiration, and by an increase in intra-abdominal pressure. The augmented pulmonary blood flow results in only slight increases in pulmonary artery pressure because of the distensibility of the large pulmonary arteries, an increased area of the pulmonary capillary bed due to the recruitment of more capillaries, and the low resistance offered by the normal pulmonary circulation (see Table 1).

The elevated cardiac output and larger stroke volume result in increased systolic blood pressure and pulse pressure even though the afterload itself is reduced. Enhanced neurohumoral activity from adrenergic stimulation of the heart and the suprarenal glands (increased circulating adrenaline and noradrenaline) effect positive inotropic changes, to which tachycardia also contributes because of the Bowditch effect. There is a shift in the Frank–Starling relationship to the left, increased speed and force of cardiac contraction, and elevated ejection fraction and stroke volume. Peak d p/dt is increased and there is a rapid rise in coronary blood flow to meet myocardial oxygen requirements that increase linearly with the product of systolic blood pressure and heart rate. During moderate exercise these changes together result in a decreased or unaltered end-diastolic volume and decreased end-systolic volume. With severe exercise, end-diastolic dimensions and end-diastolic fibre length are slightly increased and the Frank–Starling mechanism then operates and further augments the force of contraction.

The haemodynamic and ventilatory responses evoked by an increase to a new steady workload take about 2 to 3 min to equilibrate and adjust oxygen supply to the greater demand. Protocols for exercise testing are therefore usually based on work increments at 3-min intervals to allow time for a new 'steady state' to occur as, for example, in the standard Bruce Exercise Protocol. A steady state becomes progressively more difficult to maintain as maximal exercise capacity is approached. Glycogen is used by the working skeletal muscles as a source of stored energy and the anaerobic metabolism which ensues produces lactic acidosis and thereby further increases ventilation. As all cardiopulmonary transport mechanisms reach maximum levels, shortness of breath, fatigue, and muscle pain become limiting symptoms; motivation is then the final determinant of the duration of exercise. Ageing reduces the efficacy of cardiopulmonary transport mechanisms and, of course, exercise capacity. The heart rate response at peak exercise reflects this. In healthy individuals aged 20 years it is about 200 beats/min and at 65 years about 170 beats/min.

When exercise stops, the cardiopulmonary and metabolic changes return rapidly to resting levels, the rate following an exponential pattern in the first few minutes; the excretion and metabolism of lactate and other substances, and the dissipation of heat generated take longer (time constant of about 15 min or more). Reduced circulatory function slows the recovery rate.

Training effects

Regular exercise to about 60 per cent of maximal heart rate for 20 to 30 min three times a week is the minimum requirement for improved effort tolerance due to a training effect. The resting heart rate becomes slower whilst the cardiac output is maintained by an increased end-diastolic volume and ejection fraction, and therefore stroke volume. In a 'trained' exercising individual there is a reduced heart rate response to a standard submaximal work load, and systemic blood flow is more effectively distributed away from visceral and skin circulations to working muscles. Adaptive changes occur in muscle mitrochondria, permitting improved extraction of oxygen from perfusing blood so that maximum oxygen consumption increases. There is suggestive evidence that prolonged endurance training increases the calibre of coronary arteries and enlarges the capillary surface area relative to cardiac muscle mass (in animals). Myocardial protein synthesis increases. Adrenergic mechanisms appear to be involved in mediating this response. It should be noted that rhythmic exercise (such as running) and isometric exercise (such as weightlifting) have different physiological effects. The blood pressure rises disproportionately during the latter. The mechanisms are partly reflex and partly mechanical from the contracting muscles. Isometric exercise training is not recommended for cardiac patients because of the increased afterload it imposes on the heart.

Regular exercise may also partly prevent the now well documented endothelial dysfunction associated with ageing. The age-related reduction in availability of nitric oxide resulting from reduced activity of the L-arginine–nitric oxide pathway in the endothelium has now been established and is thought to be a consequence of oxidative stress. Regular exercise improves the availability of nitric oxide. Vascular effects related to nitric oxide are considered elsewhere.

There is now good evidence for exercise-induced mood changes resulting in feelings of well-being. Increased concentrations of circulating b-endorphin occur during exercise, and studies using the opiate receptor antagonist naloxone to block the effects of opioid peptides suggest that b-endorphin release may reduce exercise-induced adrenaline and noradrenaline responses. Regular exercise lowers blood pressure in normotensive and mildly hypertensive subjects, and modulation of catecholamine release by changes in endogenous opioid peptide secretion may be a possible contributing mechanism. There are other diverse exercise-induced hormonal changes, but one of particular clinical relevance is reduced glucose-stimulated insulin secretion. This is beneficial for type II diabetics, whose basal hyperinsulinaemia is the result of both hypersecretion and hypocatabolism of insulin, and for patients with insulin resistance and hyperinsulinaemia, obesity, hypertension, and dyslipidaemia—so-called syndrome X.

To summarize, changes in the four essential determinants of cardiac function—preload, afterload, heart rate, and contractility—combine to augment cardiac output and oxygen delivery during exercise. Measurement of the cardiovascular response to exercise is essential for the objective assessment of cardiac function.

15.2.1Chest pain

J. R. Hampton

Introduction

Chest pain is one of the commonest causes of emergency admission to hospital (Table 1). In the hospital context the commonest cause of chest pain is myocardial ischaemia, but in primary care other causes predominate. The majority of those admitted with chest pain will have evidence of pre-existing coronary disease (a previous myocardial infarction or known previous angina) and their pain is likely to be a manifestation of this. Perhaps 20 per cent of this group will have a definite myocardial infarction. A misdiagnosis of chest pain can have serious consequences for both patient and doctor, but the number of patients seen in accident and emergency departments with chest pain is so large that it is impracticable for all to be admitted to hospital for investigations to be completed. Similarly, it is neither necessary nor sensible for every patient with chest pain seen in primary care to be referred to hospital.

The initial management of patients with chest pain depends on an accurate history, the physical examination and simple investigations being of lesser importance.

The patient's history

Myocardial ischaemia

Coronary artery insufficiency, usually the result of atheroma but occasionally the result of arterial spasm, leads to a spectrum of conditions which can be grouped together as 'myocardial ischaemia'. The common end result is chest pain.

Stable angina

Angina was first recognized by William Heberden in 1768, and his description of the pain of myocardial ischaemia can hardly be bettered. He wrote:

> The seat of it, and the sense of strangling and anxiety with which it is attended may make it not improperly called angina pectoris.
>
> They who are afflicted with it, are seized while they are walking (more especially if it be uphill, and soon after eating) with a painful and most disagreeable sensation in the breast, which seems as if it were to extinguish life, if it were to increase or continue; but the moment they stand still, this uneasiness vanishes....The pain is sometimes situated in the upper part, sometimes in the middle, sometimes at the bottom of the os sterni, and often more inclined to the left than to the right side. It likewise very frequently extends from the breast to the middle of the left arm.

Whether myocardial ischaemia is due to stable angina, myocardial infarction, or the acute coronary syndromes, the distribution of the pain is much as Heberden described it. It is central, or sometimes left sided; rarely it is felt only in the back. The most classical—but not the most common—radiation is to the front of the neck, and the lower jaw or the teeth. The most common radiation is to the left arm, though the pain of other chest problems may also radiate here. Radiation from the front of the chest to the back is not uncommon.

The nature of the pain is usually described as 'tight', 'crushing', 'squeezing', or 'heavy'. Many patients describe a 'sensation', or an 'ache' rather than a pain. The pain of myocardial ischaemia is seldom described as 'sharp'.

The duration of the pain in stable angina depends on whether or not the patient rests: typically the pain will disappear within a minute or two when exercise ceases. Sometimes the pain will disappear if exercise continues; this has been called 'walk through' angina.

Stable angina, as opposed to the other manifestations of myocardial ischaemia, can be recognized by factors that precipitate or relieve it. Stable angina is, above all, predictable. It occurs after a constant amount of exercise—often on a particular hill, after so many metres walking, on climbing so many stairs, or on hurrying. Pain that is unpredictable is unlikely to be stable angina, though it may be due to an acute coronary syndrome. The pain of stable angina is worse on exercise in cold or windy weather, and on exercise after a meal. It is often induced by sexual intercourse, or by any emotional stress. Any chest pain, whatever its distribution, that occurs with emotional stress is likely to be angina.

Stable angina is relieved rapidly by rest, and very rapidly by a tablet or sublingual spray of a short-acting nitrate. If the problem is not relieved within 3 or 4 min by a nitrate either it is not stable angina (it could be a myocardial infarction) or the nitrate has exceeded its shelf-life and has become inactive.

Chest pain, even with the characteristic distribution of angina, that occurs at the end of a busy day rather than during exercise, that lasts for hours, and which is not helped by nitrate is most unlikely to be angina.

Angina may be associated with breathlessness, and sometimes breathlessness on exertion is the dominant symptom. Table 2 gives a check list of the features that are characteristic of angina.

Myocardial infarction

The distribution of pain due to myocardial infarction is similar to that of stable angina. It is usually in the centre of the chest, and may radiate to the jaw, teeth, arms, or back. The nature of the pain is also similar—typically squeezing or crushing—but it is usually much more severe and can be one of the worse of all pains. It is often associated with a cold sweat, and with vomiting. The pain is frightening, and many will volunteer that they thought that they were going to die. The pain typically lasts a few hours. It may occasionally be associated with heavy exertion (particularly any activity that causes a sudden rise in heart rate and blood pressure) but usually there is no obvious precipitating cause. Nothing other than a strong analgesic such as diamorphine will relieve the pain, and nitrates are completely ineffective. Some patients need a second injection of diamorphine, but few need three, and if chest pain lasts more than 24 h a diagnosis other than myocardial infarction should be considered.

Myocardial infarction can be 'silent', meaning that it occurs without much in the way of pain. Population surveys of older people suggest that some 15 per cent of previous myocardial infarctions demonstrated on ECG are unrecognized. 'Silent' infarction is more likely to happen in diabetics.

The symptoms of myocardial infarction are, of course, modified by complications such as heart failure, arrhythmias, heart block, and pericarditis.

Unstable angina

The chest pain of unstable angina is difficult to describe because unstable angina is difficult to define. The term has been used to describe the first attack of what later proves to be stable angina, stable angina of increasing frequency and severity (sometimes called 'crescendo' angina), and angina at rest. The development of new markers of myocardial infarction such as the troponins has widened the possible definition of myocardial infarction, and unstable angina with a positive troponin test merges into 'non-Q-wave' infarction.

The distribution and intensity of the pain of unstable angina resembles that of stable angina, though patients with non-Q-wave infarction can have severe chest pain indistinguishable from that of Q-wave infarction.

Typically the chest pain of unstable angina will occur at rest. Many patients with unstable angina will gain relief from nitrates, but those with non-Q-wave infarction will not.

The pain of unstable angina is seldom associated with symptoms due to immediate complications such as heart failure, though unstable angina is associated with a relatively high risk of myocardial infarction and death in the next 3 months.

Prinzmetal's variant angina and syndrome X

There are two further varieties of angina that cause ischaemic chest pain, but both are somewhat nebulous concepts and are probably overdiagnosed. In Prinzmetal's 'variant' angina, chest pain characteristic of angina occurs either on exercise or at rest. The pain is believed to result from spasm of the coronary arteries. The diagnosis is only made if an ECG shows ST segment elevation, rather than the usual depression, during an attack of pain. The ST segment returns to normal as the pain disappears, which differentiates the ECG change from that of acute myocardial infarction.

'Syndrome X' is a term used to describe the occurrence of exercise-induced stable angina with a positive exercise test but a normal coronary angiogram. The problem is assumed to be in vessels too small to be demonstrated angiographically, and the term 'microvascular angina' is sometimes used. While the syndrome undoubtedly exists, the diagnosis should only be accepted after very careful investigation.

Dissection of the aorta

Perhaps one patient in a thousand of those who are admitted to hospital with chest pain has a dissection of the aorta. It can be very difficult to diagnose aortic dissection unless the possibility is considered in all of these patients. This is important: the treatments for myocardial infarction and aortic dissection are very different.

The typical patient has a pain similar to that of myocardial infarction, but the pain is more usually sudden in onset. Like infarction, it is in the centre of the chest. It is usually very severe and it often radiates to the back. It is often described by the patient as 'tearing', and it lasts much longer than the pain of myocardial infarction. The onset of pain is often associated with a 'collapse' or with sudden neurological deficit suggesting a stroke. The position of the pain gives a rough guide to the site of dissection; anterior chest pain correlates to some extent with proximal dissection, while pain in the back correlates with distal dissection. The pain may move from the front to the back of the chest as the dissection spreads distally.

If the dissection affects the ostium of a coronary artery, myocardial infarction with its own pain may result.

Unfortunately not all patients with aortic dissection give a typical story. Since the physical examination is not always helpful and the ECG may be normal, patients are not infrequently discharged from the accident and emergency department, or from the ward, with some such diagnostic label as 'myocardial infarction excluded'. Since patients with dissection who survive the first few hours have a reasonable chance of successful surgical repair, it is essential that the diagnosis should at least be considered (if only to be rapidly excluded) before any patient presenting with acute chest pain is discharged.

Pericarditis

The most common cause of pericarditis is myocardial infarction, and the pain of infarction is sometimes replaced by that of pericarditis. Viral infection is a common cause, and pericarditis should be suspected in anyone presenting with chest pain in the context of a 'flu-like illness, particularly if they are likely to be at low risk of coronary artery disease (young men or premenopausal women with few risk factors).

Pericardial pain has some features in common with those of myocardial ischaemia and aortic dissection. It is central, and may have the same radiation. It differs, however, in being (usually) less severe and lasting longer.

The most typical feature of pericardial pain is the effect of posture. The pain is worst when the patient lies on his or her back: the pericardial fluid drains to the back of the pericardial sac, leaving the inflamed anterior visceral and parietal pericardial surfaces to come into contact and so cause pain. Sitting up and leaning forward, which allows the fluid to drain to the front, separates the pericardial layers and relieves the pain.

Pericardial pain often has a pleuritic element, being worse on deep breathing.

Pleuritic pain

Pain from the pleura—the old term was 'pleurisy'—is usually on one side of the chest only. Whatever the cause (and the main causes are infection, pulmonary embolism, and pneumothorax) it is identified because it is worse on inspiration. As a result the patient will need to take shallow and therefore rapid breaths. Unlike the pain of myocardial ischaemia it is usually described as sharp or knife-like. It can be severe, though seldom as severe as myocardial infarction or aortic dissection. Its onset can be sudden (especially when due to pneumothorax or pulmonary embolism) or slow (infection). Pleuritic pain can often be identified because it is associated with symptoms of lung disease such as breathlessness, cough, sputum production, or haemoptysis.

Oesophageal pain

Pain originating in the oesophagus can be difficult to differentiate from the pain of myocardial ischaemia. Both are common, so patients not infrequently suffer from both, and cannot always tell one from the other.

Typical oesophageal pain is central and anterior, and is often described as 'burning'. It usually has some relation to eating. It is commonly due to oesophagitis caused by acid reflux from the stomach because of a hiatus hernia. The pain is often induced by bending, when the patient can be aware of an acid and bitter taste in the mouth. Oesophagitis can cause spasm which is itself painful, and the spasm may be relieved by nitrate, sometimes leading to confusion with angina. More commonly, oesophageal pain is relieved by an antacid.

Rupture of the oesophagus causes severe central chest pain very similar to that of a myocardial infarction. It always follows vomiting, as opposed to the vomiting which can accompany myocardial infarction, which occurs after the pain has become intense.

Musculoskeletal chest pain

Pain can arise in any of the structures of the chest wall, and can mimic all other causes of pain. Pain that is induced or relieved by postural change is likely to be musculoskeletal in origin, as is highly localized pain reproduced by pressure at the affected site. Nerve root compression due, for example, to vertebral disease (collapse, metastasis, abscess) can cause pain to radiate round the ribs. If the pain results from bony collapse it can be of sudden onset, but musculoskeletal pain seldom has the time course of ischaemic pain.

Pain to the left of the sternum, with tenderness over the costochondral junctions, is common in middle-aged men. Sometimes thought to have an inflammatory basis, it

is not associated with arthritis elsewhere or with a rise in inflammatory markers. It is sometimes called Tietze's syndrome.

Under the same heading comes the pain of herpes zoster. Patients, especially the elderly, may be admitted to a coronary care unit with a severe left-sided chest pain with tenderness, and the cause becomes obvious the following day as the characteristic rash appears.

Chest pain ? cause

After all the possible causes of chest pain have been excluded there remains a group of patients, usually middle-aged men, in whom no firm diagnosis can be made. It is entirely proper to label these as 'chest pain ? cause'. Making a diagnosis of 'musculoskeletal pain' in such patients is not only incorrect, but it may prevent the diagnosis being properly reassessed on a later occasion.

'Chest pain ? cause' is the discharge diagnosis in about 10 per cent of patients admitted to hospital with suspected myocardial infarction. The pain can be similar to that of acute ischaemia, though it is seldom very severe, and while it may radiate to the left arm it never spreads to the jaw or teeth. By definition, detailed investigation fails to explain the pain, which is not infrequently recurrent. Long term follow-up of such patients shows that their prognosis is essentially that of the healthy population.

'Chest pain ? cause' is also a proper diagnosis in patients with recurrent chest pain in whom the alternative is stable angina. Here the pain is nearly always left-sided, is not predictable, is not clearly related to exercise or emotional stress, and is never brought on by sexual intercourse. This sort of pain merges into Da Costa's syndrome, which was first identified in the American Civil War. Soldiers complained of sharp, lancinating or burning pain, often on a background of a duller pain with a feeling of 'uneasiness' around the heart. The patients described by Da Costa were also troubled by palpitation and hyperventilation. The same thing was observed in the First World War, and this type of pain is considered functional: older terms used to describe it were 'soldiers' heart' and 'cardiac neurosis'. However, non-specific 'chest pain ? cause' also occurs in people who are not apparently under stress.

Physical signs in patients with chest pain

In patients with severe pain the findings on examination may be dominated by those due to pain itself: pallor, cold and clammy extremeties, and a sinus tachycardia. The blood pressure may be high due to intense peripheral vasoconstriction, or low if there has been severe myocardial damage. After pain relief, or in between episodes of pain, there may be few physical abnormalities.

When the pain sounds like chronic stable angina it is important to look for possible causes other than coronary disease, including aortic stenosis, anaemia, and brady- or tachyarrhythmias. There may be evidence of peripheral vascular disease: absent peripheral pulses, or bruits over the carotid or femoral arteries, suggesting that coronary disease is likely. There may be signs of risk factors such as those associated with hypercholesterolaemia, and hypertension may be present.

All these physical signs should be sought in patients with persistent chest pain. In addition there may be evidence of myocardial dysfunction, including heart failure (raised jugular venous pressure, a gallop rhythm, pulmonary crackles), mitral valve regurgitation due to papillary muscle dysfunction or rupture, and ventricular septal defect.

Although there are classical signs of aortic dissection, these are by no means uinversal. About one-third of the patients will have high blood pressure; a third will have a murmur of aortic regurgitation due to distortion of the aortic root; and perhaps half will have a pulse missing or a different blood pressure in each arm. A pericardial friction rub or pericardial tamponade due to blood tracking backwards into the pericardium is uncommon, but when associated with aortic regurgitation the diagnosis of aortic dissection becomes almost certain.

Pericarditis is diagnosed from the presence of a pericardial friction rub, which is best heard with the patient lying flat. It may be associated with signs of tamponade which include a rise in the jugular venous pressure and fall in the arterial pressure on inspiration. Similarly, pleuritic pain can be identified from the pleural rub if one can be heard. Otherwise there may be sounds of pulmonary consolidation or pleural effusion that make associated pleurisy likely.

Patients with viral pericarditis are likely to have a fever. In those with pleurisy, a high fever (over 38.5 °C) makes pneumonia a more likely diagnosis than pulmonary embolism. Myocardial infarction causes a low-grade fever, but this not often seen until a day or two after the event.

There are few physical signs in patients with oesophageal pain, though there may be tenderness in the epigastrium. Musculoskeletal pain is suspected when there is bony tenderness (fractures, metastases) or when the pain is reproduced by local pressure or movement. 'Chest pain ? cause', virtually by definition, has no physical signs other, perhaps, than those of anxiety.

The immediate management of patients with chest pain

Patients seen in the accident and emergency department with chest pain need urgent assessment and treatment. Those with a possible acute coronary syndrome need rapid sorting into those who need immediate reperfusion of a blocked coronary artery (identified by raised ST segments on the ECG) and those with non-Q-wave infarction or unstable angina, who have less need for immediate treatment but who will need more detailed investigation and treatment over the next few days. All these patients should be admitted to hospital, ideally to a coronary care unit, though it is frequently impracticable to admit all patients seen in an accident and emergency department with chest pain.

If the initial ECG is normal but the patient has significant pain, the ECG should be recorded again after 1 and 2 h. Patients with persistent pain at that point will have to be admitted. Early plasma markers of myocardial necrosis—the creatine kinase and creatine kinase myocardial band enzymes, and the troponins—are helpful if positive, but will often not be elevated until about 6 h after the onset of pain. Although one possible treatment strategy is to hold patients in the accident and emegency department until 6 h have elapsed and the enzymes and troponins have been shown to be normal, this is not foolproof because the troponins may not become elevated for as long as 18 h.

Chest radiographs are seldom helpful in patients with chest pain, and if anteroposterior films are taken they can be positively misleading. Obtaining a posteroanterior film may mean transferring the patient to an X-ray department where close monitoring cannot easily be maintained, but using portable X-ray equipment in the accident and emergency department will almost inevitably produce a distorted cardiac and mediastinal shadow. It is under these circumstances that widening of the mediastinum, which may be the first indication of an aortic dissection, will be missed. Portable X-ray equipment is only reliable for assessing the lung fields, and to some extent for detecting heart failure. If aortic dissection seems at all possible, then a departmental posteroanterior chest radiograph is essential.

Patient management inevitably depends to some extent on the patient's perception of what has happened and whether, for example, the pain that has led to his or her hospital attendance is like or unlike previous angina. In general, however, if the patient becomes pain free and there are no important physical abnormalities, if an ECG repeated after 2 h shows no change from the initial recording, and if a departmental chest radiograph and plasma troponin or creatine kinase are normal, then it is not unreasonable to allow the patient to go home (with notification for their general practitioner and arrangements for further investigation, for example cardiac treadmill testing, as appropriate). Total safety of diagnosis and management requires hospital admission and observation for perhaps 18 h, but in the real world this is often impracticable.

The diagnosis depends on the synthesis of the patient's history, the physical examination, and simple investigations. A carefully taken history, coupled with a high index of suspicion for important problems such as an acute coronary syndrome or aortic dissection, is the key to a successful patient management.

15.2.2 The syndrome of heart failure

Andrew J. S. Coats

Introduction

Heart failure is a common condition, carrying a high burden of disability and mortality. Many treatments have now been established that ameliorate, at least partially, its debilitating effects, but despite this it is increasing in both prevalence and cost in the developed and developing worlds as the population ages. Much disability remains, and there are many shortfalls between treatment possibilities and that which is achieved in everyday practice around the world. Major advances seem possible with the advent of greater understanding about the causes of cardiovascular disorders, including molecular mechanisms, and the development of newer, effective treatments, including surgical advances and gene therapies.

Definitions

'Heart failure' is an unfortunate term. It has negative connotations for the patient and describes imprecisely several different clinical situations. Left and right heart failure are quite distinct clinical syndromes, although they frequently coexist (biventricular failure). Historically heart failure has been further subdivided on the basis of presumed pathophysiological mechanisms into: (1)'forward' or 'backward' heart failure, depending on whether congestion or organ underperfusion was the predominant clinical feature; (2)'congestive' or 'non-congestive', depending on the presence or absence of oedema; and (3)'high-output' or 'low-output'. These subdivisions have not proved to be particularly useful. A more recent and more useful classification is dependent on the predominant pattern of left ventricular dysfunction, be it systolic, diastolic or mixed. Whatever the complexities of the ventricular pathophysiology that initiates events, a well-recognized clinical pattern is identifiable as 'heart failure' and has proved a useful description of a complex clinical syndrome for many years.

The important features of any definition of heart failure (of which there have been several) are that the clinical picture is:

1. initiated by a reduction in effective cardiovascular (usually left ventricular) functional reserve;
2. associated with symptoms either at rest or at an unexpectedly low level of exertion; and
3. associated with characteristic pathophysiological changes in many disparate organ systems.

These latter can include biochemical, hormonal, metabolic, or functional alterations. In simple terms heart failure is a syndrome in which a reduction in left ventricular function causes pathophysiology that produces symptoms and exercise limitation.

A clinical picture similar to that of heart failure can develop when ventricular function itself is normal, but where there is an extreme volume or pressure overload on the ventricle. These include volume overload conditions such as endotoxic high-output shock, severe anaemia, arteriovenous fistulas or shunts, and pressure overload conditions such as acute hypertensive crisis or prosthetic heart valve occlusion. It is appropriate both clinically and for research purposes to separate these from cases where the initiating cause is a reduction in ventricular function.

Acute and chronic heart failure

It is conventional, because of differences in assessment and management, to separate acute from chronic heart failure. Both are different stages of a single disease process, and in the clinical course of a patient with chronic heart failure acute exacerbations may be common, often described as 'acute decompensation' or 'acute on chronic' heart failure. Acute heart failure is typically a dramatic clinical presentation with an acutely dyspnoeic patient demonstrating visible signs of cardiovascular insufficiency such as tachycardia, pulmonary or peripheral oedema, and underperfusion of systemic organs. Chronic heart failure, by contrast, can be a subtle disorder, which if gradual in onset can be missed by both patient and physician. The salient features are the initiation and persistence of left ventricular dysfunction, and the pathophysiological changes in other organs that produce symptoms and which limit exercise. A persistent state of circulatory insufficiency can exist in severe chronic heart failure, with pulmonary and peripheral oedema and symptoms and signs of distress even at rest.

Epidemiology, aetiology, and pathogenesis

Epidemiology

Heart failure is a common condition with an estimated incidence of 20 to 30 per thousand of the adult population per year and an overall prevalence of about 1 per cent. The prevalence increases in frequency with increasing age, reaching 30 per cent in those aged over 80 years, and in developed countries the average age of patients with heart failure is now in excess of 75 years. It is one of the most expensive medical conditions, and is an increasing major healthcare cost. Because of its many debilitating symptoms, heart failure is a frequent cause for both acute hospital and long-stay residential care admissions, indeed it is the most common discharge diagnosis from hospitals in the developed world in people over the age of 65, and the second most common overall. Heart failure is a feature of the clinical

condition of approximately 5 per cent of patients in hospital at any time, and also the one with the greatest rate of hospital re-admission.

Paradoxically, improvements in the management of acute myocardial infarction and chronic coronary heart disease have led to more instances of heart failure rather than less, as more people survive to develop heart failure later in life. However, preventive therapies do work: multiple trials of antihypertensive treatment and the 4S trial of cholesterol reduction have shown a significant reduction in the incidence of new cases of heart failure in high-risk populations. Smoking reduction also reduces the number of new cases of heart failure, as does the selective use of angiotensin-converting enzyme inhibitors in high-risk patients after a myocardial infarction or for those with asymptomatic left ventricular systolic dysfunction. Appropriate use of thrombolytic therapy at the time of myocardial infarction will also reduce the incidence of new cases of heart failure.

Whilst there is reasonable consensus as to the prevalence of heart failure in younger and middle-aged populations, where most cases demonstrate significant deterioration in systolic function of an enlarged heart, in the elderly an increasing proportion of cases of clinically suspected cases of heart failure have small ventricular cavities and preserved systolic function. In these cases diastolic dysfunction can be frequently demonstrated, and many experts feel that the majority of cases in an older population will be due primarily to diastolic dysfunction. However, methods of assessing diastolic function are less developed than those for systolic function, and interventional trials have historically concentrated on systolic dysfunction as a cause of heart failure. As a result we know much less about how best to diagnose diastolic heart failure and how best to teat it once diagnosed. This remains a major challenge to the cardiological community in the twenty-first century.

Aetiology

Heart failure is a clinical syndrome, not a single diagnosis, and it can have many different aetiologies. In Western industrialized societies the most common underlying causes are ischaemic heart disease, hypertension, and idiopathic dilated cardiomyopathy (see Chapter 15.8.2). The Framingham study suggested that hypertension, especially when complicated by left ventricular hypertrophy, was by far the most common antecedent of heart failure. Recent intervention trials in heart failure have usually included a preponderance of patients whose heart failure was secondary to ischaemic heart disease. In recent cross-sectional studies of heart failure in the community, hypertension is cited to be a relatively minor cause of heart failure. This change has been attributed to better detection and treatment of hypertension, but it may also reflect re-labelling, with coronary artery disease more likely to be blamed for heart failure than hypertension in the many patients who have evidence of both. Some cases of hypertension may proceed to a dilated poorly functioning heart with an eventual normalization in arterial pressure. These cases may be labelled as idiopathic dilated cardiomyopathy, with the only clue to the correct underlying diagnosis being a greater than expected degree of left ventricular hypertrophy.

In industrialized societies previously common causes of heart failure such as nutritional deficiency disorders or chronic complications of rheumatic valvular disease are now rare. In less developed societies infective causes still underlie the majority of cases. Some disorders may be common in particular societies and these should always be borne in mind when assessing an individual patient: examples would include Chagas' disease in Central and Southern America, iron overload in certain tribes in southern Africa, and nutritional deficiency states in the world's poorest countries.

Classification of cause

More than one underlying cause of heart failure can coexist, such as hypertension and ischaemic heart disease. Table 1 lists the major causes of heart failure, subdivided according to the mechanisms by which ventricular disease leads to the clinical syndrome. Such a differentiation is important because of specific strategies available for certain diagnoses, such as nutritional support, cardiac valve or bypass surgery, endocrine therapy, and avoidance of a toxic agent.

Pathogenesis

There is no unique pathological finding in the heart or elsewhere that defines the presence of heart failure. Heart failure can be the result of a wide variety of cardiovascular disorders: anything that puts an excessive demand on the heart for a prolonged period can lead to myocardial failure. Alternatively, loss of myocytes or an abnormal myocardial interstitium can lead to loss of effective heart function and cause the clinical syndrome of heart failure.

Although the more severe the loss of myocyte number or reduction in cardiac pumping capacity, the more likely is clinical heart failure, there is no strict relationship between measures of global cardiac function and the presence or severity of the features of the heart failure syndrome. The severity of heart failure is measured by the severity of symptomatic limitation, and by the extent of pathophysiological abnormalities, which closely correlate with the reduction in survival. Important amongst these changes of heart failure are the body's responses such as neurohormonal overactivity, autonomic dysfunction, and immunological and metabolic derangements.

Oxygen and energy supply

Myocardial dysfunction can result from a deficient oxygen supply to the myocardium, whether caused by occlusive coronary artery disease or by a reduced blood-carrying capacity such as in anaemia or certain toxic states. In addition, endothelial dysfunction, raised ventricular myocardial tissue pressures, and reduced diastolic blood pressure and diastolic time intervals all contribute to a reduction in the net effective coronary flow. Energy metabolism is frequently abnormal within the myocardium in cases of chronic heart failure. This can be a primary defect in familial cardiomyopathies or an acquired defect, such as in the insulin resistance that complicates chronic heart failure.

Defects in myocardial contractile performance

There remains considerable controversy as to whether individual myocytes are functionally deficient in most cases of human chronic heart failure. There are isolated cardiomyopathies where such defects are likely, but in most cases the major defect is a loss of myocyte number with compensatory myocyte hypertrophy. This leads to dysfunction of myocyte relaxation, due in part to an intracellular accumulation of calcium, rather than deficient contraction. Isolated single gene defects can be the cause of rare familial cardiomyopathies and in these, and presumably in more cases in the future as we understand more of the genetic processes underlying the control of myocardial contraction, specific abnormalities of myocyte contraction can be implicated in the cardiac dysfunction evident at the organ level.

Defects in the control of myocardial function

Although in theory an abnormal control of contraction could lead to cardiac dysfunction sufficient to cause heart failure, examples of clinical syndromes demonstrating this pathophysiological mechanism are rare. Myocyte necrosis can occur in cases of persistent sympathetic overactivity such as phaeochromocytoma, and more commonly excessive blockade of sympathetic nerve endings can acutely remove this support to myocardial contractility leading to acute heart failure.

Changes in the interstitium of the heart

Excessive myocardial fibrosis, such as that seen in senile changes in the heart and as a complication of sustained hypertension and aortic stenosis, can reduce the effective myocardial performance despite individual myocyte hypertrophy. Similarly, rare cases such as endomyocardial fibrosis can cause a syndrome of cardiac failure despite individual myocytes being functionally normal if studied in isolation. The importance of the intracellular milieu has only recently been fully recognized, and this may be a target for future interventions to modify the processes of ageing of the myocardium and progression in the syndrome of chronic heart failure.

Pathophysiology

Cardiac

Structural changes

Structural changes in the heart are common, both at macroscopic and microscopic levels. The clinical picture usually includes enlargement of the left ventricular cavity (with the exception of diastolic dysfunction and restrictive or constrictive cardiomyopathies). The shape of the ventricle also changes, becoming more spherical. This can occur rapidly after a myocardial infarction via a passive process of stretching of the infarcted territory (infarct expansion), or more slowly over a period of weeks to months in a process termed 'remodelling' (see Chapter 15.4.2). A similar change in shape is seen in dilated cardiomyopathies, but not in the restrictive cardiomyopathies. The more spherical shape of the 'remodelled' and enlarged ventricle increases the stress of the myocardial wall and may thereby worsen myocardial ischaemia. The shape change may also disrupt the complex conformational change that normally occurs during the isovolumic contraction phase, in which

the apex of the ventricle constricts in a twisting motion and pushes the blood into the ventricular base. Where the ventricle is already spherical at rest, this intraventricular redistribution of blood during isovolumic contraction is not possible and the net effect is a reduction in the efficiency with which the blood is ejected.

Cardiac enlargement has long been known to be an adverse prognostic sign, even when estimated crudely as the cardiothoracic diameter on chest radiographs. More precise measurements of the internal dimensions of the left ventricle by echocardiography have confirmed the prognostic value of cardiac enlargement in patients recovering from myocardial infarction, even when accounting for the size of the myocardial infarct. Prevention of the late remodelling process was the theory behind the use of angiotensin-converting enzyme (**ACE**) inhibitors after myocardial infarction. These agents have been shown to reduce ventricular size and to reduce late mortality if given early after infarction, but whether this beneficial effect is directly related to any reduction in ventricular remodelling is not known.

Changes at the microscopic level

The failing heart also shows alterations in cardiac structure at microscopic and ultrastructural levels. There is an increase in the collagen content of the extracellular matrix, a process thought to be partly related to increased wall stress and partly due to neurohormonal activation, particularly aldosterone. This change reduces ventricular wall distensibility and may affect the efficiency with which active restorative forces can assist the diastolic filling process. Hence this microscopic structural change may help to explain the frequent coexistence of systolic and diastolic functional deterioration in an enlarging ventricle in chronic heart failure.

The enlargement of the ventricle is associated with thinning of the ventricular wall and, as there is believed to be no increase in the total myocyte population, there must be a realignment of the intercellular attachments between individual myocytes. This process, whereby there is a continual breaking and reforming of cell-to-cell junctions to allow remodelling, has been termed 'cell slippage', although exactly how this occurs has not been established. There are changes in the microscopic structure of the failing ventricle, with a reduced number of tight junctions between myocytes, and this may be involved in this process.

Overall circulatory function

The description of an objective measurement of systolic function in intact humans has proved difficult. In simplest terms, the left ventricle is a pump that generates both pressure and flow. It has a theoretical operating range from a pure pressure generator to a pure flow generator, although it always functions as a mixed pump. The function of this pump can be described in terms of the kinetic and potential energy it imparts to the blood ejected each beat, or in terms of the average power output of the circulation (flow multiplied by the mean pressure drop), assuming the left ventricle is the only significant power source in the circulation. Thus, overall ventricular function can be described as cardiac output multiplied by the pressure drop across the systemic circulation, a quantity described as cardiac power output. Cardiac power output is well preserved at rest even in severe heart failure, but the maximal reserve of cardiac power output is reduced progressively as heart failure progresses, and a significant reduction in maximal power output during inotropic stimulation is a poor prognostic sign.

The measurement of cardiac power output tells us little, however, of the mechanisms underlying any reduction in ventricular performance. This may be due to reduced ventricular filling, or emptying, or to wasted myocardial power such as in aortic stenosis. Hence, attempts have been made to define the components of ventricular function to explain the nature of a reduced overall circulatory function and to assist in monitoring a patient's clinical course and response to treatment.

Systolic dysfunction

Systole can be defined either clinically as the ejection phase between mitral valve closure and aortic valve closure, or in terms of ventricular dynamics as the phase of contraction of the myocytes within the ventricle. These two definitions do not coincide, for there is a period of isovolumic contraction at the onset of ventricular systole in which myocyte contraction generates a pressure increase within the ventricle and a conformational change in its shape, but during which no blood is ejected. Similarly during the latter phase of ventricular ejection, the blood is flowing out of the left ventricle passively and the myocardial elements may be already relaxing.

In clinical practice, systolic dysfunction is most easily recognized by direct haemodynamic measurements showing a reduced peak rate of pressure rise within the ventricle (positive d*P*/d*t* max), an increased filling pressure (left ventricular end-diastolic pressure, **LVEDP**), or by indirect measurement of ventricular volumes (see Chapter 15.3.6). If there is a reduction in myocardial contractile function an enlargement of the ventricle will develop, in which a greater preload will enhance ventricular emptying via the Frank–Starling mechanism. As a result the ventricle will operate at an increased end-diastolic and end-systolic volume. This can be measured by pressure and volume estimations, such as by ventriculography (either radiographic or radionuclear) or echocardiography. Although not a direct measure of ventricular performance, ejection fraction, being the fractional emptying of the ventricle with each beat, carries information about ventricular volumes and global ventricular function. This is only a poor predictor of the severity of symptomatic limitation, but it has been shown to be an important predictor of longevity in heart failure, independent of other measures of severity, and it has the advantage of simplicity. At the most simple level, therefore, systolic heart failure can be recognized by signs of cardiac insufficiency in the presence of an enlarged ventricle, and clinically is most conveniently estimated by the left ventricular ejection fraction.

Diastolic dysfunction

Diastole is the opposite of systole, the period of filling of the ventricle or the period of relaxation of the myocytes. Objective measurements of diastolic function are, however, more problematic than for systolic function. Whereas systole occurs rapidly and in one action, diastole is complex, with an initial rapid and active ventricular recoil producing filling of the ventricle, then a period of relative stasis as atrial and ventricular pressures equilibrate, followed by a second period of ventricular filling due to atrial contraction. These processes are affected by many factors including heart rate, atrioventricular delay, atrial contractility, active myocardial recoil, passive ventricular wall stiffness, the efficacy of ventricular systole, and the residual end-diastolic volume and pressure within the ventricle. As a result of all these interacting factors, it is not surprising that no simple measure of 'diastolic function' has been developed, and those measures that have been used clinically are profoundly affected by systolic function and heart rate. However, diastolic functional disturbance is important: there are cases of definite clinical heart failure in which the patient has a small heart, with normal or even increased left ventricular ejection fraction, and in whom the only demonstrable abnormalities of ventricular mechanics are those related to diastolic filling. These may include increased filling pressures, delayed pressure fall within the ventricle, and a greater than normal dependence on the effects of atrial contraction for ventricular filling. Such cases form the minority of cases of heart failure (estimates vary from a few per cent to about one-fifth of cases), but are seen with increasing frequency in older patients in whom senile myocardial fibrosis occurs more frequently as the major pathology underlying the heart failure. Other rarer causes include hypertrophic cardiomyopathy, infiltrative conditions such as amyloid heart disease, and the acute effects of ischaemia or the chronic effects of advanced hypertrophy in response to hypertension.

Diastolic dysfunction can be quantified by a variety of measurements: haemodynamic; echocardiographic; radionuclear; or ventriculographic. Those most commonly employed are the rate constant of isovolumic relaxation of the ventricle during early diastole (tau), the early to late peak filling velocity ratio (*E/A*) across the mitral valve on Doppler echocardiography, and the peak rate of ventricular filling on radionuclear gated acquisition (MUGA) scans in end-diastolic volumes per second. None of these parameters are independent of the loading conditions of the ventricle, nor of atrioventricular delay and heart rate, nor of the effect of systolic dysfunction.

Pure diastolic dysfunction is rare, as indeed is pure systolic dysfunction, as the two are almost inseparably interdependent. One can speak, however, of cases where the heart failure is predominantly due to systolic or diastolic impairment of the ventricle, and the simplest separation is via the size of the end-diastolic volume; if large, systolic dysfunction is likely to be the major abnormality; if small, diastolic. As will be discussed, this differentiation is important because of differing effects of treatment, in particular vasodilators, which may be less useful in diastolic dysfunction because of the requirement for high ventricular filling pressures in this condition.

Non-cardiac

General syndrome

Although initiated by ventricular dysfunction, in its chronic form heart failure is a multisystem disorder: the syndrome of chronic heart failure. The causes of many of the disparate organ pathologies that develop are poorly understood, as are the mechanisms by which these are (slowly) corrected by effective therapy, including transplantation of the heart. Much remains uncertain about this non-cardiac pathology and pathophysiology, including its genesis, symptomatic effects, and correct management. Evidence suggests, however, that non-cardiac factors become responsible both for the symptoms and the objective limitation of exercise capacity in chronic heart failure.

Specific organ systems

The microvasculature

Changes occur in the microvasculature in many organ systems and these may contribute to the organ underperfusion seen in this syndrome. There have been few reports of definite structural changes in the microvasculature, but functionally the endothelial-dependent vasomotor control systems are disordered. The endothelial-dependent vasodilator system is impaired both in the myocardial vessels and in the periphery. Tumour necrosis factor-alpha, which is elevated in some cases of chronic heart failure, has been implicated in impaired endothelial vasodilator function in addition to the enhanced activity of the endothelin vasoconstrictor system. This generalized endothelial dysfunction may contribute to some of the organ dysfunction described below, including renal, hepatic, and pulmonary vascular impairment. Specific treatments for endothelial abnormalities have not been established for heart failure, although promising results have been seen with improved endothelial function after localized exercise training or administration of the nitric oxide precursor L-arginine.

Large arterial function

In heart failure there is a reduction in large arterial compliance, which in turns leads to an increase in the impedance to ventricular outflow. Thus the efficiency of ventriculoaortic coupling is reduced, the impaired ventricular reserve is further stressed, and there is an increase in myocardial wall stress. The cause of the changes in large arteries probably relate to sympathetic and possibly local renin–angiotensin activation. In acute heart failure counterpulsation by intra-aortic balloon pumping probably helps forward aortic blood flow, at least partially by a mechanism involving improved ventriculoaortic coupling, in addition to the beneficial effects of enhanced diastolic coronary perfusion pressures.

The respiratory system

The lungs

Despite the frequency of dyspnoea as a central complaint of a patient with heart failure, relatively little is known of the role of the lung in chronic heart failure. In acute heart failure, changes within the lung are profound and easily explain much of the acute respiratory distress of the syndrome. With an acute reduction in left ventricular performance a rapid increase in left ventricular filling pressures, and hence pulmonary venous pressures, will lead to fluid accumulation in the lung parenchyma. Initially this will decrease the compliance of the lung, thereby reducing vital capacity and increasing the work of breathing. It may also, via oedematous swelling of the bronchial mucosa, cause a non-asthmatic bronchial constriction that can mimic asthma and further increase respiratory muscle work. With more severe pulmonary venous hypertension the alveolar membrane becomes thickened and oedematous and this may impair gas exchange, leading to an increase in the alveolar–arterial oxygen gradient and eventually arterial hypoxaemia. Eventually frank pulmonary oedema can form, further exacerbating the processes described above and leading to the clinical picture of gross dyspnoea, hypoxaemia, lung crepitations, and the production of copious quantities of pink frothy sputum (the alveolar oedema fluid itself).

In chronic heart failure, the patient is dyspnoeic but the changes in the lungs are far less marked. Pulmonary venous pressures may be normal if diuretic treatment is effective, and in well-diuresed and non-oedematous patients very few changes can be detected in lung histology. The changes of pulmonary siderosis seen with chronic untreated mitral stenosis are not seen in well-treated chronic heart failure cases. There have been reports of subtle changes in lung function in chronic heart failure, including a reduction in gas diffusing capacity, intermittent non-asthmatic bronchial constriction, and a purported increase in dead-space ventilation, but these are largely functional changes without an established anatomical cause. One pathophysiological change that can lead to respiratory distress is an alteration in the volume, structure, strength, and fatiguability of the respiratory musculature. The effects of these changes on the sensation of dyspnoea, or most appropriate therapy, are unknown. Similar changes are seen in skeletal muscle (see below).

Pulmonary oedema is not synonymous with heart failure. In addition to the acute respiratory distress syndrome (see Chapter 16.5.1) there are other causes of pulmonary oedema that need to be considered as differential diagnoses for heart failure: these are discussed in Section 15.15.

Respiratory control

The mechanisms of normal control of ventilation during exercise are not fully understood. It is not surprising, therefore, that the mechanisms underlying the abnormal respiratory response seen in chronic heart failure are also unclear. Patients with heart failure, even in the absence of pulmonary oedema, have an increased ventilatory response to exercise, whilst maintaining normal arterial blood gas tensions. They show reduced maximal oxygen consumption, an early dependence on anaerobic metabolism, and an increased ventilatory equivalent for carbon dioxide even at low work levels. This latter feature can be best appreciated by the plot of ventilation against the rate of carbon dioxide production (the $\dot{V}us.\dot{V}CO_2$ slope) during progressive exercise: this is significantly steeper (up to threefold) throughout both aerobic and anaerobic levels of exercise, and its steepness correlates closely with the reduction of maximal oxygen consumption. Although it is clear that this increased ventilation relative to the external work rate must indicate wasted ventilation, exactly why this occurs in non-oedematous patients is not certain. It has been assumed that there is a primary increase in dead-space ventilation due to a reduction in the ability of the right ventricle to perfuse adequately all lung regions, or the development of significant ventilation/perfusion mismatching within the lung, but these hypotheses have not been proven. An alternative hypothesis is that something other than the rate of carbon dioxide production causes the increased exertional ventilation in patients with heart failure, which is supported by the finding that, rather than being abnormal, arterial carbon dioxide during exercise is often lower than in normals, suggesting relative hyperventilation and the action of a non-carbon dioxide ventilatory stimulus. There are several candidate stimuli including an increased release of, or sensitivity to, known ventilatory stimuli such as lactate, arterial potassium, or adenosine. Skeletal muscle is abnormal in heart failure cases (see below) and releases metabolites earlier in exercise than age-matched normal controls.

There is also a neural pathway (the ergoreflex or metaboreflux) in the control of ventilation, utilizing group III and IV afferents from skeletal muscle. These are sensitive to the metabolic state of exercising muscle and transmit signals via the lateral spinothalamic tract to mediate reflex increases in ventilation as well as peripheral vasoconstriction and sympathoexcitation. Both this reflex control system and the arterial chemoreflexes that control ventilatory effort are abnormally active and oversensitive in chronic heart failure, possibly contributing to the excessive ventilation during exercise and playing a role in causing the subjective dyspnoea during low-level exercise seen in cases of chronic heart failure.

Airflow

Expiratory airflow can be restricted in patients with heart failure, even when all smokers and patients with a history of intermittent bronchospasm have been excluded. These patients can exhibit considerable dips in their peak expiratory flow rate on occasion, especially at night, which may lead to episodes of respiratory distress as well as adding to the work of breathing, and through that to the perception of dyspnoea. The mechanisms of this 'bronchoconstriction' are not known but they may involve oedema of the bronchial mucosa. Thus, a variety of lung factors can add together to contribute to dyspnoea in chronic heart failure, even in the absence of frank pulmonary oedema. Recently methoxamine in an opening of airways has been reported to improve peak flow rates and lead to an increase in exercise tolerance in these patients.

Gas exchange

Although arterial oxygen desaturation and carbon dioxide retention are rare in well-diuresed patients with heart failure, a more mild alteration in the gas exchange function of the lung can occur. These factors could reduce the rate of delivery of oxygen to the metabolizing tissues and act as a stimulus to increased ventilation. They may also explain the compensatory increase in arterial oxygen content seen in chronic heart failure if mild but intermittent hypoxia develops in this condition. This could also explain the beneficial effects of oxygen supplementation, even acutely, on exercise tolerance in patients with chronic heart failure.

It is not certain, however, that in chronic heart failure a reduction in diffusing capacity is either quantitatively important, or that oxygen supplementation works via increasing net oxygen delivery to the tissues. Alternative explanations are that the effect of a high inspired concentration of oxygen is non-specific in reducing peripheral chemoreflex drive and thereby relieving the sensation of dyspnoea, in a way akin to that produced by narcotic analgesics. Similarly, reduced gas exchange, especially for oxygen, may have more to do with inadequate expansion of the pulmonary capillary network and an inadequate time for gas transfer rather than to any alteration in the alveolar blood–gas barrier itself. The very low mixed venous oxygen saturations seen in chronic heart failure may mean that even a normal capillary transit time is inadequate for full oxygen exchange.

The sleep-apnoea syndrome

Nocturnal oxygen saturation monitoring of patients with chronic heart failure has demonstrated the presence of episodes of desaturation, often to below 80 to 85 per cent. These episodes coincide with and are caused by episodes of apnoea; they are also followed by semi-arousal from sleep and hyperventilation that may awaken and frighten the sleeping partner. In addition to obstructive sleep apnoea, which is common in patients with heart disease due to similar antecedent risk factors, the pattern is reminiscent of the Cheyne–Stokes respiratory patterns that are well recognized in patients with severe heart failure.

The mechanisms of both abnormalities of respiratory rhythm are incompletely understood. In some cases of nocturnal desaturations there is an obstructive element with obesity and pharyngeal occlusion by the tongue flopping back. In other cases there appears to be an alteration in the central sensitivity to carbon dioxide so that oscillating levels of respiratory drive, and hence of arterial oxygen saturation, develop. This second mechanism may be partly the cause for Cheyne–Stokes breathing as well. Another finding that may be related is that patients with chronic heart failure exhibit reduced total and high-frequency heart rate variability, but relatively enhanced variability of heart rate at very low frequencies (less than 0.01 Hz, or 1 cycle every 100 s). Although rhythmic variations in heart rate at higher frequencies are related to homeostatic mechanisms controlling blood pressure, in particular the vagal and sympathetic limbs of the arterial baroreflex, the genesis of this very low-frequency rhythm is not known. It does, however, have several features to suggest that chemoreflex activity may play a role in its genesis. First, this rhythm is particularly prominent in heart failure, where the circulation time is long; second, it is of similar frequency to the more obvious rhythm of Cheyne–Stokes breathing; and third, the chemoreflex loop has sufficient delay characteristics and possesses sufficient interactions with the baroreflexes and control of heart rate for a harmonic of oscillatory arterial gas concentrations to set up a similar harmonic oscillation in respiration, which would then entrain heart rate via an effect of the baroreflex. Finally, similar rhythms are particularly prominent in heart failure in pulmonary arterial pressure tracings, hence it may be that periodic sleep-apnoea (at least that which is not obviously obstructive), very low-frequency rhythms of heart rate variability, and Cheyne–Stokes respiration may all be reflections of harmonic oscillation of chemoreflex–baroreflex interactions. If this is the case then they may respond to therapies that alter chemoreflex gain or drive, and in this regard the promising reports of nocturnal oxygen supplementation and of nasal positive-pressure ventilation may be supportive for this theory. It is in any case surprising, and perhaps chastening, to note that in a condition so associated with dyspnoea that the state of the chemoreflex drive at rest, during sleep, or exercise is not known.

Musculoskeletal

Structure

Skeletal muscle biopsies in patients with moderate to severe chronic heart failure have shown a variety of pathological changes. These include individual fibre atrophy, a shift in the distribution frequency of types IIa and IIb fibres, and changes at an ultrastructural level, including a reduction in mitochondrial density, volume, and the number of cristae. It has proved impossible to define a specific pathological change characteristic of heart failure, partly because of the enormous variation in a control population, but also because muscle becomes abnormal in a limited number of ways in a variety of diseases associated with skeletal myopathy. It is also important to be sure of studying a specific heart failure-related change and not some subclinical skeletal myopathy as part of an inherited cardioskeletal myopathy. That such changes are seen with equal frequency and severity in ischaemic heart failure makes this unlikely to be the only explanation of the findings.

One of the most marked structural changes in peripheral muscle is the substantial reduction in total skeletal muscle bulk. Although it has long been recognized that in some cases of end-stage heart failure a catabolic wasting syndrome can develop (cardiac cachexia), it has only recently been stressed that more subtle evidence of muscle wasting may be both common and functionally important in chronic heart failure. If less muscle is available to do the work of the limb then each fibre will be more easily fatigued, be able to accept a lower total blood flow, and will appear metabolically more stressed and require anaerobic metabolism at an earlier point in exercise. These findings have all been taken as indicators of a deficiency in blood and oxygen delivery, rather than the alternative explanation that there simply is too little muscle for exercise to be performed efficiently.

Function

In chronic heart failure there is a reduction in the peak strength of both small and large muscle groups. In the case of the small muscles of the hand this clearly cannot be due solely to a reduced cardiac pumping capacity because of their tiny blood flow requirement. This suggests that there may be inherent defects in the quality of the muscle itself, but given the difficulty of exactly matching for active muscle bulk the difference may, however, be partly a reflection of muscle wasting.

In addition to reduced peak strength, there is an early fatiguability of muscle in heart failure. As a result, patients frequently complain that muscle fatigue is the major limitation to the performance of their daily tasks, and weakness and fatigue may both contribute to reduced physical activity that may induce physical deconditioning and further muscle wasting and dysfunction.

Metabolism

Skeletal muscle metabolism during exercise has been investigated by magnetic resonance spectroscopy. This technique allows an exploration of the rate of utilization of high-energy phosphate bonds associated with phosphocreatine and of intracellular pH, and through these the efficiency of aerobic and anaerobic metabolism within the muscle. These experiments have shown that there is an early depletion of phosphocreatine, an early acidification and accumulation of inorganic phosphate, a reduction in the rate of resynthesis of phosphocreatine, and in the removal of adenosine diphosphate (**ADP**). These changes cannot be explained by the acute effect of impaired blood flow, because the difference between normal controls and heart failure patients is seen even when both groups perform exercise in ischaemic conditions produced by regional circulatory occlusion. The metabolic abnormalities described by magnetic resonance spectroscopy probably reflect alterations in the oxidative enzymatic content of skeletal muscle described in biopsy studies. The causes of these metabolic changes are not understood, but it has been estimated that muscle wasting alone cannot explain them, because the half-time of ADP removal is independent of both the workload per unit muscle mass and the blood flow.

The only treatment that has been definitely shown to correct these metabolic abnormalities is physical exercise conditioning of the muscle, either localized or general. The time course of the possible correction of the muscle changes after cardiac transplantation has not been determined, nor has any definite effect of ACE-inhibitor treatment been described.

Autonomic and neuroendocrine systems

Much has been written about the importance of neuroendocrine activation in chronic heart failure, partly because of the established benefits of blocking two aspects of this with the ACE inhibitors and b-blockers. There is an undoubted activation of neuroendocrine systems involved in the 'fight or flight' reaction. These probably evolved, in a teleological sense, as a way of compensating for blood or fluid loss or sodium depletion, but in heart failure, although initially helping to support the circulation, continuous activation may be harmful. The neuroendocrine systems involved include the renin–angiotensin–aldosterone system, the sympathetic nervous system, and the vasopressin system, as well as that of the counteracting cardiac natriuretic peptides. Simultaneously with neuroendocrine activation there is a reduction in vasodilator influences and in vagal tone which, when maintained chronically, may be harmful. Adverse consequences have been described such as organ hypoperfusion, myocardial toxicity, an increased susceptibility to ventricular arrhythmias, and a possible progression of the underlying disease process, whether it be myocardial ischaemia or cardiomyopathy.

The renin–angiotensin–aldosterone system

In untreated heart failure there is mild activation of the renin system, which is dramatically augmented by the first use of diuretics in the treatment of the heart failure. After that there is a reasonable relationship between the severity of the heart failure and further increases in circulating renin and angiotensin II levels. In addition, all the components of the circulating renin–angiotensin system also exist in tissue sites and there is probably activation of these local tissue systems in the heart, kidney, brain, and blood vessel walls. The role and effects of these in health and in the progression of heart failure are unknown, but some of the beneficial effects of ACE inhibition described in other sections stress how important these systems may be in the syndrome of chronic heart failure.

At an organ level, the effects of elevated local and circulating angiotensin II can be very profound. In the kidney it can cause either a preservation of glomerular filtration rate (**GFR**) in the presence of low arterial pressure, or a reduced renal blood flow and GFR if the kidney is already dependent on angiotensin II-mediated efferent arteriolar constriction to maintain an adequate filtration pressure in the glomerulus. Such dependence can be seen in renal artery stenosis. In the heart, local increases in angiotensin II can cause coronary vasoconstriction and toxic effects on the myocytes, and in the periphery local angiotensin activation can elevate

systemic vascular resistance and thereby increase the afterload to the failing heart.

The clinical effects of inhibition of the renin–angiotensin–aldosterone system are dealt with more fully in other chapters, but it is important to note that we still do not know how they mediate their beneficial effects, whether by reduced circulating or tissue-based angiotensin II, or by augmentation of bradykinin or other kinin systems.

The autonomic nervous system

Early in the progression of heart failure from mild asymptomatic left ventricular dysfunction to the full clinical picture of chronic heart failure there is an activation of the sympathetic nervous system and a concomitant reduction in resting vagal tone. These changes are further enhanced by the administration of diuretics. There is no clear mechanism for either the activation of the sympathetic system in mild heart failure, or to explain why the activation should persist and progress in the chronic syndrome. In severe heart failure there may be a reduction in blood pressure, but this is often the result of aggressive therapy. By contrast, in asymptomatic left ventricular dysfunction, or mild heart failure, sympathetic activation commences at a stage when there is no perceptible change in blood pressure. It has been said that the activation is secondary to the withdrawal of the chronic sympathoinhibitory effects of the arterial baroreflexes, but there are flaws in this explanation. Even complete denervation of the baroreceptors does not lead to such persistent sympathoexcitation as seen in chronic heart failure, and in heart failure it also begs the question as to what caused the baroreceptor inhibition in the first place. If it is thought to be sympathetic activation, as seems likely, then we are left with a circular argument. No significant sympathoexcitatory influence has been demonstrated to underlie the very high levels of sympathetic tone in established heart failure. Two candidate mechanisms that have received little attention are the skeletal muscle ergoreceptor system and an interaction between the arterial chemoreflex and the baroreflex and cardiovascular autonomic centres. Both the ergoreflex and the chemoreflex cause sympathetic activation and may be abnormal throughout the progression of chronic heart failure.

The investigation of sympathovagal balance is limited by the lack of precise and quantifiable methods. Apart from a measurement of plasma norepinephrine (noradrenaline) levels there is no easily available clinical test for the activity of the sympathetic limb, and for the vagal limb the problem is even more difficult. Analysis of variations of heart rate variability has identified characteristic frequency harmonic oscillations in cardiovascular parameters, the relative oscillatory power of which show promise in the estimation of sympathovagal balance. The pattern in heart failure is very abnormal, with a dramatic reduction in total heart rate variability and a selective loss of the higher frequency (predominantly vagally mediated) rhythm characteristic of respiratory sinus arrhythmia, and a relative preservation of low- and very low-frequency rhythms which have their genesis more in the action of the sympathetic (low frequency) and renin–angiotensin or chemoreflex systems (very low frequency). Analysis of total heart rate variability, and in particular of individual frequency components, has shown that the pattern seen in heart failure is one associated with a high risk for the development of unstable ventricular arrhythmias and cardiac sudden death, although why this should be the case is not certain.

Beta-receptor function

With chronic sympathetic activation there is depletion of myocardial catecholamine stores and a downregulation of b1-receptors on the myocardium. There is also a decoupling of receptors from the postreceptor response, all of which lead to a loss of myocardial response to increased sympathetic drive. Clinically this manifests as chronotropic incompetence, loss of response to sympathomimetic stimulation, and a further impairment of exercise tolerance. Specific treatments are few, but there has been some improvement after b-blockade, ACE inhibition, and even very short-duration intermittent sympathomimetic stimulation.

The natriuretic peptide systems

The atria and ventricles contain granulated cells that release peptides, atrial natriuretic peptide (**ANP** or **ANF**) and brain natriuretic peptide (**BNP**), in response to stretch. In addition, the vasculature of the heart and other organs is the site of production of a closely related peptide, C-type natriuretic peptide (**CNP**), the physiological role and normal modulation of which is less clearly understood. These peptides are natriuretic agents that also relax peripheral vasculature and thereby oppose the actions of the sympathetic and renin–angiotensin systems. There is an increased release of these peptides in chronic heart failure associated with cardiac enlargement, but the significance of the increased plasma levels is uncertain. The use of exogenous ANP or neutral endopeptidase inhibitors, to increase endogenous levels by inhibiting the breakdown of these peptides, have produced only minor natriuretic and haemodynamic effects in heart failure, although the effects may be greater if administered on the background of inhibition of the opposing renin–angiotensin–aldosterone system. BNP has been shown to be quite accurate in determining the degree of systolic dysfunction of the heart in selected hospital series, and there is such a close relationship between myocardial stretch and BNP release that estimation of BNP has been shown to quite accurately predict in population surveys which patients are likely to be diagnosed as suffering from heart failure.

The vasopressin system

Elevated plasma concentrations of vasopressin, also known as antidiuretic hormone (**ADH**), are found in chronic heart failure, but the importance of vasopressin in the pathophysiology of the condition is not certain. Its actions are a combination of haemodynamic, with profound arteriolar vasoconstriction increasing peripheral resistance, and renal, with an action on the collecting duct to increase reduce free water reabsorption and thereby cause antidiuresis.

Other hormonal systems

Abnormalities have been described in several other hormonal systems in chronic heart failure, but the significance of these changes is uncertain. Thyroid hormone metabolism is deranged, with an increase in reverse T3 similar to that seen in the so-called 'sick cell syndrome'. Plasma insulin levels are increased in heart failure, whether of ischaemic, valvular, or idiopathic aetiology, and this is associated with a decreased sensitivity to the glucose transport effects of insulin. Alterations in sex hormones and growth factors are likely in advanced cardiac cachexia, but to what extent these are specific to the syndrome of chronic heart failure is uncertain.

The kidney

Control of fluid and electrolyte balance is impaired in heart failure. This is due to the reduced renal perfusion pressure in advanced disease, to the effects on intrarenal haemodynamics of the neuroendocrine activation described above, and to the effects and side-effects of commonly prescribed medications.

Fluid overload and hence oedema is common in heart failure, and electrolyte disturbances are both common and important. In mild heart failure fluid retention is due to the effects of aldosterone, vasopressin and catecholaminergic renal vasoconstriction. The kidney itself is partly a passive organ, responding to neuroendocrine activation outside its control, but it is also an active endocrine and autocrine organ responding to reduced renal perfusion pressure in heart failure.

The renin–angiotensin–aldosterone system

The juxtaglomerular apparatus, adjacent to the distal convoluted tubule, senses a reduction in the rate of delivery of sodium to the distal tubule and releases renin in response, thereby playing an important part in the activation of the circulating renin–angiotensin system described above. Activation leads, via aldosterone, to an increased reabsorption of sodium in the distal renal tubules, and an additional effect of angiotensin on thirst and possibly salt hunger completes the response, all encouraging the retention of sodium and water in the body.

All the components of the renin–angiotensin system also exist within the kidney and there can be local autocrine activation with important effects on intrarenal haemodynamics. These may either increase or decrease GFR, depending on the level of renal perfusion pressure and other factors operating on the kidney, such as the renal sympathetic nerves and circulating vasoactive factors.

The kallikrein–kinin system

This second autocrine system of the kidney is less well studied because of the short half-life of some of its active components and the difficulty in isolating them. In simple terms the kinin system appears complementary to the renin–angiotensin system, causing vasodilatation where the latter causes vasoconstriction. It is also thought to be involved in the control of renal tubular function, but its precise role in heart failure and the effects of ACE inhibitors (which also block the enzyme that breaks down bradykinin) are unknown.

The cardiorenal syndrome

Some of the causes of heart failure, most notably atherosclerotic arterial disease and hypertension, can have direct effects on the kidney. This is one reason for an increased coexistence of cardiac and renal failure. Other less common conditions that can cause both organs to fail include amyloid, sarcoid, and certain vasculitidies. A more common finding is that an apparently reasonably well-functioning kidney can progressively fail in the presence of severe heart failure. This is partly the effect of hypovolaemia and low blood pressure (prerenal azotaemia), but is also due to the circulating and intrarenal neurohormonal systems described above, and the renal effects of drugs used in treatment. The net effect is that renal failure is an extremely common and clinically important complication of severe heart failure. Aggressive diuretic therapy can precipitate a significant worsening of renal function that then blunts their effectiveness. The ACE inhibitors usually lead to a small increase in serum creatinine concentrations, but in a few patients they can precipitate clinically important renal failure.

Electrolyte disturbances

Electrolyte disturbances are not common in untreated heart failure, except when this is severe. There is an initial retention of sodium and a loss of potassium due to the effects of increased levels of aldosterone. Later, and especially after diuretics have been administered, there is a further depletion of potassium and also of magnesium. Both these disturbances may be important in generating cardiac arrhythmias, especially in digoxin toxicity. A dilutional hyponatraemia can develop in patients with severe heart failure: this can be both difficult to manage and is a poor prognostic sign.

The careful management of fluid and electrolyte balance in patients with heart failure can lessen renal complications and improve both symptoms and prognosis. There is no simple therapeutic regime that will ensure this, just careful repeated clinical examination and monitoring, judicious use of drugs, with knowledge of their potential side-effects.

Haematological system

Haemoglobin

Increased haemoglobin content has been described as an adaptive response in heart failure. This may be secondary to chronic tissue hypoxia, perhaps most importantly in the kidney in which it may stimulate an increase in erythropoietin production. It is doubtful if the increase in haemoglobin is very effective in increasing oxygen delivery to the tissues, for if the haematocrit increases too much then the resulting increased whole blood viscosity will reduce net tissue perfusion by increasing the resistance to blood flow. In more severe chronic heart failure anaemia becomes more common. It is similar to the anaemia seen in other chronic illnesses.

Other haematological changes

Impaired clotting factor production can result from hepatic dysfunction (see below) and resulting abnormalities in haemostatic function are not uncommon. The white blood cell count may be mildly elevated in heart failure as part of a more generalized, but poorly understood, immune activation.

Other organ systems

The liver

In heart failure the liver can be affected by an increased venous back-pressure, by an impaired arterial supply, and by the metabolic complications of the syndrome. The underlying process that leads to heart failure, for example alcohol excess or haemachromatosis, can also affect it.

The most common hepatic abnormality in chronic heart failure is congestion due to the effects of right heart failure on venous pressures. This leads to increased venous engorgement of the liver and can result in a noticeable increase in hepatic size, local tenderness, and minor derangements in liver function, causing modest increases in transaminase levels in its mildest form. In more severe cases, nausea and right hypochondrial discomfort develop, and in severe cases jaundice, impaired albumin and clotting factor production, and malabsorption of fats may result. These changes can have clinically important effects on clotting, especially as warfarin is commonly prescribed, and also on the hepatic metabolism of certain drugs. The nausea and malabsorption can worsen the catabolic state of the patient and can contribute to the wasting seen in cardiac cachexia. There is no specific treatment for this complication of chronic heart failure, other than the correct dosage of diuretics and the maximization of cardiac function with vasodilators.

Gastrointestinal tract

This is mainly affected by the increased venous pressure of right heart failure. Intestinal mucosal oedema can contribute to malabsorption and possibly nausea. Cardiac conditions are also associated with a higher rate of intestinal angiodysplasia: this can lead to recurrent blood loss, which can be a considerable management problem in the patient who requires anticoagulation.

Central nervous system

Certain conditions that cause heart failure can also produce neurological effects: these include alcoholism, amyloid, and heavy metal poisoning. Apart from the abnormalities of autonomic and neuroendocrine function described earlier, specific neural complications of heart failure are not common.

Immune function

Immune abnormalities in heart failure include both an excess of proinflammatory cytokines and a deficiency of inhibitory and immunomodulatory cytokines. Some cytokines are released in excessive amounts in both acute heart failure and in cases of relapsing or severe heart failure. Important amongst these is tumour necrosis factor-alpha (**TNF-a**), important because it has been shown to produce harmful effects that are common in chronic heart failure. These include endothelial dysfunction, myocyte depression, necrosis and apoptosis (programmed cell death), and loss of skeletal muscle mass. This cytokine has been implicated in the generation of severe wasting, both in cancer-related cachexia and in the syndrome of cardiac cachexia. Although the exact pathogenic mechanisms for the high cytokine levels in chronic heart failure are unknown, several theories have been proposed. These include the possibility that the failing heart itself is a site of production, or that recurrent bacterial loads due to bowel-wall oedema and bacterial-product translocation to the circulation cause an endotoxaemia that is known to be able to stimulate cytotoxic cytokine release. TNF-a has the properties to be harmful in heart failure and studies are underway to evaluate whether antitumour necrosis-factor strategies, such as the use of monoclonal antibodies or subantibody fusion-protein fragments, which neutralize tumour necrosis factor, would benefit the clinical course of patients with advanced chronic heart failure.

Cause of non-cardiac pathophysiology in heart failure

The changes described in different organ systems as part of the syndrome of chronic heart failure remain largely unexplained. We have proposed a 'muscle hypothesis' in which we explain the generation of many of these abnormalities via the combined effect of physical deconditioning and metabolic dysfunction, combining a release of catabolic factors with a loss of normal anabolic function. Figure 1 describes the general pathway by which these changes could lead to skeletal and respiratory muscle abnormalities, and via these to fatigue, dyspnoea, exercise limitation, and sympathoexcitation.

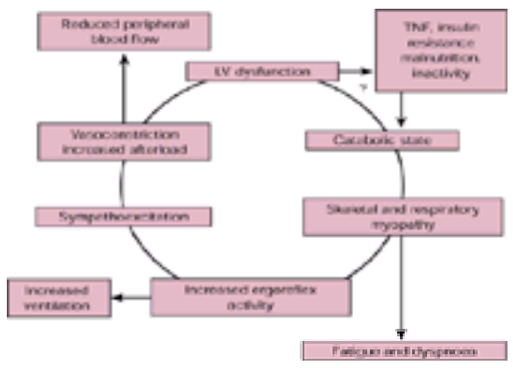

Fig. 1 The Muscle hypothesis in chronic heart failure. A proposal to explain the genesis and effects of several components of the non-cardiac pathophysiology of heart failure. As proposed by Coats *et al*. 1996. TNF, tumour necrosis factor.

Clinical assessment

The assessment of a patient with heart failure requires a careful history and examination, both at initial presentation and when assessing progress and response to treatment. Confirmation of heart failure can be aided by chest radiography, echocardiography, and, in selected cases, by cardiac catheterization, radionuclide ventriculography, and other imaging modalities. Invasive haemodynamic monitoring has a role in the assessment of acute severe heart failure. The use of a biochemical test (such as estimation of brain natriuretic peptide, BNP) to detect heart failure shows promise, but is not yet recommended in routine clinical practice.

Cardiopulmonary exercise testing with respiratory gas analysis can help to establish the cause of symptoms in patients with coexisting heart and lung disease, and to determine whether heart failure is causing the symptoms limiting the patient. When the respiratory exchange ratio (CO_2 produced per unit of oxygen consumed) exceeds 1.0, muscle metabolism has become anaerobic, indicating that a point of limiting cardiac reserve has been approached. If it does not exceed 1.0 at peak exercise then the true cardiac limitation cannot be assessed. Significant hypoxaemia and/or hypercapnia on exercise are rare in non-oedematous chronic heart failure, and when present suggests the limiting factor is pulmonary or (less commonly) a right to left shunt.

Regular assessment of the severity of heart failure is usually made by a history of symptomatic limitation and by clinical examination. The occasional use of chest radiography, echocardiography, and cardiopulmonary exercise testing can also help. Repeated haemodynamic monitoring has little role in chronic heart failure. Whether monitoring levels of plasma norepinephrine (noradrenaline) or atrial natriuretic peptides would materially assist in clinical management is uncertain: regular assessment of clinical biochemistry is certainly essential.

Symptoms

Heart failure is defined as symptomatic left ventricular dysfunction. As a result classical symptoms must be present to make the diagnosis. These most commonly are dyspnoea or fatigue, but initial presentation can be collapse, syncope, oedema, chest pain, or palpitations (Table 2).

Clinical examination

The physical examination of any patient with suspected heart failure is important. It can be a way of detecting the cause of the heart failure, such as the detection of aortic stenosis, leading to a definitive treatment option. Most cases of treated heart failure do not demonstrate florid signs such as seen in acute or decompensated heart failure, hence skilled clinical examination is necessary to obtain all the available clues as to cause, severity, and complicating factors (Table 3).

Investigations

Investigations may be necessary to confirm the diagnosis of heart failure, to establish the cause, and to stratify for the risk of complications or deterioration. A chest radiograph, an electrocardiogram, and an assessment of full blood count, urea, and electrolytes are essential in all cases of suspected heart failure. The electrocardiogram may give specific evidence of ischaemia/infarction, left ventricular hypertrophy, arrhythmia, and other causes of pathological Q-waves, and can combined with stress testing to detect reversible myocardial ischaemia.

Many studies have demonstrated the inaccuracy of diagnosis and assessment of the cause of heart failure in primary-care settings without the use of more specialized investigations, with up to one-third of cases being misclassified. As a result it is now a recommendation that all suspected cases of heart failure should have, if at all possible with local resources, an echocardiogram to assess the nature and extent of ventricular dysfunction and to detect those causes of heart failure identifiable by echocardiography. It can be used to detect and grade valvular disease, for the differentiation of a globally impaired left ventricle (for example, dilated cardiomyopathy) from segmental dysfunction (for example, ischaemic heart disease), and may also reveal ventricular hypertrophy, aneurysms, amyloid and other infiltrates, and specific forms of cardiomyopathy.

Specific blood tests can be used to check for certain rare causes of cardiac failure: hypocalcaemic cardiomyopathy; thyroid heart disease (hyper- or hypothyroidism); iron storage diseases; anaemia; heavy metal poisons; amyloid (serum electrophoresis); and sarcoid (serum ACE). Occasionally coronary angiography, and rarely ventricular biopsy, may be indicated in cases where the presentation is at a young age or specific features suggest a high likelihood of a treatable condition.

Certain investigations may be useful in assessing the severity of ventricular dysfunction in addition to or as alternatives to echocardiography, for example rest or exercise radionuclide ventriculography. Monitoring by 24-h Holter electrocardiography to detect ventricular arrhythmias and blood tests for associated renal or liver dysfunction or electrolyte disturbances can be used to give a rough guide to prognosis, although this is rarely reliable on an individual patient basis.

Other specialized investigations such as cardiopulmonary exercise testing, CT or MR scanning, cardiac catheterization, and myocardial biopsies are covered in other chapters to which the reader is referred for more detailed explanation.

Treatment

The major elements of treatment of heart failure are listed in Box 1 and Box 2. This has undergone a revolution in the last two decades, with substantial treatment efficacy established first for the ACE inhibitors and more latterly for b-blockers (a group previously considered absolutely contraindicated in heart failure) and the aldosterone antagonist spironolactone.

Box 1 Treatment of chronic heart failure

General	No added salt	Treat hypertension
	Maintain optimal weight	Detect alcohol abuse
	Stop smoking	Prevent coronary disease
	Encourage exercise	
Mild	Thiazide/loop diuretic	b-blocker

	ACE inhibitor	
	Digoxin if atrial fibrillation	
Moderate	Loop diuretic	b-blocker
	ACE inhibitor	
	Combine diuretics	
Severe	Increase loop diuretic	Spironolactone
	Combine diuretics	? b-blocker
	Metolazone	? digoxin
	ACE inhibitor	Transplant

Box 2 Options in the treatment of severe chronic heart failure

1. Drugs	Diuretics	Loop, thiazide, and potassium-sparing combination
	ACE inhibitors	
	Vasodilators	Nitrates, hydralazine
	Positive inotropes	Digoxin, IV intermittent inotrope
	Anticoagulants	
	b-blockers, calcium antagonists, or anti-arrhythmics	
2. Implantable cardiac defibrillator—ICD		
3. Haemofiltration		
4. Peritoneal dialysis or haemodialysis		
5. Aortic balloon pump or ventricular assist device		
6. Transplantation or cardiomyoplasty		

ACE, angiotensin-converting enzyme; IV, intravenous.

Diuretics

Diuretics remain the mainstay of the management of oedema in heart failure and are often the first agents to be used in new cases. This is not because their role for this indication has been proven, but rather they are used to treat what is frequently the first manifestation of heart failure, peripheral or pulmonary oedema. In acute heart failure intravenous loop diuretics lead to a dramatic and rapid improvement in condition, and in almost all patients with moderate or severe heart failure diuretics will be essential for adequate symptom control. Concern has been expressed about the potential adverse effects of diuretic agents, including activation of the sympathetic and renin–angiotensin systems, but until an alternative mechanism for the control of oedema fluid is achieved there remains no viable alternative.

In the modern era of evidence-based therapies diuretic use remains an example of the art of medicine surviving despite a marked lack of proof. No single placebo-controlled trial of a loop diuretic has proven a convincing improvement in either mortality or morbidity rates: the treatment was introduced and popularized before the modern era of randomized controlled trials. The only significant treatment trial of diuretics was with a low dose of the weak diuretic spironolactone 25–50 mg per day, which showed a significant reduction in total mortality in severe heart failure in the RALES study published in 1999. This effect was probably due to the inhibition of the harmful effects of the neurohormonal factor aldosterone than to the diuretic effect of spironolactone.

Initially the thiazide diuretics may be sufficient in patients with mild heart failure, but in more severe cases of heart failure one of the loop diuretics—furosemide (frusemide), bumetanide, or torasemide—will be necessary. These are very familiar agents, particularly furosemide, but there remains some confusion about the best mode of treatment. Furosemide and bumetanide both give an acute and relatively short-acting diuresis that some patients find disabling. Others actually prefer this, as they can time their outings to avoid periods of diuresis. The newer torasemide has a much more prolonged action over 24 h and the increase in urine flow is said to be much less obvious to the patient.

Initially 40 mg of furosemide or its equivalent (about 1 mg of bumetanide) may be sufficient to control oedema, but some patients will need much higher doses (e.g. furosemide 80 or 120 mg twice daily) for oedema control. A better alternative to increasing the dose of loop diuretic is to use combination diuretics by adding agents with different modes of action, such as amiloride, thiazides, or spironolactone, or all three together. This is often far more effective than even extremely high-dose intravenous loop diuretics. The potassium-sparing drugs have the added advantage of ameliorating the loss of potassium produced by the other agents, although this is now less of a problem because the majority of patients with heart failure will be taking an ACE inhibitor, which has potassium-sparing effects.

In an acute exacerbation, switching to intravenous administration can boost response, as can a short period of bed rest, or the use of a short period of positive inotropic therapy with dopamine or dobutamine, especially as these have some renal vasodilator action.

It should also never be forgotten that diuretic therapy should go hand in hand with sodium and fluid restriction. The 'Chinese take-away syndrome', due to the effects of an acute sodium load and water retention, describes an episode of acute pulmonary oedema occurring several hours after a high sodium meal in a previously stable patient with chronic heart failure. This should remind us of the effects of excessive sodium intake.

In patients with severe heart failure fluid restriction may be necessary, but care should be taken not to produce dehydration and further deterioration in renal function. In the long term, fluid restriction should not be to less than 1500 ml per day.

Metolazone is a thiazide-like diuretic with a profound diuretic action when given on the background of loop-diuretic therapy. This combination therapy can be very powerful, often considerably stronger than the intravenous administration of furosemide alone, even in high doses. As little as 2.5 or 5 mg of metolazone given in this way can lead to several litres of extra urine output; this should never be started for the first time in an outpatient, but should be reserved for specialist hospital use, except under special instruction. Profound electrolyte disturbance can accompany this diuresis. A small number of outpatients with severe oedematous heart failure require chronic administration of metolazone, but often only 2.5 mg on alternate days or once or twice a week may be needed. Care should be taken to monitor electrolytes, urea, and creatinine very carefully in patients so treated.

Digoxin

Digoxin is the oldest drug therapy available for heart failure, and it still retains a place as the only safe chronically administered positive inotropic agent. Its use in patients with sinus rhythm remains controversial, for although it is considered as first-line standard therapy in the United States and many European countries, cardiologists in the United Kingdom point to the lack of any data demonstrating its long-term benefits in a large prospective placebo-controlled trial. The only definitive

large-scale trial of digoxin against placebo, the DIG trial, showed no significant effect on mortality, despite a significant reduction in the number of hospital admissions. With its narrow therapeutic window the routine use of digoxin in patients with sinus rhythm remains a matter of debate. In severe heart failure, where the patient remains very symptomatic, it may be worth trying: some respond with an improvement in symptomatic status. (See Chapter 15.5.1 for further information.)

Direct-acting vasodilators

The major agents in this class in regular use for heart failure are the combination of hydralazine and isosorbide dinitrate. Although an advance at the time, their use has been largely supplanted by the more effective ACE inhibitors. Other agents such a prazosin have proved less effective, and the calcium-antagonist vasodilators, particularly the short-acting dihydropyridine group, such as nifedipine, are significantly negatively inotropic and can worsen heart failure. Longer acting agents that cause less reflex tachycardia appear to be preferable, with amlodipine in particular seeming to be at least safe in chronic heart failure if its use is needed for its antianginal profile. The routine use of vasodilators in chronic heart failure cannot be supported by clinical trial data. (See Chapter 15.5.1 for further discussion.)

Angiotensin-converting enzyme (ACE) inhibitors

In heart failure

The introduction of ACE inhibitors has had a profound effect on the treatment of heart failure. Their benefits are not restricted to patients with end-stage heart failure, but extend also to patients with mild to moderate heart failure, and even to modifying the progression of the disease in patients with asymptomatic left ventricular dysfunction or extensive left ventricular dysfunction after myocardial infarction. The ACE inhibitor enalapril was the first agent to be shown to dramatically reduce mortality in severe heart failure: 253 patients in the CONSENSUS I study were randomly allocated to enalapril or control and, with an overall 6-month mortality in the placebo group of 44 per cent, there was a significant 40 per cent reduction in mortality in those randomized to enalapril. These patients were in end-stage heart failure, symptomatic at rest or on minimal effort, and this treatment was a clear therapeutic breakthrough, so much so that almost immediately ACE inhibitors became standard therapy in this situation.

Within a few years of the CONSENSUS I study similar evidence of benefit was shown for ACE inhibitors in the treatment of mild to moderate heart failure (New York Heart Association, NYHA class II and III), patients in whom moderate exertion led to symptoms, but in whom the 1-year mortality rate was 10 to 20 per cent rather than the 50 per cent or more of the CONSENSUS I study patients. Despite the lower overall mortality rate in these patients, the ACE inhibitor enalapril produced further significant reductions in mortality. The SOLVD treatment study looked at 2569 patients with mild to moderate heart failure randomized to enalapril or control and showed a statistically significant 16 per cent reduction in mortality. The V.HefT II study looked at 804 patients randomized between enalapril and the vasodilator combination of hydralazine and isosorbide dinitrate and found a significantly lower mortality with enalapril.

The prevention limb of the SOLVD trial, despite not showing any significant reduction in overall mortality, did show a reduction in the rate of progression of disease, with less new diagnoses of clinical heart failure, and a reduction in the rate of hospital admissions for heart failure. This suggests there may be both clinical and economic gains from the use of ACE inhibitors in this clinical situation.

See Chapter 15.5.1 for further discussion of the use of ACE inhibitors in heart failure.

After myocardial infarction

After a myocardial infarction the area of infarcted myocardium does not form a stable scar immediately, but rather undergoes a complex series of changes over weeks to months and even years (see Chapter 15.4.2). Some of these changes are beneficial and some are not, and this process may hold some of the clues to why patients after a myocardial infarction can develop heart failure months or even years later, without any evidence of further infarction.

In the first few days after the infarction there is an increased load on the residual myocardium, which undergoes compensatory hypertrophy, partly stimulated by activation of some of the neurohormonal pathways described earlier. The infarcted area is not protected from these influences, and as it is under increased mechanical stress as well, the overstimulation of the adjacent myocardium by the sympathetic and renin–angiotensin systems can lead to an even greater mechanical stress on the freshly infarcted region. These processes can lead to infarct expansion, a process whereby the infarcted wall is stretched and thinned by the mechanical stress exerted upon it, and to an apparent increase in the extent of infarcted myocardium expressed in absolute size or as a percentage of the total left ventricular wall. This should be distinguished from infarct extension, where previously living myocardium at the fringes of the infarcted area itself infarcts, leading to an increased size of wall motion abnormality.

Over a period of weeks to months and possibly years, a second process develops where the wall of the whole myocardium becomes thinned and enlarged. This affects the residual myocardium and involves realignment between myocytes, a process called 'cell slippage', leading to a progressive alteration in the shape of the ventricle, not requiring any further episodes of infarction. The shape of the ventricle becomes more globular and enlarges and the ventricle is said to have 'remodelled'. Very good animal experimental data and observational data on patients have shown that this remodelling process precedes and predicts the development of heart failure, and that the administration of an ACE inhibitor could delay or prevent left ventricular remodelling and reduce mortality in this setting.

The first large trial reported orally was the CONSENSUS II study. This indicated a non-significant trend towards an adverse effect on mortality when enalapril was given to relatively high-risk patients recovering from infarction. Therapy was commenced with intravenous enalaprilat within 24 h of the infarct, and included subjects with quite low blood pressure at entry. The trial was terminated early with no definite effect on mortality. This trial was rapidly followed by the SAVE trial, which studied captopril in a target dose of 50 mg thrice daily in patients recovering from a myocardial infarction. Unlike the CONSENSUS II study the patients were recruited after the initial infarct-healing phase had been completed, after most infarct expansion and scar formation had begun, but before the later remodelling process had become established. The patients were all thoroughly investigated, including documentation of significantly impaired left ventricular function by a radionuclide ventriculogram ejection fraction of 40 per cent or less, and all had undergone correction of clinically important residual myocardial ischaemia by either angioplasty or bypass surgery prior to entry to the trial. A total of 2231 patients were randomized between 3 and 16 days after infarction to receive captopril or placebo and followed for 42 months. After the first 6 months of follow-up the survival curves for the two groups separated and at the end of the trial there was a significant 19 per cent reduction in total mortality; there was also a 22 per cent decrease in the rate of hospital admission for heart failure.

Following the SAVE trial there was rapid confirmation of its results. The AIRE study, co-ordinated from Leeds, recruited 2006 patients who had clinical evidence of transient heart failure after a myocardial infarction, including radiological evidence of pulmonary oedema or chest crepitations, or the presence of a third heart sound on auscultation. Patients were randomized to ramipril (5 mg twice daily) or placebo between 3 and 10 days postinfarction: there was a significant 27 per cent reduction in mortality at 15 months of follow-up. The survival benefit appeared to commence within the first few weeks of follow-up.

These beneficial effects have been confirmed with a number of ACE inhibitors in different trial settings. The overwhelming conclusion from these studies is that ACE inhibitors beneficially affect the recovery process after a myocardial infarction, and in the longer term reduce mortality by preventing the progression to heart failure. Based on available evidence, the vast majority of patients either with heart failure or at high risk of developing heart failure, should be on long-term ACE inhibitor therapy. These large trials have shown benefits postinfarction and in heart failure, with a variety of ACE inhibitors, including enalapril, captopril, ramipril, lisinopril, and trandolapril. It would seem a reasonable conclusion that the benefit of the ACE inhibitors is largely a class effect.

b-Blockers

This is an interesting therapeutic area because everything from total b-receptor antagonists (for example, metoprolol), through partial agonists (xamoterol), to totally positive agonists has been tried or suggested for the treatment of heart failure. Until recently b-blockers were routinely prohibited for patients with heart failure. However, the last few years have seen a sequence of well-designed randomized controlled trials that have demonstrated a profound reduction in mortality, improvement in left ventricular function, and a reduction in the need for hospital admission in patients with mild, moderate, and severe heart failure. This has been shown for metoprolol in a slow-release preparation, bisoprolol, and the combined b- and a-receptor antagonist carvedilol, but it is too early to say if the beneficial effects are a class effect.

The difficulty of using b-blockers in significant heart failure should not, however, be underestimated. Patients were carefully selected in the major trials, almost always stable outpatients at the time of treatment initiation, and with recent episodes of oedema or decompensation. b-Blockade was commenced at very low initial starting doses and increased slowly under careful observation. In addition, treatment was commenced and monitored by physicians expert in the care of patients with heart

failure. Those with stable heart failure should not be denied the benefits of b-blockade, but only specialists in the care of patients with heart failure should start this therapy, which can sometimes be difficult. (See Chapter 15.5.1 for specific guidance.)

Antiarrhythmic agents

Ventricular arrhythmias are extremely common in those with heart failure. As sudden death is a common mode of demise for these patients it is tempting to think that antiarrhythmic therapy, which can suppress the ventricular arrhythmias, may reduce the incidence of sudden death. Unfortunately this approach has not proved to be effective, and many agents that have been tried appear to induce more sudden deaths than they prevent. The most promising drug is amiodarone, despite its formidable list of side-effects. The GESICA trial in South America, which included a high proportion of patients with Chagas' cardiomyopathy, even suggested a net reduction in mortality in heart failure patients regardless of the presence of ventricular arrhythmias, but subsequent trials in ischaemic left ventricular dysfunction failed to confirm this promise. By and large, unless symptomatic, non-sustained episodes of ventricular tachycardia are best left alone. The implantable defibrillator is more effective at reducing mortality in patients resuscitated from sudden death or those with frequent potential fatal ventricular tachycardia, but costs are high and they are not uniformly available to all patients who might benefit from their use. (See Chapter 15.6 for further discussion.)

Oral, positive inotropic agents

This group of drugs, including the phosphodiesterase inhibitors and calcium sensitizers, were heralded as a major advance when introduced into practice, but trial after trial comparing them against placebo have not only shown a loss of effect with time, but have suggested an increased mortality. With the exception of digoxin there is no safe, chronically administered, positively inotropic agent.

Anticoagulants and antiplatelet agents

There is clear evidence for the benefits of aspirin or other antiplatelet agents in patients recovering from a myocardial infarction. As most people with heart failure in the developed world appear to have extensive ischaemic heart disease, it is likely the majority will be treated with aspirin to reduce the chance of coronary arterial occlusion. Another indication for aspirin is in the prevention of cerebral embolism in chronic atrial fibrillation in patients with significantly impaired left ventricular function. Several studies have shown a positive effect of aspirin in this situation, although it is probably less effective than full anticoagulation with warfarin, although there are some patients in whom it would be preferable. This indication for aspirin would incorporate patients with dilated cardiomyopathy as well as those with extensive ischaemic heart disease. However, some as yet unconfirmed fears have arisen that aspirin may interfere with some of the beneficial effects of ACE inhibitors in heart failure, so it is not considered routine to use aspirin in all patients with this condition. Full anticoagulation is usually reserved for those with heart failure who also have chronic or regularly recurrent atrial fibrillation, who have suffered a prior thrombotic or embolic stroke, or who suffer from transient ischaemic attacks. (See Chapter 15.5.2 for further discussion.)

Angiotensin-II receptor antagonists

Following the great success of the angiotensin-converting enzyme inhibitors in heart failure, much was expected of a group of agents that specifically blocked the harmful effects of angiotensin-II at its main site of action, the AT-1 receptor. However, the trials published to date have failed to prove that these agents are superior to ACE inhibitors in terms of reducing mortality, nor can it yet be said with confidence whether they are as good as the older agents. They do appear to be better tolerated, with less likelihood of producing cough as a side-effect, but their role, if any, in the management of patients with heart failure remains unclear. The largest trial to date, ELITE-II, of approximately 2000 elderly patients with chronic heart failure, compared captopril 50 mg three times a day with losartan 50 mg once a day. There was no significant difference in mortality between the two treatments. The trial was not large enough to prove that the angiotensin-II receptor antagonist was equivalent or an alternative to the ACE inhibitors. (See Chapter 15.5.1 for further information.)

Non-pharmacological treatments

Patient education

Patients and their families are often confused and bewildered by the term 'heart failure'. Alternatives such as 'weak heart', 'congestion', or 'large heart' may be better at giving the correct impression as to the nature of the condition. In can be extremely useful for long-term adherence to treatment recommendations to spend some time explaining to the patient and partner some simple physiology of left ventricular dysfunction, the body's compensatory mechanisms, and why these lead to symptoms and signs that the patient may have already noted. The patient will then be much more aware of the need for diuretics and vasodilators, and the effects of alterations in fluid and salt intake, intercurrent illness, etc. This could improve oedema control and lessen the frequency with which a patient needs to attend the outpatient department or be admitted to hospital for stabilization. Simple measures such as information on low-salt diets, fluid restrictions, and monitoring daily weight at home can significantly improve long-term heart failure management.

Specialist heart failure clinics and outreach nursing services

Recent trials have suggested that there can be a reduction in the need for emergency hospital admissions if patients are enrolled into specialist services to help them, their relatives, and their general practitioners manage their heart failure after discharge from hospital. Important amongst these services is adequate education about the correct way to take their heart failure medication. Specialized nursing services with home visits and improved liaison between the primary care and secondary care of patients with heart failure appears to be particularly helpful in improving the quality of care.

Rest and exercise

There is very good evidence in acute heart failure, or in an acute decompensation in chronic heart failure, that bed rest can improve renal blood flow and the response to diuretics. This is presumably via a reduction in the level of stimulation of the sympathetic and renin–angiotensin systems. Admission to hospital for a few days' rest is thus a common treatment for heart failure, and one with a very long history. Initial enthusiasm for the benefits of longer periods of bed rest (weeks to months) as a management strategy for chronic heart failure and cardiomyopathy have not been borne out; in fact this practice is accompanied by the considerable and well-known complications of prolonged bed rest. On the contrary, benefits have been shown after exercise training in carefully selected patients with chronic heart failure. Improvements are seen in exercise tolerance, skeletal muscle and respiratory function, and in autonomic balance. This raises the possibility that profound physical deconditioning may be contributing to some of the pathophysiological changes described in the sections above. In a patient with stable chronic heart failure, with no evidence of exercise-induced ventricular arrhythmias, regular exercise should be encouraged rather than prohibited. The reader is referred to Chapter 15.5.3 for a discussion of the benefits that can be obtained from a careful and selected use of exercise training programmes in patients with stable chronic heart failure.

Other treatments

Cardiac transplantation and mechanical assist device therapies are described in Chapter 15.5.4.

Prognosis

In severe heart failure, where patients are symptomatic at rest (NYHA class IV), the prognosis is dire, with survival expected to be 1 year or less. The prognosis remains poor even in mild heart failure (class II–III), being comparable to that of many solid tissue malignancies with a mortality rate of between 20 and 30 per cent per year. Although major treatment advances have been achieved in mild, moderate, and even severe heart failure, these have led to only a very partial correction of the excess mortality associated with this condition.

Prognostic factors and markers

Many different parameters have been described as having prognostic value in patients with heart failure. It is important to differentiate between prognostic factors, which have a direct functional link to increased mortality, and prognostic markers which merely reflect a worse prognosis, without themselves being involved in the mechanism. It can be dangerous to base treatments on the supposition that improving an adverse prognostic feature will improve outlook: treatment may improve a

marker but have either a neutral, or even a detrimental effect on survival.

The presence of non-sustained ventricular tachycardia on Holter monitoring is a sign of an increased mortality risk for sudden death. Class I antiarrhythmic agents can reduce the frequency of ventricular tachycardia, and as a result they were suggested for this purpose in heart failure. However, the Cardiac Arrhythmia Suppression Trial (**CAST**), a randomized controlled trial of three such agents in left ventricular dysfunction, showed that despite reducing the frequency of ventricular arrhythmias there was an increased rate of sudden death, presumably due to some proarrhythmic effect. Similarly, a low ejection fraction is an adverse prognostic sign in heart failure, and it was expected that agents that improve ejection fraction should increase survival. However, in controlled studies, positively inotropic agents such as milrinone (a phosphodiesterase inhibitor) increase ejection fraction but reduce survival. Hence, improving a risk marker should never be used as the justification for treatment, unless we have proof that in so doing we improve survival. The only justifications for treatment are to slow the progression of the underlying disease, to relieve symptoms that trouble the patient, or to use agents proven to improve survival.

Specific prognostic indicators

These can be divided into several relatively independent groups. The most important factors are:

1. the extent of the left ventricular dysfunction;
2. the degree of functional limitation;
3. electrolyte disturbances;
4. the degree of neurohormonal or autonomic dysfunction; and
5. certain electrophysiological or electrocardiographic indicators of ventricular arrhythmogenesis.

There are also general factors such as age or the presence of comorbidities. It has not been established whether estimation of these predictive variables materially improves patient management. An improved scheme for accurate risk stratification can be used to prioritize patients for more careful and regular medical follow-up, or to select patients for expensive or limited treatment options such as transplantation. Table 4 lists some of the established risk markers for poor survival in patients with chronic heart failure.

15.2.3 Syncope and palpitation

A. C. Rankin and S. M. Cobbe

Syncope and palpitation are symptoms that are commonly of cardiovascular origin, which may be related to abnormalities of cardiac rhythm. However, there are a number of aetiologies for both, and the prognosis for either can range from benign to life-threatening, hence a major priority in assessment is the identification of patients who may be at risk of dying. Treatment options may also range from reassurance with no therapy, to curative or lifesaving treatments for cardiac arrhythmia. The investigation, diagnosis, and management of cardiac arrhythmias are described in more detail in Section 15.6.

Syncope

Syncope is defined as a transient loss of consciousness with the loss of postural tone, and is most commonly due to cardiovascular mechanisms resulting in reduced cerebral perfusion. It is a common presentation, resulting in 1 to 2 per cent of emergency department visits and up to 6 per cent of hospital admissions. The cause is often initially uncertain and assessment must first differentiate syncope from other causes of loss of consciousness, in particular epileptic seizures. The next priority is to identify high-risk patients.

Syncope can be considered in three categories, namely (1) neurally-mediated, (2) cardiac, and (3) neurological or psychiatric (Table 1). The commonest cause is reflex-mediated or vasovagal syncope, which has a benign prognosis, whereas cardiac causes of syncope have been reported to have 1-year mortality rates as high as 18 to 33 per cent. Patients without underlying heart disease in whom no aetiology of syncope is established have a good prognosis, but they may have recurrent syncope.

Where a cause is eventually identified, the diagnosis is indicated by the initial clinical assessment—including history, physical examination, and an electrocardiogram (**ECG**)—in up to 50 per cent of cases. The history is most important and may strongly suggest a vasovagal origin or an epileptic seizure. However, the diagnosis may be complicated by an overlap in features, such as convulsive movements during a vasovagal episode due to anoxic convulsive seizures. It is increasingly recognized that many patients who attend clinics for epilepsy have been misdiagnosed and are suffering from recurrent syncope. Some of these patients have potentially lethal ventricular arrhythmias and should be receiving treatment.

Aetiology

Neurally mediated syncope

There are many disorders of autonomic control that can cause orthostatic intolerance and thereby syncope. To simplify, these can be considered as causing either reflex syncope, due to an increased sensitivity of normal reflex responses, or autonomic dysfunction, where abnormal neurovascular control results in orthostatic hypotension.

Vasovagal syncope

Vasovagal or neurocardiogenic syncope is the most common cause of syncope. It can affect all age groups and varies from infrequent episodes associated with obvious triggering factors to frequent unprovoked collapses, which may be debilitating. The pathophysiology most commonly involves the upright posture with venous pooling of blood and reduced venous return to the heart. Reduced cardiac output and blood pressure stimulate arterial baroreceptors with resultant increased sympathetic activity and catecholamine levels. The vigorous contraction of relatively empty ventricles results in the activation of mechanoreceptors that would normally respond to stretch in the left ventricular wall. Afferent nerve fibres conduct to the cerebral medulla and activate the reflex withdrawal of peripheral sympathetic tone and activation of vagal parasympathetic activity. The resultant vasodilatation and bradycardia cause reduced cerebral perfusion and loss of consciousness. However, there is debate about these mechanisms and other factors may be involved in the aetiology of syncope, as illustrated by the documentation of neurocardiogenic syncope, despite cardiac denervation, in orthotopic heart transplant recipients. Certainly, it is well recognized that vasovagal syncope can result from other stimuli, such as pain, emotional shock, or the sight of blood. In these instances, the reflex activation is central in origin.

The development of tilt-testing has allowed the study of the pathophysiology of neurocardiogenic syncope. The patient is strapped to a tilt-table and is tilted, head upright, usually at 70 degrees for up to 45 min. Protocols that use additional provocation with isoprenaline or nitrates are also commonly used. Blood pressure and cardiac rhythm are monitored throughout the tilt-test. In neurocardiogenic syncope, the patient classically maintains normal blood pressure initially, until the sudden onset of syncope is associated with severe hypotension and bradycardia, often preceded by tachycardia. These features resolve with return to the supine posture. Some patients have a mainly vasodepressor response, with hypotension and little change in heart rate, while others have a marked cardioinhibitory response, with severe bradycardia or asystole of several seconds' duration (Fig. 1). However, most patients exhibit a mixed response, and those patients with marked cardioinhibition also have a preceding vasodepressor response. This is an important observation when treatment is considered since permanent pacing to maintain cardiac rhythm may not cure all symptoms, because falls in blood pressure may still occur even when bradycardia is prevented.

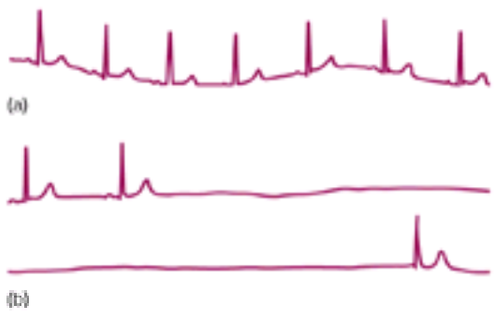

Fig. 1 Cardioinhibitory response to tilt-testing. (a) After 6 min of head-up tilting at 70° the patient complained of presyncope. Heart rate was 60 per min but blood pressure was 70 mmHg. (b) By 7 min the patient had lost consciousness, associated with an asystolic pause of 10 s duration and an unrecordable blood pressure. Recovery was rapid following the patient's return to the supine position.

Carotid sinus hypersensitivity

This is an abnormal sensitivity of a normal reflex that is responsible for syncope. Activation of the carotid sinus baroreceptors (for example by physical pressure, such as carotid sinus massage) results in sympathetic withdrawal and parasympathetic activation. Bradycardia is usually a prominent feature.

Situational reflex-mediated syncope

In susceptible individuals, similar abnormal reflex sensitivity can result in syncope in response to afferent activity from other mechanoreceptor activation. Syncopal responses to cough, micturition, defaecation, or swallowing have been reported.

Autonomic dysfunction

Hypotension may occur in patients in whom there are abnormalities in the autonomic control of cardiovascular function. Abnormalities of afferent or efferent pathways, or of peripheral vascular control, can result in low blood pressure in the upright posture, that is to say orthostatic hypotension. This may be diagnosed by a fall in systolic pressure of more than 20 mmHg, or to less than 90 mmHg, within 3 min of standing. During tilt-testing there may be an immediate drop in blood pressure with head-upright tilting, or a progressive fall may be observed in some patients, in contrast to those with reflex-mediated syncope in whom blood pressure is maintained until the sudden onset of symptoms. Orthostatic hypotension is more common in elderly patients, where it may be multifactorial, often exacerbated by drugs (Table 2). Nocturnal symptoms may occur, with a fall in blood pressure exacerbated by sudden rising from a warm bed.

Autonomic failure is an uncommon cause of syncope and patients may present with other features, including disturbances of bowel, bladder, or sexual function. Pure autonomic failure can be acute or chronic, primary (of unknown origin) or secondary to systemic disease. Multiple system atrophy is characterized by autonomic dysfunction, parkinsonism, and ataxia. Orthostatic hypotension may be a marked feature (the Shy–Drager syndrome), with additional parkinsonian features or cerebellar symptoms. Secondary autonomic failure can result from the central or peripheral involvement of certain diseases, including multiple sclerosis, a cerebral tumour, diabetes, and amyloidosis. A recently reported milder form of autonomic dysfunction, the postural orthostatic tachycardia syndrome (**POTS**), causes symptoms because of inappropriate tachycardia on standing, and occasionally syncope secondary to hypotension.

Cardiac syncope

Loss of consciousness of cardiac origin may result from abnormalities of heart rhythm, due to extremes of rate, either fast or slow, or from some major disturbance of cardiovascular function, with resultant reduced cerebral perfusion. The importance in establishing the diagnosis of cardiac syncope is the associated adverse prognosis, which may be improved with appropriate reatment. The probability of cardiac syncope is increased in the presence of structural cardiovascular disease identified from the history, clinical examination, or investigation.

Bradycardia

A sudden decrease in heart rate, onset of ventricular standstill, or asystole may be a cause of syncope. When due to sinoatrial dysfunction (Sick-sinus syndrome) this is not associated with a poor prognosis, but syncope due to intermittent complete atrioventricular (**AV**) block is. Syncope in a patient with a permanent pacemaker may indicate pacemaker malfunction.

Tachycardia

Syncope may be caused by tachycardia, most commonly ventricular, but supraventricular tachycardia can also be associated with loss of consciousness if it is very fast or in patients with structural heart disease (Fig. 2). Syncope, rather than cardiac arrest, may result from self-terminating ventricular tachycardia or from sustained tachycardia with hypotension at the onset, but with a subsequent recovery of blood pressure. Whether or not a tachycardia causes syncope is related to its rate, underlying left ventricular function, and to the patient's baroreceptor sensitivity. Structural heart disease, for example prior myocardial infarction, is the commonest substrate for ventricular tachycardia, but this may also occur in patients with structurally normal hearts. *Torsade de pointes* in a patient with the Long-QT syndrome is an important diagnosis to consider in young people with a history of loss of consciousness and possible epilepsy, in whom the episodes of collapse may be due to syncope caused by ventricular arrhythmia.

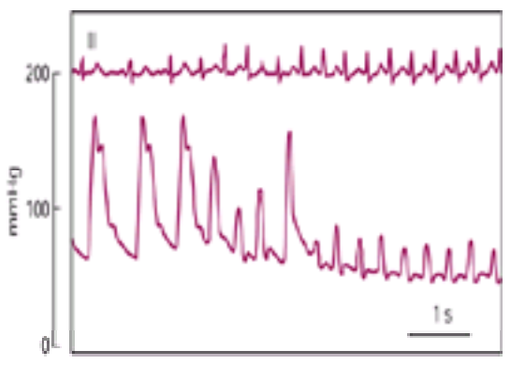

Fig. 2 Hypotension with the onset of supraventricular tachycardia. Surface ECG lead II and intra-aortic pressure are shown.

Structural cardiovascular disease

Aortic stenosis may be associated with syncope, particularly during sudden exertion when the demand for increased cardiac output cannot be met because of the mechanical obstruction. Hypertrophic cardiomyopathy may also be associated with syncope, either because of outflow obstruction or ventricular arrhythmia. Obstruction of blood flow through the mitral valve by an atrial myxoma or thrombus is an extremely uncommon cause of syncope, and a number of other cardiac diseases may be associated with loss of consciousness by a variety of mechanisms (arrhythmia, reflex-mediated or haemodynamic), including myocardial infarction, pulmonary embolism, congenital heart disease, or cardiac tamponade. Vascular diseases may also be involved, such as aortic dissection and extracranial vascular disease.

Neurological or psychiatric causes of syncope

When epilepsy is excluded, neurological aetiologies are rare causes of loss of consciousness, but possible causes include migraine, transient ischaemic attacks, vertebrobasilar vascular disease, and subclavian steal syndrome. A psychiatric origin of syncope implies the absence of neurally mediated, neurological or cardiac abnormalities, and may occur in association with anxiety, depression, and conversion disorders. For instance, apparent syncope may occur during tilt-testing but with normal pulse and blood pressure. Hyperventilation may be an associated mechanistic factor in psychogenic syncope.

History

The importance of the clinical history in assessing a patient with syncope cannot be overemphasized. If possible an eyewitness description of the patient during the syncopal event should always be obtained.

Provocative factors

Vasovagal syncope is classically associated with upright posture, often with aggravating circumstances such as prolonged standing, a hot environment, or hunger. However, episodes may also occur when seated, including when driving. Specific stimuli may be responsible for neurocardiogenic syncope in susceptible individuals.

Ventricular arrhythmia, in particular *torsade de pointes* in the Long-QT syndrome, may be provoked by sudden stimuli such as a noise, for example an alarm clock. Exertional syncope is a feature of aortic stenosis or hypertrophic cardiomyopathy.

Preceding symptoms

Sweating and feeling hot or nauseated may precede vasovagal syncope. Cardiac arrhythmia may be associated with palpitation, chest pain, or breathlessness. Bradycardia, such as intermittent complete heart block, may produce no preceding symptoms and may cause loss of consciousness without warning. Sinoatrial dysfunction is a cause of symptoms of dizziness and light-headedness in addition to syncope. A psychiatric origin may be suggested by multiple associated symptoms including hyperventilation, paraesthesiae in fingers and lips, palpitation and chest pain, which may precede syncope. Epilepsy may be preceded by a characteristic aura, which would strongly point away from syncope as the diagnosis.

The syncopal episode

The duration of loss of consciousness is usually short in syncope, with recovery after a few minutes. A longer duration of loss of consciousness would suggest an alternative diagnosis. An exception to this is when the patient has remained upright during the attack, possibly aided by well-meaning but misguided helpers. Incontinence is a feature of epileptic seizure but may also occur (uncommonly) with syncope. Description of the patient during the episode is of great value. The classic description of an episode of syncope due to cardiac arrhythmia, in particular sudden-onset severe bradycardia, is of a sudden loss of colour, becoming deathly pale, with flushing on recovery (Stokes–Adams attack). Cyanosis may be a feature of an arrhythmic origin of syncope. Convulsive movements during the episode would raise the possibility of epilepsy, but they also occur with syncope.

The recovery period

By contrast to the postictal phase following epilepsy, there is commonly a rapid recovery of cerebral function following syncope. Vasovagal syncope may be followed by persisting nausea or vomiting.

Family history

There are a few specific causes of syncope in which a family history of syncope or sudden death may have prognostic significance. Long-QT syndrome is hereditary and may be associated with sudden death. A family history of syncope is of adverse prognostic significance in hypertrophic cardiomyopathy.

Associated injury

In addition to concern about prognosis in cardiac syncope, there is the possibility of injury occurring with any cause of syncope. The exception to this is syncope of psychiatric origin when injuries are absent despite frequently recurring symptoms.

Investigation

The investigation of cardiac disease and arrhythmia are dealt with in the appropriate chapters, but the approach to the patient with syncope will be described briefly.

Electrocardiogram

An ECG should be performed on all patients with syncope. This may provide evidence of either aetiology of syncope, such as the Long-QT syndrome, or of structural heart disease, such as prior myocardial infarction or left ventricular hypertrophy. An arrhythmia may be documented if it is sustained. There may be evidence of arrhythmia, or sinoatrial disease or conduction system disease, such as trifasicular block, bundle-branch block, or first- or second-degree block. In the absence of carotid bruits, carotid sinus massage, with digital pressure to the carotid artery for up to 5 s, may cause marked bradycardia, with pauses of more than 3-s duration, in carotid sinus hypersensitivity.

Ambulatory monitoring

Documentation of cardiac rhythm during syncope is desirable but is difficult to obtain because of the intermittent and usually infrequent nature of the symptom. Holter monitoring is unlikely to record the rhythm during an episode but may provide evidence of lesser degrees of abnormality, which may support a diagnosis such as sinoatrial dysfunction. Real-time event-recorders are also of limited value in the investigation of syncope because they require a conscious patient to make the recording. Patient-activated loop-recorders, which can store the rhythm prior, during, and following an episode, may be of more value. Implantable loop-recorders are of value in difficult cases.

Tilt-testing

When the history is suggestive of vasovagal syncope, the tilt-test is of value in confirming the diagnosis, allowing reassurance of the patient and clarification of treatment options. However, if cardiac syncope is likely then tilt-testing may be deferred until cardiac investigations are completed. A negative tilt-test does not exclude neurocardiogenic syncope and repeating the test with provocation (isoprenaline or nitrate) may increase its sensitivity.

Electrophysiological testing

Abnormal sinus node function or evidence of atrioventricular conduction disease may be elicited by electrophysiological testing, but demonstrating bradycardia during ambulatory monitoring more reliably makes both these diagnoses. In patients with structural heart disease in whom arrhythmia is suspected, programmed electrical stimulation of the ventricles can induce sustained monomorphic ventricular tachycardia. This is a relatively specific response and shows that the patient is at risk of recurrent ventricular arrhythmia, and makes an arrhythmic origin of syncope likely. The diagnostic yield of electrophysiological testing is low in patients with a structurally normal heart.

Other investigations

Assessment for structural heart disease is important. Physical examination will detect most significant valve disease, but other diagnoses, for example hypertrophic cardiomyopathy or atrial myxoma, may produce little in the way of clinical signs. An echocardiogram is therefore worthwhile. A strong suspicion of diagnoses other than syncope should lead to other investigations, including EEG and brain imaging, but these have a low diagnostic yield in patients with syncope and should not be routine.

Treatment

Neurocardiogenic syncope may require no treatment other than reassurance and avoidance of provocative factors. Treatments of vasovagal syncope, bradycardia, and cardiac arrhythmia are discussed in Chapter 24.13.5 and Chapter 15.6. In up to one-third of patients the aetiology of syncope may not be found: these patients have a good outcome unless they have underlying heart disease.

Palpitation

The symptom of palpitation is defined as an awareness of one's heart beating. This may be due to an awareness of an abnormal heart rhythm but it may also be due to an abnormal awareness of normal rhythm. A careful and detailed history can provide a likely diagnosis. The most important aim in investigation is to correlate symptoms with cardiac rhythm.

History

A description of the symptom should include an estimate of heart rate, duration of symptom, regularity of rhythm, suddenness of onset and offset. It may be helpful to ask the patient to tap with their finger on a desk to describe their palpitation. Trigger factors, including exercise, and aggravating factors such as alcohol and caffeine should be detailed. The length of history may be of interest.

Sinus tachycardia

An awareness of a rapid heart rate of gradual onset and offset is often associated with feelings of alarm and panic in patients with anxiety.

Premature beats

Atrial and ventricular beats commonly occur in normal individuals and may be associated with symptoms. The patient may describe 'missed beats' or forceful beats. These symptoms relate to the pause that follows a premature beat. The premature beat produces a short diastolic filling interval and the low ventricular volume results in reduced ventricular contraction with a small stroke volume. However, the subsequent pause provides a long diastolic filling period and the resultant stretching of the ventricular walls is associated with an increased and forceful systolic contraction. The combination of the diminished premature beat and the enhanced postextrasystolic beat is responsible for the symptoms.

Atrial fibrillation

This common arrhythmia may produce a variety of symptoms depending on ventricular rate, irregularity, and persistence. Paroxysmal atrial fibrillation is typically associated with self-terminating episodes of atrial fibrillation when there is a rapid and irregular ventricular response. The patient is aware of an increased heart rate and often describes the irregular nature of the symptom. The variations in diastolic interval produce symptoms by similar mechanisms to that described above for premature beats, with 'missed' and 'forceful' beats. Patients with sinoatrial dysfunction may be most symptomatic on termination of the atrial fibrillation, which can be followed by sinus bradycardia or prolonged sinus pauses. Atrial fibrillation may be persistent or permanent, and the severity of symptoms will be related to the ventricular rate and irregularity.

Paroxysmal junctional re-entry tachycardia

A history of sudden onset, rapid, regular palpitation in a healthy patient with no underlying structural heart disease is suggestive of paroxysmal junctional re-entry tachycardia. It may stop spontaneously or with vagotonic manoeuvres, or the patient may have had to attend hospital for intravenous therapy. In addition to palpitation, patients commonly report fatigue, malaise, light-headedness, or dyspnoea, but because they have normal hearts such episodes of tachycardia are usually well tolerated. Polyuria is a common associated symptom, which results from the release of atrial natriuretic peptide secondary to atrial stretch.

Ventricular tachycardia

Ventricular arrhythmias can present with the symptom of palpitation, but more severe symptoms such as syncope or cardiac arrest also occur. Characteristically the symptom of palpitation would be of sudden onset and offset of a rapid regular heart rhythm. A history of structural heart disease should be sought.

Investigation

Electrocardiogram

The first aim is to document cardiac rhythm during symptoms. This may be possible with a standard ECG if the arrhythmia is sustained or persistent. Atrial or ventricular premature beats, or evidence of structural heart disease, for example myocardial infarction, may be documented. The presence of pre-excitation indicates the diagnosis of Wolff–Parkinson–White syndrome and suggests symptoms due to episodes of junctional re-entry tachycardia.

Ambulatory monitoring

The success of ambulatory monitoring in documenting the rhythm during symptoms will be dependent on the frequency of symptoms. If they occur daily then a 24- or 48-h Holter recording should suffice. However, palpitation is often infrequent and other patient-activated devices can be of more value. These include handheld, patient-activated event recorders that allow the transtelephonic transmission of recordings. These devices do not allow retrospective recording and require symptoms of sufficient duration to allow their use. Shorter episodes may be captured using loop-recorders.

Electrophysiological studies

Invasive studies are of most value in determining the mechanism of a previously documented tachyarrhythmia, particularly with a view to treatments such as radiofrequency catheter ablation.

Management

Documentation of the cardiac rhythm during palpitation allows appropriate management, with reassurance as the only treatment in those with sinus tachycardia or premature beats. The treatment of other cardiac arrhythmias is discussed in Chapter 15.6.

15.2.4 Physical examination of the cardiovascular system

J. R. Hampton

Introduction

The cardiovascular system is perhaps more accessible to physical examination than any other. Examination is most helpful if it is approached logically: there is a group of general abnormalities that can be detected in cardiovascular disease, there is a group of signs associated with the arterial side of the circulation, a group associated with the venous side, and a group associated with the heart itself.

General examination

Pain due to cardiovascular disease (as in myocardial infarction or aortic dissection) may cause pallor, cold and clammy extremities, and a sinus tachycardia.

Breathlessness and an inability to lie flat (orthopnoea) may result from pulmonary congestion due to left heart failure. Pulmonary oedema will cause extreme breathlessness with the coughing up of frothy and sometimes bloodstained sputum, and peripheral vasoconstriction will cause cold and clammy extremities.

Central cyanosis (affecting the lips and tongue as well as the hands and feet) may indicate heart failure or pulmonary disease but may be due to polycythaemia. Central cyanosis, especially when associated with finger clubbing, is characteristic of a right to left shunt. Peripheral cyanosis indicates a high tissue oxygen extraction, and will be seen when the hands or feet are cold, or when there is peripheral arterial occlusion.

Infection of the heart valves (infective endocarditis) will cause fever, anaemia, weight loss, finger clubbing, 'splinter haemorrhages' under the finger and toenails, a large spleen, loss of arterial pulses and/or neurological abnormalities due to embolization of infected material, and skin lesions such as petechiae and nodules in the fingertips (Osler's nodes).

Physical signs in the arterial circulation

Peripheral pulses

A pulse can be felt whenever an artery is near the surface of the body. In fat or muscular people some pulses may be difficult to feel, but asymmetry of pulses is usually abnormal. Pulses may be lost through atheromatous disease, embolization, or injury. Pulses that are unusually easy to feel—for example in the abdomen, or the popliteal pulses—may be due to aneurysmal dilatation.

The pulses that should be checked are the superficial temporals, carotids, brachials, radials, the aorta, femorals, popliteals, dorsalis pedis, and posterior tibials. Tenderness over the superficial temporal pulses may indicate temporal arteritis. Auscultation over the carotid and femoral pulses, and over the aorta, should be routine as bruits will indicate narrowing, usually atheromatous.

Blood pressure

The blood pressure should be measured in the brachial artery using a cuff around the upper arm. It is essential to use a large cuff in fat people, because a small cuff will result in the blood pressure being overestimated. The diastolic pressure is taken as the point where the sound disappears (Karotkov V). For further discussion see elsewhere in Section 15.

In patients with chest pain, or if ever the radial pulses appear asymmetric, the pressure should be measured in both arms because a difference between the two may indicate aortic dissection.

Heart rate and rhythm

Although the heart rate is usually—and most conveniently—counted in the radial artery, this can be unreliable. In uncontrolled atrial fibrillation there may be a 'pulse deficit', with the true rate being faster than is apparent at the radial artery. The 'apex rate', counted by listening to or feeling the cardiac apex, is more reliable. Similarly, it is easier to distinguish irregularities of the heart rhythm by auscultation than by feeling a peripheral pulse.

Arterial waveform

Descriptions like 'strong' and 'weak' should not be used: these essentially reflect systolic pressure and are best indicated by the blood pressure itself.

The true 'waveform' in an artery can only be obtained by recording the intra-arterial pressure, and the 'pulse character', which describes the rate of rise and fall of pressure, is a crude reflection of this and an unreliable physical sign. It is best felt in large arteries such as the carotid or brachial. In aortic stenosis the rise is slow and the waveform feels flat—the 'plateau' pulse. In aortic regurgitation the arterial pressure falls rapidly, as it does in the left ventricle, causing a 'collapsing' or 'water hammer' pulse. These abnormalities are not easy to detect and are an unreliable guide to the severity of disease. Severe aortic regurgitation, classical of syphilitic aortitis, can cause the head to jerk with each pulse (de Musset's sign).

Abnormalities of the venous circulation

Peripheral veins

Venous thrombosis can occur in the arms, but is much more common in the legs. Thrombosis of an arm vein probably indicates local obstruction (perhaps by a tumour) or a thrombotic tendency. In the legs, superficial phlebitis causes local inflammation in the line of a vein, and the vein is usually palpable and tender. There may be associated swelling. Detecting deep venous thrombosis is much more difficult, but it must be suspected in any painful leg and particularly when there is

unilateral swelling. The 'classical' signs of deep vein thrombosis—calf or thigh tenderness, warmth, and Homan's sign (pain in the calf on dorsiflexion of the foot)—are all unreliable.

The jugular venous pulse

The abbreviation 'JVP' may be used for jugular venous pulse or jugular venous pressure. The importance of the jugular venous pressure is that it directly reflects the pressure in the right atrium and is the best clinical indication of heart failure.

A pulse can be detected in either the external or internal jugular vein. The external vein (running diagonally from the midpoint of the clavicle to the midpoint of the mandible) is usually easy to see. Unfortunately it is a less reliable guide to venous pressure than the internal jugular vein, because flow can be obstructed in the external vein as it passes through the fascia in the neck. The internal jugular vein runs with the carotid artery from the sternoclavicular joint to the lateral end of the mandible, crossing under the sternocleidomastoid muscle and the external jugular vein. The pulsation in the internal jugular is usually seen as a flickering movement under the skin, rather than as an obvious venous pulsation.

The jugular venous pressure is taken as the highest point at which a pulsation can be seen, measured vertically above the manubriosternal angle. The position of the patient does not affect this measurement, because the height of the manubriosternal angle above the right atrium varies little as position changes. The patient should therefore be placed at whatever angle allows the pulsation to be seen most clearly. A patient with a high jugular venous pressure might need to sit upright, whilst a patient with a low pressure might need to lie flat. The key to successful observation of the jugular venous pulse is careful positioning of the patient, and arranging a tangential light, which will make movement under the skin of the neck more obvious.

A jugular venous pulsation has characteristics that allow it to be differentiated from an arterial pulse:

- The position of the pulsation in the neck varies with the patient's posture, reflecting its constant vertical height above the manubriosternal angle.
- A venous pulsation has a complex waveform compared with the single peak of an arterial pulse. In the venous pulse there is the 'a' wave due to atrial contraction, which is followed quickly by the 'c' wave. This has been variously attributed to tricuspid valve closure or to transmission from the carotid artery, and while it can be detected with an external pressure transducer, it is seldom possible to see it. There is then the 'x' descent due to the downward movement of the tricuspid valve as the right ventricle contracts. This is followed by a rise called the 'v' wave, which corresponds with the late stage of atrial filling during ventricular systole, followed by the 'y' trough as the atrium drains into the right ventricle.
- A venous pulse cannot be felt (except sometimes in triscuspid regurgitation).
- A venous pulse can be obliterated by light pressure at the root of the neck.
- The height of the pulsation is affected by respiration, becoming less as intrathoracic pressure falls during inspiration.
- Pressure on the abdomen increases venous return and raises the jugular venous pressure (hepatojugular reflux).
- A prominent external jugular vein, which does not pulsate or move with respiration, may indicate superior mediastinal obstruction by a tumour.

The jugular venous pulse is abnormal in a number of disease states:

- The 'a' wave is lost in atrial fibrillation.
- The 'a' wave becomes more prominent (sometimes described as 'flicking') when the right atrial pressure is high, as in pulmonary hypertension.
- When the atrium contracts against a closed tricuspid valve, as occurs intermittently in complete heart block, large 'a' waves called 'cannon' waves are seen.
- If the tricuspid valve is incompetent the right ventricle expels part of its stroke volume through the right atrium and up the jugular veins, causing a 'cv' or 'systolic' wave. This is followed by a sudden and deep 'y' descent.
- If there is pericardial constriction the jugular venous pressure will rise rather than fall on inspiration.

The liver

If the right atrial pressure is high the liver will be distended and be palpable below the costal margin. It will be smooth and tender. With tricuspid regurgitation the liver will pulsate, and pulsation may also be seen in varicose veins in the legs. With marked and longstanding right heart failure there may also be splenic enlargement. Heart failure causes liver malfunction and—especially when tricuspid regurgitation is present—there may be jaundice.

Oedema

A combination of a high right heart pressure and hormonal changes cause fluid retention, with oedema fluid collecting in dependent areas. There will be symmetrical ankle and leg swelling, and if the patient is in bed for a prolonged period there will be oedema over the sacrum. Fluid can collect in all serous cavities causing pleural and pericardial effusions and ascites.

It is logical to think of the lungs at the same time as the veins: a rise in left atrial pressure will cause pulmonary congestion and eventually pulmonary oedema. These can be recognized by a soft wheeze ('cardiac asthma') and crackles at the lung bases.

Examination of the heart

Palpation

The apex beat is the furthest point outward from the midline, and downwards, where a cardiac impulse can be felt. It is important to accept this definition, and not to confuse the apex beat with the 'point of maximum impulse', because it provides the best guide to the size of the heart. The normal position of the apex beat is in the fifth rib interspace in the mid-clavicular line. The apex beat may be displaced by:

- left ventricular hypertrophy or dilatation
- right ventricular hypertrophy
- mediastinal shift.

Right ventricular hypertrophy is detected from a diffuse 'heaving' movement just to the left of the sternum; remember that the right ventricle forms the anterior surface of most of the heart. Mediastinal shift is identified if the trachea is moved to one side of the suprasternal notch. If the apex beat is displaced laterally and downwards but the trachea is central and there is no parasternal heave, then the left ventricle must be enlarged. A diffuse and abnormal movement medial to the apex may indicate a left ventricular aneurysm.

The precordium should be felt with the flat of the hand over the cardiac apex and the upper right sternal edge where thrills may be present. A thrill is simply a palpable murmur. A loud first sound may be felt as a tapping apex beat.

Heart sounds

There are four possible heart sounds and various extra sounds called clicks or snaps. These discrete noises arise from sudden movements in the circulating blood; they are not the result of valve cusps coming into contact with each other. Their pitch varies, and it is necessary to listen with the bell of the stethoscope for low-pitched sounds, and with the diaphragm for high-pitched sounds. Auscultation should be performed at the cardiac apex, to the left side of the top and bottom of the sternum and at the top of the right sternal edge. These positions are sometimes called the mitral, tricuspid, pulmonary, and aortic areas, but these descriptions are inappropriate because murmurs from these valves are not localized in these areas. The terms should be abandoned.

The first sound is associated with closure of the mitral and tricuspid valves at the beginning of systole. It is sometimes possible to hear separation, or splitting, of these two components but this is not a useful sign.

The second sound, best heard at the upper left sternal edge, is associated with closure of the aortic and pulmonary valves. The aortic valve closes first, and in

inspiration, when pulmonary closure becomes delayed due to the increased blood flow through the right heart, the two components separate more widely. Variable splitting of the second heart sound is heard almost invariably in the young, but becomes less marked with age. Fixed splitting of the second sound is associated with right bundle branch block on the electrocardiogram, and may indicate an atrial septal defect. Reverse splitting is associated with left bundle branch block on the electrocardiogram. Aortic valve closure is delayed in left bundle branch block, so pulmonary closure is heard first. On inspiration pulmonary closure becomes delayed, so the pulmonary sound moves back to join the sound of aortic closure and the second sound becomes single.

The third and fourth sounds are due to rapid ventricular filling. The third sound is in early diastole soon after the second sound, and the fourth sound is associated with atrial contraction and therefore comes just before the first sound. Both are low pitched and are best heard at the apex with the patient rolled slightly onto the left side. A third sound is normal in children and young adults, but after middle age it is a sign of heart failure. A fourth sound (which can be difficult to differentiate from a split first sound) is nearly always abnormal and is said to indicate reduced ventricular distensibility. Right ventricular third and fourth sounds can sometimes be heard at the lower left sternal edge; they are louder on inspiration.

An ejection click, occurring just after the first sound, indicates a deformed but mobile aortic or pulmonary valve. The click may be associated with 'doming' of the valve before it opens. Late systolic clicks are heard with mitral valve prolapse.

An opening snap is a diastolic sound, just after the second sound, and is associated with the opening of a stenosed but mobile mitral or tricuspid valve. Unlike a third sound it is high pitched, and an opening snap can often be heard towards the left sternal edge while a third sound is always localized to the apex.

Heart murmurs

Heart murmurs are the result of turbulent blood flow associated with stenosed, leaking, or incompetent valves (when the murmur is said to be 'regurgitant') and with abnormal connections between the pulmonary and systemic circulation. A loud murmur can sometimes cause a palpable thrill. Murmurs can be systolic or diastolic (referring to the ventricles). A systolic murmur occurs when the mitral and tricuspid valves are shut, and the aortic and pulmonary valves are open. Conversely, diastolic murmurs are heard when the aortic and pulmonary valves are shut and the mitral and tricuspid valves are open.

Most murmurs originate in the left heart. Right heart murmurs are usually quiet but may become louder on inspiration. It should be remembered that the loudness of a murmur is only an extremely crude guide to its haemodynamic significance.

Murmurs originating in the mitral valve are best heard at the cardiac apex with the patient rolled a little to the left side. Mitral regurgitation (or incompetence) causes a medium pitch 'pansystolic' murmur, which begins immediately after the mitral valve closes and persists throughout systole. Murmurs can be recorded and displayed pictorially by the old technique of phonocardiography: Figure 1 shows a murmur of mitral regurgitation.

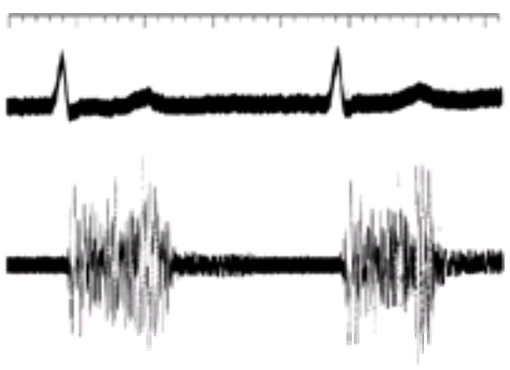

Fig. 1 Phonocardiographic recording of a patient with mitral regurgitation. The ECG recording (top line) determines that the murmur is systolic.

Murmurs spread, or radiate, in the direction of flowing blood and the murmur of mitral regurgitation radiates round the axilla and through to the back, as turbulent blood flows into the left atrium which forms the posterior part of the heart. When mitral regurgitation is due to mitral valve prolapse the murmur is still systolic, but it comes late in systole and is not pansystolic.

In mitral stenosis the opening snap is followed by a murmur, which rises to a peak and then falls, making a 'diamond' shape on a phonocardiogram (Fig. 2). This sort of murmur is called 'ejection'.

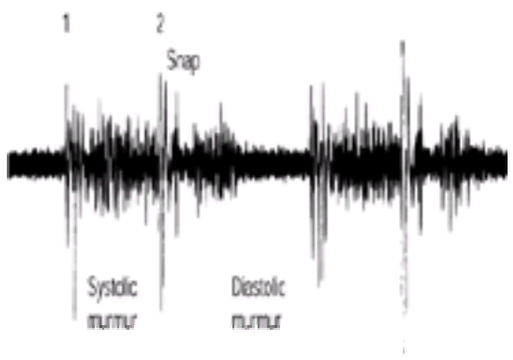

Fig. 2 Phonocardiographic recording of a patient with mixed mitral valve disease.

Tricuspid regurgitation causes a systolic murmur similar to that of mitral regurgitation, but it is loudest at the low left sternal edge, on inspiration. However, many patients with tricuspid regurgitation also have mitral regurgitation, and it can be difficult to differentiate the two. Tricuspid regurgitation is diagnosed from the large 'cv' wave with a steep 'y' descent in the jugular venous pulse, and from an enlarged and pulsating liver. Tricuspid stenosis can occur with congenital or rheumatic heart disease and causes a similar ejection diastolic murmur to mitral stenosis, but the murmur of tricuspid stenosis occurs at the lower left sternal edge and is loudest on inspiration. Such a murmur is also heard as a 'flow' murmur in patients with an atrial septal defect, because increased flow through the right heart causes turbulence even through a normal valve.

Aortic stenosis causes the classic ejection systolic murmur (Fig. 3) heard at the upper right sternal edge. It radiates up the carotids, and this radiation has to be differentiated from a bruit due to narrowing of the carotid arteries. Carotid artery bruits are usually asymmetrical. An aortic ejection systolic murmur may also be heard when the valve is abnormal (for example, when it is bicuspid) but does not impede blood flow, or where there is an increased flow through a normal valve as in anaemia or pregnancy.

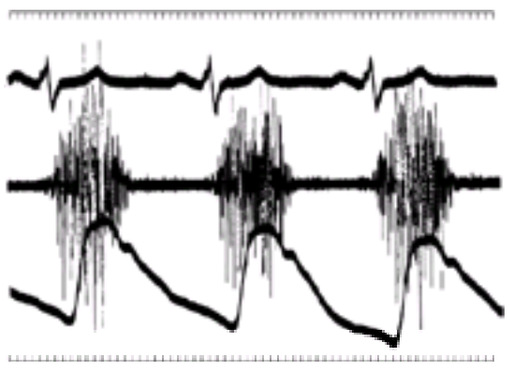

Fig. 3 Phonocardiographic recording of a patient with aortic stenosis. The ECG recording (top line) determines that the murmur is systolic. The bottom line records intra-arterial pressure.

Aortic regurgitation causes a high-pitched murmur that begins immediately after aortic valve closure and dies away, usually by mid-diastole. It is described as an 'early diastolic' murmur, and is best heard at the mid left sternal edge—hence the fallacy of calling the upper right sternal edge the aortic area. The murmur of aortic regurgitation is best heard with the patient leaning forward and breathing out. The regurgitant jet of aortic regurgitation may impinge on the anterior cusp of the mitral valve causing it to flutter. This can cause a murmur (the Austin Flint murmur) that is very similar to that of mitral stenosis, but there is no associated opening snap.

Pulmonary systolic and diastolic murmurs share many of the characteristics of aortic stenosis and regurgitation and are also heard at the left sternal edge. They are quieter and are heard best on inspiration. Pulmonary regurgitation, characteristic of pulmonary hypertension, is sometimes called the Graham Steell murmur.

Murmurs associated with congenital heart disease may be systolic, diastolic, or continuous. The systolic and diastolic murmurs depend on obstruction to flow or regurgitant flow. Continuous murmurs occur in both systole and diastole, with their greatest intensity at the time of the second heart sound. The most typical is the murmur of a patent ductus arteriosus, heard under the left clavicle, but similar sounds are made by artificial shunts such as a Blalock operation.

A ventricular septal defect causes a murmur at the low left sternal edge: it is typically pansystolic, but a small defect can cause a very loud ejection murmur that radiates up the left sternal edge. An atrial septal defect does not cause a murmur itself, but increased right heart blood flow can cause a pulmonary systolic and a tricuspid diastolic murmur.

The importance of the physical examination

An accurate diagnosis of cardiovascular disease depends on the history and on the identification of a group of physical signs. It is always more efficient to look for things rather than at things. In a patient with chest pain look for signs of risk factors (smoking, hypertension, hypercholesterolaemia), evidence of vascular disease elsewhere (absent pulses, arterial bruits), and cardiac damage (signs of heart failure, mitral regurgitation due to papillary muscle dysfunction, postinfarct ventricular septal defect). In patients with palpitations check the rhythm and look for evidence of cardiac disease (especially rheumatic disease) or of other diseases such as thyrotoxicosis. In patients with breathlessness look for signs of heart failure (a rapid heart rate, raised jugular venous pressure, distended liver, ankle swelling, a gallop sound at the cardiac apex).

Individually, almost all physical signs are fallible. Finger clubbing, the identification of which varies between individuals, can be a congenital abnormality totally unrelated to cardiac disease. Splinter haemorrhages may be due to trauma. Cyanosis may be due to polycythaemia rubra vera. A raised jugular venous pressure may due to a 'high output' state such as pregnancy. The loudness of a murmur gives little information about its importance—and so on. But grouped together (for example a mitral regurgitant murmur with a displaced apex beat due to left ventricular hypertrophy) and used intelligently they become much more reliable.

It is true that there is considerable variability in the identification of physical abnormalities, particularly between non-specialists. But to abandon physical signs in favour of the ECG, the echocardiogram, and the chest radiograph is impracticable and expensive. In appropriate patients all these and other investigations may be essential. But for the initial assessment of patients, and for monitoring progress of disease, physical examination is both essential and adequate. It maintains a holistic approach to patient care, and can be an extremely satisfying art.

15.3.1 Chest radiography in heart disease

M. B. Rubens

Introduction

The chest radiograph is often abnormal in patients with congenital heart disease, but in most patients with acquired heart disease it is normal and rarely provides a precise diagnosis. Nonetheless, a chest radiograph remains part of the routine work-up of virtually all patients with known or suspected heart disease because it is relatively inexpensive and non-invasive and it provides a record of cardiac size and shape, sometimes also suggesting specific chamber enlargement. Abnormal cardiac calcification may be visible, and analysis of the pulmonary vessels may indicate particular physiological disturbances. Analysis of the skeleton may provide evidence of associated systemic disease or previous surgery, and abnormalities of situs may be apparent. Occasionally, unsuspected non-cardiac abnormalities are discovered.

A routine examination always includes a frontal view and sometimes a lateral view. Ideally, the frontal view is posteroanterior, with the patient upright and at end-inspiration. Patients who are too ill to be taken to the X-ray department may be examined with mobile equipment when an anteroposterior film is taken. In this projection the heart appears magnified because it is further from the film. A lateral film may give additional information on heart size and shape, and cardiac calcification is often best demonstrated in this view. Frontal and lateral films combined with a barium swallow may provide data on left atrial size and the presence of aberrant branches of the great vessels.

As in all areas of clinical examination, the chest radiograph should be analysed in a careful, systematic manner. It must be remembered that poor radiographic technique may produce spurious appearances. Moreover, the cardiovascular silhouette is such an obvious focus of attention that the bones, soft tissues, and upper abdomen may be overlooked. The cardiac shadow provides information about anatomy, but the lungs provide information about haemodynamics. A recommended order of analysis is as follows: technical factors, the bones, the upper abdomen, the lungs, and, finally, the cardiovascular silhouette. Discussion in this chapter will focus on the appearance of the heart and vessels and other changes on the chest radiograph produced by cardiovascular disease.

The normal chest radiograph

The cardiovascular silhouette

The right border of the cardiovascular silhouette (Fig. 1) comprises, from above downwards, the superior vena cava, the body of right atrium, and the inferior vena cava. The normal superior vena cava produces a low-density vertical shadow, just lateral to the spine. The azygos vein may be visible as a convex density above the origin of the right main bronchus and superimposed on the superior vena cava. The lower part of the right cardiovascular silhouette is convex and produced by the body of the right atrium. Occasionally, the inferior vena cava is visible as a short vertical shadow in the right cardiophrenic angle.

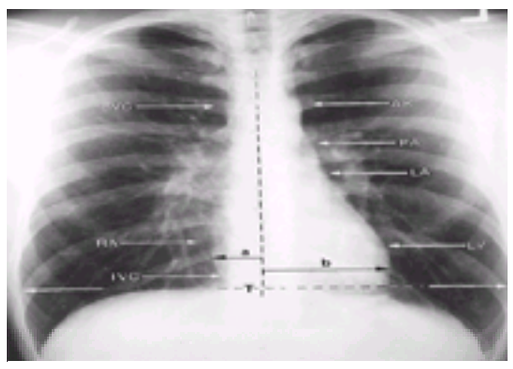

Fig. 1 Normal chest radiograph. The right border of the cardiovascular silhouette comprises superior vena cava (SVC), right atrium (RA), and inferior vena cava (IVC), and the left border comprises aortic knuckle (AK), pulmonary trunk (PA), left atrial appendage (LA), and left ventricle (LV). Transverse cardiac diameter=a+b. Cardiothoracic ratio=(a+b)/ T.

The left border of the cardiovascular silhouette comprises, from above downwards, the aortic knuckle, the pulmonary trunk, the left atrial appendage, and the left ventricle. The aortic knuckle is produced by the posterior part of the aortic arch. The proximal descending aorta may be visible as a vertical shadow, continuous with the knuckle and eventually merging with the left paraspinal shadow. The pulmonary trunk is situated below the aortic knuckle, and below this is a short segment of left atrial appendage. The bulk of the left heart border is formed by the body of the left ventricle. The left cardiophrenic angle may be occupied by a low-density shadow representing an apical pericardial fat pad. Less often, a fat pad is visible in the right cardiophrenic angle.

On the lateral film (Fig. 2) the heart is seen immediately posterior to the inferior half of the sternum. The anterior border of the cardiac shadow is formed almost entirely by the right ventricle, although in atrial diastole the right atrial appendage may come in contact with the sternum. The right ventricular outflow tract is continuous with the main pulmonary artery that arches posteriorly and continues into the left pulmonary artery. The branches of the right pulmonary artery cast an ovoid shadow anterior to the right bronchus. Part of the ascending aorta may be visible above the pulmonary trunk, and the aortic arch is seen passing posteriorly and then descending for a variable distance. The aortic arch is separated from the left pulmonary artery by the subaortic fossa. The upper part of the posterior aspect of the cardiac silhouette is formed by the body of left atrium and the pulmonary veins, and the lower part by the left ventricle. The inferior vena cava may be visible as a short, straight vertical shadow extending from the diaphragm and overlapping the posterior heart border.

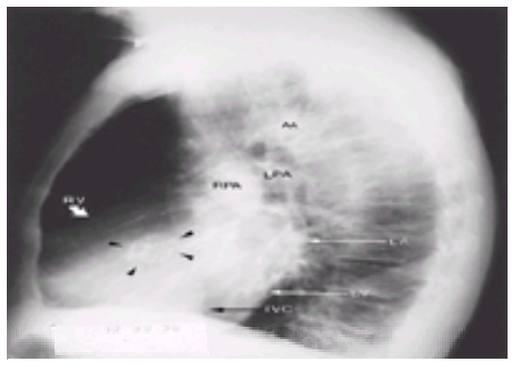

Fig. 2 Lateral chest radiograph. Patient with calcific aortic stenosis. The aortic valve is heavily calcified (arrowheads). AA=aortic arch; IVC=inferior vena cava; LA=left atrium; LPA=left pulmonary artery; LV=left ventricle; RPA=right pulmonary artery; RV=right ventricle.

The normal cardiovascular silhouette changes with age. In infancy, the thymus occupies much of the anterior mediastinum and may obscure the aorta, the pulmonary trunk, and the right ventricular outflow tract. By early adolescence, the thymus is no longer visible on the chest radiograph, and the normal pulmonary trunk is often prominent. In adulthood, the pulmonary trunk is less prominent, and with advancing years the left ventricular contour becomes more convex. In old age, the ascending aorta may become tortuous and project lateral to the superior vena cava, and the aortic knuckle and descending aorta may be increasingly prominent.

Heart size

The commonest methods of assessment of cardiac size using the chest radiograph are the measurement of the transverse cardiac diameter and the measurement of cardiothoracic ratio (Fig. 1).

The transverse cardiac diameter is measured on a posteroanterior film by adding the maximum distance of the right heart border from the mid-line to the maximum distance of the left heart border from the mid-line. The upper limit of normal is 16 cm for men and 15 cm for women. A change of 1.5 cm in cardiac diameter should be regarded as significant. Apparent increase in heart size may be due to a poor inspiration; on anteroposterior films geometric magnification of the heart shadow occurs.

The cardiothoracic ratio is the ratio of transverse cardiac diameter to maximum internal diameter of the thorax. There are racial differences in the normal ratio, which should not exceed 50 per cent in white subjects or 55 per cent in black subjects.

The pulmonary vasculature

The pulmonary trunk normally forms a short segment of the left cardiovascular silhouette. The pulmonary arteries are not visible on the chest radiograph until they emerge from the pericardium and are surrounded by aerated lung. The right pulmonary artery lies anterior to the right main bronchus and usually divides into upper lobe and descending arteries just before emerging from the pericardium. The descending branch is usually clearly seen lateral to the right heart border, where it forms the bulk of the right hilum. Its diameter should not exceed 15 mm in women and 16 mm in men. The left pulmonary artery arches posteriorly over the left main bronchus, and the left hilum is therefore higher than the right. The branching pattern of the pulmonary arteries is similar to that of the bronchi. As the pulmonary arteries pass peripherally, they taper smoothly and are not normally visible in the outer third of the lung.

The anatomy of the pulmonary veins is variable. The upper lobe veins run lateral to the corresponding pulmonary arteries and can often be identified crossing the pulmonary arteries at the hilum prior to the left atrium. The lower lobe veins run more horizontally and medially than the accompanying arteries.

On the frontal chest radiograph of a normal, erect subject the pulmonary vessels should be clearly visible and are larger in the lower zones than in the upper zones. The upper zone veins in the first anterior intercostal space should not exceed 3 mm in diameter. On a supine film, the upper zone and lower zone vessels appear similar in size.

The abnormal chest radiograph

Technical considerations

On an over-exposed chest radiograph the lungs appear blacker than usual and may mimic pulmonary oligaemia. Conversely, an under-exposed film may accentuate the pulmonary vascular pattern, or even suggest diffuse lung disease. A chest radiograph taken on expiration may show increased basal shadowing and suggest pulmonary oedema or other some other interstitial pulmonary abnormality, and the heart may appear enlarged. A rotated film may make some structures appear unusually prominent and others unusually small.

The bones

Deformity of the thoracic skeleton may alter the appearance of the heart. Sternal depression (pectus excavatum) usually displaces and rotates the heart to the left producing a characteristic straight left heart border). In the 'straight back syndrome', the anteroposterior diameter of the thorax is decreased and the heart may be compressed between sternum and spine producing a spurious appearance of cardiomegaly on the frontal chest radiograph. Severe scoliosis may not only alter the shape of the mediastinum but may actually cause cardiopulmonary disease.

Congenital deformity of the thoracic skeleton may be associated with cardiac disease. Both sternal depression and 'straight back' are associated with mitral valve prolapse. Many systemic diseases and congenital syndromes which involve the cardiovascular system may also have skeletal manifestations, for example in Down's syndrome there may be an atrioventricular septal defect and only 11 pairs of ribs.

Rib notching is usually associated with coarctation of the aorta, but may also be seen in pulmonary atresia and vena caval obstruction or following creation of a Blalock–Taussig shunt. Evidence of previous surgery, such as rib deformity, sternal sutures, and prosthetic valves, may be seen on the chest radiograph.

The upper abdomen

Rarely, patients presenting with chest pain have a hiatus hernia or gallstones that may be visible on the chest radiograph. In those with congenital heart disease, information about situs may be visible on the chest radiograph and it is worth noting if the stomach and liver are normally situated, also the visibility and location of the spleen. The best indication of atrial situs, however, is given by the tracheobronchial anatomy.

The lungs

The normal radiographic appearance of the lung is produced by pulmonary vessels outlined by aerated lung. Any opacity that is not a vessel should be carefully considered. Since smoking is an important aetiological factor in both cardiovascular and pulmonary disease, it is not surprising that the routine chest radiograph in a cardiac patient may uncover previously unsuspected lung disease.

The pulmonary vascular pattern may be normal, increased, decreased, or uneven. Normal pulmonary vascularity does not exclude significant myocardial disease, mild valvular disease, or a small intracardiac shunt.

Increased pulmonary vascularity

There are four distinct patterns of increased pulmonary vascularity:

1. pulmonary venous hypertension;
2. pulmonary arterial hypertension;
3. pulmonary over-circulation;
4. systemic supply to the lungs.

Any of these patterns may coexist.

Pulmonary venous hypertension

Pulmonary venous hypertension is most commonly caused by left ventricular failure, mitral valve disease, or aortic valve disease. Rarely, it is due to pulmonary venous obstruction. When pulmonary venous pressure rises, the upper lobe veins distend, becoming similar in size to the lower lobe veins and eventually larger. This phenomenon may be described as 'upper lobe blood diversion' (Fig. 3). When the pulmonary venous pressure exceeds the plasma osmotic pressure, fluid accumulates in the interstitial spaces of the lung. This appears radiographically as interstitial pulmonary oedema: the lower zone and hilar vessels may become indistinct (perihilar haze) and interstitial lines may appear. Kerley B lines are caused by fluid-filled interlobular septa and appear as fine, non-branching horizontal lines in the periphery of the lower zones (Fig. 4). Kerley A lines are less common and are longer, fine-line shadows that radiate from the hila into the mid and upper zones. They also represent distended interlobular septa. Excess interstitial fluid around bronchi may appear as peribronchial cuffing. A further rise in pulmonary venous pressure leads to accumulation of fluid in the alveolar spaces (Fig. 5). Classically, alveolar oedema is perihilar, but it may be patchy and asymmetric, or even nodular, and it may be indistinguishable from other forms of pulmonary consolidation. Pleural effusions are common in pulmonary venous hypertension.

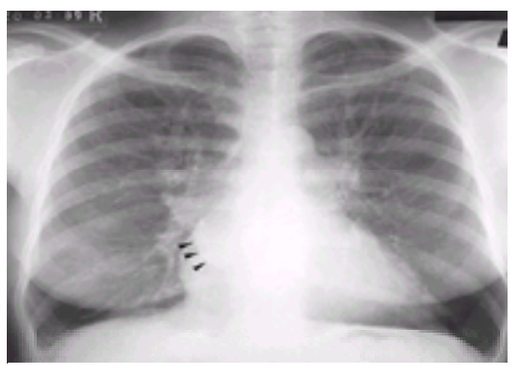

Fig. 3 Upper lobe blood diversion. Patient with mitral valve disease. The extra density over the right heart border (arrowheads) is due to left atrial enlargement.

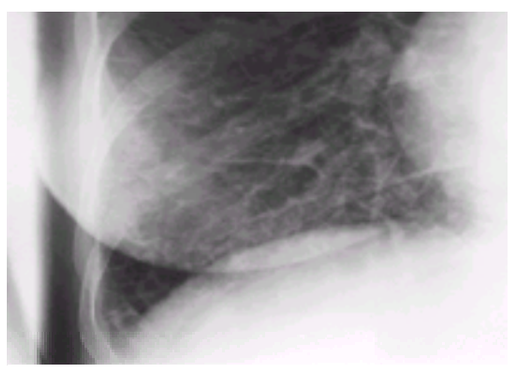

Fig. 4 Kerley B lines. Patient with interstitial pulmonary oedema due to mitral stenosis.

Fig. 5 Severe pulmonary venous hypertension. Patient with acute myocardial infarction. In addition to upper lobe blood diversion, perihilar haze and basal septal lines indicate interstitial oedema, and right lower zone consolidation indicates alveolar oedema.

In the untreated patient there is a fairly close correlation between the pulmonary capillary wedge pressure and the radiographic signs of pulmonary venous hypertension. A normal vascular pattern corresponds to a wedge pressure of less than 12 mmHg, redistribution of blood flow corresponds to 12 to 18 mmHg, interstitial oedema corresponds to 18 to 22 mmHg, and above 22 mmHg there is usually overt alveolar oedema. If a patient has received diuretic therapy, this correlation is less reliable.

In patients with long-standing pulmonary venous hypertension, radiographic signs of pulmonary arterial hypertension may also be present. Chronic pulmonary venous hypertension may also be associated with pulmonary haemosiderosis or pulmonary ossicles. The former appears as a fine nodular pattern throughout both lungs, and the latter as calcified basal nodules of up to 1 cm in diameter.

Although redistribution of blood flow and septal lines are most often a manifestation of pulmonary venous hypertension, there are other causes that should be considered. Redistribution of blood flow may occur in patients who have basal emphysema and no evidence of pulmonary venous hypertension. Septal lines may be seen in non-cardiogenic pulmonary oedema, lymphangitis carcinomatosa, sarcoidosis, and silicosis.

Pulmonary arterial hypertension

Pulmonary arterial hypertension may be defined as a pulmonary artery systolic pressure exceeding 30 mmHg. The commonest causes of this condition are chronic lung disease, pulmonary emboli, pulmonary venous hypertension, and intracardiac shunts. It may also be idiopathic. The typical radiographic appearances are enlargement of the central pulmonary arteries and attenuation of the peripheral arteries. In severe, long-standing pulmonary arterial hypertension, calcification may be

seen in the central pulmonary arteries.

An indication of the underlying cause may be present on the chest radiograph; for example there may be signs of chronic obstructive airways disease or pulmonary embolism. Bilateral hilar lymph node enlargement may mimic enlarged central pulmonary arteries, but usually lymphadenopathy is lobulated, whereas enlarged arteries have a smooth outline.

Pulmonary over-circulation

Pulmonary over-circulation or plethora implies increased blood-flow through the lungs. It is usually due to a left-to-right shunt, less commonly due to bidirectional shunting and rarely due to increased cardiac output. Small shunts may not be perceptible on the chest radiograph, but shunts with a pulmonary-to-systemic flow ratio of 2:1 or greater should be apparent unless there is coexisting heart failure. The central pulmonary arteries are larger than normal and peripheral pulmonary vessels are visible in the outer third of the lung (Fig. 6). Pulmonary plethora in a non-cyanosed patient indicates a left-to-right shunt, whereas in the presence of cyanosis it indicates bidirectional shunting.

Fig. 6 Pulmonary plethora. Infant with transposition of the great arteries. The pulmonary vascular pattern is accentuated; there is also cardiomegaly.

Systemic supply to the lungs

Systemic arterial supply to the lungs, which is sometimes referred to as 'bronchial circulation', develops in patients with severe right ventricular outflow obstruction. The pulmonary trunk is either small or absent, and the peripheral vessels are disorganized and may produce a reticular or nodular pattern that mimics diffuse lung disease.

Decreased pulmonary vascularity

Pulmonary oligaemia

Pulmonary oligaemia implies decreased blood flow through the lungs. It is usually due to right ventricular outflow obstruction in association with a right-to-left shunt, for example tetralogy of Fallot. The lungs appear to have fewer and smaller vessels than usual, and the pulmonary trunk may be small or inapparent. Pulmonary oligaemia due to restricted filling of the right heart, such as occurs in cardiac tamponade, is rarely perceptible on the chest radiograph.

Uneven vascularity

Uneven pulmonary vascularity is most commonly due to pulmonary disease. A previous lung resection will obviously alter the vascular pattern. Apart from pulmonary thromboembolism, cardiovascular causes of uneven vascularity are rare but include previous shunt operations for congenital heart disease, pulmonary artery stenoses, and pulmonary arteriovenous fistulae.

Abnormalities of the heart and great vessels

The systemic veins

Enlargement of the superior vena cava may be caused by either increased flow or increased pressure. Increased flow occurs in supracardiac anomalous pulmonary venous return. Increased pressure occurs in right heart failure, tricuspid valve disease, cardiac tamponade, and constrictive pericarditis. The superior vena cava may also dilate secondary to obstruction caused by mediastinitis or mediastinal tumour. The superior vena cava may be displaced laterally by a tortuous or dilated ascending aorta or a right-sided aortic arch.

The azygos vein may enlarge for the same reasons as enlargement of the superior vena cava. An enlarged azygos vein is also seen in superior vena caval obstruction, portal vein obstruction, and absence of the hepatic portion of the inferior vena cava in polysplenia.

The inferior vena cava may enlarge in secondary to tricuspid valve disease and right heart failure.

The right atrium

Right atrial enlargement rarely occurs in isolation, and is usually associated with right ventricular enlargement. Classically, right atrial enlargement produces increased prominence of the lower half of the right side of the cardiac shadow. It occurs in right heart failure, tricuspid valve disease, and in atrial septal defect and other shunts that enter the right atrium.

The right ventricle

The normal right ventricle is not a border-forming structure on the frontal chest radiograph. An enlarging right ventricle tends to displace the left ventricle laterally so that the cardiac apex becomes elevated. In gross right ventricular enlargement, the right ventricle may actually form the left heart border, and dilatation of its outflow tract may produce a bump just below the pulmonary trunk. On the lateral view, right ventricular enlargement may manifest as increased contact of the heart with the sternum. Right ventricular enlargement occurs in pulmonary arterial hypertension, tricuspid valve disease, pulmonary valve disease, left-to-right shunts, and tetralogy of Fallot.

The pulmonary trunk

Enlargement of the pulmonary trunk is due to increased pressure, increased flow, poststenotic dilatation, or idiopathic dilatation (Fig. 7). In pulmonary arterial hypertension, it may be associated with enlargement of the central pulmonary arteries and peripheral pruning. In situations of increased flow, it is associated with pulmonary plethora. In cases of poststenotic and idiopathic dilatation, it is usually associated with enlargement of the left pulmonary artery and normal peripheral vascularity.

Fig. 7 Patient with mitral stenosis. The transverse cardiac diameter size is normal, but the left atrial appendage is enlarged (curved arrow), and there is also prominence of the pulmonary trunk (arrowhead).

In corrected transposition of the great arteries, the pulmonary trunk is not visible on the chest radiograph. In tetralogy of Fallot and pulmonary atresia, the pulmonary trunk is small, producing an obvious pulmonary bay.

The left atrium

The body of the left atrium is situated beneath the carina and in front of the oesophagus. Enlargement superiorly may increase the angle between the left and right bronchi by elevating the left bronchus and displacing it posteriorly. Posterior enlargement may displace the oesophagus posteriorly. Enlargement to the right may produce an extra density over the right heart border (Fig. 3), and if grossly enlarged the left atrium may actually form the right heart border. Enlargement of the left atrial appendage causes straightening or convex bulging of the upper left heart border (Fig. 7). Left atrial enlargement occurs most obviously in mitral valve disease, but is seen in other forms of left heart failure, in shunts at ventricular and great vessel level, and in association with left atrial tumours.

The left ventricle

Left ventricular hypertrophy produces increased convexity of the left heart border, but not cardiac enlargement unless heart failure develops. Left ventricular dilatation causes displacement of the cardiac apex downward and to the left, and on the lateral view the heart shadow extends more posteriorly than usual. Left ventricular hypertrophy results from systolic overload, and dilatation from diastolic overload. In left ventricular aneurysm, a discrete bulge may develop on the left heart border.

The aorta

Selective enlargement of the ascending aorta is seen in poststenotic dilatation due to aortic valvar stenosis and in association with aneurysms. The aortic knuckle may be prominent due to aneurysm, patent ductus arteriosus, tetralogy of Fallot, and pulmonary atresia. In coarctation of the aorta, the knuckle always appears abnormal—it may be prominent, flat, high, low, or have an abnormal contour. In non-obstructing coarctation or pseudocoarctation, the arch appears elongated and kinked. Selective enlargement of the descending aorta may be due to aneurysm. Generalized prominence of the thoracic aorta may be part of the ageing process but is also seen in systemic hypertension and aortic regurgitation.

The aortic arch is usually left-sided, arching posteriorly over the left main bronchus. However, it can be right-sided, when it arches over the right bronchus and indents the right side of the trachea, the usual shadow of the left arch is absent, and the superior vena cava may be displaced laterally. A right arch with an aberrant left subclavian artery is not usually associated with heart disease, but if its branches are the mirror image of normal there is a high incidence of congenital heart disease. Tetralogy of Fallot, pulmonary atresia, truncus arteriosus, and ventricular septal defect may be associated with a right arch. An aberrant subclavian artery can be identified on a barium swallow.

The pericardium

Pericardial effusion may produce non-specific globular enlargement of the heart shadow and rapid increase in heart size on serial films is suggestive of this condition. Pulmonary vascularity is usually normal. A pericardial cyst may appear as a well-circumscribed, rounded opacity adjacent to the heart. Partial pericardial defects may allow herniation of the left atrial appendage causing a prominent bulge on the left heart border. In congenital absence of the pericardium there is usually displacement of the entire heart to the left.

Cardiac calcification

Calcification may occur in any cardiovascular structure, and is usually the result of inflammatory disease or infarction. Although cardiac calcification may be visible on the chest radiograph it is better demonstrated by fluoroscopy when movement of an abnormally calcified structure aids its detection, in contrast to the chest radiograph where movement causes blurring.

Myocardial and endocardial calcification most commonly occur in the left ventricle secondary to coronary artery disease. Curvilinear calcification may occur in the wall of left ventricular aneurysms, in thrombi, and in infarcts. Left atrial wall calcification may be due to rheumatic myocarditis, and left atrial thrombi may calcify.

Aortic valve calcification usually lies over the spine on the frontal chest radiograph and may, therefore, be obscured. It is best seen on the lateral view (Fig. 2), and tends to lie mostly above a line drawn from the carina to the anterior costophrenic angle. Mitral valve calcification usually lies to the left of the spine, and on a lateral view lies below the line drawn from carina to the anterior costophrenic angle. Calcification is rarely seen in the tricuspid and pulmonary valves, but commonly occurs in right ventricular outflow tract homografts.

Calcification is frequently seen in the aortic arch of older patients as part of the normal ageing process. Extensive aortic calcification is most likely to be due to atheroma, but it may be the result of an arteritis or syphilitic aortitis, which characteristically involves the ascending aorta. Calcification in a healed dissecting aneurysm may be seen in any part of the aorta. Chronic traumatic aneurysms in the region of the aortic isthmus may calcify. Coronary artery calcification indicates atheroma, but does not necessarily correspond to significant coronary artery narrowing. A patent ductus arteriosus may calcify, and calcification may develop in the central pulmonary arteries in long-standing, severe pulmonary arterial hypertension.

Pericardial calcification may be a sequel to pericarditis and haemopericardium, and it may be associated with pericardial constriction. Rare causes of cardiac calcification include tumours, hydatid disease, and coronary artery fistulae.

15.3.2 Electrocardiography

D. J. Rowlands

The resting 12-lead ECG

Historical introduction

The first electrocardiographic recording of the human heart was made in 1887 by A. D. Waller, who expressed the view that it was unlikely that such recordings would be of much use in clinical practice. This view was not shared by Einthoven, who noted the differences between recordings taken from healthy and from sick persons and was, in consequence, convinced that the technique would prove to be of great clinical value. Einthoven suggested the P, QRS, T, U terminology which is in universal use today, and recognized that a better recording device than the capillary electrometer (used by Waller) would be necessary. He modified and developed the string galvanometer for this purpose. The resulting instrument was unwieldy, weighing over a quarter of a ton (254 kg) and requiring five people for its operation, but it produced electrocardiograms of remarkable quality. The first commercially available machine for recording the electrocardiogram (ECG) was made in England in 1911 by the Cambridge Scientific Instrument Company and was delivered to Sir Thomas Lewis at University College Hospital in London. In the early 1900s Einthoven and Lewis were undoubtedly the pioneers who did most to advance the clinical study of electrocardiography. In the early 1930s the most productive research worker in this field was Frank N. Wilson of Ann Arbor, Michigan, who had been stationed in England during World War I in a rehabilitation hospital under the command of Sir Thomas Lewis. Wilson's early research work was, therefore, undertaken in England and, whereas Lewis had concentrated on the cardiac rhythm, Wilson's work was centred on the QRS complexes and T waves. It was Wilson who developed the unipolar recording system, by developing an 'indifferent' electrode that gave a stable reference potential with respect to which the potential at a single exploring electrode could be measured. This reference potential was obtained from a central terminal connected to the left arm, the right arm, and the left leg through equal resistors.

The development of electrocardiographic recording techniques continues (witness the rapidly expanding use of electrophysiological studies of the heart), but the standard 12-lead ECG still forms an essential part of any full clinical cardiological assessment more than 100 years after the first human ECG recording was made. It is estimated that in excess of 100 million 12-lead ECGs are recorded annually worldwide, a fact that would surely have astonished Waller. Electrocardiography developed empirically and its basic diagnostic criteria remain empirical. The criteria given in this chapter represent a reasonable compromise between sensitivity and specificity.

Normal ECG appearances

The basic ECG waveform

The basic ECG waveform consists of three recognizable deflections termed 'P wave', 'QRS complex', and 'T wave', by Einthoven (Fig. 1). The P wave is the surface electrocardiographic manifestation of atrial myocardial depolarization. Depolarization of the sinoatrial node is not recognizable on the surface ECG and can only be inferred from the shape and direction of the P wave. The QRS complex is the surface electrocardiographic manifestation of ventricular myocardial depolarization. The S–T segment and T wave represent ventricular myocardial repolarization. Atrial myocardial repolarization is indicated by the Ta wave, which is a small, asymmetrical negative wave following the P wave, usually obscured by the QRS complex which occurs at the same time. The Ta wave usually becomes easily recognizable during sinus tachycardia (especially during exercise), since it then increases in size and becomes a rounded negative wave beginning before the QRS complex and extending into the S–T segment. A prominent atrial repolarization wave occurring during an exercise stress test is frequently wrongly interpreted as S–T-segment depression. The key to avoiding this error is to recognize that the negativity begins before the QRS complex. The P wave and T wave have relatively simple shapes which exhibit few variations. The QRS complexes exhibit more readily recognizable differences in pattern in different leads within the same ECG.

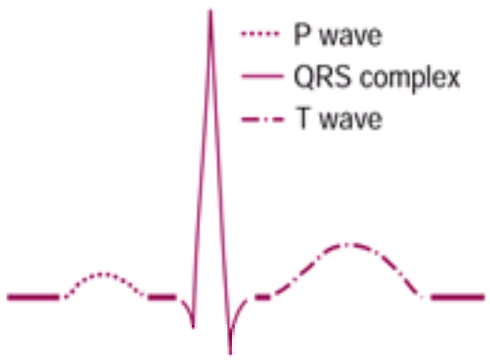

Fig. 1 The basic ECG waveform.

QRS waveform nomenclature

The QRS complexes usually have the largest voltages and virtually always the highest frequency components of the various ECG deflections, and typically consist of 'sharp', pointed deflections. The presence and relative size of the several possible components of the QRS complex may be indicated by a convention using combinations of the letters q, r, s, Q, R, S (Fig. 2). If a given component is considered to be large, an UPPER CASE letter is used, if it is considered to be small a lower case letter is used.

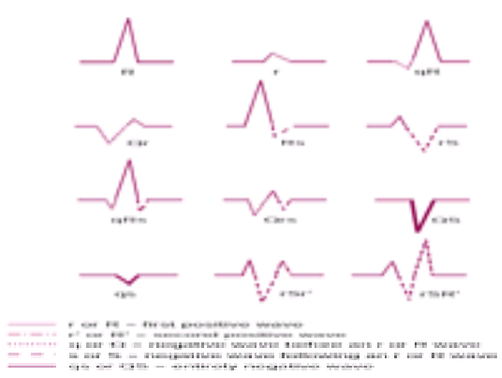

Fig. 2 QRS waveform nomenclature.

The 12 conventional ECG leads

Unipolar, bipolar, and augmented leads

Leads I, II, and III are the bipolar limb leads, introduced originally by Einthoven. The remaining three limb leads and the six precordial leads are unipolar (they involve the use of the central reference terminal of Wilson) and are termed V leads (the 'V' originally stood for 'voltage', to reflect the fact that these unipolar leads effectively measure the voltage at the location of the recording electrode). All currently available ECG machines use augmented (a) limb leads (that is to say they record aVR, aVL, and aVF as opposed to VR, VL, and VF; VR (right arm), VL (left arm), VF (left leg)) as a result of the use of a standard, but no longer necessary, modification of the original Wilson central terminal, designed to produce a 1.5-fold amplification in the recorded voltage.

The six limb leads (frontal plane leads)

The limb leads are remote from the heart and give (spatially) general rather than localized (spatially specific) information. In this respect they differ markedly from the precordial leads. The limb leads consist of the three bipolar leads (leads I, II, and III) and the three augmented, unipolar leads aVR, aVL, and aVF. The orientation around the heart of the six limb leads is illustrated in Fig. 3. The orientation of leads aVR, aVL, and aVF with respect to the heart is intuitively obvious since the limbs act as linear conductors (like wires). The left arm connection is therefore effectively 'looking at the heart' from the left shoulder (i.e. the left arm is acting as part of the wire connecting the ECG machine to the patient's left shoulder). Similarly, the right arm connection 'looks at the heart' from the right shoulder and the foot lead connection from the pelvic area. One practical consequence of the fact that the limbs act as linear conductors is that it does not matter whereabouts on any given limb the electrode is attached. The orientation of the bipolar leads with respect to the heart is not intuitively obvious (simply because they are bipolar leads), but may be worked out from the known polarities of the conventional connections used in the bipolar leads. Thus, for example, since lead I is recorded with the left arm connected to the positive and the right arm to the negative terminal of the recorder, the position of lead I is effectively that obtained by subtracting the right arm vector from the left arm vector. To subtract vector R from vector L one reverses the direction of vector R and adds it to vector L. Inspection of Fig. 3 reveals that if this is done the resulting 'direction' of lead I is effectively horizontally to the left of the heart. In a similar manner it can be shown that the effective orientations of leads II and III with respect to the heart are as shown in Fig. 3.

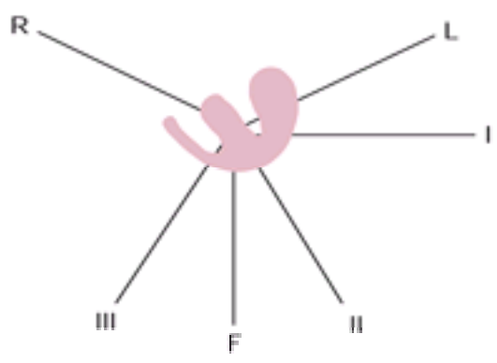

Fig. 3 The arrangement of the frontal plane leads. Note that leads II, III, and F are inferior to the heart, I and L are anterolateral to the heart, and R looks into the cavity of the heart.

The six precordial leads (chest leads)

For each precordial lead, the positive (recording) terminal is connected to an electrode at an agreed site on the chest wall. Since the connection to the negative terminal of the recorder is the 'indifferent' one formed by joining together leads R, L, and F, the chest leads are 'V' leads and are designated V_1, V_2, V_3, V_4, V_5, and V_6. Because the torso, unlike the limbs, acts as a volume conductor, the waveform obtained depends critically on the siting of the recording electrode. A standard anatomical siting of the precordial electrodes was agreed between the British Cardiac Society and the American Heart Association and is shown in Fig. 4. The important relationships of the precordial leads to the cardiac chambers are shown in Fig. 5.

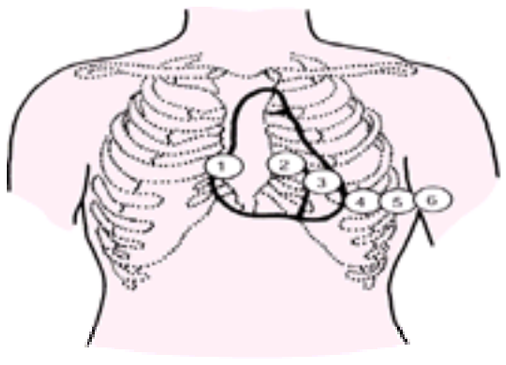

Fig. 4 The positions of the precordial leads. V1 is located at the right sternal margin in the fourth intercostal space, V_2 at the left sternal margin at the fourth intercostal space, V_4 at the intersection of the left midclavicular line and left fifth intercostal space, V_3 midway between V_2 and V_4, V_5 at the intersection of the left anterior axillary line with a horizontal line through V_4, and V_6 at the intersection of the left midaxillary line with a horizontal line through V_4 and V_5.

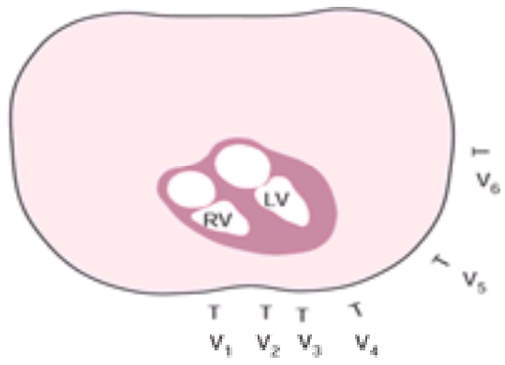

Fig. 5 The precordial leads and their important anatomical relationship to the main cardiac chambers.

The 12 conventional ECG leads

Figure 6 shows the relationship of the 12 conventional electrocardiographic leads to one another and to the heart.

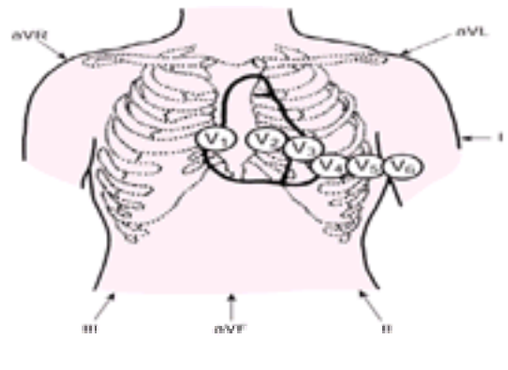

Fig. 6 The conventional 12 ECG leads and their relationships to the heart.

Recognizing the normal electrocardiogram

This is the most difficult and the most important aspect of understanding the electrocardiogram, which is recognized as being within or beyond normal limits by the normality or otherwise of the shape and dimensions of its various substituent deflections, and by the frequency of the deflections and their relationship in time to the deflections preceding and succeeding them. This introduction to the subject considers only morphological normality or abnormality. The presence of sinus rhythm will therefore be assumed. The criteria for normality of the P waves obtain in any rhythm where atrial depolarization is of sinus origin (sinus tachycardia, sinus bradycardia, sinus arrhythmia, first-, second-, or third-degree heart block). Those for the QRS complexes, S–T segments, and T waves obtain in any rhythm of supraventricular origin, provided the rate is not so rapid as to induce functional bundle-branch block. A supraventricular rhythm is one initiated at a site above the bifurcation of the His bundle.

All the criteria described below are dependent upon a normal (standard) calibration and a normal paper recording speed.

Precordial leads

Normal precordial P waves

The P waves are usually upright from V_4 to V_6. Upright or biphasic P waves may occur in V_1 and V_2. If the P waves are biphasic, the negative (terminal) component of the P wave should have an area no greater than the positive (initial) component.

Normal QRS appearances in the precordial leads

QRS morphology

The QRS complex in V_1typically shows a small initial positive wave followed by a larger negative wave, and in V_6a small initial negative wave followed by a large positive wave. In general, the size of the initial positive wave (r or R wave) increases progressively from $V_1$to V_6(Fig. 7(a)) The direction of the initial part of the QRS is generally upward (i.e. positive) in V_1 to V_3, and downward (i.e. negative) in V_4 to V_6That is, V_1 to V_3 show initial r waves and V_4 to V_6 initial q waves. Leads showing an rS complex are being primarily influenced by right ventricular myocardium, and leads showing a qR complex by left ventricular myocardium. The transition zone between right and left ventricular epicardial leads is seen (Fig. 7(b)) to be between V2 and V4. When the transition zone falls outside this region the heart is said to be rotated. If the transition zone occurs further to the left in the precordial series (for example, between V_5 and V_6) then the heart is said to be clockwise rotated. Conversely if the transition zone is moved to the right in the precordial series, the heart is said to be counter-clockwise rotated. Clockwise and counter-clockwise rotation refer to a normal state of variability between one subject and another and are not in themselves indicative of abnormality. More extensive works should be consulted for a detailed understanding of clockwise and counter-clockwise rotation. Although, as stated above, V_1usually shows an rS complex and V_6a qR complex, it is also possible for V_1 to show a QS complex and for V_6 to show a monophasic R wave, a QRS complex, or an Rs complex (Fig. 7(c)).

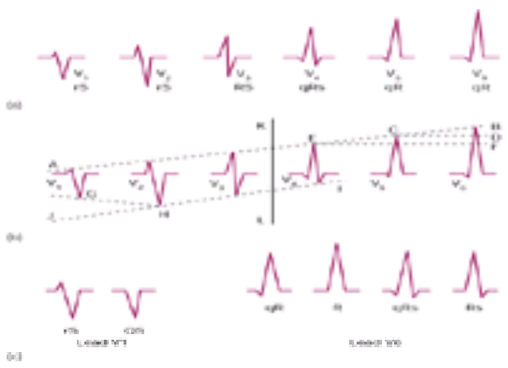

Fig. 7 Morphology of the precordial QRS complexes. (a) Typical normal QRS morphology of the precordial leads. (b) Normal variations of R-wave amplitude and S-wave depth in the precordial leads. The R wave in each precordial lead is usually larger than in the preceding lead in the series from V_1 to V_6 (line AB). However, it is quite normal for the R wave in V_6 to be smaller than that in V_5 (line CD) or for the R wave in V_5 to be smaller than that in V4, provided that the R wave in V_6 is also smaller than that in V_5 (line EF). The size of the S wave diminishes progressively across the precordial leads (line JI), although the S wave in V_2 is often greater than that in V_1 (line GHI). Leads before line KL have an initial deflection which is positive, while those after line KL have an initial deflection which is negative. This line marks the transition zone between right and left ventricular QRS configurations (i.e. between rS and qR configurations, respectively). (c) Possible normal QRS configurations in leads V1 and V6. Typically, V_1 has an rS configuration, but a QS configuration is also normal in this lead. Typically, V_6 has a qR configuration, but it is also normal for V_6 to show an R wave, a qRs complex, or an Rs complex.

QRS dimensions

The dimensions of the individual waves making up each part of the precordial QRS complexes are of crucial importance in determining normality or otherwise. Figure 8 shows how measurements within the QRS complexes are obtained. The criteria for normality of these individual waves are:

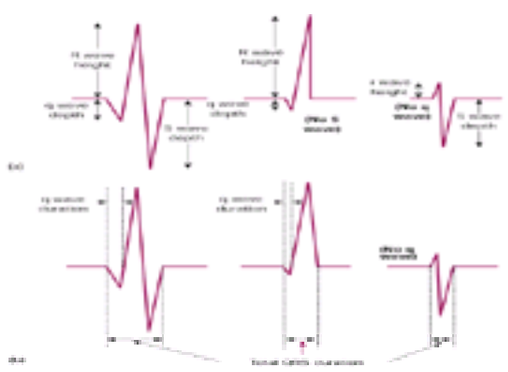

Fig. 8 The dimensions of constituent waves within QRS complexes. (a) Wave voltage measurements. (b) Wave duration measurements.

1. *minimum voltage*: at least one R wave in the precordial leads must exceed 8 mm in height;
2. *maximum voltage*: (a) the tallest R wave in the left precordial leads must not exceed 27 mm, (b) the deepest S wave in the right precordial leads must not exceed 30 mm, (c) the sum of the tallest R wave in the left precordial leads and the deepest S wave in the right precordial leads must not exceed 40 mm;
3. *maximum duration*: the total QRS duration in any one precordial lead must not exceed 0.10 s (2.5 small squares);
4. *q-wave criteria*: (a) no precordial q wave should equal or exceed 0.04 s (1 small square), (b) precordial q waves must not have a depth greater than a quarter of the height of the R wave in the same lead; and
5. *the ventricular activation time*, also known as 'intrinsic deflection time', in leads facing the left ventricle (i.e. showing qR complexes) must not exceed 0.04 s (one small square).

Normal precordial S–T segments

There is a single rule for normality of the S–T segment. It must not deviate by more than 1 mm above or below the isoelectric line in any precordial lead. The isoelectric line is that vertical position of the ECG recording when no part of the heart is being depolarized or repolarized (i.e. the interval between the end of one T wave and the beginning of the next P wave—the T–P interval).

Normal precordial T waves

The criteria given below for normality of the T waves are applicable to adults only.

T waves in lead V_1

In this lead 80 per cent of normal adults have upright T waves and 20 per cent have flat or inverted T waves. Therefore, the finding of an inverted T wave in Vl cannot be considered an abnormality (unless it was upright in a previous ECG).

T waves in lead V_2

About 95 per cent of normal adults show upright T waves and 5 per cent have flat or inverted T waves in V_2 Therefore there is a 1 in 20 possibility of inverted T waves in V_2 occurring by chance and not indicating an abnormality. However, if the T wave in V_2 is inverted when it was formerly upright, it is abnormal. Further, if there is T-wave inversion in V_2 with an upright T wave in V_l then the T wave in V_2 is abnormal.

T waves in leads V_3 to V_6

The T wave is normally upright in these leads. T-wave inversion in V_4, V_5, or V_6 is always abnormal. T-wave inversion in V_3, as well as in V_l and V_2, may (rarely) be found in healthy young adults.

T-wave size

There are no strict criteria for T-wave size. In general, the tallest precordial T wave is found in V_3 or V_4, and the smallest in V_1 and V_2,and, as a general rule, the T wave should not be less than one-eighth and not more than two-thirds of the height of the preceding R wave in each of the leads V_3 to V_6.

Limb leads

Normal limb lead P waves

The limb lead that normally best shows the P wave is lead II. In this lead the normal P-wave duration does not exceed 0.12 s and its height does not exceed 2.5 mm

Normal limb lead QRS complexes

Only three criteria need to be applied to the limb leads to determine the normality or otherwise of the QRS complexes:

1. *the size of any q waves* in aVL, I, II, or aVF;
2. *the size of the R waves* in aVL and aVF; and
3. *the electrical axis of the heart*.

Q waves

Any q wave present in lead I, II, or aVF must not exceed one-quarter the height of the ensuing R wave and must not equal or exceed 0.04 s in duration. Any q wave present in aVR or lead III should be ignored, irrespective of its size. Q waves present in aVL should fulfil the same criteria as those in leads I, II, or aVF unless the frontal plane QRS axis is more positive than +60°, in which case large q waves in aVL are acceptable, since aVL is then a cavity lead (and may therefore have a QS complex as aVR, which is virtually always a cavity lead, usually has).

R-wave size

The R wave in aVL must not exceed 13 mm, while that in aVF must not exceed 20 mm.

The frontal plane axis

The value of the axis is determined using the hexaxial reference system (Fig. 9) in which lead I is arbitrarily assigned the value 0°, with the convention that rotation clockwise from this point is denoted positive ('+') and rotation anticlockwise is denoted negative ('–'). The mean frontal plane QRS axis in the adult lies within the range from –30° to +90° (travelling clockwise). The frontal plane axis represents the dominant direction of ventricular myocardial depolarization on the frontal plane. The axis is closest to that frontal plane lead with the tallest QRS complex, but because of the uneven distribution of the limb leads the axis cannot reliably be determined by simple inspection of the limb lead QRS complexes.

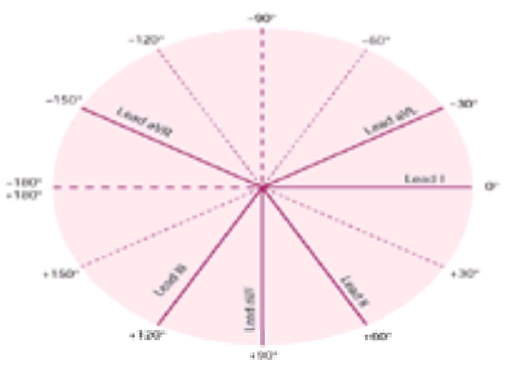

Fig. 9 The hexaxial reference system. The hexaxial reference system is constructed by taking each of the six frontal plane limb leads (continuous lines) and extrapolating them through the origin to create six additional lines (discontinuous), thereby producing 12 lines each at 30° to its neighbour on either side thus dividing the 360° of the frontal plane into equal (30°) sections.

Thegeneral direction of ventricular depolarization in the frontal plane in a normal record is typically towards lead II (60°), but can lie anywhere between aVL (–30°) and aVF (+90°). When the axis lies within the range –30° to +30° the heart is said to be horizontal and the tallest QRS complexes will be found in aVL and I. When the axis lies within the range +60° to +120° the heart is said to be vertical and the tallest QRS complexes will be found in aVF and II. With a typical normal axis of +60°there areupright QRS complexes in lead II, and to a lesser extent in aVF, and smaller QRS complexes in III and aVL. Lead aVR 'looks into' the cavity of the heart. Since depolarization of the ventricles is from endocardium (where the Purkinje tissue is) to epicardium, the cavity leads record depolarization travelling away from them and therefore have negative QRS deflections.

A knowledge of the axis is helpful in understanding the variation in appearances in the limb leads between different subjects with similar (normal or abnormal) precordial ECG appearances. Thus, for example, in a patient with left ventricular hypertrophy, if the heart is horizontal (axis lies in the region of –30° to +30°) appearances similar to those in V_5 and V_6 will be seen in aVL and I (Fig. 10), whereas if the heart is vertical (axis +60° to +120°) appearances similar to those in V_5 and V_6 will be seen in II and aVL.

Fig. 10 Left ventricular hypertrophy. There is also evidence of left atrial hypertrophy.

Determination of the mean frontal plane QRS axis

To determine the mean frontal axis to the nearest 30° requires two steps, which can be illustrated using Fig. 10 as follows:

1. Inspect the six frontal plane (limb) leads to find the lead in which the algebraic sum of the deflections in the QRS complexes approximates to zero (i.e. the lead in which the sum of all the positive deflections minus all the negative deflections gives a result closest to zero). In doing this one is looking for the smallest mean QRS deflection. The axis will always be approximately at right angles to the lead with the smallest QRS. Let the lead showing the smallest net QRS size be called lead 'x'. (In the example of Fig. 10 this is lead II.)
2. Using the hexaxial reference diagram (Fig. 9), decide which other lead (y) is at right angles to lead 'x'. (In Fig. 10 this is aVL.) There will always be one such a lead. The axis must either be: (a) in the same direction as or very close to lead y (in this example, aVL, i.e. –30°) or (b) directly opposite to y or very close to that

position (in this example, +150°), both of which possible positions are approximately at right angles to x. To determine which of these two possibilities indicates the correct orientation of the axis look again at the given ECG and inspect the QRS in lead y (in this case aVL). It must either have a large dominant positive wave, or a large dominant negative wave. If the former, the axis of the heart is along lead y (i.e. approximately –30°), if the latter the axis is directly away from lead y (i.e. approximately +150°). To the nearest 30°, therefore, the axis in the ECG of Fig. 10 is –30°.

3. To assess the axis to the nearest 15° it is necessary to take one further step
4. Look again at the QRS in that lead where the algebraic sum of QRS deflections is close to zero (II in Fig. 10). Assess whether that sum is (a) indistinguishable from zero, (b) close to zero but clearly slightly positive, or (c) close to zero but clearly slightly negative. If (a), then the current estimate of the axis is now correct to the nearest 15°; if (b), then the axis estimate must be 'bent' from the 30° accuracy estimate, 15° towards the lead where the QRS algebraic sum is close to zero; if (c), then the axis estimate must be 'bent' from the 30° accurate estimate, 15° away from the lead where the QRS algebraic sum is close to zero. In this case the QRS in II is clearly slightly positive and the 30° accuracy estimate (–30°) must be 'bent' 15° towards lead II, giving an axis of –15 (to a 15° accuracy). (Had the algebraic sum of QRS deflections in lead II, Fig. 10, been negative it would have been necessary to 'bend' the estimated axis 15° away from lead II, giving –45°).

Significance of the mean frontal plane QRS axis

The normal range for the frontal plane axis in adults is from –30°to +90° (travelling clockwise). Axes that are more negative than –30° are described as left-axis deviation (LAD). Axes more positive than +90° are described as right-axis deviation (RAD). These terms (LAD and RAD) are descriptive, in the same manner as the term 'hypertensive' is descriptive. Axes of –60°and –90° are both examples of left-axis deviation, but the difference is significant. It is therefore preferable to describe the axis in an individual case in degrees, just as it is preferable to give their measured blood pressure in mmHg. The other reason for preferring to describe the axis in degrees is that axes in the quadrant from –180° to –90°, which are uncommon, could be described either as extreme left- or as extreme right-axis shift.

The axis in the newborn tends to be around +120°. As the child grows the axis swings towards the left. In adult life the normal axis lies within the range –30° to +90°. In older age groups the axis typically lies between –30°and +30°. Tall, thin people have axes nearer the right end of the normal range and short fat people have axes nearer the left end of the normal range. The most common normal axis lies between 0° and +60°.

Deviation of the axis to the right, beyond +90 degrees (that is, RAD) occurs in cor pulmonale, right ventricular hypertrophy (pulmonary stenosis, pulmonary hypertension), and ostium secundum atrial septal defect.

Left-axis deviation occurs in left ventricular disease, when the superior division of the left bundle-branch system is blocked, in hyperkalaemia, in some cases of inferior infarction, and in ostium primum atrial septal defect.

Determination of the axis itself is primarily important in the diagnosis of right ventricular hypertrophy (RVH) and left anterior hemiblock (LAH). When the axis is in the range –30° to +30°, the heart is said to be 'horizontal'. When the axis is in the region of +60° to +120° the heart is said to be 'vertical'.

Normal limb lead S–T segments

Normal S–T segments do not deviate above or below the isoelectric line by more than 1 mm.

Normal limb lead T waves

In general, the T waves and QRS complexes in the limb leads are concordant: that is to say, when the QRS complexes are upright, the T waves are upright, and when the QRS complexes are negative, the T waves are negative. A normal T wave will always be negative in aVR and positive in I and II. T waves can be positive or negative in aVL, aVF, and II without necessarily indicating abnormality. A rough guide to assess normality of the T waves in the limb leads is:

1. in any lead in which the QRS is predominantly upright, the T wave must be clearly upright;
2. in any lead in which the QRS is predominantly negative, the T wave should be clearly negative;
3. in any lead in which the algebraic sum of QRS deflections is close to zero, the T wave may be positive or negative (though small in either case) or isoelectric (flat); and
4. the normal T wave is always upright in leads I and II.

Myocardial hypertrophy

Appreciable hypertrophy of the right or left ventricle produces characteristic changes in the electrocardiogram. Lesser degrees of hypertrophy may be present without electrocardiographic changes or with only minor, non-specific changes. This is more often true of right than of left ventricular hypertrophy.

Left ventricular hypertrophy

Left ventricular hypertrophy is not an all-or-none phenomenon, and the same is true of its recognition on the ECG. Several scoring systems have been devised. The most sensitive (and least specific) criteria consider the precordial lead voltages. The increased bulk of the left ventricle increases the voltage that is induced during left ventricular depolarization. This results in taller R waves in the left precordial leads and deeper S waves in the right precordial leads. The increased ventricular wall thickness also results in prolongation of the time taken for the depolarization wave to travel from endocardium to epicardium, that is to say it increases the ventricular activation time. In addition, secondary changes in depolarization occur, altering the S–T segments and T waves. The electrocardiographic criteria for left ventricular hypertrophy are:

1. at least one R wave in the left precordial leads exceeds 27 mm;
2. at least one S wave in the right precordial leads exceeds 30 mm:
3. the sum of the tallest R wave and the deepest S wave in the precordial leads exceeds 40 mm;
4. the largest positive or negative deflection in the limb leads exceeds 20 mm;
5. the intrinsic deflection time (ventricular activation time) exceeds 0.04 s;
6. S–T-segment depression and T-wave inversion may occur in the left precordial leads and in those limb leads that face the left ventricle.

The presence of one or more of the above abnormalities suggests the presence of left ventricular hypertrophy, only provided that the total QRS duration does not exceed 0.10 s. The greater the number of criteria fulfilled, the more confident one can be of the diagnosis. The voltage criteria have the greatest sensitivity, and the intrinsic deflection time the greatest specificity. However, one must exercise caution in diagnosing left ventricular hypertrophy on the basis of voltage criteria alone, especially if the patient is slim—and also note that the sensitivity for the diagnosis of left ventricular hypertrophy is very low in those who are obese. An example of clear-cut electrocardiographic changes of left ventricular hypertrophy is shown in Fig. 10.

Right ventricular hypertrophy

Increased bulk of the right ventricle gives rise to higher voltages during right ventricular depolarization, increasing the size of the positive deflection in the right precordial leads. In addition, it shifts the electrical axis towards the right and changes the S–T segments and T waves in leads facing the right ventricle, because of secondary changes in the repolarization process. The electrocardiographic criteria for right ventricular hypertrophy are:

1. a positive deflection equal to or greater than the negative deflection in V_1 (RS, Rs, qR, rR') in the presence of a normal total QRS duration;
2. a mean frontal plane QRS axis more positive than +90°; and
3. S–T-segment depression and T-wave inversion in right precordial leads.

The more features present, the more convincing is the electrocardiographic evidence for right ventricular hypertrophy, but, in general, the combination of a dominant positive deflection of the QRS in V_1 and an abnormal degree of right-axis deviation (axis more positive than +90°) establishes the diagnosis. Examples are shown in Fig. 11(a) and Fig. 11(b). In both examples there is abnormal right-axis deviation and a dominant R wave in V_1. Figure 11(a) shows an Rs complex in $V_1$and Fig. 11(b)

shows a qR complex. The more common finding is of an Rs in V_1. An initial q wave (qR complex) can appear in V_1 in right ventricular hypertophy, which results from hypertrophy of the right side of the upper part of the interventricular septum with resultant redirection of initial septal depolarization relatively posteriorly and therefore away from (and negative with respect to) V_1. Figure 11(b) also shows pronounced clockwise cardiac rotation, which often accompanies right ventricular hypertrophy.

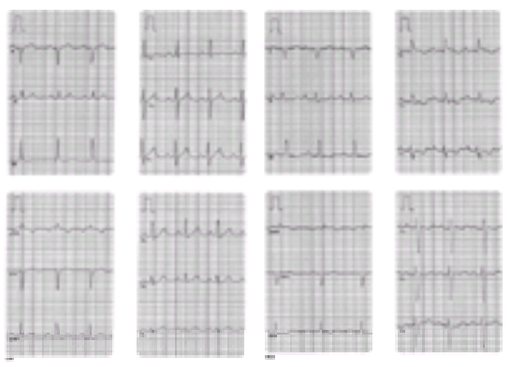

Fig. 11 Two examples of right ventricular hypertrophy. There is also right atrial hypertrophy. Fig. 11(a) shows an Rs complex in V_1;(b) shows a qR complex.

Atrial hypertrophy

The electrocardiographic changes produced by left atrial hypertrophy are those produced by an increase in the voltage and duration of the left atrial depolarization wave. Since the terminal part of the normal P wave is produced by left atrial depolarization, it follows that the total P-wave duration is prolonged in left atrial hypertrophy. In addition, the P wave tends to be bifid in lead II and biphasic in V_1. In $V_1$the area of the (terminal) negative component exceeds the area of the (initial) positive component (Fig. 10 and Fig. 12). Left atrial hypertrophy is most commonly seen in association with left ventricular hypertrophy and (in countries where rheumatic heart disease is rare) is most commonly due to systemic hypertension. The finding of left atrial hypertrophy in the absence of evidence of left ventricular hypertrophy suggests mitral valve obstruction (mitral stenosis or, very rarely, left atrial myxoma).

Fig. 12 Left atrial hypertrophy. Broad, bifid P waves in lead II. Biphasic P waves in V1, with dominant negative component. Since there is no evidence of left ventricular hypertrophy, the most likely cause of the left atrial hypertrophy is mitral valve obstruction. The patient had mitral valve stenosis.

The electrocardiographic change produced by right atrial hypertophy is an increase in the peak voltage of the P wave. This is usually best seen in lead II. In lead II the P-wave voltage is abnormal when it exceeds 3 mm (see Fig. 11(b)). Right atrial hypertrophy is most commonly seen in the presence of right ventricular hypertrophy. The finding of right atrial hypertrophy in the absence of right ventricular hypertrophy suggests tricuspid valve obstruction.

Bundle-branch block

Total failure of conduction in the right or left branches of the bundle of His (bundle-branch block) can only be diagnosed with confidence from the appearances in the precordial leads, although necessarily there are also changes in the appearances in the limb leads.

Right bundle-branch block

In right bundle-branch block, the primary change induced is a delay in depolarization in the right ventricular free wall. This results in the development of a second positive wave in the right ventricular leads (and a second negative wave in left ventricular leads), and prolongs the total QRS duration. The essential electrocardiographic features of right bundle-branch block are:

1. a total QRS duration of 0.12 s or more; and
2. the presence of a secondary positive wave in V_1 (rsR', rR').

In addition, secondary changes occur, but these are not in themselves essential for the definitive diagnosis. They include:

1. deep and slurred S waves in lead I, aVL, and V_4–V_6; and
2. secondary S–T, T changes in leads V_I–V_3.

An example of the appearances in right bundle-branch block is shown in Fig. 13.

Fig. 13 Right bundle-branch block. The total QRS duration is prolonged. There is an rsR' in V_1 and there are broad, slurred S vaves in V_3–V_6.

Left bundle-branch block

Left bundle-branch block induces changes in the ECG which are more extensive than those produced by right bundle-branch block. In left bundle-branch block not only is depolarization of the free wall of the left ventricle delayed (a precise corollary of the changes in right bundle-branch block), but also the direction of depolarization of the interventricular septum is from right to left instead of from left to right as in the normal electrocardiogram. This reversal of the direction of septal depolarization gives rise to widespread and major alterations in the QRS complexes in every lead of the electrocardiogram. The diagnostic criteria for left bundle-branch block are:

1. a total QRS duration equal to or in excess of 0.12 s; and
2. absence of the normal (septal) q waves in lead I, aVL, and V_4–V_6; and
3. absence of a secondary r wave in V_1.

This latter criterion is necessary to prevent confusion in cases of right bundle-branch block occurring in the presence of pronounced clockwise cardiac rotation, which gives a loss of q waves in left ventricular leads. (The finding of a secondary r wave in V_1 in the presence of an abnormally wide QRS complex indicates the presence of right bundle-branch block.) Secondary changes also inevitably occur, but these are not part of the diagnostic process. These include:

1. secondary S–T depression and T-wave inversion in leads I, aVL, and V_4–V_6;
2. broad QS waves in V_1–V_3;
3. notching of the R waves giving rise to rsR' or 'M-shaped' QRS complexes, and
4. broad, R waves in leads I, aVL, and V_4–V_6.

An example of the ECG appearances in left bundle-branch block is shown in Fig. 14. The changes in left bundle-branch block so disturb the normal pattern of the ECG that none of the usual criteria can be applied for determining any other abnormality of the QRS complexes, S–T segments, or P waves. When left bundle-branch block is present, a diagnosis of right or left ventricular hypertrophy, myocardial ischaemia or infarction, or of non-specific changes in the S–T segments and T waves cannot easily or reliably be made.

Fig. 14 Left bundle-branch block. The total QRS duration is prolonged and no q wave is seen in I, avL, and V_4–V_6. In addition there is no secondary R wave in V_1.

The hemiblocks

During normal intraventricular conduction the anterosuperior and the posteroinferior divisions of the left bundle-branch system conduct more or less simultaneously. This has the result that the dominant direction of depolarization of left ventricular myocardium lies midway between these two divisions and is therefore downwards and to the left, giving an axis in the range –30° to +90° and most typically in the region of +60°.

Left anterior hemiblock

When there is failure of conduction in the anterosuperior division of the left bundle branch ('left anterior hemiblock') the direction of the initial part of the QRS vector moves marginally to the right as a result of the loss of the opposing initial leftward voltage. However, the bulk of the QRS vector is slightly delayed and moves strongly to the left. This is because depolarization of the superior and left part of the left ventricular myocardium is dependent upon spread from the initially depolarized rightward and inferior aspects of the ventricle. The resulting changes in the ECG are therefore (1) a trivial increase in the QRS duration (but the QRS duration is not prolonged beyond normal limits) and (2) a shift of the axis to the left (more negative than –30°). The other common cause of abnormal left-axis deviation is inferior myocardial infarction. The ECG criterion for left anterior hemiblock is a mean frontal plane QRS axis more negative than –30° in the absence of abnormal q waves in aVF (which would indicate inferior infarction).

Left posterior hemiblock

Left posterior hemiblock, as would be expected from the above, gives rise to abnormal right-axis deviation (axis more positive than +90°). Unfortunately, there are numerous causes of abnormal right-axis deviation. It is therefore not possible, from the 12-lead ECG, to diagnose left posterior hemiblock. One can only raise the possibility of this in those situations in which there is an abnormal degree of right-axis deviation without any clear electrocardiographic or clinical explanation.

Ischaemic heart disease

ECG changes in ischaemic heart disease are very variable, depending on the site and severity of ischaemic damage. However, certain patterns are commonly produced.

Acute coronary syndromes (Q-wave infarction, non-Q-wave infarction, and unstable angina)

The terms 'transmural infarction' and 'Q-wave infarction' are often used interchangeably, as are the terms 'subendocardial infarction' and 'non-Q-wave infarction'. These two types of myocardial infarction are not separable on clinical grounds alone, and the distinction between the two depends entirely on the presence or absence of abnormal Q waves on the ECG. It is generally agreed that the terms 'Q-wave infarction' and 'non-Q-wave infarction' are preferable to 'transmural infarction' and 'subendocardial infarction', because autopsy data indicate that the ECG does not have sufficient sensitivity and specificity to guarantee reliable distinction between transmural and subendocardial infarction. However, the distinction between Q-wave and non-Q-wave infarction should not be used to determine management. The full spectrum of Q-wave infarction and unstable angina is now designated under the overall label of 'Acute coronary syndromes'.

Patients presenting clinically with an acute coronary syndrome may or may not have initial S-T elevation. Most (75 per cent) of those with S-T elevation subsequently develop abnormal Q waves and most of the remaining 25 per cent develop reduction in R wave height. Occasionally the ECG may return entirely to normal after initial S-T elevation. Those who present without initial S-T elevation do not usually develop abnormal Q waves. In such cases there may be (non-specific) S-T segment depression (flat, down sloping or up sloping), flattening or inversion of the T waves or a combination of non specific S-T and T changes and the final diagnosis can then be either non-Q-wave infarction or unstable angina. The distinction between these two depends entirely on whether or not serum markers of infarction are present.

In contrast to the typical, striking evolutionary changes of acute Q-wave infarction, the ECG findings in non-Q-wave infarction are less dramatic and less predictable. The electrocardiographic evidence consists of primary S–T-segment depression ('primary' implies in the absence of any detectable S–T elevation) or of deep,

symmetrical T-wave inversion without any change in the QRS complexes. Each of these changes can be produced by myocardial ischaemia without infarction, and the diagnosis of non-Q-wave infarction cannot be made on a single electrocardiogram alone. Either (1) a single such record accompanied by clinical or enzyme evidence of infarction, or (2) serial records that persistently show primary S–T depression or that show deep symmetrical T-wave inversion, is required. The persistence of non-specific S–T and/or T changes that were not formerly present, and which accompany clinical and enzymatic evidence of acute infarction, are the hallmark of non-Q-wave infarction. When the primary change is S–T depression it will often be visible in all or most leads, with the exception of the cavity leads (aVR is always a cavity lead, aVL is a cavity lead if the heart is vertical (axis +60° or more positive) and lead III is a cavity lead if the heart is (axis +30° or further to the left)). The cavity leads may also show reciprocal S–T elevation. The only exception to the rule 'that when S–T elevation and S–T depression are both present in the same recording, it is the elevation which is the primary change' occurs when, as in this case, the reciprocal S–T elevation occurs in cavity leads (which, by definition, all show QS complexes).

QRS changes of myocardial infarction

Two QRS changes are indicative of myocardial infarction. These are:

1. inappropriately low R-wave voltage in a local area; and
2. abnormal q waves.

These two changes represent parts of the same process. The development of increased negativity (abnormal q waves) and the reduction in the normal positivity (loss of R-wave height) of QRS complexes in the precordial leads each results from a loss of underlying viable muscle, with a consequent reduction in the normally generated positive voltage. When there is full-thickness (transmural) myocardial infarction in an area of myocardium underlying the precordial leads there is total loss of the positive deflection. In this situation a totally negative wave (QS complex) occurs. This totally negative wave occurs as a result of depolarization of the posterior wall of the ventricle travelling (posteriorly) from endocardium to epicardium in the normal way, which is no longer swamped by the usual simultaneous and dominant depolarization towards the exploring electrode of the anterior wall of the ventricle.

The normal precordial QRS complexes show a progressive increase in the R-wave height from V_1 to V_6 (Fig. 15). The positive (upgoing) part of the deflection in each precordial lead is predominantly the result of depolarization from underlying endocardium to epicardium. In the presence of infarction of part of the left ventricle, the positive waves overlying the necrotic area will be reduced in size (Fig. 16). Loss in R-wave height can only be used as a criterion for myocardial infarction if either: (1) larger, normal R waves are visible on both sides of the infarcted zone, or (2) previous ECGs are available demonstrating the normal R-wave height for that particular lead in that particular subject. If a major part of the thickness of the myocardial wall is infarcted, the positive wave generated by any remaining viable left ventricular myocardium underlying the electrode is insufficient to overcome the negative deflection induced by the normal depolarization of the interventricular septum, from left to right, and of the free wall of the right ventricle (or the posterior wall of the left ventricle) from endocardium to epicardium. In this situation an abnormal q wave will develop. In the precordial leads, a q wave is abnormal if its duration is equal to or in excess of 0.04 s or if its depth is equal to or greater than a quarter the height of the ensuing R wave in that lead. In Fig. 16, the q wave in V_4 satisfies this criterion. If the infarction involves the full thickness of the ventricular wall (transmural infarction), no R wave is generated at all and an entirely negative (QS) wave develops (Fig. 17). Figure 18 shows (in diagrammatic form) the appearances produced in the precordial leads when infarcts of varying thickness occur under each of three precordial electrodes. The QRS complex in V_3 is of QS type and indicates transmural infarction at this site. The appearances in V_4 indicate a substantial loss of myocardium underlying that electrode. The q wave is abnormal in duration and depth. The appearances in V_5 indicate a thinner zone of infarction. The q wave is not, in itself, abnormal, but the R-wave height is less than would be predicted from the height of the R waves present in V_2 and V_6.

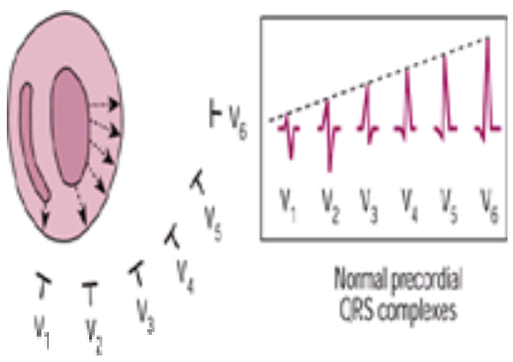

Fig. 15 Normal R-wave progression in the precordial series.

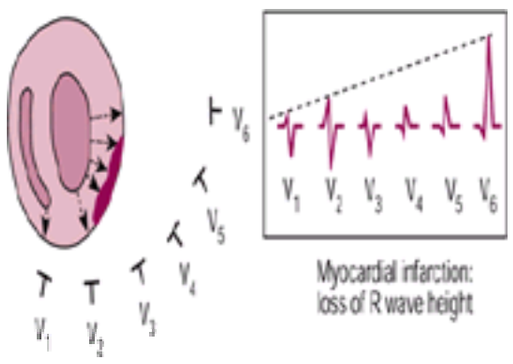

Fig. 16 Loss of R-wave height in myocardial infarction. The R-wave height is reduced in leads V3 to V5.

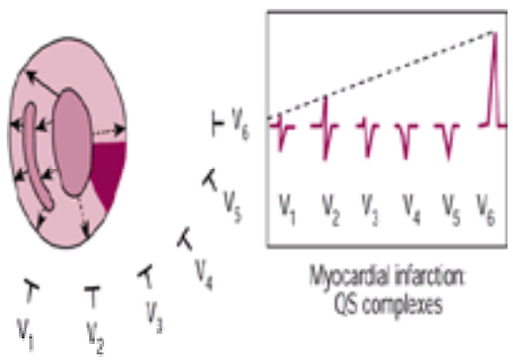

Fig. 17 Transmural myocardial infarction. QS complexes are seen from V_3 to V_5.

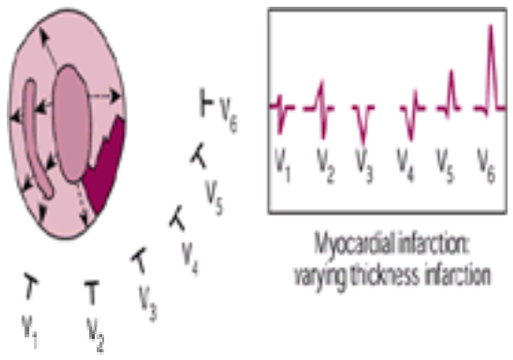

Fig. 18 Varying thickness infarction.

The diagnosis of myocardial infarction from the limb leads depends entirely on the presence of abnormal q waves. Q waves of any size may be seen in the normal ECG in aVR and in lead III. In leads I, II, and aVF, q waves which are equal to or greater than 0.04 s in duration or which have a depth in excess of a quarter the height of the ensuing R wave are abnormal and, unless a defect of intraventricular conduction is known to be present, indicate myocardial infarction. The same is also true of abnormal q waves in aVL, except when the mean frontal plane QRS axis is equal to or more positive than +60°, for in this situation aVL becomes a cavity lead like aVR.

S–T-segment changes of infarction

Only changes in the QRS complexes provide definitive electrocardiographic evidence of infarction, but an S–T-segment shift occurs in the acute stages of Q-wave infarction. Strictly speaking, this shift is evidence of injury to, rather than infarction of, the myocardium. Thus, although in the vast majority of cases the development of typical S–T-segment elevation is followed by the development of definitive QRS changes, occasionally the ECG with S–T-segment elevation of myocardial injury will revert to normal within hours. This does not happen if definitive QRS changes of infarction are also present. It is marginally more likely to occur following the use of thrombolytic therapy but is still relatively uncommon. The essential change of myocardial injury is deviation of the S–T segment above the isoelectric line. The S–T-segment shift must be in excess of 1 mm to be significant. Minor degrees of S–T-segment elevation in the right precordial leads are very common in normal ECGs, and S–T-segment elevation of up to 2 mm may be accepted as being within normal limits in V_1 and V_2. Significant S–T-segment elevation occurs in transmural and subepicardial infarction in leads facing the infarct. S–T-segment depression occurs in leads facing the infarct when it is subendocardial. Secondary S–T-segment depression also occurs as a reciprocal change (see below) in leads opposite to those showing the primary changes of acute infarction.

T-wave changes of infarction

A variety of T-wave changes occur in association with myocardial infarction. These include flattened, biphasic, and inverted (negative) T waves. None of these changes is specific. Whilst they are always abnormal in leads V_4 to V_6 and in those limb leads showing clearly upright QRS complexes, they may be caused by factors other than infarction or ischaemia, including electrolyte changes, digitalis effect, pericarditis, myocarditis, changes in body position, and changes in oesophageal temperature. T-wave changes are never, in themselves, reliable indicators of infarction, although characteristic T-wave changes do occur in relation to the latter. The most typical T-wave change associated with infarction is the development of deep, symmetrically inverted T waves (Fig. 19).

Fig. 19 Deep, symmetrical T-wave inversion. This is not truly specific but is typically found in association with myocardial ischaemia or infarction.

The sequence of ECG changes in Q-wave infarction

Any combination of the QRS, S–T-segment, and T-wave changes described above may occur in relation to acute infarction of the myocardium, but commonly a typical sequence of changes can be recognized in relation to Q-wave infarction (Fig. 20). Typically, S–T-segment elevation (which is convex upwards) appears within hours of the onset of symptoms. At this stage no change in the QRS complex can be recognized. Within 1 to 3 days, reduction in the R-wave height occurs, abnormally deep and broad q waves develop, some reduction in the extent of S–T-segment elevation occurs, and there is development of T-wave inversion. After the first few days the S–T-segment elevation disappears completely. The deep, symmetrical T-wave inversion typically persists for weeks before reverting to normal. The changes in the QRS complex are usually permanent. The QRS changes may occasionally disappear altogether if the infarct is small and the myocardial scar subsequently shrinks.

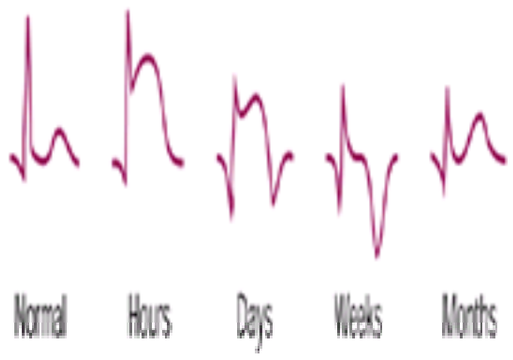

Fig. 20 Sequential changes in acute myocardial infarction.

Location of ECG changes in myocardial infarction

Primary ECG changes of the type described above occur in leads facing the infarct. It follows that the leads in which such primary changes occur indicate the location of the infarct (Table 1).

Reciprocal changes

In addition to the primary changes, 'reciprocal' changes occur in leads opposite those facing the infarct. Reciprocal changes are the inverse of primary changes (e.g. S–T-segment depression instead of S–T-segment elevation and tall, pointed T waves instead of symmetrical T-wave inversion). The inferior limb leads (II, III, and aVF) are reciprocal to the anterior leads (the precordial leads, lead I, and aVL) and vice versa. Examples of ECGs showing recent and old anterior and inferior infarctions are shown in Fig. 21, Fig. 22, Fig. 23, Fig. 24, and Fig. 25.

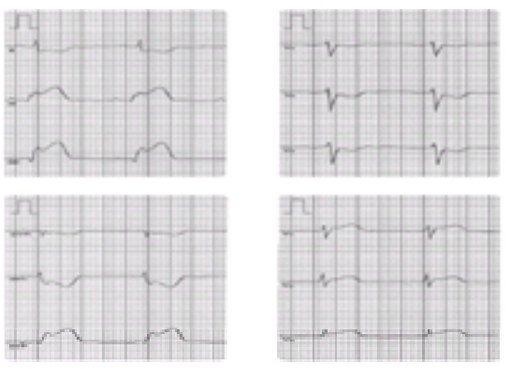

Fig. 21 Acute inferior myocardial ischaemic damage. Primary S–T elevation is visible in leads II, III, and aVF. S–T elevation is also visible in V_4–V_6, indicating that the damage extends to the lateral wall of the ventricle. There is reciprocal S–T-segment depression in I, aVL, aVR, and from V_1 to V_3

Fig. 22 Inferior myocardial infarction of intermediate age. The Q waves are abnormal in aVF (and also in III) and the q waves in II are borderline abnormal. There is T inversion in II, III, and aVF. The S–T segments are still minimally elevated in these leads. There is inversion of the terminal part of the T wave in V_5 and V_6, suggesting that the ischaemic area extends to the lateral wall of the ventricle. The T waves are strikingly tall in V_2 and V_3. This is not necessarily abnormal but could indicate true posterior ischaemia.

Fig. 23 Acute anteroseptal infarction. There is obvious S–T elevation in V_1–V_4 with minimal reciprocal S–T depression in III and aVF. There is obvious loss of initial R-wave height in V_2 and V_3.

Fig. 24 Old anterior myocardial infarction. There are QS complexes in $V_2$and V_3.

Fig. 25 Extensive anterior infarction. There are abnormally wide, abnormally deep Q waves from V_3–V_6 and in I. The T waves are of low voltage in most leads. This

latter abnormality is non-specific.

Pitfalls in the diagnosis of myocardial infarction

Left bundle-branch block

Left bundle-branch block so distorts the normal ECG that the usual criteria for the diagnosis of myocardial infarction are no longer applicable. It is sometimes possible to diagnose myocardial infarction in the presence of left bundle-branch block, but commonly the presence of left bundle-branch block obscures all other possible ECG diagnoses involving the QRS complexes, S–T segments, or T waves. The reason for this is that the two most important determinants of ventricular myocardial depolarization (and therefore also of repolarization) are radically altered in left bundle-branch block. These two determinants are (1) the direction of depolarization of the interventricular septum (which is reversed in left bundle-branch block), and (2) depolarization of the free wall of the left ventricle (which is appreciably delayed in left bundle-branch block). However, the changes of acute myocardial infarction can sometimes be recognized against a background of pre-existing left bundle-branch block, in which situation three independent criteria have been shown to have value in the diagnosis of acute infarction. These are: (1) S–T-segment elevation concordant with (i.e. in the same direction as) the QRS complex in a given lead; (2) S–T-segment depression of 1 mm or more in leads V_1, V_2, or V_3; and (3) S–T-segment elevation of 5 mm or more discordant with the QRS complex. Figure 26 shows an example of acute anterior infarction with pre-existing left bundle-branch block. There is in excess of 5 mm of S–T elevation concordant with the QRS in leads V_2 to V_4 and there is concordant S–T elevation in V_4 and V_5.

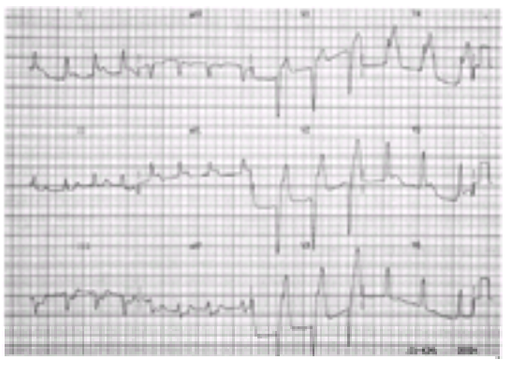

Fig. 26 Acute myocardial infarction with pre-existing left bundle-branch block. There is in excess of 5 mm of S–T elevation in leads V_2–V_4 and concordant S–T elevation in V_4 and V_5.

Right bundle-branch block

Right bundle-branch block does not interfere with the diagnosis of acute or of old myocardial infarction. (Fig. 27)

Fig. 27 Anteroseptal myocardial infarction with right bundle-branch block. Right bundle-branch block is diagnosed by the combination of (a) a total QRS duration of 0.12 s or more, plus (b) a secondary R wave in V_1. Anterior myocardial infarction is indicated by the presence of abnormally deep, abnormally wide Q waves in V_1–V_3. The presence of S–T elevation from V_2 to V_5 suggests that the infarct is recent.

Ventricular pre-excitation

When present, ventricular pre-excitation effectively precludes the diagnosis of left bundle-branch block and of myocardial infarction (see below). Very occasionally, substantial S–T elevation may provide an important clue to the diagnosis of acute infarction even when pre-excitation is seen.

Miscellaneous abnormalities

Abnormalities associated with the effects of drugs (including digitalis), hypokalaemia, hyperkalaemia, pericarditis, and hypothyroidism are discussed in other parts of this textbook. It is appropriate here, however, to mention ventricular pre-excitation, even though this is also dealt with in more detail elsewhere. The reason for this is that an incorrect diagnosis of bundle-branch block (right or left), ventricular hypertrophy (right or left), or myocardial infarction may easily be made if ventricular pre-excitation is present but not recognized.

Ventricular pre-excitation

Ventricular pre-excitation is found in approximately 0.1 per cent of the general population and failure to recognize it may lead to serious misdiagnosis. The term 'ventricular pre-excitation' implies that some part of the ventricular myocardium is depolarized (during normal sinus rhythm or any supraventricular rhythm) earlier than would be anticipated. This occurs as a result of the presence of one or more accessory (anomalous) pathways linking atrial and ventricular myocardium in such a way as to permit the depolarization wave descending through the atria from the sinoatrial node to bypass the atrioventricular node, partially or completely, intermittently or consistently. A variety of pathways exist which may, for example, pass (1) from atrial myocardium to ventricular myocardium, (2) from atrial myocardium to the distal part of the atrioventricular node, or (3) from the atrioventricular node to the ventricular myocardium. The commonest are those that link atrial and ventricular myocardium directly, and such pathways can exist at any point around the atrioventricular junction since, embryologically, the atrial and ventricular muscle masses were in continuity around the whole atrioventricular junction. These muscular remnants bear no resemblance to the junctional structures described by Kent; the use of the term 'Kent bundle' to describe the anomalous atrioventricular muscular connections that form the anatomical substrate for ventricular pre-excitation, though in widespread usage, is anatomically unjustifiable.

The presence of dual atrioventricular (AV) conduction routes (an accessory atrioventricular conduction pathway and the AV node) provides a substrate that facilitates the development of circus movement tachycardia. Patients with such pathways are at risk of developing paroxysmal tachycardia, but only a proportion do so: 10 per cent in the 20 to 39 age group and 36 per cent in the over-60s. In the presence of such a pathway, an appropriately timed atrial or ventricular premature beat may

initiate atrioventricular node re-entrant tachycardia (AVNRT).

Recognition of the presence and of the location of such pathways has assumed greater practical importance with the advent of the technique of radiofrequency ablation. This makes it possible to destroy, or at least to render non-functional, the accessory conduction pathway, thereby removing the anatomical substrate upon which the occurrence of AVNRT is dependent.

ECG appearances in the presence of anomalous AV pathways

Space constraints prevent a detailed discussion of this important topic, but the typical ECG appearances have the following features:

1. an abnormally short PR interval (0.11 s or less); and
2. an abnormally wide QRS complex (0.11 s or more), and
3. slurring of the initial 0.03 s of the QRS complex (a delta wave).

An example is shown in Fig. 28. This figure also illustrates the point that the presence of an accessory pathway does not guarantee that atrioventricular conduction will always occur via this route. Atrioventricular conduction can occur:

Fig. 28 Ventricular pre-excitation. (a) and (b) both show the essential features of ventricular pre-excitation. The PR interval is short in both and delta waves are seen in leads I, II, aVR, aVL, and V_2–V_6 in (a), and in leads I, II, III, aVR, aVL, aVF and V_2–V_6 in (b). In (a) the dominant R wave in V_1 and the 'pseudo RBBB' pattern indicates a left-sided AP. In (b) the small r waves in V_1 and the 'pseudo LBBB' pattern indicates a right sided AP.

1. always via the accessory pathway;
2. always via the AV node;
3. sometimes via the pathway and sometimes via the AV node;
4. simultaneously via the pathway and the AV node (giving 'fusion beats in respect of the QRS complexes.

When, in a given patient, conduction never occurs via the pathway, the 12-lead ECG never shows any evidence of ventricular pre-excitation and the pathway is said to be 'concealed'. Such pathways can sustain AVNRT in just the same way as revealed pathways: ventriculoatrial conduction in the re-entrant arrhythmia being via the pathway (which can therefore conduct backwards), and atrioventricular conduction occurring via the AV node.

When ventricular pre-excitation is seen on the 12-lead ECG no further interpretation of the electrocardiogram should be attempted in respect of the QRS complexes, S–T segments, or T waves, except in respect of assessment of the QRS complexes to try to determine the location of the accessory pathway. Ventricular pre-excitation may mimic left bundle-branch block, right bundle-branch block., left ventricular hypertrophy, right ventricular hypertrophy, and myocardial infarction.

Location of the accessory pathways

Accessory pathways may remain at any site around the atrioventricular junction, but the sites can be broadly categorized as:

1. left free wall (lateral) (55 per cent),
2. posteroseptal (25 per cent),
3. right free wall (15 per cent), and
4. anteroseptal (5 per cent).

The 12 lead ECG provides some information concerning the approximate location of any manifest accessory pathway (i.e. any pathway along which conduction is occurring at the time of the recording). Anterograde conduction along the pathway initiates early ventricular depolarization at the site of insertion of the pathway into the ventricular myocardium. Thus the initial part of the QRS complex (the delta wave in the case of a pre-excited beat) is determined by the ventricular location of the pathway and will be positive in V) in left sided accessory pathways (just as it is in right bundle branch block and in the case of left ventricular premature beats — two other situations in which left ventricular depolarization is initiated earlier than right ventricular depolarization). Similarly the initial part of the QRS in V, will be negative in right-sided accessory pathways (just as it is in left bundle branch block and in the case of right ventricular premature beats—two other cases which right ventricular depolarization is initiated earlier than left ventricular depolarization).

Numerous algorithms have been proposed to predict the location of accessory pathways from the QRS configuration. However, the majority of each QRS complex (i.e. excluding the delta wave) is determined by the relative contribution of (a) conduction along the accessory pathway and (b) conduction via the normal AV nodal route. This relative distribution varies greatly between subjects and can vary very significantly within subjects (being influenced, for example, by autonomic effects on AV nodal function). Furthermore the physical orientation of the heart within the chest, the presence of QRS abnormalities unrelated to pre-excitation, and the possibility of multiple accessory pathways are all potential confounding factors. It follows that the value of the surface ECG in determining the location of accessory pathways is limited.

As a general guide to the approximate location of an accessory pathway (AP), the following features are helpful. A left sided AP will typically give rise to a positive QRS in V_1 (i.e. a dominant R wave or an equiphasic RS complex) with a 'pseudo RBBB' pattern (Fig. 28(a)). A right sided AP will typically give rise to a small r wave in V_1 and V_2. There may be delta waves in V_6 with a 'pseudo LBBB' pattern (Fig. 28(b)). The smaller the r waves in the right precordial leads and the later in the precordial leads the RS transition (from dominant S in the right precordial leads to dominant R in the left precordial leads), the further to the right of the septum is the accessory pathway. The more posterior the location of the pathway, the more likely it is that there will be negative delta waves in the inferior leads and that there will be a superior QRS axis. The more anterior the pathway location the more likely it is that the QRS axis will be inferior.

The exercise ECG

Historical background

The present-day use of the exercise stress electrocardiogram in the diagnosis of coronary heart disease (in the form of the graded-exercise stress test—GXT) has evolved as a result of numerous observations and developments.

In 1908, Einthoven observed S–T depression after exercise but did not comment on it. In 1918, Blousfield recorded S–T-segment depression in leads I, II, and III during spontaneous angina. Feil and Siegel, in 1928, exercised patients known to have angina and observed S–T-segment and T-wave changes. Master and Oppenheimer, in 1929, developed an exercise test to assess 'circulatory efficiency' (using pulse and blood pressure) but did not use the ECG. In 1931, Wood and

Wolferth described S–T changes associated with exercise, but felt that the test was too dangerous to use in patients with coronary disease. In 1932, Goldhammer and Scherf reported S–T depression in 75 per cent of patients with angina—a figure indicating a remarkably similar false-negative rate to that of current-day studies. In 1941, Master and Jaffe suggested that the ECG recorded before and after exercise could be used to detect 'coronary insufficiency'. Paul Wood and colleagues, in 1950, at the National Heart Hospital in London, described their experience of a test in which the patients had to run up 84 steps adjacent to the laboratory. They showed an 88 per cent reliability (compared with 39 per cent in the Master's test) and emphasized that the amount of work required should be adjusted to the patient's physical capacity.

The era of modern, stress testing began in 1956 when Bruce reported his findings and established guidelines for a standardized GXT procedure. Subsequently, the application of Bayesian techniques of analysis; the addition of nuclear techniques (myocardial scintigraphy and cardiac blood pool analysis) and echocardiographic stress testing; and the use on non-exercise stress techniques (using dipyridamole, dobutamine, and adenosine) have all brought greater sophistication and applicability to cardiac stress testing.

This section will be confined to the use of the exercise stress ECG in the assessment of the heart and circulation and, in particular, to the role of the GXT in the detection and assessment of ischaemic heart disease.

Current usage

Although the exercise ECG may be used for several purposes, its commonest uses are in the diagnosis and assessment of ischaemic heart disease (IHD). In this respect, however, it is extremely important at the outset to recognize that the test has a significant false-negative rate, even in populations with an appreciable prevalence of IHD, and that the false-negative rate may be unacceptably high in populations with a low prevalence. The test is therefore of very limited value in screening low-risk, asymptomatic subjects. Most subjects who have undergone exercise stress testing as a screening procedure and who subsequently experience sudden cardiac death are found in retrospect to have had a normal exercise test result. A meta-analysis of 147 consecutive studies involving a total of 24 074 patients who had undergone both exercise stress testing and coronary angiography revealed sensitivities ranging from 23 to 100 per cent (mean 68) and specificities ranging from 17 to 100 per cent (mean 77). In patients with multivessel coronary disease the sensitivities ranged from 40 to 100 per cent (mean 81) and the specificities from 17 to 100 per cent (mean 66). For patients with single-vessel disease a positive GXT is most likely for lesions in the left anterior descending artery. Patients with lesions in the circumflex artery are least likely to give a positive result, while those with lesions in the right coronary artery occupy an intermediate position.

Exercise electrocardiography is also used in the estimation of prognosis in patients with known IHD, for risk stratification following myocardial infarction, for screening of professionals in high-risk situations (e.g. pilots and professional athletes), and in the assessment of some cardiovascular symptoms (e.g. palpitations, tachyarrhythmias, and syncope) when these are exercise related. The database for the evaluation of the usefulness of the technique in these situations is less well established than is the case in relation to its use in the assessment of IHD.

Exercise testing in females

The specificity of exercise testing is less in women than in men. It seems likely that this is, in part at least, related to their lower prevalence of IHD. However, biological differences might be relevant. It has been suggested that oestrogens (with certain chemical structural similarities to digitalis) contribute to S–T-segment depression, but it has also been pointed out that women secrete more catecholamines during exercise than men. Both of these postulated mechanisms have been thought possibly to act via coronary vasoconstriction.

Risks

High-level exercise carries a cardiovascular mortality risk, and a maximal-exercise stress ECG is, basically, supervised high-level exercise. Inevitably, therefore, a GXT carries a risk, but multiple studies have shown the risk to be remarkably low. In 1971 a survey of 73 medical centres summarized the risks in relation to approximately 170 000 stress tests. A total of 16 deaths were reported (mortality rate 0.01 per cent), and 0.04 per cent required admission within 24 h because of arrhythmia or prolonged chest pain. The risks are greater when the test is conducted soon after an ischaemic event. Even in this situation, however, the test is still remarkably safe. A survey of 151 941 tests undertaken within 4 weeks of acute myocardial infarction revealed a mortality rate of 0.03 per cent and a 0.09 per cent rate of non-fatal reinfarction or (successfully resuscitated) cardiac arrest.

Contraindications

Exercise stress testing is contraindicated to some extent whenever the pre-existing clinical state indicates a significantly increased risk of mortality or morbidity. In some situations the additional risk is so great as to constitute an absolute contraindication. In other situations the presenting clinical state indicates the need for more vigilant supervision than usual. Exercise, whilst not 'contraindicated', is of limited or negligible value in situations where abnormalities of the resting ECG make interpretation of the exercising record difficult or impossible.

Absolute contraindications

These include:

- acute ischaemic syndromes:
  - unstable angina,
  - suspected acute myocardial infarction,
  - known acute myocardial infarction within 5 days;
- known left main-stem stenosis;
- acute myocarditis;
- acute pericarditis;
- severe aortic stenosis;
- severe congestive cardiac failure;
- recent acute pulmonary oedema;
- current acute systemic illness;
- absence of trained supervisory staff or of resuscitation equipment;
- failure of the patient to understand the procedure or to give informed consent

Situations requiring intensive supervision

These include:

- known severe coronary disease;
- known moderate or mild aortic stenosis;
- severe or moderate systemic hypertension;
- severe or moderate pulmonary hypertension;
- severe impairment of ventricular function;
- known history of ventricular tachycardia;
- known history of supraventricular tachycardia;
- existing second- or third-degree atrioventricular block;
- hypertrophic cardiomyopathy;
- severe congestive cardiomyopathy;
- known hypokalaemia.

Situations where interpretation of the exercising record is difficult or impossible

Abnormalities of the resting ECG that preclude effective interpretation of the exercising record include:

- left bundle-branch block;
- ventricular pre-excitation;
- currently paced ventricular rhythm;
- widespread S–T,T changes;
- widespread QS complexes (especially across the precordial leads).

Procedures

Lead positioning

During exercise it is not possible to maintain adequate physical and electrical stability in relation to limb lead connections at their usual (for the standard 12-lead ECG) location. Instead, the 'limb' lead electrodes are positioned on the torso: with the right and left arm connections situated at the most lateral aspects of the respective infraclavicular fossa, and the right and left leg electrodes positioned halfway between the respective anterior iliac crest and the rib margin. This Mason–Likar modification of the standard 12-lead ECG results in a rightward shift of the axis, which is more marked in the standing than in the recumbent position. This rightward shift (typically giving an axis of +90° to +120°) sometimes results in the appearance of new q waves in aVL (but it should be noted that, whenever the mean frontal plane QRS axis is +90° or more positive, aVL becomes a 'cavity' lead and the finding of a q wave in a cavity lead is not abnormal).

Exercise protocols

Various exercise modalities can be used, including static or dynamic exercise, arm or leg exercise, and bicycle ergometry or treadmill procedures, but the commonest procedure by far is dynamic treadmill exercise. The most popular protocol is the Bruce protocol. This has a starting walking speed of 1.7 mph (1 km/h) at a 10 per cent slope, giving an oxygen consumption of about four metabolic equivalents, which in general use has proved very satisfactory. One major advantage of the Bruce protocol is that large diagnostic and prognostic databases exist for this test.

Exercise endpoints

Exercise is continued until one of the following endpoints is reached:

- subject wishes to stop (chest pain, dyspnoea, fatigue, leg weakness, light headedness, exhaustion, claudication);
- target endpoint is reached (target heart rate or exercise level);
- operator terminates the procedure:
  - early or severe (>2 mm) S–T depression,
  - S–T elevation,
  - ventricular tachycardia,
  - second- or third-degree heart block,
  - fall in heart rate (20 beats/min or more),
  - fall in blood pressure (20 mmHg or more),
  - perceived patient distress,
  - failure of monitoring equipment.

Assessment of the exercise electrocardiogram

As the heart rate increases with exercise, the PR, QRS, and QT intervals all reduce in normal subjects. The P-wave amplitude increases and the atrial repolarization wave (the Ta wave) increases in amplitude.

Atrial repolarization wave

Sinus tachycardia is associated with an increase in the depth and duration of the Ta wave. This gives a curved upsloping segment between the QRS complex and the T wave, often misconstrued as S–T-segment depression, and a common cause of an incorrect conclusion that an exercise test is positive. A Ta wave can be recognized when it is noted that back-extrapolation of a depressed S–T segment shows it to be continuous with downsloping depression in front of the QRS complex (Fig. 29).

Fig. 29 Negative exercise ECG. This ECG is the record taken at peak exercise in a maximal stress test. The heart rate is 180 beats/min. There is no S–T depression. A prominent atrial depolarization wave (Ta wave) is clearly seen in II, III, aVF, and V_4–V_6 (best in II). As would be expected aVR shows an 'upside down' Ta wave (since it is a cavity lead).

Standard criteria for a positive test

By definition, a positive test occurs when 1 mm (0.1 mV) of horizontal or downsloping S–T depression occurs during exercise (usually at peak exercise) or in the early recovery period. Upsloping S–T depression is less reliably predictive of the presence of coronary disease than flat or downsloping S–T depression. Greater (than 1 mm) degrees of S–T depression are more reliably predictive of coronary disease, as are S–T depression occurring earlier in the exercise period, more prolonged S–T depression, and a more widespread (within the ECG recording leads) S–T change. Figure 30 shows an example of significant (2 mm) S–T depression in the left precordial leads.

Fig. 30 Positive exercise ECG. This ECG is the record taken at peak exercise in a maximal stress test. The heart rate is only 136 beats/min. The test was stopped before the 'target' heart rate was reached because the patient had chest pain and the test was already clearly giving a positive result. There is 2 mm of S–T depression in the left precordial leads.

Sometimes the S–T depression is most marked or only occurs during the recovery period (Fig. 31).

Fig. 31 Positive exercise ECG. Record (a) was taken at peak exercise. It is not abnormal. It shows a prominent atrial repolarization wave. Record (b) was taken 6 min into the recovery period (after 9 min of exercise). Although no S–T depression occurred during exercise (a) there is clearly abnormal S–T depression during recovery. Coronary angiography confirmed the presence of significant disease in the anterior descending and diagonal branches of the left coronary artery.

An example of a negative stress test is shown in Fig. 29.

Interpretation of the test result

Positive or negative. Pre- and post-test probability. Bayesian analysis

The criterion for positivity of an exercise ECG is widely accepted as being 1 mm of flat or downsloping S–T segment depression during or early after exercise. The interpretation of a positive result is more problematical. Usually the question being asked is whether or not the test result indicates a high probability that the patient has coronary heart disease. Bayesian analysis of this problem indicates the enormous impact of the prevalence of coronary disease in the population group from which the subject is drawn (the prior probability of the condition) in answering this question. In essence, Bayes's theorem states the self-evident truth that interpretation of the future (probability of disease in the given subject) is helped by a knowledge of past experience (prevalence of the disease in the population from which the subject comes) as well as present observations (the test result).

Bayesian analysis expresses the probability that a subject with a positive exercise test result does actually have coronary heart disease, in terms of the sensitivity and specificity of the test and the prevalence of the disease, as follows:

$$\text{Probability} = [\text{prevalence} \times \text{sensitivity}]/[\text{prevalence} \times \text{sensitivity} + (1 - \text{prevalence})\ (1 - \text{specificity})\ ].$$

If one inserts reasonable (on the basis of published results of exercise testing) values for the sensitivity (say 0.8, i.e. 80 per cent) and specificity (say 0.9, i.e. 90 per cent) into this equation and then looks at the impact of variations in prevalence on the predictive value of a positive test, then the values shown in Table 2 are obtained. Clearly the false-positive rate is very high in low-prevalence populations (the healthy population) and this limits the value of exercise testing as a screening procedure in asymptomatic, presumptively healthy groups.

The likelihood that a subject with a positive stress-test result has coronary artery disease (the 'post-test or posterior probability') is therefore dependent on the prevalence of the disease in the population from which the subject is derived (the 'pretest or prior probability'). Equally, of course, the likelihood that a subject with a negative stress-test result does not have coronary artery disease (the 'post-test probability') is also dependent on the prevalence of the disease in the population from which the subject is derived (the 'pretest probability'). This concept is shown graphically in Fig. 32.

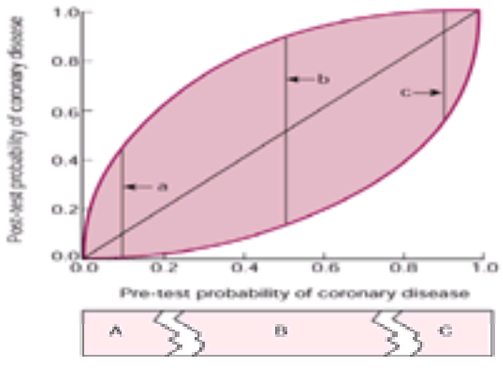

Fig. 32 Predictive value of positive and of negative exercise stress tests. The pretest probability of the condition (prevalence) is shown on the abscissa and the post-test probability (likelihood of the condition in the light of the test result and in the population from which the subject exercised was drawn) on the ordinate. The 45° line shows the impact of a completely non-predictive test result (for example, tossing a coin), the post-test probability being unchanged by the test result. Curves for clearly positive (= 2 mm flat or downsloping S–T depression) and clearly negative (no S–T depression at peak exercise with target heart rate achieved) test results are shown. The upper curve is for positive and the lower curve for negative results. The vertical distance between the curves shows the relative diagnostic 'benefit' (additional diagnostic probability) from the test result. This is greatest (b) where the pretest probability is intermediate (B). In a low-prevalence population (A), such as young, asymptomatic persons being screened, the pretest probability of the condition is (by definition) very low, and even the contribution of a strongly positive test result (upper curve) only results in a post-test probability of 40 per cent, i.e. the false-positive rate in this low-prevalence population is 60 per cent. In such a low-prevalence population a clearly negative result (lower curve), i.e. one concordant with the initial statistical probability, would be powerfully effective in confirming the initial likelihood. In this case a pretest probability of about 10 per cent would give way to a very low post-test probability of about 1 per cent. In a high-prevalence population (C) the pretest probability in this case is about 89 per cent and the post-test probability of a positive result would give about a 99 per cent probability of coronary artery disease. In such a population a clearly negative result would give about a 55 per cent probability of coronary disease, i.e. there would be a very

significant false-negative rate. In general, therefore, a positive exercise stress-test result in a high-prevalence population is likely to be a true-positive and a negative result in a low-prevalence population is likely to be a true-negative. Conversely, a positive result in a low-prevalence population and a negative result in a high-prevalence population are both significantly likely to be false results. The stress test will make its greatest diagnostic contribution (b) where the prevalence is intermediate (B), i.e. where the initial diagnostic position is unclear.

Degree of abnormality of the test result

The degree of abnormality of the stress-test result also has a powerful bearing on the predictive value of the result. Greater or lesser degrees of abnormality may be shown by:

1. the depth of the S–T depression;
2. the time of onset of the S–T depression;
3. the duration of the S–T depression;
4. the number of ECG leads showing significant S–T depression.

Only in respect of the depth of S–T depression, however, is there currently a large database of information. The effect of varying degrees of S–T depression on the predictive value of a positive test is shown in Fig. 33.

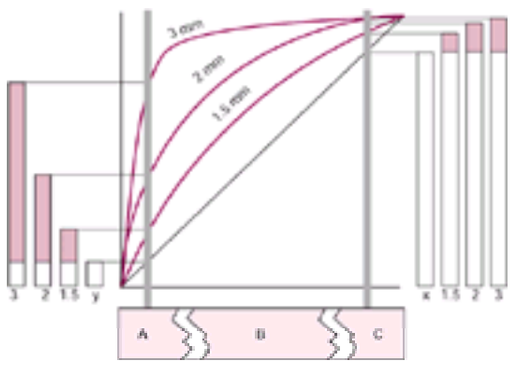

Fig. 33 Predictive value of different degrees of positivity of exercise stress tests. In a high-prevalence population (C) the pretest probability of coronary disease is high (×) and positive test results of increasing degree (1.5, 2, and even 3 mm S–T depression) only minimally increase the probability of the condition. In a low-prevalence population (A) a 1.5-mm and a 2-mm S–T depression result still leave less than a 50 per cent probability that the subject has significant ischaemic heart disease. In such a population only a really strikingly positive result (3-mm depression) would result in a significant (75 per cent) probability of the condition.

Confounding ECGs

Interpretation of the exercise ECG is dependent upon the assessment of the timing, duration, degree, and distribution of S–T depression occurring during exercise. When the pre-exercise ECG shows significant S–T-segment abnormalities (left bundle-branch block, ventricular pre-excitation, ventricular paced rhythm, non-specific S–T-segment depression, etc.), interpretation of changes in the S–T segments occurring during exercise is virtually impossible. In these situations the exercise stress ECG makes no useful contribution to the diagnosis of or to the exclusion of significant coronary artery disease.

15.3.3 Echocardiography

A. P. Banning

Introduction

Modern transthoracic echocardiography combines real-time two-dimensional imaging of the myocardium and valves with information about velocity and direction of blood flow obtained by Doppler and colour flow mapping. It is non-invasive and a complete examination can be performed in most patients in less than 30 min.

Doppler echocardiography has revolutionized the diagnosis and follow-up of patients with valvular heart disease. Serial cardiac catheterization to assess severity and progress of valvar stenosis has been almost completely superseded by echocardiography, and the role of invasive investigation is increasingly limited to assessment of the coronary arteries prior to corrective surgery.

Transoesophageal echocardiography is available in larger cardiac centres. Under sedation, an ultrasound probe is passed into the oesophagus to a position behind the heart producing excellent resolution of cardiac structures. It is used diagnostically in many emergency situations, including aortic dissection and suspected prosthetic mechanical valve dysfunction, and as an additional method of monitoring cardiac performance during cardiac and non-cardiac surgery.

The dramatic expansion in the availability of echocardiography has been accompanied by continuing technological development. Stress echocardiography can be used to detect occult coronary disease and predict cardiac risk, whilst the administration of contrast agents may allow visualization of myocardial perfusion. Although three-dimensional reconstruction is currently a research tool, real-time three-dimensional imaging is an increasingly realistic goal. In the future, these and other developments seem likely to ensure that echocardiography will maintain its central role in the diagnosis and management of most cardiac and many non-cardiac patients.

Principals of echocardiography

The transducer used for most echocardiographic examinations contains piezo-electric crystals that emit ultrasound frequencies of 2.5 to 5 MHz. Most of the sound energy is scattered or absorbed, but reflection occurs at interfaces between tissues of different acoustic impedance (e.g. between blood and muscle). The transducer collects these reflections and the time delay between emission and reception is calculated. This allows the depth of the reflection to be derived and its position to be displayed on a screen as a dot (pixel). The brightness of the dot is related to the magnitude of the reflected signal. In general, higher frequency transducers allow better discrimination between structures but more ready attenuation leads to reduced penetration.

There are three main echocardiographic techniques: cross sectional (two-dimensional), M-mode, and Doppler.

Cross sectional echocardiography (two-dimensional echo)

Cross sectional (two-dimensional) images are constructed as the ultrasound beam sweeps across the heart. Between 50 and 100 cross sections are presented each second and this gives the impression of a moving picture. These images are readily interpretable by an observer with a knowledge of cardiac anatomy and this technique is the cornerstone of modern echocardiography.

M-mode echocardiography

M-mode echocardiography preceded modern two-dimensional imaging. Unlike two-dimensional imaging, which uses a series of sweeps across the heart, M-mode uses a single static beam of very frequent ultrasound pulses. The narrow beam is analogous to a vertical mineshaft passing through various layers of rock. Displayed in real time this results in reflections from cardiac structures being displayed as horizontal lines with superficial structures at the top of the screen and the deeper structures at the bottom. These data are interpretable when one knows which structure each line represents and the technique has excellent spatial resolution. With the advent of two-dimensional and Doppler, M-mode is now principally used for measurement of cardiac chamber dimensions and observation of the relative movement of cardiac structures to each other, for example the relationship of the anterior leaflet of the mitral valve to the septum in hypertrophic cardiomyopathy.

Doppler echocardiography

The Doppler principal allows the velocity and direction of movement of an object (or moving blood in the case of cardiac ultrasound), to be calculated from the shift in the frequency of a reflected waveform relative to the observer. Cardiac imaging employs pulsed wave, continuous wave, and colour Doppler techniques.

Pulsed wave Doppler allows information about flow to be obtained from a particular point within the heart. The range of detectable velocities is limited, and it is used for sampling normal and low velocities, for example mitral valve flow.

Continuous wave Doppler measures the peak velocity encountered along the ultrasound beam and is particularly valuable for measuring high velocity jets, for example aortic stenosis. It is important to remember that failure to align the transducer exactly parallel to flow results in measurement of artefactualy low velocities and an underestimation of the valvular stenosis.

Colour Doppler allows a dynamic representation of the direction and velocity of flow to be superimposed onto a two-dimensional image of the heart. Velocities towards the transducer are coded in red and velocities away are coded in blue. Turbulent flow produces variable velocities and results in a mosaic pattern that is ideal for characterization of regurgitant lesions. This technique is now so sensitive that it can detect trivial regurgitation during the closure of many normal heart valves.

Imaging

Imaging is usually performed with the patient lying on their left hip in the left lateral position, with their left arm behind their head (Fig. 1). Ultrasound cannot travel through bone and thus cardiac imaging is performed in intercostal spaces to the left of the sternum and at the apex of the heart in the axillary line. These 'echo

windows' provide standard views described as the parasternal short and long axis and apical two, four, and five chamber. Useful additional views can be obtained from the subxiphoid and suprasternal approach in some patients.

Fig. 1 Patient in the standard position undergoing transthoracic echocardiography.

A standard echo examination involves two-dimensional imaging from the parasternal approach followed by M-mode measurements and colour Doppler. Apical two-dimensional views are followed by colour and continuous and pulsed Doppler interrogation.

Applications of echocardiography

Valvular heart disease

Transthoracic Doppler echocardiography is the investigation of choice for patients with suspected valvular heart disease. All four cardiac valves can be visualized and interrogated by Doppler. Concomitant abnormalities in ventricular performance can be assessed simultaneously.

Aortic stenosis

Two-dimensional echocardiography can usually image the aortic valve cusps and if they are thin and freely mobile it is unlikely that there is significant aortic stenosis. However, if the valve cusps are thickened and calcified, interrogation by continuous wave Doppler is mandatory. The severity of aortic stenosis is expressed as the peak pressure difference (or gradient) across the valve, and is calculated from the maximum flow velocity (V) using the modified Bernoulli equation (pressure gradient=$4V^2$). The gradient measured by continuous wave Doppler is not directly comparable with a gradient measured at cardiac catheterization, which can lead to confusion. Doppler measures the peak instantaneous gradient and is higher than peak-to-peak gradient measured by catheterization (Fig. 2). In patients with normal left ventricular systolic function a peak-to-peak catheter gradient of 50 mmHg suggests significant aortic stenosis (Fig. 3 and Plate 1): this corresponds to a peak instantaneous gradient measured by Doppler of about 70 to 80 mmHg.

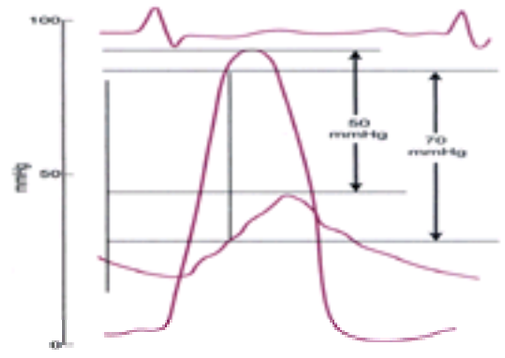

Fig. 2 Representative pressure traces of left ventricular pressure (lower line) and aortic pressure (upper line). The measured gradient at cardiac catheterization is the difference between the two peak pressures (peak-to-peak) and in this case it is 50 mmHg. Continuous wave Doppler measures the maximum difference between the pressures or the peak instantaneous gradient which in this case is 70 mmHg.

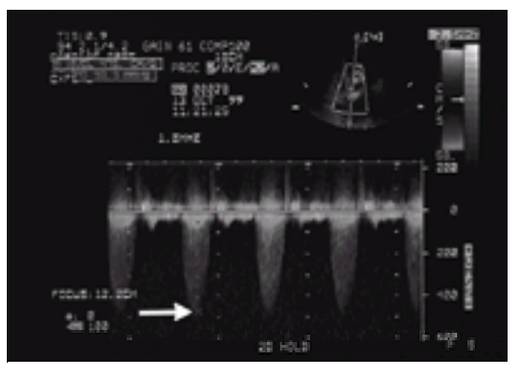

Fig. 3 Apical continuous wave Doppler across the aortic valve in a patient with severe aortic stenosis. The peak velocity (arrow) is greater than 4.5 m/s consistent with a peak instantaneous gradiant across the aortic valve of 90 mmHg. (See also Plate 1.)

When chronic critical outflow obstruction results in declining left ventricular function and reduced cardiac output, the gradient produced by any degree of valve obstruction also falls. Doubt about the severity of the stenosis can usually be resolved by calculating the valve area using the continuity equation which uses data from Doppler and two-dimensional echo. In experienced hands this provides valuable additional information, but accurate measurement of the left ventricular outflow tract diameter can be difficult and if the findings are not consistent with other data, the investigation should be either be repeated or the patient should be referred for cardiac catheterization.

Aortic regurgitation

Assessment of the mechanism and severity of aortic regurgitation requires a combination of all three echo modalities. M-mode may demonstrate fluttering of the anterior leaflet of the mitral valve and in the setting of acute severe aortic regurgitation, premature closure of the mitral valve. Two-dimensional will occasionally demonstrate prolapse of one more of the aortic cusps, but even severe aortic regurgitation can occur through an aortic valve that appears to be structurally normal.

The severity of aortic regurgitation can be estimated using continuous wave and colour Doppler, although assessment can be difficult as it is influenced by left ventricular function. Doppler-derived pressure half-time and measurement of regurgitant fraction and/or flow convergence zone are valuable when there is uncertainty

over lesion severity. M-mode and colour Doppler can be combined and when the regurgitant jet fills more than 50 per cent of the left ventricular outflow tract the regurgitation is classified as severe.

In patients with severe asymptomatic aortic regurgitation, a serial increase in left ventricular dimensions or a progressive fall in ejection fraction are indications for surgery. However, any increase in ventricular dimension should be at least 0.5 cm before it is regarded as significant given the limited reproducibility of echocardiographic parameters.

Mitral stenosis

Mitral valve stenosis is well visualized using either M-mode or cross-sectional echocardiography. Its severity can be determined by estimating the area of the valve orifice either by direct planimetry of the two-dimensional short axis image or from the Doppler pressure half-time (MVA=220/Pt $_{1/2}$). A valve area of less than 1.0 cm^2 indicates severe mitral stenosis. Transthoracic echocardiography is also used to assess the suitability of the mitral valve for balloon dilation, although transoesophageal imaging is necessary to exclude left atrial thrombus.

Mitral regurgitation

Transthoracic echocardiography will usually demonstrate the mechanism and severity of mitral regurgitation. Two-dimensional imaging identifies abnormalities of the valve leaflets and colour flow shows jet direction and area. Severe mitral regurgitation is suggested by increased left ventricular end-diastolic dimension and hyperdynamic wall motion due to volume overload. Precise quantification of the amount of regurgitation is demanding as it is influenced by left ventricular function, the direction of the jet, and left atrial size. Various algorithms have been devised to improve quantitation of mitral regurgitation, including measurement of the flow convergence zone and the PISA method, but most centres simply classify the extent of regurgitation as mild, moderate, or severe.

Pulmonary and tricuspid valve disease

In adults, two-dimensional imaging of the pulmonary valve may be difficult, particularly if there is lung disease. Despite this, accurate Doppler information is usually obtainable. Tricuspid stenosis is very uncommon but some degree of tricuspid regurgitation is detectable even in healthy individuals. Measurement of the peak velocity of tricuspid regurgitation (V) is valuable as in the absence of pulmonary valve disease it can be used to estimate pulmonary artery systolic pressure:

$$\text{PA systolic pressure (mmHg)} = 4V^{2+}\text{right atrial pressure (usually assumed to be 5–10 mmHg)}$$

Prosthetic valves

Transthoracic echo is commonly performed as part of the routine follow-up of prosthetic valves. It is usually able to assess biological valves accurately, but for mechanical mitral valve prostheses in particular, attenuation artefact produced by the metal may be problematic. Transoesophageal imaging is recommended when transthoracic imaging is suboptimal or if improved resolution is required, for example suspected prosthetic valve endocarditis.

Abnormal left ventricular function

In most patients a full transthoracic echo study will confirm or refute a clinical suspicion of left ventricular dysfunction and identify the likely aetiology of any abnormality. Systolic and diastolic left ventricular function can be assessed and a variety of methods can be used to derive an estimate of left ventricular ejection fraction. In patients with ischaemic heart disease, assessment of regional wall motion is valuable and may occasionally demonstrate evidence of aneurysm formation. Left ventricular hypertrophy is detected by echocardiography and a measurement of left ventricular mass can be derived.

Echocardiography is a pivotal investigation in suspected heart failure, particularly as an ejection fraction of less than 40 per cent has been used as an inclusion criteria for most therapeutic trials in this condition. Community studies have demonstrated that many patients treated with diuretics for mild heart failure (usually ankle swelling) do not have left ventricular systolic impairment, and screening with echocardiography was initially recommended before initiation of treatment with angiotensin-converting enzyme inhibitors. However, subsequent studies have shown that impaired systolic function is very unlikely when the ECG and clinical examination are normal, and conversely that angiotensin-converting enzyme inhibitors can be initiated without waiting for echocardiography in patients with evidence of ischaemic heart disease and radiographic evidence of pulmonary oedema, as the ejection fraction is almost invariably less than 40 per cent under these circumstances.

Transthoracic echo may detect mural thrombus, particularly in patients with impaired systolic ventricular function. However, differentiation between thrombus and myocardium can be problematic at the left ventricular apex and tissue harmonic imaging and/or contrast agents may be necessary.

Minor concentric left ventricular hypertrophy is common in patients with hypertension. In hypertrophic cardiomyopathy, two-dimensional imaging may demonstrate asymmetrical septal hypertrophy with disproportionate thickening of the interventricular septum compared with the left ventricular free wall, or dramatic concentric hypertrophy with left ventricular cavity obliteration. Other characteristic features of hypertrophic cardiomyopathy include systolic anterior motion of the mitral valve (Fig. 4 and Fig. 5 and Plate 2) and partial mid-systolic closure of the aortic valve, which usually correlates with the presence of outflow tract obstruction. In the absence of conditions that may induce ventricular hypertrophy, for example aortic stenosis, these findings are diagnostic of hypertrophic cardiomyopathy. Colour Doppler can demonstrate turbulence in the outflow tract and continuous wave Doppler may detect characteristic 'dynamic' gradients that increase in severity as systole progresses. Other associated echocardiographic abnormalities in hypertrophic cardiomyopathy include mitral regurgitation and severe diastolic dysfunction.

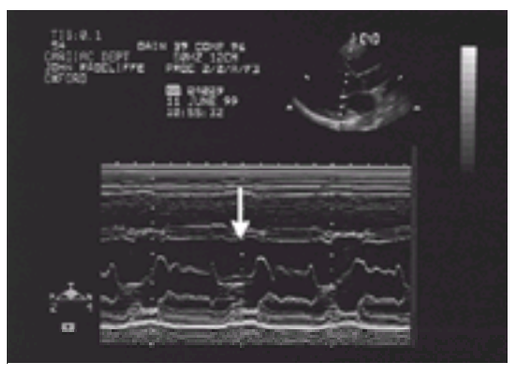

Fig. 4 M-mode echocardiogram through the mitral valve in a normal patient. Opening of the leaflets during ventricular diastole and closing during systole (arrow) can be observed. Contrast the behaviour of the mitral valve with that in Fig. 5. (See also Plate 2.)

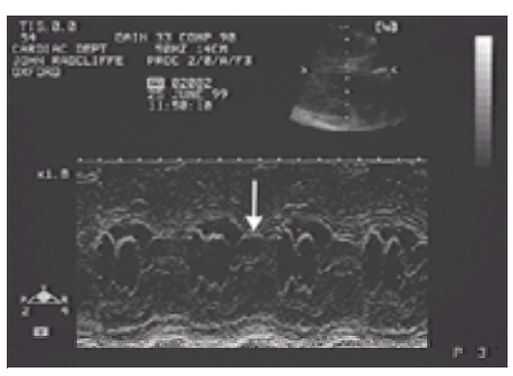

Fig. 5 M-mode echocardiogram through the mitral valve in a patient with obstructive hypertrophic cardiomyopathy. Closure of the valve during systole is accompanied by marked movement of the valve apparatus towards the left ventricular septum (arrow)—this is referred to as systolic anterior motion (SAM) of the mitral valve.

Atrial fibrillation

Echocardiography readily excludes a structural cause for atrial fibrillation (e.g. mitral stenosis) and facilitates thromboembolic risk stratification. It also allows measurement of left atrial dimension, which is valuable as cardioversion is less likely to be successful when this is large.

Following an embolic event/stroke

Echocardiography is the investigation of choice when a cardiac source of an embolus is suspected. It is mandatory in all patients presenting with embolic occlusion of a peripheral artery, or thromboembolic episodes in more than one vascular territory. Echocardiography should not, however, be performed in circumstances when the result is unlikely to influence patient management, but in patients with ischaemic stroke and a low likelihood of atheromatous arterial disease an echo can be considered as occasionally it will detect occult abnormalities such as atrial myxoma or cardiac thrombus.

Pericardial disease

Echocardiography readily diagnoses the presence of pericardial fluid and is useful when percutaneous drainage is attempted. Echocardiographic signs of pericardial tamponade include exaggerated respiratory variation in the mitral valve Doppler, presystolic closure of the aortic valve, and (particularly) right atrial and right ventricular diastolic collapse. Constrictive pericarditis is a difficult diagnosis to make using standard echocardiographic techniques and patients complaining of episodic breathlessness/fluid retention with characteristic abnormalities of the venous pressure require particularly careful interrogation by Doppler.

Pulmonary embolism

Echo can be useful in patients with pulmonary embolism as it can demonstrate right ventricular dilation and/or impaired right ventricular systolic function. Tricuspid regurgitant velocity can be used to estimate pulmonary artery systolic pressure, although it is unusual for this to be more than 70 mmHg acutely. Exceptionally, two-dimensional imaging may show thrombus within the right heart and/or the proximal pulmonary arteries. Although echocardiography is useful diagnostically when it demonstrates features consistent with pulmonary embolism, it cannot exclude the diagnosis.

Infective endocarditis

Echocardiography cannot be used to exclude endocarditis but is valuable when endocarditis is suspected clinically but there is insufficient data to make a formal diagnosis. Under these circumstances a typical vegetation detected by an experienced observer is regarded as a major criterion in the Duke diagnostic classification, and this may facilitate appropriate management. Transoesophageal echo should be performed when there is a suspicion of aortic root abscess, if prosthetic endocarditis is suspected, or occasionally in cases where there is persistent diagnostic doubt and the additional sensitivity and spatial resolution might be valuable.

Congenital heart disease

Echocardiography is the diagnostic modality of choice for patents with suspected congenital heart disease. Detailed transthoracic cardiac imaging is possible in co-operative babies and children but occasionally sedation or a short anaesthetic may be required. Rates of cardiac catheterization have been reduced by miniaturization of transoesophageal probes that facilitate diagnosis and follow-up of complex congenital heart disease. Fetal echocardiography is performed when surveillance obstetric ultrasound is abnormal or in cases where previous history suggests a possible cardiac problem.

Transoesophageal echocardiography

Transoesophageal echocardiography is available in cardiac centres and some smaller hospitals. The ultrasound probe is similar to the endoscope used for upper gastrointestinal investigation, except that there are no optical fibres. With the patient under sedation, the probe is manipulated into the oesophagus where its position behind the heart produces excellent resolution, particularly of posterior cardiac structures.

Transoesophageal echocardiography is an invasive procedure and the patient's written consent is required. After fasting for a minimum of 4 h, local anaesthetic spray (10 per cent lidocaine) is applied to the upper pharynx and the patient is usually sedated with a short acting benzodiazopine (e.g. midazolam). Blood pressure and oxygen saturation are monitored throughout and both resuscitation equipment and the benzodiazepine antagonist flumazanil should be readily available (Fig. 6).

Fig. 6 Patient in the standard position undergoing a transoesophageal echocardiogram. Non-invasive monitoring of pulse rate, oxygen saturation, and blood pressure is mandatory when intravenous sedation is being administered.

Even though transoesophageal echo is commonly performed in high-risk haemodynamically unstable patients, the rate of serious complications (aspiration and oesophageal rupture/tears) is less than 1 per cent. Absolute contraindications to transoesophageal echo include oesophageal tumours, strictures, varices, and diverticulae.

Who should have a transoesophageal echocardiogram?

The principal indications for transoesophageal echocardiography are listed in Table 1. Its principal advantages over transthoracic imaging are improved spatial resolution and the ability to image posterior structures such as the left atrium and descending aorta. It is valuable in a number of emergency situations including suspected aortic dissection, prosthetic mechanical valve failure, and possible endocarditis. It may be used to image patients in whom data from transthoracic imaging is unsatisfactory because of obesity, lung disease, or chest deformity. Other indications include screening for left atrial thrombus before cardioversion of atrial fibrillation and monitoring cardiac performance during cardiac and some non-cardiac surgery.

Valve disease

Patients with mitral stenosis are at particular risk of thromboembolism and transthoracic echo has limited sensitivity for the detection of left atrial thrombus (Fig. 7).

Transoesophageal echocardiography is recommended in those with mitral stenosis ifembolic events occur despite therapeutic anticoagulation and may demonstrate spontaneous echo contrast (smoke-like echoes produced by the interaction of erythrocytes and plasma proteins under conditions of stasis). This is an independent predictor of left atrial thrombus and/or cardiac thromboembolic events. Transoesophageal echo is also used to assess anatomy and exclude left atrial thrombus before balloon valvuloplasty in patients with mitral stenosis and to assess anatomy, severity, and suitability for surgical repair in patients with mitral regurgitation. In patients with mitral prostheses, reverberation artefact overlying the left atrium limits the ability of transthoracic imaging to detect paraprosthetic regurgitation. Transoesophageal imaging provides excellent visualization of the left atrium and is particularly recommended under these circumstances.

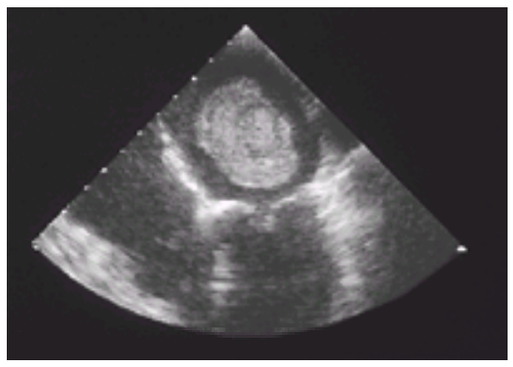

Fig. 7 Two-dimensional transoesophageal echocardiogram of the left atrium demonstrating a large mobile thrombus in a patient with mitral stenosis.

Endocarditis

Characteristic vegetations or evidence of abscess formation identified by echocardiography are increasingly used as diagnostic criteria in patients with possible endocarditis. The excellent spatial resolution (less than 1 mm) of transoesophageal echo makes it superior to transthoracic imaging for the detection of vegetations and its sensitivity may exceed 90 per cent. Transoesophageal echo should be considered when there is a high clinical suspicion of endocarditis but blood cultures are sterile and transthoracic imaging is not diagnostic, or under circumstances when the sensitivity of transthoracic imaging is particularly poor, for example prosthetic valves or calcific valvular disease. Transoesophageal echo is also recommended if there is a possibility of aortic root abscess formation as this complication is not easily identified using transthoracic imaging and surgery is usually necessary.

Aortic disease

Transthoracic imaging of the aorta is limited to the proximal aortic root and the arch in most patients. Using transoesophageal imaging most of the ascending and all of the descending thoracic aorta can be visualized and image quality is improved. This is particularly useful in patients with suspected acute aortic dissection and in many cases it is the only imaging necessary before emergency surgery. Large, mobile or pedunculated aortic atheroma in the descending aorta may be detected by transoesophageal echocardiography and several studies have suggested an association with ischaemic stroke.Transoesophageal imaging of the aorta has also been recommended in suspected cases of cholesterol embolization and to assess thromboembolic risk prior to cardiac intervention or surgery.

Thromboembolism

In patients with thromboembolism, there has been extensive debate over the value of imaging with transoesophageal echocardiography. Clinical examination, electrocardiography, and transthoracic echocardiography provide sufficient information to determine optimal management in the majority. However, transoesophageal echocardiography is indicated when embolic events occur in anticoagulated patients with native or prosthetic valvular heart disease, especially if endocarditis is suspected, or when transthoracic images are inconclusive.

In patients with unexplained or cryptogenic ischaemic stroke, wider use of transoesophageal echo has been advocated. Transthoracic echo and exclusion of alternative pathologies such as thrombophilia and carotid stenoses should precede the transoesophageal examination as under these circumstances minor cardiac structural abnormalities are more likely to be clinically relevant.

The transoesophageal approach is superior to transthoracic echocardiography for imaging the interatrial septum for atrial septal aneurysm (a redundant bulge in the area of fossa ovale, with respiratory movement greater than 10 mm) and assessing patency of the foramen ovale (Fig. 8). The clinical relevance of these atrial septal abnormalities can be questionable as the relationship to the thromboembolic event is commonly speculative. Currently, anticoagulation is the usual management following a otherwise unexplained single embolic event, but occasionally percutaneous or surgical correction of the defect is recommended.

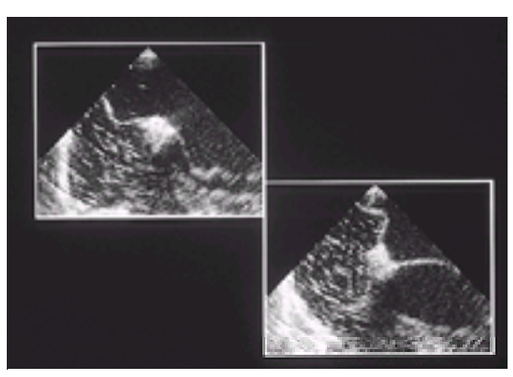

Fig. 8 Two-dimensional transoesophageal echocardiogram of the atria. In the upper panel contrast is principally contained within the right atrium although two bubbles can be seen in the left atrium. There is marked excursion of the atrial septum towards the left atrium during expiration (lower panal). These appearances are consistent a diagnosis of an atrial septal aneurysm with patent foramen ovale.

Stress echocardiography

Diagnosis of reversible ischaemic myocardial dysfunction is now possible using echocardiography. Imaging can be performed either during or immediately after exercise, but more commonly an intravenous infusion of dobutamine is used to mimic the cardiac response to exercise. Development of reversible systolic regional wall motion abnormalities suggests coronary artery disease and stress echo is used increasingly as a diagnostic test in patients with chest pain. Stress echo also has an increasing role in risk stratification prior to general surgical procedures and in assessing myocardial viability prior to revascularization.

15.3.4 Nuclear techniques

H. J. Testa and D. J. Rowlands

Nuclear imaging of the heart plays an important role in the investigation of patients with heart disease, giving valuable information for the practical management of patients and contributing to the understanding of the physiology of myocardial perfusion. The techniques may be used to:

1. localize areas of ischaemia induced by exercise or by drugs;
2. demonstrate the extent and distribution of viable myocardium;
3. provide an assessment of global and of regional left ventricular function; and
4. demonstrate recent myocardial cell damage.

The investigations are scarcely invasive and of little discomfort or inconvenience to the patient.

In recent years, the use of nuclear imaging tests has increased dramatically. This increase is largely due to two factors: (i) development of new radiopharmaceuticals labelled with technetium to aid in the imaging process, and (ii) recognition of the value of pharmaceuticals for the induction of cardiovascular stress, permitting stress studies to be undertaken without exercise, which is particularly useful when exercise is difficult or contraindicated. There has also been considerable improvement in the quality of the images obtained thanks to substantial improvement in gamma-camera technology and to the widespread use of single photon emission computer tomography (SPECT). Recent estimates suggest that, in the United States, the annual number of procedures undertaken has doubled from 2.9 million in 1990 to 5.8 million in 1997. In our department, the number of cardiac studies has increased from 300 per year in 1995 to more than 1000 in 1999; the main area of increase being in the use of myocardial perfusion studies to investigate myocardial ischaemia.

Myocardial perfusion imaging in the recognition and assessment of myocardial ischaemia

Myocardial perfusion imaging is undertaken using an injection of a radiopharmaceutical that is taken up by the myocardium in proportion to the myocardial blood flow at the time of the injection and which remains in the myocardial cells during the period of the imaging. Studies are performed both at rest and under stress, in order to evaluate differing regional perfusion in these two states. The three compounds mainly used in current clinical practice are thallium ^{201}, technetium-99m-Cardiolite (sestamibi-MIBI), and technetium-99m-Myoview (tetrofosmin).

Thallium^{201} is an analogue of the potassium ion. It is taken up only by myocardial cells that are both viable and adequately perfused. A dose of 75 MBq, (approximately 2 mCi) is injected intravenously (i) at maximal chosen or achievable exercise, or (ii) after pharmacological stress, or (iii) in association with a combination of these procedures (exercise plus pharmacological stress). Pharmacological stress can be induced with powerful vasodilators (dipyridamole or adenosine) or with inotropic and chronotropic stimulators (dobutamine). The initial myocardial distribution of thallium ^{201} reflects regional blood flow. Redistribution of the isotope to all viable myocardial cells occurs approximately 3 to 4 h later. Images are taken immediately after exercise (to reflect blood flow) and 3 to 4 h later to reflect viable myocardium.

The patient is positioned supine on the SPECT couch with the left arm placed over the head to avoid attenuation artefacts. The gamma camera rotates around the patient through 180° from the right anterior oblique 30° to the left posterior oblique 30°, at 6° increments of 30 s duration. The orbit of rotation may be circular or non-circular; the latter is preferred. The acquired data is computer analysed and slice images are constructed using the techniques of filtering back projection at approximately 1-cm intervals. Short axis (SA), vertical long axis (VLA), and horizontal long axis (HLA) slices are reconstructed for clinical evaluation. An example of images obtained in this way is shown in Fig. 1.

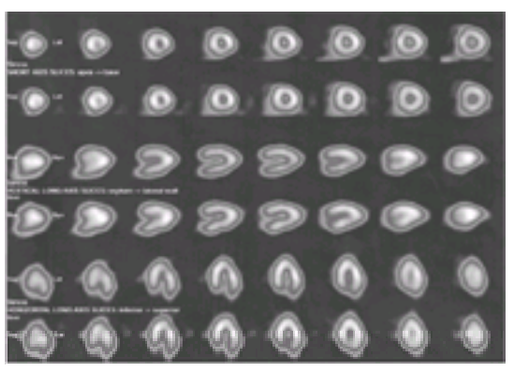

Fig. 1 Normal stress and rest study with thallium-201.

Any localized defects occurring in association with stress are indicative of non-viability (infarction) or of underperfusion (ischaemia). Defects of thallium uptake occurring at rest or after redistribution during a period of rest following stress (exercise or pharmacological) correlate well with areas of infarction. A defect in tracer uptake immediately post-exercise or stress that shows redistribution after rest is indicative of myocardial ischaemia. It is now known that redistribution can be very slow in hypoperfused but viable myocardium, and a further injection of thallium may help to improve the differentiation between reversible and fixed perfusion defects. Furthermore, the comparison of images taken immediately after injection at rest with those taken at rest 3 to 4 h later (rest-redistribution protocol) can be used in viability assessment and investigation of hibernating myocardium.

The drawback of thallium is its long physical half-life of 72 h (which limits the dose that can be used so as to minimize radiation exposure to the patient) and the low photon energy (60–90 keV) which cause significant attenuation and degradation of the images.

As a consequence of the physical limitations of thallium ^{201}, technetium-labelled radiopharmaceuticals have been developed. Technetium ^{99m} has a higher photon energy (140 keV) than thallium^{201} and a shorter physical half life of 6 h. Two compounds are used in routine practice—technetium-99m-MIBI and technetium-99m-Myoview. Both are lipophilic and, like thallium, are taken up by the myocardium in proportion to myocardial blood flow. The maximum dose injected to the patient for the study (stress/rest) is of 1000 MBq (approximately 25 mCi).

Technetium-99m-MIBI is an isonitrile complex which after intravenous injection diffuses from the blood into cardiac myocytes and it is retained by the mitochondria within the cell. Its clearance from the blood is rapid, but only 40 to 60 per cent is extracted on the first pass through the myocardium. However, at about 20 min the percentage uptake by the myocardium is similar to thallium. This compound does not have a significant clinical redistribution (less than 15 per cent from its initial uptake) and the concentration in the myocardium remains constant over a period of 4 or 5 h. Images can be taken several hours after injection, when they still represent the distribution of coronary blood flow in the myocardium at the time of injection. Because of this lack of redistribution it is necessary to inject the patient

twice, at maximum stress/exercise and at rest.

Technetium-99m-Myoview is also a lipophilic compound which, after intravenous injection, is rapidly cleared from the blood, taken into myocytes and retained in the mitochondria. Myocardial uptake is of the order of 1.2 per cent of the injected dose and reaches this level at about 5 min. It shows little redistribution and, as with technetium-99m-MIBI, two injections are necessary for a comparison of rest and stress/exercise uptake. Its advantage is that it has less liver uptake than technetium-99m-MIBI with resulting improvement in the interpretation of images in the inferior wall.

Several imaging protocols have been developed for the technetium compounds including rest and stress injections either on 1 or 2 days. Ideally the two studies should be carried out on separate days, but if they are performed on the same day at least a three times larger dose is given with the second injection in order to swamp activity from the first. It is also possible to use thallium ^{201} to obtain resting images and technetium compounds for stress studies. This later protocol permits stress and rest studies to be completed in about 2 h.

Interpretation of the images is, in practical terms, similar to that of thallium: any localized defects occurring in association with stress or exercise indicate either infarction or ischaemia. Defects of uptake occurring on the rest study are indicative of areas of infarction. A defect in tracer uptake immediately postexercise or stress that improves during the rest study is indicative of myocardial ischaemia. Figure 2 shows an example of a patient with myocardial ischaemia mainly affecting the apex.

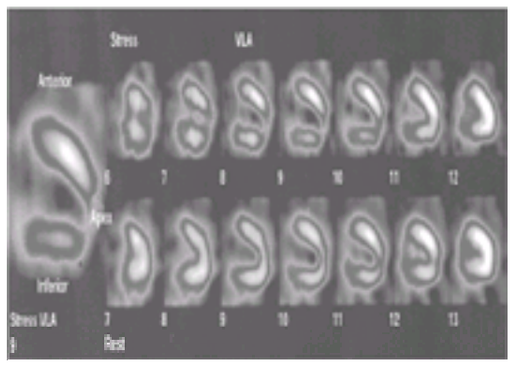

Fig. 2 Myocardial study carried out with Myoview showing, in the vertical long axis (VLA) view, an area of decreased tracer uptake at the apex on the images obtained after exercise (stress—row of seven images at the top of the figure) and improvement in this area at rest (row of seven images at the bottom of the figure). Views in other axes would be obtained simultaneously but are not shown.

The main clinical indications for myocardial perfusion scintigraphy, in patients without a clear diagnosis of coronary artery disease, include:

1. the assessment of patients with acute chest pain and non-diagnostic electrocardiograms;
2. use as a screening test in patients with
   a. familial hyperlipidaemia,
   b. a family history of coronary artery disease, and
   c. a perceived cardiac ischaemic risk in relation to proposed non-cardiac surgery.

In patients with known coronary artery disease the main indications include:

1. evaluating the functional significance of coronary stenoses detected by angiography;
2. assessment of the most significant functional stenoses in patients with multiple coronary lesions;
3. evaluation of postinfarction patients to establish the size of the infarct and the presence or absence of ischaemia in other areas of the myocardium.

It is also of value in the investigation of restenosis after revascularization with angioplasty or coronary artery bypass grafting.

The procedure is useful in relation to exercise stress testing (both for patients with known coronary disease and in those with no definite evidence of ischaemic disease) where the ECG in not able to yield useful information on stress-induced ischaemia (pre-existing left bundle branch block, ventricular pre-excitation, functioning ventricular pacemaker, or initial widespread abnormality).

SPECT perfusion studies for the diagnosis of coronary artery disease have a higher sensitivity and specificity than electrocardiography, particularly when state of the art systems are used (average sensitivity of about 90 per cent and specificity 80 per cent). They also provide better localization with respect to the vascular beds of the three coronary arteries. Sensitivity is higher for lesions occurring in the left anterior descending artery and lower for the right coronary artery. Sensitivity and specificity appear to be lower for female than for male populations. Stress tests or exercise tests have similar diagnostic performances, but exercise testing in patients who do not reach the target heart rate (220–age) has decreased sensitivity.

It is important to recognize that patients with left bundle branch block may have perfusion abnormalities in the septum that are not due to coronary artery disease; in these patients pharmacological stress studies improve the sensitivity of the test. Reversible perfusion defects have also been reported in patients with hypertrophic cardiomyopathy, aortic stenosis, and left ventricular hypertrophy.

Scintigraphic determination of ventricular function

The assessment of left ventricular function is one of the most important aspects of the evaluation of the cardiac status. Scintigraphy can provide the following information:

1. estimates of ventricular ejection fraction (the proportion of the ventricular end-diastolic volume ejected per beat, i.e. the stoke volume expressed as a percentage of the end diastolic volume), which is an overall measure of left ventricular performance;
2. estimates of regional ventricular performance by observation of the movements of the margins of the ventricle.

Two approaches can be taken: the 'first pass technique' and the 'gated equilibrium' method. Both involve the intravenous injection of technetium ^{99m}, which for first pass studies may be used in its ionic form as technetium-99m-pertechnetate, and for gated equilibrium studies by labelling the patient's own red blood cells. Both techniques (first pass and gated equilibrium) can be performed with a single injection of radioactive tracer.

In the first pass technique the first circulation of the radioactive bolus through the heart is studied and sequential images show the passage of the tracer through the right and left ventricles, separated in time. The single most useful view is probably the right anterior oblique (the projection of choice in single plane contrast radiography of the left ventricle). Images are taken at 1-s intervals and stored in the computer. A region of interest for the left ventricle is outlined and a high frequency activity–time curve for that region is plotted. Each point on the curve represents accumulated counts for a period of 0.04 s. The amount of radioactivity in the heart is proportional to the volume of blood in the cardiac cavities. Thus the change in the precordial count rates reflects the cyclical volume changes in the heart. A second region of interest is taken (usually as a horse-shoe-shaped region surrounded the left ventricular region of interest) to sample background activity variation with time. The background curve is 'normalized' to the left ventricular curve and then subtracted point-for-point from the high frequency left ventricular activity–time curve to give the corrected high frequency left ventricular activity–time curve (Fig. 3). It is usual to take two to six cycles around the peak of the left ventricular curve and then average the calculated ejection fraction for these cycles.

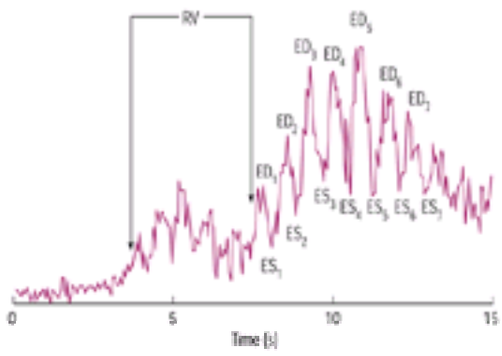

Fig. 3 High frequency activity—time curve recorded from the region of the left ventricle during the first passage of radioactive tracer through the central circulation. The time, in seconds, after the injection is shown on the abscissa. The ordinate displays the scintillation counting rate on a linear scale, after background correction. The early hump shows increased activity during the passage of the tracer through the right ventricle (RV). The later, larger hump shows the count rate during the passage through the left ventricle. Peaks and troughs are visible in relation to each cardiac cycle. Estimates of ejection fraction can be made for each cardiac cycle: (ED_1–ES_1/ED_1, ED_2–ES_2/ED_2, etc).

The gated equilibrium technique, referred to as gated cardiac blood pool imaging or as multigated acquisition (MUGA) imaging, depends upon complete mixing of the marker throughout the circulating blood volume and it therefore requires a marker that remains intravascular. The marker of choice is technetium-99m-labelled red blood cells. The cells do not have to be removed from the patient to be labelled: the ' *in vivo* labelling' technique may be used, which involves predisposing the patient's red cells to accept the technetium label by the administration, 30 min prior to technetium, of non-active stannous pyrophosphate. Subsequently, 600 to 800 MBq (approximately 15 to 20 mCi) of technetium-99m-pertechnetate are injected intravenously and imaging is begun after 10 min or so. As there is complete mixing of the marker throughout the blood volume, all four cardiac chambers are seen simultaneously and various degrees of superimposition of the chambers inevitable. Proper alignment of the gamma camera is therefore crucial for the optimal separation of the cardiac chambers. In general, maximal separation of the right and left ventricles is achieved in the left anterior oblique view, to which a caudal tilt of 15° may be added.

For the determination of ejection fraction, a region of interest over the left ventricle and a second region of interest for background correction are assigned in the same manner as for the first pass technique. A background-corrected activity–time curve of the left ventricular area is obtained: Fig. 4 (normal), Fig. 5 (abnormal). With the equilibrium technique this is usually displayed as a single cycle representative activity–time curve being produced as a composite of many (typically hundreds) consecutive cycles, synchronization of the cycles being achieved by means of the R wave of the electrocardiogram.

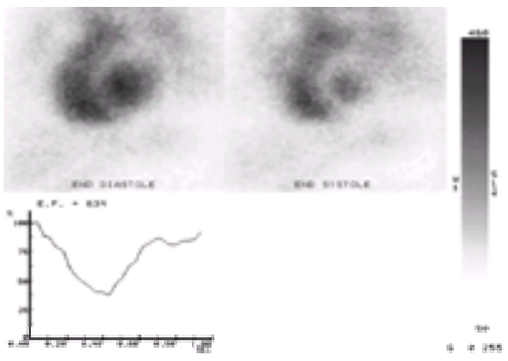

Fig. 4 Normal, resting multigated acquisition scan in the left anterior oblique 45° view. *Top view*, end-diastolic frame. The circular outline of the left ventribular cavity and the crescentic outline of the right ventricular cavity are seen. The curved zone of decreased activity between the two represents the interventricular septum. *Top right*, end-systolic frame. The left ventricular end systolic volume is clearly much smaller than in the end-diastolic frame and all regions of the left ventricule have contracted well. *Bottom left*, background corrected activity–time curve showing the overall count rate from the region of the left ventricle with the end-diastolic count rate normalized to 100 per cent. The ejection fraction is normal at 63 per cent.

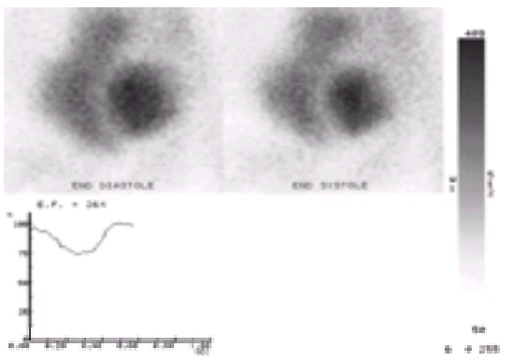

Fig. 5 Abnormal, resting multigated acquisition scan in the left anterior oblique 45° view. The format and layout are as in Fig. 4. There is very little difference between the end-diastolic and end-systolic left ventricular activities and, therefore, volumes (top left and top right respectively) and the reduction in left ventricular contractile performance is uniform. The background corrected activity–time curve shows an ejection fraction of only 26 per cent. The appearances are typical of a congestive cardiomyopathy.

Regional wall motion studies can also be carried out with this technique. Left ventricular images are collected for each of many short time intervals (typically 0.03 s, giving 25 images per cardiac cycle at a heart rate of 80/min) and images for corresponding parts of numerous cardiac cycles (typically several hundred) are summed to produce a composite. In this way 25 'frames' of a 'representative cine cycle' are produced. Figure 4 and Figure 5 show examples of end-diastolic and end-systolic 'frames' of such a representative cine-cycle. Comparison of the end-diastolic and end systolic ventricular boundaries permits the assessment of regional wall motion. In Fig. 4 this reveals normal contraction of those parts of the ventricular wall that are displayed in the view shown. In Fig. 5, from a patient with congestive cardiomyopathy, there is uniformly reduced myocardial contraction.

Currently available non-scintigraphic techniques for the assessment of ventricular function (echocardiography, angiography, etc.) are, in general, less satisfactory when applied to the right than to the left ventricle. The differences are less marked in respect of nuclear techniques, such that scintigraphic procedures currently offer one of the best approaches to the assessment of right ventricular function. The basic techniques involved are the same as for the left ventricle. First pass radionuclide angiography provides adequate temporal anatomical separation of activity within right-sided and left-sided cardiac structures and provides a valuable method for the assessment of right ventricular ejection fraction. The gated equilibrium technique is less useful in the assessment of right ventricular function because of the overlap between the two ventricles, but it is possible to obtain useful information concerning right ventricular size and regional wall motion (usually visually assessed) from this technique. The best approach is to combine the two techniques to obtain a gated first pass study.

Radionuclide imaging in the diagnosis of myocardial infarction

Two general approaches have been used for the detection of myocardial infarction:

1. Recent myocardial damage may be demonstrated using radiopharmaceuticals that concentrate selectively in acutely injured cells. This 'positive imaging', 'infarct-avid imaging', or 'hot spot scanning' can clearly only be applied when infarction has occurred recently (within several days).
2. Non-viable myocardium (i.e recent or long-standing infarction) may be demonstrated by the absence of uptake of several tracers such as thallium ^{201}, technetium-99m-MIBI, or technetium-99m-tetrofosmin as previously described (see above). This is called 'negative imaging' or 'cold-spot scanning'.

Infarct-avid imaging

Three main radiopharmaceuticals have been used for infarct avid imaging: technetium-99m-stannous pyrophosphate, indium-111-antimyosin and, more recently and still in process of investigation, technetium-99m-glucaric acid.

Technetium-99m-stannous pyrophosphate is the compound most extensively used to date. The observation that calcium is deposited in irreversibly damage myocardial cells led to the idea of using this tracer, a bone scanning agent, as a mean of demonstrating myocardial necrosis. The cellular death of myocardial infarction is accompanied by an influx of calcium ions, which are deposited in crystalline and subscrystalline form within the mitochondria, and it has been suggested that calcium accumulation in this way is an index of irreversible cell damage. However, it has also been suggested that the tracer is associated with cytoplasmic denatured macromolecules rather than with mitochondrial hydroxyapatite. Irrespective of the mechanism of tracer uptake, research and clinical work confirm that this radiopharmaceutical localizes in infarcted and severely injured myocardium. For a scan to be positive there must be both (i) significant myocardial necrosis (to give rise to myocardial uptake) and also (ii) persistent residual collateral coronary blood flow into the area of myocardial damage (to permit delivery of the tracer to the infarcted myocardium).

The time interval between the clinical onset of the infarction and scanning is critical. Scans are unlikely to be positive within the first 12 h and the optimum scanning time is 24 to 96 h, but scans can occasionally be positive 2 weeks after an isolated episode of infarction. Between 200 and 600 MBq (approximately 5 to 15 mCi) of technetium-99m-stannous pyrophosphate are given intravenously, with scanning undertaken 60 to 90 min later. Figure 6 shows a normal study and Fig. 7 one of a patient with myocardial infarction.

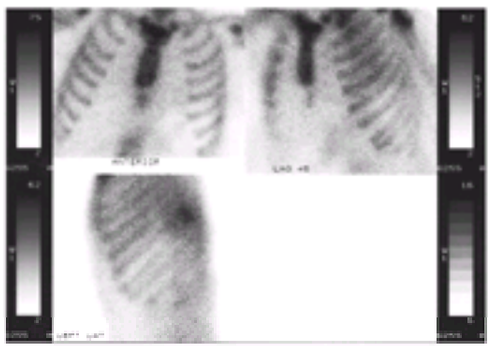

Fig. 6 Normal technetium-99m-stannous pyrophosphate scan, seen in the anterior 45°, and left lateral views. Normal uptake is seen in the sternum and ribs. There is no recognizable activity in the region of the myocardium.

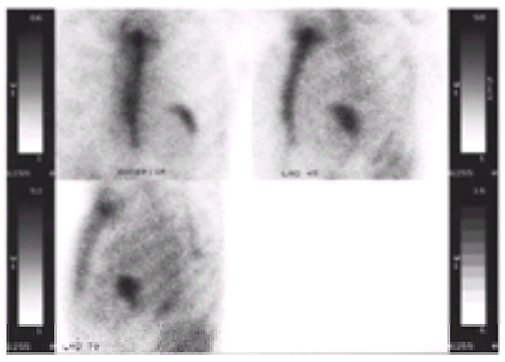

Fig. 7 Abnormal technetium-99m-stannous pyrophosphate scan, seen in the anterior, left anterior oblique 45°, and left lateral views. In addition to the normal uptake in the sternum (well seen) and ribs (less well seen), there is clearly a large area of localized uptake lateral and posterior to the sternum, in the region of the left ventricle. The patient had had an acute myocardial infarction.

False negative and false positive results occur. In 14 different series involving 562 patients with acute myocardial infarction, the false negative rate was 6 per cent. A further group of 15 different series involving 1083 patients with no evidence of acute infarction showed a false positive rate of 17 per cent. The 'efficiency' of the procedure (i.e. its overall ability correctly to classify patients as to whether or not they have acute infarction) is 86 per cent. False positive results have been described in patients with unstable angina, left ventricular aneurysms, cardiomyopathy, valvular calcification, myocardial contusion, persistent blood pool activity, rib fractures, breast tumours, calcified costal cartilages, skeletal muscle damage, and recent cardio-version (the latter giving either skeletal muscle or cardiac damage).

The drawback of this technique is the delay of 1 day before reliable diagnosis of infarction in the non-reperfused myocardial infarction can be made. It is clearly of no value in identifying patients who will benefit from thrombolytic therapy and this is one reason why the technique has not been commonly used in clinical practice.

Indium-111-labelled monoclonal antimyosin, which binds selectively to irreversibly damaged myocytes, has also been used for the investigation of acute myocardial infarction. Clinical studies have shown a sensitivity between 87 and 98 per cent and a specificity of 93 per cent. Because of the high sensitivity and specificity, the technique has been used in the investigation of equivocal myocardial infarction, and in the investigation of right ventricle myocardial infarction. The main drawback is again delay: 12 to 24 h between the administration of tracer and imaging, due to very slow clearance from blood.

More recently, some experience has been gained with the use of technetium-99m-glucaric acid, developed with the hope of achieving an early diagnosis of myocardial infarction. This is a natural dicarboxylic acid sugar which clears from the blood with a very short half-life, allowing images to be carried out within a few hours after injection. Uptake is due to its affinity for the histone of the necrotic myocytes. The clinical usefulness of this compound remains to be determined.

Functional images

Functional images of the heart can be obtained by applying the mathematical technique of Fourier analysis to the left ventricular volume–time curve. The time activity curve is fitted with the first Fourier harmonic, a cosine function with a period equal to the period of the cardiac cycle. The amplitude and phase of this function are adjusted to match the left ventricular curve optimally. The amplitude image reflects the change in ventricular volume through the cycle. It is similar to the stroke volume but may give a more reliable index of the change in chamber volume. The phase image represents the time at which the maximum contraction occurs, and gives information on the mechanical contractility of the heart. Phase data are also presented as histograms in which the number of pixels in an image with a particular phase is plotted against the phase.

Positron emission topography (PET)

This technique uses positron emitting radionuclides and emission computed axial tomography to produce tomographic images of coronary flow and cardiac metabolism. The instrumentation consists of detector systems working in coincidence to register the paired annihilation photons emitted from the radiopharmaceuticals.

PET devices record multiple slices (usually between three and 18) of the heart simultaneously. Perfusion studies can be carried out after injecting radiopharmaceuticals such as ammonia-13, $H_2{}^{15}O$, or rubidium-82. Because of the short half life of this radiopharmaceutical, it is necessary to inject the patient twice, at rest and during maximum exercise. Metabolic studies of the heart have been carried out using carbon-11-palmitate or glucose analogues such as fluorine-18-deoxyglucose. Although these procedures are now more commonly used, they are only performed in routine clinical practice in selected centres. The main drawback of these techniques is cost: they require expensive detectors and a cyclotron on site for the production of radionuclides.

15.3.5 Cardiovascular magnetic resonance and computed X-ray tomography

S. Richard Underwood, Raad H. Mohiaddin, and M. B. Rubens

Magnetic resonance

Cardiovascular magnetic resonance imaging (**MR**I) has an established clinical role, particularly for the assessment of congenital heart disease and diseases of the aorta and pericardium. However, its clinical impact is currently more limited than that of echocardiography, nuclear cardiology, and invasive investigation. As MRI technology evolves, rapid imaging techniques allow acquisition within a breath-hold and even in real-time. Such techniques promise to extend the capabilities of cardiovascular magnetic resonance to imaging of the coronary arteries and assessment of myocardial perfusion, when it may then play a more important clinical role. For information on the technical aspects of magnetic resonance imaging and spectroscopy, the reader is referred to other texts (see bibliography).

Congenital heart disease

Spin echo images in multiple contiguous slices and in several planes provide excellent anatomical information (Fig. 1). Magnetic resonance compares favourably with echocardiography and cardiac catheterization in providing a complete anatomical diagnosis in 90 per cent of cases, although congenital anomalies of the valves and small defects of the interatrial and interventricular septum are often difficult to visualize on spin echo images alone. Cine gradient echo images provide additional information such as ventricular function, particularly on the right. They also show turbulent blood flow in a manner similar to colour-coded Doppler, and this improves the detection of small ventricular and atrial shunts. The combination of cine imaging with velocity mapping provides further information, improving the detection of shunts and allowing flow to be measured in conduits, great vessels, and within the heart. Shunts can be measured either from the difference in stroke volumes of left and right ventricles or, more flexibly, by measuring flow directly in the aorta and pulmonary artery.

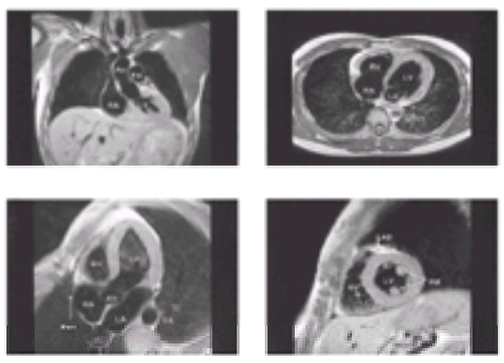

Fig. 1 Spin echo images showing normal anatomy. Top left, coronal; top right, transverse; bottom left, horizontal long axis; bottom right, short axis. LV, left ventricle; RV, right ventricle; LA, left atrium; RA, right atrium; Ao, aorta; DA, descending aorta; PA, pulmonary artery; AV, aortic valve; LAD, left anterior descending coronary artery; peri, pericardium; PM, papillary muscles.

Pulmonary arteries

Several studies have shown the ability of MRI to identify the central pulmonary arteries in patients with pulmonary atresia, which is particularly helpful for determining the feasibility of creating a shunt surgically and for monitoring the growth of the pulmonary artery after shunting. In these patients, magnetic resonance is also able to assess shunt patency accurately, although complete evaluation of systemic collateral arteries, particularly their distal connections, may require selective angiography. Peripheral pulmonary artery stenoses can be missed by MRI.

Pulmonary and systemic veins

Normal pulmonary veins can be identified in most patients and 95 per cent of pulmonary venous abnormalities can be diagnosed. This is superior to cardiac catheterization and to transthoracic echocardiography. Abnormalities of the systemic veins such as a left-sided superior vena cava and its drainage are clearly seen.

Transposition of the great arteries

Postoperative follow-up with MRI is a valuable addition to transthoracic echocardiography for the detection of superior vena caval obstruction in patients with a transposition that has been surgically repaired. Cine gradient echo imaging can improve the assessment by demonstrating abnormal flow patterns associated with residual ventricular septal defects, subpulmonary stenosis, obstruction of the pulmonary venous atrium, and baffle leaks. Because the right ventricle supports the systemic circulation in these patients, outcome is partly determined by right ventricular function and competence of the tricuspid valve. Magnetic resonance can be used to monitor both of these accurately and reproducibly. In a minority of patients, artefacts caused by sternal wires may preclude complete assessment of the right ventricle.

Surgical conduits

Obstruction of conduits between the right ventricle and the pulmonary circulation, such as in tricuspid atresia after the Fontan operation (Fig. 2), may be difficult to detect clinically because patients may be asymptomatic despite having significant obstruction. Magnetic resonance imaging can demonstrate the anatomy of the proximal and distal anastomoses, and of obstruction within the conduit caused by intimal proliferation or 'peel'. A pressure gradient can be determined by velocity mapping and invasive investigation avoided in many cases. By contrast, echocardiography often fails to visualize the conduit because of its position behind the sternum. Palliative systemic to pulmonary shunts are also difficult to assess by echocardiography, but MRI is able to provide anatomical and functional information in

most patients.

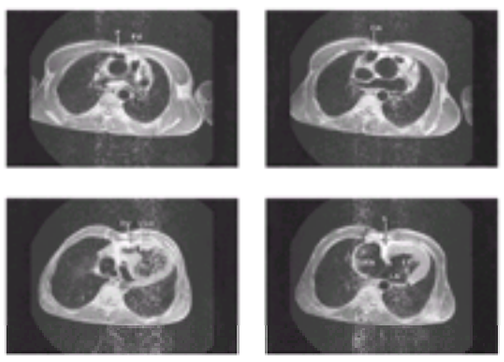

Fig. 2 Transverse spin echo images from superior (top left) to inferior (bottom right) in a patient with tricuspid atresia (S) and a Fontan conduit (F) connecting the right atrial appendage (RA) to the pulmonary artery (>PA). The right ventricle (RV) is hypoplastic and has a ventricular septal defect (VSD) connecting it to the left ventricle (LV). There is also an atrial septal defect connecting the right atrium and left atrium (LA).

Complex disease

Another group of patients in whom MRI has advantages over other techniques are those with complex congenital disease such as single or common ventricles. These anomalies are frequently associated with abnormal thoracic or abdominal situs, and abnormal venous and ventriculoarterial connections. Spin echo imaging is as effective as angiography in demonstrating ventricular morphology and size, the orientation of the septum relative to the atrioventricular valves, and the origins and relationships of the great vessels. Magnetic resonance imaging is superior to other imaging techniques for assessing thoracic and abdominal situs and systemic and pulmonary venoatrial connections.

The aorta

The advantages of magnetic resonance in imaging aortic dissection are its ability to image in oblique planes and the fact that it does not require contrast injection, but it is undoubtedly more difficult to image sick patients in the current generation of scanners than to use other techniques that might be applied in this clinical context (computed tomography (**CT**) or transoesophageal echocardiography). Dissection is readily detected and its extent can be seen, including the involvement of the arch and other vessels (Fig. 3). The ability to demonstrate aortic regurgitation and rupture into the pericardial space are important additional features when assessing these patients. Because the intimal flap is thin it may not always be revealed in spin echo images unless static blood in the false lumen leads to natural contrast with the true lumen. If there is any doubt, then the flap will be more easily seen using a gradient echo sequence, and velocity mapping will confirm the diagnosis by demonstrating the differential flow velocities in each lumen.

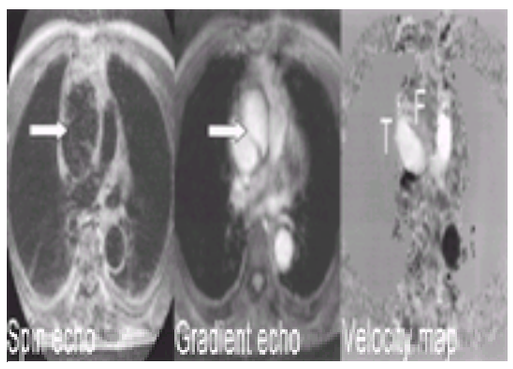

Fig. 3 Three images in the same plane in a patient with aortic dissection. The ascending aorta is dilated and there is an intimal flap (arrow), better seen in the gradient echo image. The velocity map shows rapid systolic flow in the true lumen (T—in white), and absent flow in the false lumen (F—in grey).

Comparisons of MRI with other imaging techniques have concluded that magnetic resonance should be the primary investigation in stable patients and transoesophageal echocardiography the primary investigation in patients who are too ill to be imaged by magnetic resonance. In most cases the investigation performed will depend upon practical issues such as local expertise and availability of equipment.

Other aortic abnormalities that can be seen by magnetic resonance are aneurysms and coarctation. The combination of anatomical imaging and velocity mapping to assess the gradient across the coarctation means that surgical decisions can be taken without invasive investigation in many cases. It is an ideal method for the long-term follow-up of patients following coarctation repair and those with Marfan's syndrome. A further application is in suspected myocardial or mediastinal abscess in postoperative patients with infection that is difficult to control. Echocardiography is often equivocal in such patients and magnetic resonance will usually produce a definitive answer.

Tumours

Magnetic resonance imaging can provide additional information in many patients with masses previously identified by echocardiography. Although it is not possible to identify the nature of a mass from its signal with certainty, the high signal of lipomas and the appearance of angiomas are often characteristic.

Gadolinium–diethylene-triamine-pentaacetic acid (**Gd-DTPA**) may be helpful for demonstrating vascularity and for distinguishing a myxoma from a thrombus. However, even in the absence of a typical signal, a diagnosis can often be made from the site and size of the tumour and from its involvement of neighbouring tissues.

Metastatic tumours are much more frequent than primary cardiac tumours. These can also be imaged successfully, whether as direct invasion of the heart, for example in carcinoma of the bronchus, or distant metastases as in melanoma. Involvement of the myocardium or pericardium can be identified, with the large field of view having a considerable advantage over echocardiography for determining the extent of a tumour.

Thrombus

Atrial or ventricular thrombus is easily identified by MRI, although transoesophageal echocardiography is also reliable in the left atrium, and the transthoracic approach often provides clear images in the ventricles. It is important to combine spin echo MRI with cine gradient echo imaging because it may be difficult to distinguish signal from thrombus and from slowly moving blood in spin echo images. Although the contrast is not as great in cine gradient echo images, it is more consistent, and the presence of a fixed filling defect is characteristic of a thrombus.

Pericardium

Pericardial thickening is readily demonstrated by magnetic resonance and by computed X-ray tomography: both techniques are more accurate than echocardiography. The commonest clinical question is to distinguish between pericardial constriction and myocardial restriction. Visualizing a thickened pericardium with the haemodynamic features of constriction makes the distinction reliably. Cine imaging shows immobility of the pericardium; additional features that indicate constriction are dilated atria and caval veins, small ventricles with retained systolic function, and a reduced diastolic caval flow peak, suggesting impaired right

ventricular filling. Magnetic resonance cannot detect calcification reliably and this may be a drawback if pericardectomy is planned.

Pericardial effusion is clearly seen on spin echo images but its appearance is variable (Fig. 4). Moving fluid gives no signal but static fluid gives a high signal, particularly if haemorrhagic. It can also appear with varying signal in cine gradient echo imaging because rapid through plane refreshment of fluid reduces magnetic saturation. Cine imaging is therefore particularly helpful to distinguish thickened pericardium from a pericardial effusion.

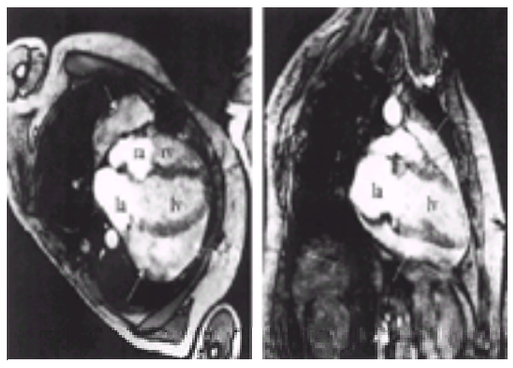

Fig. 4 End diastolic frames from a gradient echo cine acquisition in the horizontal (left) and vertical (right) long axis planes in a patient 3 weeks after heart transplantation. There is a large pericardal effusion (arrows). la, Left atrium; ra, right atrium; rv, right ventricle.

Myocardium

Hypertrophy

The measurement of myocardial volume and mass has been extensively validated in animal experiments and in humans and, because of its accuracy, magnetic resonance should now be the standard against which other techniques are judged. Increased muscle volume (and hence mass) can be observed in athletes and patients with left ventricular hypertrophy, and the regression of hypertrophy following treatment of hypertension can be monitored.

Hypertrophic cardiomyopathy

The location and severity of hypertrophic cardiomyopathy is readily assessed (Fig. 5). Many patients do not have the classical form of asymmetrical septal hypertrophy, and apical hypertrophy in particular is better shown by MRI than by echocardiography. Metabolic abnormalities have also been observed using phosphorus-31 spectroscopy, with a reduced ratio of phosphocreatine to adenosine triphosphate compared with control subjects and patients with dilated cardiomyopathy, and a lower myocardial pH. It is not yet clear whether these changes are specific and whether they will be helpful in distinguishing hypertrophic cardiomyopathy from other forms of hypertrophy.

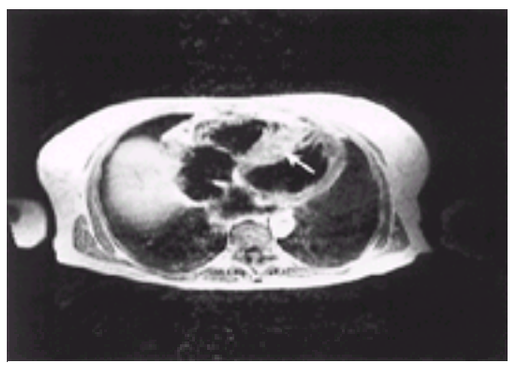

Fig. 5 Transverse spin echo image acquired at mid-ventricular level in a patient with hypertrophic cardiomyopathy. The interventricular septum is asymmetrically thickened (arrow).

Dilated cardiomyopathy

Chamber dilatation and impaired myocardial thickening are clearly demonstrated. Because of the reproducibility of MRI measurements even modest changes of systolic and diastolic function can be monitored serially. Metabolic abnormalities have been demonstrated by magnetic resonance spectroscopy, with a reduced ratio of phosphocreatine to ATP in patients with heart failure and an improvement with therapy.

Other myocardial disease

Non-coronary myocardial disease can manifest itself by abnormalities of global and regional left ventricular function or by abnormalities of relaxation times that lead to differential contrast within the myocardium. Myocardial sarcoidosis is an example of a condition where magnetic resonance may have a useful role because there is a high incidence of subclinical involvement: conventional methods of detection include electrocardiography, echocardiography, and thallium-201 or gallium-67 scintigraphy, but the sensitivity of all these techniques is limited; magnetic resonance can show active involvement either by an increased myocardial signal, indicating active inflammation, or by regional wall motion abnormalities.

Generalized thickening of the myocardium and valves is seen in advanced cardiac amyloidosis. Early involvement may not be apparent, although abnormal diastolic function may be suggestive. Other myocardial diseases in which abnormalities have been demonstrated include myocarditis, systemic lupus erythematosus, Pompe's disease, and Fabry's disease.

Endocardium

Magnetic resonance is not as good as echocardiography at demonstrating small moving structures such as thickened valves and vegetations, but it is able to detect complications of infective endocarditis such as aneurysms and abscesses. The interpretation of spin echo images is only minimally compromised by the presence of a prosthetic valve and, because infection of these valves is a frequent cause of perivalvular abscess, MRI should be used if there is any doubt after echocardiography.

Valve disease

Regurgitation

If only a single valve is regurgitant, comparison of the left and right ventricular stroke volumes allows the regurgitant fraction to be calculated. If single valves on both sides of the heart are regurgitant, the method can be extended by comparing ventricular stroke volumes with flow in the great vessels, the latter measured by magnetic resonance velocity mapping. The regurgitant fraction then compares well with the regurgitant grade assessed by Doppler echocardiography. The method still fails if both valves on one side of the heart are regurgitant, but flow studies in the proximal aorta (or pulmonary artery) can be used to measure aortic (or

pulmonary) regurgitation alone from the amount of retrograde diastolic flow in the artery, and it is then possible to assess even the most complex cases.

Regurgitation can also be detected using cine gradient echo imaging when a turbulent jet of regurgitation is seen as an area of signal loss (Fig. 6). The size of the jet can be used as a semiquantitative measure of regurgitation, although factors other than the size of jet can affect the area of signal loss.

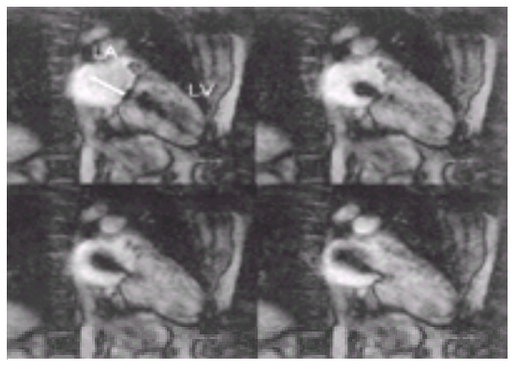

Fig. 6 Four systolic frames from a cine gradient echo acquisition in the vertical long axis plane in a patient with rheumatic mitral stenosis and regurgitation. The regurgitant jet from the left ventricle (LV) to the left atrium (LA) is seen by virtue of signal loss (black) from the turbulence. The size of the jet indicates that regurgitation is moderate.

Stenosis

As with regurgitant jets proximal to a valve, a turbulent distal jet can be used to detect potential stenosis, although abnormal valves that are not stenosed can also generate turbulence. The best method of assessing stenosis is therefore to use cine velocity mapping to measure the peak velocity within the jet. The modified Bernoulli equation, commonly used in Doppler echocardiography, can then be used to estimate the pressure gradient across the stenosis. A disadvantage of magnetic resonance is that it is not yet real-time and so careful alignment of the imaging plane is required in order to obtain an accurate measurement.

Ischaemic heart disease

Myocardial infarction

Magnetic resonance imaging can be used in a number of ways to detect and measure the extent of acute myocardial necrosis. The simplest methods are to use spin echo or cine gradient echo imaging to image the associated wall motion abnormality: the findings agree well with X-ray left ventriculography. Alterations in the myocardial signal can also be observed, an increase of signal in *T*2-weighted spin echo images occurring only a few hours after occlusion of a coronary artery. The changes are most likely related to oedema and the abnormal area may include viable as well as necrotic myocardium.

Abnormal signal can also be observed in *T*1-weighted images, but these changes follow a different time course to the changes of *T*2 and are maximal at 6 weeks, possibly corresponding to cellular infiltration and repair rather than to oedema. Intravenous contrast agents can highlight the abnormalities and have helped to distinguish reperfused from continuing ischaemia in animal models. The same has not been possible in humans.

Reversible ischaemia

Dynamic exercise is impractical within a scanner, but pharmacological intervention using dipyridamole or dobutamine is a suitable alternative. Regional function is assessed using cine gradient echo imaging and global function can also be measured from cine velocity mapping of aortic flow. New wall motion abnormalities imply myocardial ischaemia, and there is a close correspondence between these abnormalities and regional perfusion assessed by radionuclide perfusion imaging. The sensitivity of this approach for detecting coronary artery disease depends upon whether a vasodilator or a b-agonist is used. Because the heterogeneities of myocardial perfusion provoked by dipyridamole do not always cause myocardial ischaemia, sensitivity is not as high (60 per cent) as with dobutamine (91 per cent). The latter is therefore the preferred agent for provoking abnormalities when using a wall motion technique.

An alternative method of assessing reversible perfusion abnormalities is to study the transit of a bolus of magnetic resonance contrast medium through the myocardium. This is not possible using conventional triggered images, but with ultra-fast gradient echo (or echo planar) techniques, images can be acquired in more than 100 ms (or more than 50 ms). Images in each cardiac cycle show the arrival and transit of a bolus of contrast (Gd-DTPA) injected into a central vein. Territories supplied by diseased arteries have a delayed arrival of contrast and a reduced signal increase, and abnormalities can be provoked by dipyridamole vasodilatation. Such bolus-tracking studies of perfusion cannot yet replace radionuclide techniques, but they do have the advantage of higher resolution and the potential to provide measurements of myocardial perfusion in absolute terms.

Coronary vessels

Bypass grafts

Coronary artery bypass grafts can be imaged relatively easily using conventional spin echo or gradient echo techniques. In spin echo images, the appearance of a low intraluminal signal, contrasting with the high signal of the surrounding fat or other soft tissue, implies that the graft contains moving blood and is patent, particularly if it can be followed distally to its insertion. If a graft cannot be identified, or if its origin is seen but it cannot be followed distally, then it is likely to be occluded. Using these criteria, sensitivity and specificity for the detection of patent grafts in the region of 90 per cent can be achieved. Internal mammary artery grafts are more difficult to visualize than saphenous vein grafts, partly because of their smaller size and partly because they can be tortuous and therefore more difficult to follow through multiple slices.

Cine gradient echo imaging has been used with similar results and the cine technique is helpful for identifying a graft if there is doubt from the spin echo images alone. Metallic clips and sternal sutures produce larger artefacts in gradient echo than in spin echo images. They are not ferromagnetic and imaging is perfectly safe, but the artefacts can complicate image interpretation. More recently, contrast-enhanced magnetic resonance angiography has proved useful for demonstrating the anatomy of the tortuous bypass coronary graft.

Native arteries

The coronary arteries are small, tortuous, and rapidly moving: three properties that conspire against successful imaging. Despite this, the proximal vessels can nearly always be identified in conventional spin echo images and their appearance with a low intraluminal signal implies that they contain moving blood and are patent. Unfortunately, resolution is not sufficient to identify stenoses reliably. Rapid gradient echo techniques and acquisition within a single breath-hold provide much better images; moreover, the resolution is adequate for detecting atheromatous disease (Fig. 7). Spiral and echo planar imaging have also been used, all of which can be combined with velocity mapping. Rapid, magnetic resonance flow measurement techniques allow quantification of coronary blood flow reserve, but there is a need to improve the resolution and the reliability of coronary artery imaging and flow measurements non-invasively by magnetic resonance.

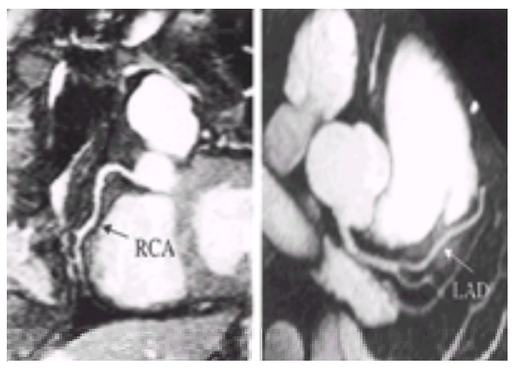

Fig. 7 Breath-hold, contrast-enhanced magnetic resonance angiogram of the right (a) and left (b) coronary arteries in a healthy volunteer. RCA, right coronary artery; LAD, left anterior descending artery.

Computed X-ray tomography

Computed X-ray tomography (CT) is widely available and has an established clinical role in imaging the heart, particularly the pericardium and great vessels (Table 1). Resolution was degraded on earlier generation scanners by cardiac and respiratory motion. State-of-the-art spiral scanners can image the entire heart volume within a single breath-hold, but even the fastest conventional scanner requires 300 ms to acquire a single slice. The best temporal resolution is achieved with electrocardiographic gating and an electron-beam CT scanner (**EBCT**). This uses an electron beam that is focused and deflected on to a stationary target to generate a fan of X-rays that pass through the patient (Fig. 8). In its fastest mode this scanner can acquire two contiguous 8-mm thick slices in 50 ms with a repetition rate of 34 images a second.

Fig. 8 Constrictive pericarditis. Electron-beam CT scan with contrast showing thickened and calcified pericardium, dilated atria, and normal-sized ventricles.

Pericardium

The normal pericardium is seen in 95 per cent of patients by conventional CT, particularly over the anterior surface of the heart. The posterior pericardium is most frequently seen at its caudal insertion into the central tendon of the diaphragm, where it may be 3 to 4 mm thick. It is less easily seen laterally and posteriorly because of the absence of epicardial fat. Pericardial cysts, thickening, calcification, and effusion can be readily identified. The presence of thickening can differentiate pericardial restriction from restrictive cardiomyopathy, although thickening is also seen in a variety of conditions without necessarily implying constriction (Fig. 8).

Aortic dissection

CT is sensitive (83 to 100 per cent) and highly specific (90 to 100 per cent) for the identification of thoracic aortic dissection. This is similar to MRI and transoesophageal echocardiography, but CT is more widely available. The true and false lumens are commonly seen separated by an intimal flap (Fig. 9). Other features that indicate dissection include differential opacification of the true and false lumens, compression of the true lumen by a thrombosed false lumen, inward displacement of intimal calcification, and intramural haemorrhage. Although CT is particularly successful in identifying the distal extent of dissection and the presence of a haemopericardium, it has limitations. Artefacts may create difficulties, and the intimal tear or flap may not be identified in all cases. Therefore, if findings are negative despite strong clinical suspicion of dissection, further investigation is necessary.

Fig. 9 Aortic dissection. Electron-beam CT scan with contrast showing a dilated ascending aorta with almost circumferential dissection. The descending aorta is also involved.

Intracardiac masses

The presence, location, and extent of a thrombus and tumour in the cardiac chambers can be defined with both CT and EBCT. In patients with right heart lesions appropriate windowing of the images will allow assessment of the lungs for pulmonary embolism, and in patients with malignant tumours for metastatic disease.

Cardiac structure and function

Using electrocardiographic gating and intravenous contrast medium, EBCT provides cine images at multiple contiguous levels in approximately eight cardiac cycles. This allows a qualitative assessment of ventricular function and morphology. Planimetry can then provide cavity, muscle area, and hence volume at any part of the cardiac cycle. Regional and segmental left ventricular wall motion can be assessed at rest and during pharmacological stimulation, and changes induced by exercise in patients with ischaemic heart disease can be measured.

Coronary calcification

Coronary artery calcification occurs only in the intima, and microcalcification detected by EBCT indicates the presence of atheroma (Fig. 10), arising when lipid pools first collect within the plaque and not necessarily a sign of advanced disease. A reliable and reproducible scoring system for quantifying calcium has been developed, and a significant relationship between the calcium score and the extent and severity of coronary artery disease as assessed by coronary angiography has been established. However, there is only a weak relationship between the presence of calcium and the severity of luminal stenosis at the same site. The absence of calcification on EBCT does not exclude the presence of coronary atheroma, but it does make significant stenosis unlikely.

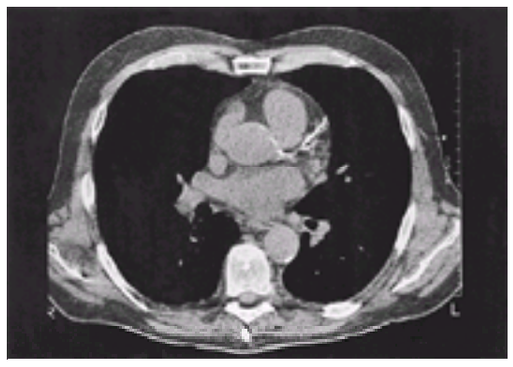

Fig. 10 Coronary calcification. Electron-beam CT scan without contrast. There is high-intensity calcification in the aortic root, the left main stem, left anterior descending, and diagonal coronary arteries.

EBCT offers the possibility of a non-invasive screening test for coronary artery disease, but this use is controversial because the implications of a positive scan are uncertain. It is likely that the incidence of future coronary events is related to the degree of calcification, but the evidence is conflicting. If a relationship between calcium and coronary risk were firmly established, then the technique could play an important role in detecting individuals at risk of coronary events, in selecting people who may benefit most from primary prevention such as lipid-lowering therapy, and in monitoring the progression of disease.

Although EBCT technology is expensive and not widely available, it is possible that modern mechanical CT scanners may also be used to detect coronary calcification, even if in a less sensitive and reproducible fashion.

Coronary angiography

When combined with intravenous X-ray contrast media, EBCT can be used to image the lumen of the coronary arteries and bypass grafts, and three-dimensional images of the coronary tree can be reconstructed from multiple contiguous tomograms. The patency of the arteries and grafts can be determined accurately, but individual stenoses are detected with lesser accuracy and so the technique does not currently provide an alternative to invasive angiography. It is roughly equivalent in terms of accuracy and capability to magnetic resonance coronary angiography. Disadvantages include incomplete visualization of the distal coronary arteries and their branches, and the lack of opportunity to proceed to an intervention if a suitable lesion is demonstrated.

15.3.6 Cardiac catheterization and angiography

Edward D. Folland

Introduction

Invasive cardiac diagnosis by means of catheterization and angiography developed hand-in-hand with cardiac surgery throughout the twentieth century. It answered the need for precise information about cardiac physiology and anatomy, which arose in the 1940s when surgical techniques for the treatment of congenital and rheumatic heart disease first became available. A few years earlier, in 1929, Werner Forsman of Germany successfully and safely passed a filiform urinary catheter from a median basilic vein into the right atrium of his own heart and documented it on X-ray film. Although this feat cost him his own job, it enabled Andre Cournand and Dickenson Richards a decade later to use catheters for sampling blood, measuring pressure and flow, and injecting radio-opaque contrast medium (angiography) into the intact, beating human heart, ushering in the era of invasive cardiac diagnosis. Cournand and Richards later won the Nobel Prize for their important work. This chapter will review the diagnostic applications of cardiac catheterization and angiography.

Indications for cardiac catheterization and angiography

Because catheterization is expensive and entails some degree of risk and discomfort, patients should be carefully selected. In broadest terms, it is indicated for detailed evaluation of patients having coronary, valvular, and congenital heart disease once they have been identified as candidates for surgery or other forms of intervention. It may also be indicated for patients whose diagnosis is uncertain from non-invasive evaluation.

Coronary artery disease

The vast majority of patients presenting for cardiac catheterization have coronary artery disease. Angiography of the coronary arteries performed during cardiac catheterization is essential for patients in whom revascularization is indicated. In spite of the limitations discussed later in this chapter, no other imaging modality, including magnetic resonance imaging and computed tomography, can provide the detailed anatomy of the entire coronary circulation that is needed for planning revascularization procedures such as coronary artery bypass surgery and percutaneous intervention.

Coronary angiography is indicated for patients having chronic stable angina, which persists in spite of reasonable efforts at pharmacological therapy. It is also indicated for patients whose survival would be improved, regardless of symptoms. Such patients are those with severe stenosis of the main left coronary artery and those with severe two- and three-vessel coronary artery disease in combination with impaired left ventricular function. These patients may be identified by the following features of stress testing: ischaemia at low workload (especially in stage 1 of the Bruce Protocol), marked depression of the electrocardiographic ST segment (greater than 2 mm), failure to augment systolic blood pressure during exercise, and large exercise-induced defects or increased lung uptake during radionuclide perfusion imaging. In addition, patients having high-risk clinical presentations such as unstable angina and postmyocardial infarction ischaemia are candidates for angiography. Depending upon the availability of emergency revascularization, patients having acute myocardial infarction may be best served by immediate catheterization. The indications for emergency catheterization and percutaneous revascularization instead of thrombolytic therapy will be covered in more detail in Chapter 15.4.5. Finally, catheterization is sometimes indicated for obtaining a definitive diagnosis when non-invasive testing has yielded equivocal or inconsistent results.

Valvular disease

Catheterization was once considered essential prior to the surgical treatment of valvular heart disease. This is no longer the case because of advances in non-invasive testing using ultrasound and Doppler techniques. Nevertheless, catheterization is a frequently helpful technique for gathering the information needed to properly select patients for surgical therapy and to guide the surgeon in providing optimum treatment. The most common reason for catheterization in these patients is to assess the need for coronary artery revascularization, particularly amongst those with aortic stenosis since coronary artery disease is often present in the age group in which this disease commonly occurs. Haemodynamic study may also be necessary in cases where non-invasive diagnostic data are limited or equivocal. By contrast, it is often possible to avoid catheterization in young patients in whom non-invasive studies yield unequivocal conclusions and there is no evidence of coronary artery disease.

Congenital disease

Most patients with congenital heart defects can be definitively diagnosed by transthoracic or transoesophageal ultrasound. As in valvular disease, catheterization is most useful in cases where the abnormality is unusually complex, the non-invasive data incomplete, or the patient is suspected of having coronary artery disease. Catheterization is particularly useful in quantifying shunt flow and pulmonary vascular resistance, both of which are important considerations in the treatment of intracardiac defects. The physical passage of a systemic venous catheter across the atrial septum into a pulmonary vein or the left ventricle is diagnostic of an atrial septal defect.

Pericardial disease

Pericardial tamponade and constriction lend themselves particularly well to diagnosis by catheterization. Although ultrasound has superseded catheterization as a rapidly available method of confirming the clinical diagnosis of tamponade, it is usually inconclusive for patients with pericardial constriction. At catheterization, patients with both conditions usually demonstrate equalization of all intracardiac diastolic pressures. In addition, unique pressure waveforms are exhibited in the right atrium and right ventricle, which usually distinguish the two diagnoses (Fig. 1).

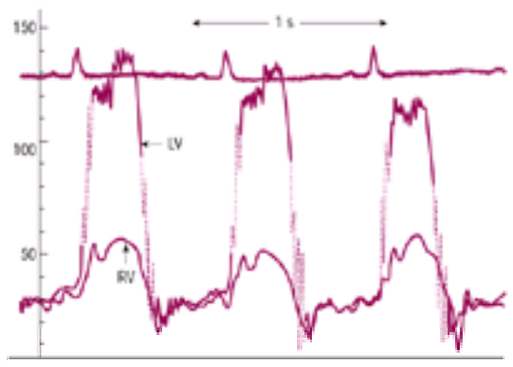

Fig. 1 Pericardial constriction. This is a tracing of simultaneous left ventricular (LV) and right ventricular (RV) pressure in a patient with pericardial constriction. Generally, the diastolic pressure of the left ventricle is higher than that of the right ventricle. For patients with a constriction, the pericardium determines the diastolic compliance of both chambers, causing the diastolic pressures to be equal. Note also the typical 'dip-plateau' pattern or 'square-root sign' of both chambers in diastole. Although diastolic ventricular pressures are also equal for patients having tamponade, the dip-plateau pattern is usually absent.

Congestive heart failure

The aetiology and pathophysiology of congestive heart failure are readily elucidated by catheterization. States of pressure and volume overload as well as systolic and diastolic dysfunction of the ventricles can be easily identified, as explained in detail later in this chapter. Furthermore, catheterization is uniquely suited for identifying transient or reversible causes of left ventricular dysfunction caused by ischaemia or myocardial hibernation due to underlying coronary artery disease. Sometimes exercise or other interventions are performed during a catheter study to elicit transient abnormal haemodynamic function. Myocardial biopsy performed during catheterization can often identify the aetiology of primary myocardial dysfunction.

Pulmonary vascular disease

Patients with primary pulmonary hypertension (see Chapter 15.15.2.1) should undergo catheterization to measure pulmonary vascular pressure and resistance. Certain vasodilating drugs may or may not benefit the patient, depending upon their effect on pressure and resistance during acute administration. Pulmonary angiography performed during right heart catheterization is still regarded as the most definitive test for pulmonary embolism, in spite of advances in radioisotope lung scanning and spiral computed tomography.

Preparing the patient for catheterization

Precatheterization evaluation should consist of a careful history and examination particularly aimed at eliciting details of prior cardiac procedures, reactions to contrast medium, renal function, peripheral vascular status, and haemostatic function. The patient should be carefully advised of the indications, alternatives, risks, discomforts, and expected benefits of the procedure. The skilled clinician does this while building the patient's confidence and avoids creating undue alarm. Following an uncomplicated diagnostic catheterization the patient should usually expect to go home the same day and to resume customary physical activities within a day or two.

Approaches to cardiac catheterization and angiography

Vascular access

The traditional approach to vascular access is via a cut-down near the antecubital fossa. Isolating and mobilizing the brachial or antecubital vein and the brachial artery for right and left heart catheterization may thereby achieve arterial and venous access. Following the procedure the arterial entry site is repaired by suture and the vein is usually tied off. This approach has the advantages of enabling earlier postprocedure ambulation and the security of direct arterial closure in anticoagulated patients. It has the disadvantage of being more time-consuming for most physicians and less cosmetic for the patient.

Percutaneous vascular access is achieved by direct puncture with a needle through which a flexible spring guidewire is passed into the vessel. Catheters may then be passed into the vessel over the guidewire. (The guidewire is placed in the catheter to maintain access during catheter exchanges.) Following the procedure haemostasis is achieved by applying pressure over the puncture site until bleeding stops. Percutaneous access is most frequently employed at the femoral site, although it may also be used at brachial, axillary, internal jugular, and radial locations. It has the advantage of speed, simplicity, and, when performed from the femoral vessels, frees the upper body and arms during angiographic filming. However, percutaneous access has the disadvantage of requiring several hours' immobilization of the catheterization site following the procedure, which is particularly troublesome after femoral puncture since 6 h of postprocedure bedrest is frequently required. Nevertheless, the percutaneous femoral approach has become the preferred choice in 90 per cent of cases, with the recent use of smaller catheters (4 and 5 French) and closure devices for the arterial puncture site enabling earlier ambulation. The percutaneous radial approach is becoming increasingly popular for outpatients.

Right heart catheterization

Right heart catheterization can be performed from any of the approaches described above. Although traditionally performed with a stiff, woven Dacron, end-hole catheter, it is often done with a flexible, balloon-tip, flow-directed catheter (Swan–Ganz) because this is safer and enables the measurement of cardiac output by thermodilution.

Catheterization of the right heart is indicated by itself for the study of pulmonary vascular disease and haemodynamic response to exercise or drug administration. It is indicated in combination with left heart catheterization for patients requiring haemodynamic study of valvular, congenital, or myocardial disease, and for patients being studied primarily for coronary artery disease who also have heart failure, valvular, or pulmonary disease.

Left atrial pressure can be measured indirectly via right heart catheterization by wedging the tip of the catheter in a pulmonary arteriole, or y occluding a pulmonary artery branch with the inflated balloon at the tip of a Swan–Ganz catheter. In either case, this creates a static column of blood from the tip of the catheter, through the pulmonary capillary bed, to the left atrium. This static column of blood has the effect of extending the tip of the catheter to the left atrium for pressure-measuring purposes. The resulting pressure is identical to the directly measured left atrial pressure, except that it is delayed temporally by approximately 80 milliseconds. This pressure, commonly known as the pulmonary (artery) capillary wedge (**PCW**) pressure, is very useful in the management of left heart failure and shock, and for estimating the diastolic gradient across the mitral valve in patients with mitral stenosis.

Left heart catheterization

Left heart catheterization is generally performed in conjunction with coronary angiography, but is specifically required for the assessment of left ventricular function and assessment of stenosis or regurgitation of the left-sided valves (mitral and aortic). It is most often accomplished by femoral or brachial arterial access, and by retrograde crossing of the aortic valve to enter the left ventricle. Left heart catheterization may also be achieved by controlled puncture of the interatrial septum with a catheter originating from the right femoral vein (trans-septal left heart catheterization): this can then be used to measure left atrial pressure directly, and be passed antegradely through the mitral valve to measure pressure and perform angiography of the left ventricle. Retrograde access of the left atrium from the left ventricle is technically difficult and seldom done. The left ventricle may also be entered via transthoracic needle puncture. This approach, known as direct left ventricular puncture, is occasionally necessary for studying patients who have mechanical prosthetic valves at both mitral and aortic positions. The passage of the needle into the left ventricle from the cardial apex is facilitated by echocardiographic guidance.

Information obtained from cardiac catheterization and angiography

Intracardiac pressures

Methodology

Pressure at the tip of the catheter is transmitted through the fluid inside the catheter (usually saline) to a device called a transducer, which converts the pressure signal to an electrical signal that can then be amplified and displayed on a television screen or on a strip-chart paper recording. Once calibrated, the pressure at the tip of the catheter can be read graphically from the recording screen or paper. The fidelity of recording depends upon the physical characteristics of the fluid-filled catheter, stopcocks, connecting tubing, and the pressure transducer itself. A fluid-filled system is usually capable of responding to transient pressure changes up to 20 or occasionally 30 Hz. This is sufficient fidelity to reproduce diagnostically useful pressure waveforms from the heart. However, it is not responsive enough to accurately reproduce the rate of rise of left ventricular pressure during the isovolumic phase of systole (d *P*/d*t*). This requires responsiveness to transient pressure changes of at least 60 Hz, of which fluid-filled catheter systems are not capable. For such applications catheter-tip manometers are available (Millar catheters) in which the transducer is placed at the tip of catheter, eliminating the need for an intervening column of fluid. These devices are expensive and are used only when such fidelity is required, usually in research applications.

Normal intracardiac pressures

The upper limits of all normal intracardiac pressures measurable from a right heart catheter are approximate multiples of six, hence they are easily remembered by 'The Rule of Sixes' (Table 1). For example, the mean right atrial pressure is 6 mmHg or less, mean left atrial pressure is 12 mmHg or less. A further aid to remembering normal pressures is the 'Corollary of Continuity', which means that contiguous chambers have a common pressure when the intervening valve is open. For example, the right ventricle and right atrium are essentially a common chamber when the tricuspid valve is open in diastole, therefore the upper limit of right ventricular end-diastolic pressure is the same as the upper limit of the normal right atrial pressure, or 6 mmHg. This assumes there is no significant stenosis or regurgitation across the tricuspid valve, and that the right ventricle has normal compliance. The same condition applies to the mitral valve in diastole and the pulmonic and aortic valves in systole. Another practical rule is that the pulmonary artery diastolic and pulmonary artery capillary pressures approximate each other in the absence of severe pulmonary vascular disease. Once this has been established for any given patient, the pulmonary artery diastolic pressure can be followed as a surrogate for pulmonary capillary wedge pressure in situations where a pulmonary artery catheter is used for intensive-care monitoring.

All intracardiac pressures rise and fall phasically with breathing due to transmission of shifting intrapleural pressure during respiratory effort. Usually this variation is no more than a few mmHg from inspiration to expiration, but it can be quite marked in patients with obstructive lung disease. Standards of normal pressure are based upon measurements taken during resting respiration, averaging several respiratory cycles. Pressures in the catheterization laboratory should be similarly measured: asking a patient to hold his or her breath may generate misleading data.

Waveforms

The shape of intracardiac pressure waveforms carries useful diagnostic information. Atria and ventricles have characteristic waveforms, the left-sided chambers normally demonstrating similar patterns at relatively higher pressures than right-sided chambers. The state of volume loading and the relative compliance or 'stiffness' of the respective ventricles during diastolic filling determines pressures in the right and left atria. The left ventricle is generally thicker, stiffer, and less compliant to the stretch of increasing volume than the right ventricle; hence the left atrial and left ventricular diastolic pressures are higher than the respective pressures in the right heart. Conditions such as pericardial constriction and tamponade alter this normal relationship (Fig. 1).

Cardiac flow and output

Measurement of cardiac output was one of the earliest applications of catheterization. Most methods entail application of the indicator dilution theory (the 'Fick' principle), summarized graphically in Fig. 2. Stated simply: the rate of flow can be measured if an indicator substance is added to the moving vehicle (for example, blood) at a known rate, and the concentration of the indicator is also known proximal and distal to the point where the indicator is added. The indicator can be any readily measured substance such as oxygen, indocyanine green dye, or saline, the temperature of which is known and different from that of the bloodstream.

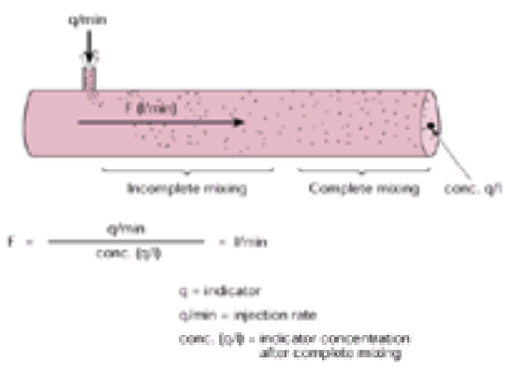

Fig. 2 The Fick principle. The flow rate (*F*) through a vessel (cardiac output, in this case) can be measured if an indicator is added to the flowing liquid at a known rate (*q/min*) and the concentration (*q/L*) of the indicator is measured after complete mixing has occurred.

Cardiac output by oximetry

In this method, commonly called the 'Fick method', the indicator is oxygen which is carried physiologically by the blood. The method requires that the subject be in a metabolic steady state where the use of oxygen is constant. Such a steady state exists at rest and also during exercise, provided that the workload is constant for at least 3 min. As seen in Fig. 3, the pulmonary blood flow can be calculated when the oxygen consumption rate is known and the oxygen contents of blood in systemic and pulmonary arteries are known. In the absence of intracardiac shunts the pulmonary blood flow equals the systemic blood flow, or cardiac output.

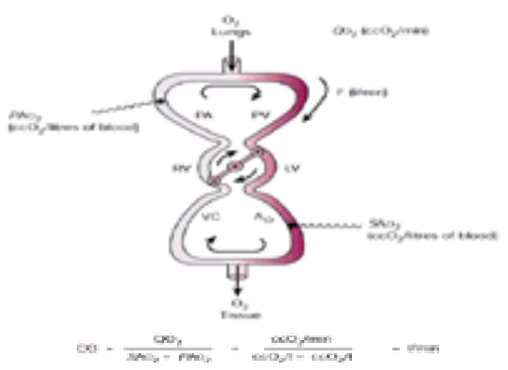

Fig. 3 Cardiac output measured by oximetry. This is an application of the Fick principle in which oxygen is the indicator carried by flowing blood. The patient's metabolism must be at steady state, a condition where oxygen consumption and utilization are matched. It requires three measurements: oxygen consumption rate (QO_2), systemic arterial oxygen content (SAO_2), and pulmonary arterial oxygen content (PAO_2). Other abbreviations: Ao, aorta; CO, cardiac output; LV, left ventricle;

PV, pulmonary vein; RV, right ventricle; VC, vena cava; cc, cm_3.

Dye dilution

This method entails the rapid injection of a known quantity of indocyanine dye into the pulmonary artery. Blood is then sampled by withdrawal at a constant rate from a systemic artery. The sampled blood passes through a spectrophotometer, which is calibrated to measure the concentration of dye. A concentration curve is inscribed when the injected bolus of dye passes the sampling point (Fig. 4). Dividing the quantity of dye injected by the area of the time–concentration curve (corrected for recirculation) yields the cardiac output.

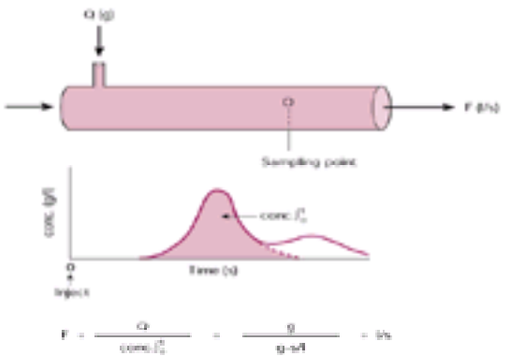

Fig. 4 Cardiac output measured by dye curve. The concentration curve of indocyanine green dye generated by sampling distal to an injection point can be analysed to yield cardiac output. See text for more details. Thermodilution cardiac output employs the same principle, except that temperature is the measured indicator. F, flow or cardiac output; Q, quantity of indicator injected.

Thermodilution

Measurement of cardiac output by thermodilution uses the same principle as dye dilution, with the indicator being 'negative calories' (the difference in caloric content of the injected bolus of cool saline compared to the caloric content of the same quantity of the subject's blood). The downstream 'concentration' of injected negative calories is measured as a transient drop in temperature by a thermistor at the tip of the injection catheter several centimetres from the point of injection. Dividing the negative calories injected by the area of the distal time–temperature curve yields cardiac output. The advantages of speed, automaticity, and repeatability of this method make it particularly suitable for serial measurements during different haemodynamic states.

Angiographic output

This is the only commonly used method that does not employ the indicator dilution or Fick principle. The left ventricular stroke volume calculated from quantitative angiography is multiplied by the heart rate to yield the left ventricular output. In the absence of valvular regurgitation this is the same as cardiac output. As explained in greater detail later in the chapter, this method is particularly useful in assessing mitral and aortic valvular regurgitation.

Quantitative angiography

Quantitative left ventricular angiography enables the measurement of left ventricular volume at instants throughout the cardiac cycle. Radiographic contrast medium is rapidly injected into the left ventricle and the shadow image of the opacified ventricle captured on film or electronically at a particular frame rate in any chosen projection. The most common projection is 30 degrees right anterior oblique at a filming rate of 30 frames per second. In this view the image of the left ventricle is parallel to its long axis, resembling an ellipse, or an American football/rugby ball. Arvidsson and Greene first suggested that the volume of the left ventricle could be calculated from the volume formula for an ellipsoid, the three-dimensional structure created by rotating an ellipse on its long axis. Dodge and Sandler improved upon this concept by deriving the minor hemi-axes from an idealized ellipse of the same length and area as the projected image of the ventricle. This method is still commonly used and is often referred to as the area–length method. Images captured at end-diastole and end-systole are analysed and corrected for magnification to yield end-diastolic and end-systolic volumes, the difference between these volumes being the stroke volume and the product of the stroke volume and heart rate, the angiographic left ventricular output. These indices are useful in the assessment of left ventricular function and valvular regurgitation as discussed later in this chapter.

Intracardiac shunts

The same methods of oximetry and indicator dilution utilized in measuring cardiac output can be employed for the detection and quantitation of intracardiac shunts. Under normal resting conditions, blood is approximately 75 per cent saturated as it returns from the body to the right heart and pulmonary artery. As it leaves the lungs in the pulmonary veins blood is 99 per cent saturated. Intracardiac shunts can be detected, localized, and quantified by measuring the oxygen saturation in various locations. Left to right shunts will cause a step-up in the saturation of the blood at the location of the shunt; for example, in a patient with an atrial septal defect the saturation will rise in the right atrium, whereas with a ventricular septal defect the saturation will rise in the right ventricle. A patient with Eisenmenger's syndrome (pulmonary hypertension and right to left shunting) will exhibit a drop in saturation at the location of the shunt, namely at the left atrium or ventricle in the case of atrial and ventricular septal defects, respectively. The degree of the change in saturation is proportional to the size of the shunt, and enables calculation of the shunt flow in either direction in litres per min. Figure 5 presents a scheme and formulas for calculating shunt volume.

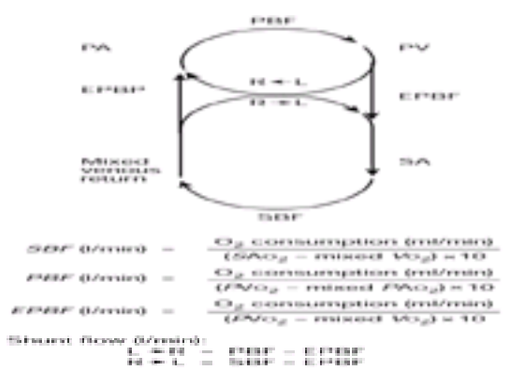

Fig. 5 Quantitation of intracardiac shunts. Shunts between the left and right sides of the heart due to septal defects can be quantified by oximetry using this scheme. PBF, pulmonary blood flow; SBF, systemic blood flow; EPBF, effective pulmonary blood flow, which is that part of the systemic venous return that actually passes through the lungs and is oxygenated; PAO_2, pulmonary artery oxygen content; PVO_2, pulmonary vein oxygen content; SAO_2, systemic artery oxtygen content; mixed VO_2, mixed systemic venous oxygen content.

Vascular resistance

Methodology

Blood flow through the pulmonary and systemic circulations can be compared to the flow of an electric current through a circuit. Pressure is the driving force analogous to voltage, flow rate is analogous to current, and the impediment to flow through the vascular bed is resistance. Pressure, flow, and resistance relate to each other in a fashion analogous to Ohm's law:

$$\text{Resistance} = \text{pressure/flow}.$$

In the above formula 'pressure' is the difference in mean pressure across the systemic vascular bed (systemic arterial pressure—right atrial pressure) or the pulmonary vascular bed (pulmonary artery pressure—left atrial pressure). In the absence of intracardiac shunts 'flow' is the same for both circulations and is measured as cardiac output by methods already described. In cases of intracardiac shunting the systemic and pulmonary flows will differ according to the degree of shunting, and can be calculated as described under the section on cardiac shunts. Normal values for pulmonary vascular and systemic vascular resistance are expressed either in dyne s cm^{-5} or Wood units and are displayed in Table 2. Total pulmonary resistance is a useful concept for expressing the total resistance against which the right ventricle must work, and includes not only the pulmonary vascular resistance, but also the resistance engendered by the static pressure in the left atrium. Hence, pulmonary vascular disease, left heart failure, or both, can increase the total pulmonary resistance.

Clinical application

Measurement of resistance is useful for assessing the state of the pulmonary circulation in congenital heart disease with intracardiac shunting: high pulmonary vascular resistance may preclude the safe correction of an intracardiac shunt, particularly if the shunt is from right to left. It is also useful in diagnosing the relative contribution of left heart failure and pulmonary vascular disease in patients with pulmonary hypertension, and is the best indicator of the effectiveness of vasodilating drugs for patients with pulmonary hypertension.

Valvular stenosis

Valvular stenosis is assessed by measuring the transvalvular pressure gradient and by calculating the valvular orifice area using a formula introduced in the late 1940s by cardiologist Richard Gorlin and his father, an engineer. The Gorlin formula for valve area was initially developed for patients with rheumatic mitral stenosis. It is based upon a study which utilized data from right heart catheterization alone, validated by relatively crude intraoperative estimates of valve area using the index finger of surgeon Dwight Harken during closed mitral commissurotomy operations at the Peter Bent Brigham Hospital in Boston, Massachusetts. In spite of this, the formula has stood the test of time and remains the standard for the haemodynamic assessment of valvular stenosis. In its generalized form it is expressed as follows:

$$\text{Valve area} = \text{transvalvular flow rate}/K \text{ Ögradient}.$$

In the above formula K is a constant unique to mitral or aortic valve analysis (38 and 44.5, respectively). The transvalvular flow rate (**TFR**) is cardiac output normalized for the time that the valve is actually open. In aortic valve applications TFR is the cardiac output divided by the product of heart rate and systolic ejection period. In mitral valve applications it is the cardiac output divided by the product of heart rate and diastolic filling period. Cardiac output is the effective systemic blood flow as determined by Fick, thermodilution, or dye dilution methods unless there is associated valvular regurgitation, in which case it is the total left ventricular output as determined by quantitative left ventricular angiography. Gradient is the mean pressure gradient in mmHg during the time when the valve is open.

Figure 6 shows tracings that demonstrate typical gradients from patients with aortic and mitral stenosis. The ranges of calculated valve area associated with various levels of stenosis for both aortic and mitral valves are displayed in Table 3. In general, procedures performed for the relief of anatomical stenosis are expected to be beneficial in symptomatic patients with severe valvular obstruction. However, many factors enter into such a decision and individual clinical judgement is required. Although patients with large transvalvular gradients generally experience the best result from intervention, the gradient by itself can be misleading due to its exponential relationship to cardiac output.

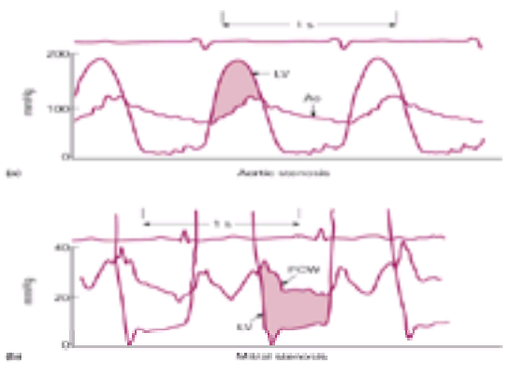

Fig. 6 Pressure gradients associated with valvular stenosis. The upper panel shows simultaneous tracings of left ventricular (LV) and ascending aortic (Ao) pressure in a patient with severe aortic stenosis. The mean systolic gradient across the aortic valve is 60 mmHg. The lower panel shows simultaneous tracings of left ventricular (LV) and pulmonary capillary wedge (PCW) pressure in a patient with severe mitral stenosis. The mean diastolic pressure gradient across the valve is 16 mmHg. The respective valvular gradients are cross-hatched.

Valvular regurgitation

Qualitative assessment

Regurgitation of all four cardiac valves can be qualitatively assessed by angiography. The downstream side of the valve in question is opacified by a rapid injection of radiographic contrast medium. Regurgitation is visualized as upstream leakage of contrast across the closed valve. In the case of mitral regurgitation systolic opacification of the left atrium occurs during injection of the left ventricle. In aortic regurgitation diastolic opacification of the left ventricle occurs during supravalvular injection of the aorta. The degree of regurgitation is graded on an arbitrary scale from mild (1+) to severe (4+).

Quantitative assessment

Aortic and mitral regurgitation can be quantified in terms of regurgitant flow in litres per min or regurgitant fraction as a percentage of left ventricular output. The method requires measurement of the total left ventricular output by the angiographic method and subtraction from that of the effective forward output measured by the Fick or indicator dilution methods (both described earlier). It is the best method for measuring the severity of regurgitation, provided that the left ventricular angiogram, which itself changes cardiac output, is performed soon after the Fick measurement. Furthermore, both measurements must be made with considerable care to ensure accuracy. Regurgitation is considered clinically severe when 50 per cent or more of the total left ventricular output is simply shuttling or regurgitating across the defective valve. The ability to quantify regurgitation across either valve is lost when both mitral and aortic valves are leaky.

Left ventricular function

Global function

Global function of the left ventricle is broadly described by its ability to generate pressure and flow under particular conditions of preload and afterload. Plotting the pressure and volume of the left ventricle at instants in time for a single cardiac cycle generates a pressure–volume loop displayed in Fig. 7. Most of the commonly

used indices of left ventricular function can be derived from such a loop, including end-diastolic volume, end-systolic volume, stroke volume, ejection fraction, end-diastolic pressure, and d*P*/d*t*. Of these, the ejection fraction is most useful because it correlates with prognosis in a variety of cardiac diseases.

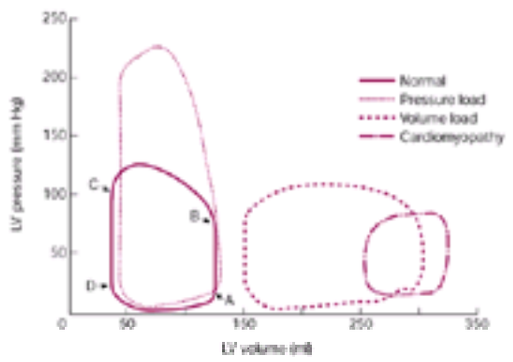

Fig. 7 Pressure–volume loops. Simultaneously plotting the instantaneous pressure and volume of the left ventricle throughout a single cardiac cycle produces these loops. The loop is a synthesis of most information relevant to left ventricular function. In this figure a loop from a normal patient is contrasted with those from patients with pressure load (hypertension or aortic stenosis), volume load (aortic or mitral regurgitation), and cardiomyopathy. Point A represents mitral valve closure; segment A–B, isovolumic contraction; point B, aortic valve opening; segment B–C, systolic ejection; point C, aortic valve closure; segment C–D, isovolumic relaxation; point D, mitral valve opening; and segment D–A, diastolic filling.

Grading angiographic wall motion in various segments of the left ventricle as normal, hypokinetic, akinetic, or dyskinetic assesses the regional function of the left ventricle. Regions of abnormal function generally correspond to locations of infarcted myocardium.

Contractility

This parameter is difficult to assess in the intact heart, because all pressure and volume indices are dependent upon preload and afterload. Although ejection fraction is clinically useful it can be misleading in situations of high afterload (for example, severe aortic stenosis) and low afterload (for example, severe mitral regurgitation). The concept of 'elastance' has gained favour as a useful index of intrinsic contractility, because it is relatively independent of loading conditions. Elastance is the slope of the line generated by plotting the end-systolic left ventricular pressure from a series of pressure–volume loops generated at differing afterloads created by the infusion of pressor or vasodilator drugs. The method is laborious and generally reserved for research applications.

Diastolic function

Diastolic function of the left ventricle is best appreciated from the slope of the pressure–volume loop during the period from mitral valve opening to its closure at the onset of systole. The curve becomes steeper as the left ventricle becomes less compliant due to the effects of hypertrophy, ischaemia, or infiltrative disease. In general, left ventricular end-diastolic pressure (**LVEDP**) rises as diastolic compliance falls, accounting for the high left atrial pressure and heart failure seen in diastolic left ventricular dysfunction.

Assessment of coronary arterial anatomy and function

Disease of the coronary arteries may be characterized at catheterization by both anatomical and functional assessment. Coronary angiography images the lumen of the vessel, which has been rendered radio-opaque by injection of radiographic contrast medium. It is a shadowing technique, which displays the impact of the lesion on the arterial lumen, but does not image the plaque *per se*. Intracoronary ultrasound provides a tomographic image of the vessel wall and is capable of demonstrating the thickness and sonic density of the vessel wall and any associated plaque. Angiography and intravascular ultrasound are complementary methods of assessing vascular anatomy. To learn the haemodynamic importance of a coronary lesion it may be necessary to analyse its effect on function by measuring pressure and flow in the affected vessel. All these anatomical and functional modalities may be accomplished by catheterization.

Coronary arteriography or angiography

Coronary arteriography or angiography is presently the single most essential application of cardiac catheterization. The anatomy of coronary arteries in living, conscious humans was first demonstrated by non-selective injection of the aortic root. In the early 1960s David Littmann developed a loop catheter that enabled the injection of contrast medium preferentially in the outer circumference of the aortic root, opacifying the left and right coronary arteries simultaneously. At the time it was commonly believed that selective injection of contrast material into a coronary artery would have fatal consequences. This changed when Mason Sones accidentally performed the first selective coronary angiogram without harm. He was intending to inject the left ventricle, but the catheter recoiled across the aortic valve and into the right coronary artery. Sones, a cardiologist by training, went on to develop a safe method of selective coronary angiography from the brachial artery cut-down approach using the flexible-tip catheter bearing his name. At the same time Melvin Judkins, a radiologist by training, was perfecting his own method of selective coronary angiography, using preshaped catheters, from a percutaneous femoral artery approach. Both methods have continued to be practised, although the percutaneous femoral, or Judkins' approach, has become most popular because of its speed and simplicity. In recent years there has been a return to the brachial and even radial artery approach using percutaneous methods, which enable more rapid patient ambulation.

Normal coronary anatomy is demonstrated in Fig. 8. A patient's anatomy is considered to be right- or left-dominant, depending upon whether the posterior descending artery arises from the right or left coronary artery, respectively. Approximately 80 per cent of humans are right-dominant.

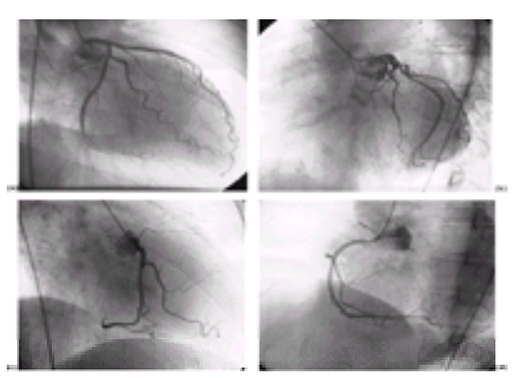

Fig. 8 Normal coronary anatomy. Left coronary angiogram showing main stem, left anterior descending, and left circumflex arteries from right anterior oblique (RAO) view (a) and left anterior oblique (LAO) view (b). Right coronary angiogram showing right coronary and posterior descending arteries from RAO view (c) and LAO view (d).

Atherosclerotic disease is manifest by lesions that encroach upon the opacified lumen of the coronary artery (Fig. 9). Various approaches are used to grade the severity of these lesions. Most commonly a visual estimate of the percentage of the diameter of stenosis is given to each lesion. Lesion severity may be quantified by comparing the minimal lumen diameter within a lesion to the diameter of the nearest normal segment of artery. This can be done manually using callipers or automatically using computer-based systems for edge detection and contrast densitometry. Quantitative coronary angiography is a complex subject because it

requires attention to many variables, such as selection of view and frame, and choice made from among several analytical techniques.

Fig. 9 Atherosclerotic coronary artery disease. The constrictions and blunt terminations seen in this patient's coronary angiogram represent atherosclerotic lesions.

Early work by Lance Gould determined that a lesion must impair coronary blood flow to be clinically important. Although flow at rest is usually not reduced until the diameter of the stenosis exceeds 90 per cent, flow under stress may be reduced when the diameter of the stenosis is 70 per cent. The clinical impact of a stenosis of any given severity is also dependent upon the degree of collateral flow into the vascular bed distal to the stenosis.

Flow and pressure may be directly measured in the coronary artery by means of special guidewires that have pressure transducers or Doppler flow transducers mounted near their tips. As mentioned above, the flow at rest may be normal across a particular coronary artery stenosis. Coronary flow normally increases after maximal vasodilatation induced by local vasodilators. The quotient of the vasodilated flow divided by the resting flow is called the coronary flow reserve, which is normally greater than two. If not, the lesion in question is considered to be haemodynamically important. Pressure can be measured in the coronary artery at a location distal to a lesion using a guidewire with a transducer at its tip. The quotient of pressure distal to a lesion compared to the proximal pressure during maximal vasodilatation is called the fractional flow reserve. A quotient less than 0.75 is considered to be clinically important.

Intravascular ultrasound

Intravascular ultrasound (**IVUS**) is accomplished by advancing a catheter over a guidewire previously placed into a coronary artery. The catheter has a miniature ultrasound transducer near its tip, which enables rotational Doppler imaging of the vessel wall in a plane perpendicular to its axis. IVUS is particularly useful for assessing the nature of angiographically questionable lesions, determining the true size of the vessel prior to stent deployment, and assessing the completeness of stent deployment. It is also probably the best method for serial studies of coronary anatomy during drug treatment trials, because it is able to image the plaque itself and is therefore a more sensitive method than angiography.

Complications

Although cardiac catheterization is a relatively safe procedure, it is nevertheless important for both the patient and the referring physician to recognize the nature and likelihood of potential complications. Table 4 lists the complications of bilateral heart catheterization including coronary, left ventricular, and aortic angiography in a prospective study of valvular heart disease from the United States Veterans Administration. Even though these data were collected over 20 years ago from a particularly high-risk group of patients, the frequency of complication is a realistic estimate of what should currently be expected. The rate of each particular complication will vary with the age and general health of the patient. For example, the risk of vascular complication is considerably increased by the presence of vascular disease, and the risk of renal failure due to contrast medium is particularly high in diabetic patients with pre-existing renal dysfunction. Therefore, in counselling the patient regarding the likelihood of untoward events it is important to give individualized advice based upon the patient's particular circumstances. Finally, the decision to recommend catheterization must be based upon the anticipation that its benefits justify its cost and risk.

15.4.1.1Influences acting *in utero* and early childhood

D. J. P. Barker

The fetal origins hypothesis

Over the past 10 years epidemiological studies have shown that people who had low birthweight, or who were thin or short at birth, are at increased risk of developing ischaemic heart disease and the related disorders stroke, hypertension, and non-insulin dependent diabetes (NIDDM). Associations between small size at birth and later disease, first recorded in Britain, have now been extensively replicated in studies in Europe and the United States. The associations extend across the whole range of birthweight and depend on lower birthweights in relation to the duration of gestation rather than the effects of premature birth. They are not the result of confounding variables acting in later life, such as low socio-economic status and smoking.

These observations have given rise to the 'fetal origins hypothesis', which proposes that cardiovascular disease originates through adaptations which are made by a fetus when it is under-nourished. Unlike adaptations made in adult life, those made during early development tend to have permanent effects on the body's structure and function—a phenomenon sometimes referred to as programming.

Fetal nutrition

In common with other living creatures, human beings are 'plastic' in their early life, and are shaped by their environment. Although the growth of a fetus is influenced by its genes, studies in humans and animals suggest that it is limited by the environment, in particular by the nutrients and oxygen the fetus receives from the mother. The fetus responds to undernutrition in a number of ways. It can redistribute its cardiac output to protect key organs, the brain in particular; it can alter its metabolism, for example by switching from glucose to amino acid oxidation; and it can change the production of, or tissue sensitivity to, hormones regulating growth, in which insulin has a central role. Slowing of growth is also adaptive because it reduces the requirement for substrate. Experiments show that even minor modifications to the diets of pregnant animals may be followed by life-long changes in the offspring in ways that can be related to human disease, for example raised blood pressure and altered glucose–insulin metabolism.

Birthweight serves as a marker of fetal nutrition and growth, but it is an imperfect one. The fetus can adapt to undernutrition and continue to grow at the same rate, but with permanently altered physiology and metabolism. Furthermore, the same birthweight may be the outcome of many different paths of growth. Where more detailed measurements of body size at birth are available they can give insights into adaptations that the fetus has made. For example babies that are thin, though within the normal range of birthweight, tend to be insulin resistant as children and adults and are therefore liable to develop NIDDM. It seems that the thin baby responds to undernutrition through endocrine changes.

Ischaemic heart disease

An important clue suggesting that ischaemic heart disease might originate during fetal development came from studies of death rates among babies in Britain during the early 1900s. The usual certified cause of death in new-born babies at that time was low birthweight. Death rates in the new-born differed considerably between one part of the country and another, being highest in some of the northern industrial towns and the poorer rural areas in the north and west. This geographical pattern in death rates was shown to closely resemble today's large variations in death rates from ischaemic heart disease, variations that form one aspect of the continuing inequalities in health in Britain. One possible conclusion suggested by this observation is that low rates of growth before birth are in some way linked to the development of ischaemic heart disease in adult life.

The subsequent studies that confirmed the association between ischaemic heart disease and small size at birth were based on the simple strategy of examining men and women in middle and late life whose body measurements at birth were recorded. In the first study of this kind, 16 000 men and women born in Hertfordshire, United Kingdom, during 1911 to 1930 were traced from birth to the present day. Death rates from ischaemic heart disease fell two-fold between those at the lower and upper ends of the birthweight distribution (Fig. 1). A study in Sheffield, United Kingdom, showed that it was people who were small at birth because they failed to grow, rather than because they were born early, who were at increased risk of the disease. The association between low birthweight and ischaemic heart disease has been confirmed in studies of men in Uppsala (Sweden), Helsinki (Finland), and Caerphilly (Wales), and among women in Helsinki and the United States. Among 80 000 women in the American Nurses Study there was a two-fold fall in the relative risk of non-fatal ischaemic heart disease across the range of birthweight. An association between low birthweight and prevalent ischaemic heart disease has recently been shown in a small study in South India. Among Indian men and women aged 45 years and over the prevalence of the disease fell from 18 per cent in those who weighed 5.5 lb (2.5 kg) at birth to 4 per cent in those who weighed 7 lb (3.2 kg) or more.

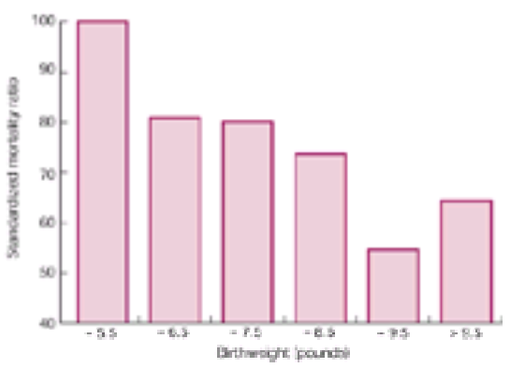

Fig. 1 Death rates from ischaemic heart disease in 15 726 men and women born in Hertfordshire according to their birthweights.

Some of these epidemiological studies included birth length, and other measurements of size at birth, in addition to weight. In Sheffield and in India, rates of ischaemic heart disease were higher in men who had short body length at birth. Thinness at birth, as measured by a low ponderal index (birthweight/length ^{3}), has also been found to be associated with ischaemic heart disease. Among men born in Helsinki, Finland, while low birthweight was associated with raised death rates for ischaemic heart disease, there was a stronger association with thinness at birth, especially in men born at term (Fig. 2). Among women in the same cohort, those who developed ischaemic heart disease also had low birthweight but were short at birth rather than thin. Since the men and women were born to the same group of mothers this difference may reflect intrinsic differences between the sexes in their paths of fetal growth. In the whole cohort, body proportions at birth differed in the sexes: the girls tended to be short while the boys tended to be thin. This may reflect differences in rates of fetal growth at similar levels of maternal nutrition. Female fetuses grow more slowly from an early stage of gestation and are therefore less vulnerable to undernutrition. The lower rates of ischaemic heart disease among women could be related to their slower rates of growth *in utero*.

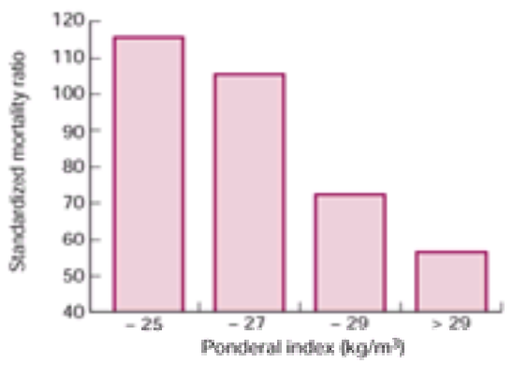

Fig. 2 Death rates from ischaemic heart disease in 3302 Finnish men born at term according to their ponderal indices at birth (birthweight/length ^{3}).

Stroke

The pattern of body proportions at birth which predicts stroke is different to that which predicts ischaemic heart disease. Whereas stroke is similarly associated with low birthweight it is not associated with thinness or shortness. Instead, the studies in Sheffield and Helsinki found increased rates among men who had a low ratio of birthweight to head circumference. One interpretation of this is that normal head growth was sustained at the cost of interrupted growth of the body in late gestation. 'Brain-sparing' patterns of growth can result from diversion of cardiac output to the brain at the expense of the abdominal viscera, importantly the liver. Preliminary evidence suggests that this has lasting effects on liver function including altered regulation of low density lipoprotein cholesterol and raised plasma fibrinogen concentrations, a known risk factor for stroke.

Hypertension

Studies of the mechanisms linking low birthweight with ischaemic heart disease have shown that the progressive fall in disease rates across the range of birthweight (Fig. 1) is paralleled by progressive falls in two of its major biological risk factors—hypertension and NIDDM. Associations between low birthweight and raised systolic and diastolic pressure in childhood and adult life have been extensively documented around the world. Averaged across 69 studies, the difference in systolic pressure associated with a 1-kg difference in birthweight is around 3.5 mmHg. In clinical practice this would be small, but it is a large difference between the mean values of populations. Available data suggest that lowering the mean systolic pressure in a population by 10 mmHg would correspond to a 30 per cent reduction in total attributable mortality. Although in these studies alcohol consumption and higher body mass were also associated with raised blood pressure, the associations between birthweight and blood pressure were independent of them. Nevertheless, body mass remains an important influence on blood pressure and, in humans and animals, the highest blood pressures are found in those who were small at birth but become overweight as adults.

Table 1 shows the systolic pressures of a group of 50-year-old men and women who were born at term in Preston, United Kingdom. The subjects are grouped according to their birthweights and placental weights. Consistent with findings in other studies, systolic pressure fell between subjects with low and high birthweight. In addition, however, there was an increase in blood pressure with increasing placental weight. Subjects with a mean systolic pressure of 150 mmHg or more, a level sometimes used to define hypertension in clinical practice, comprised a group who as babies were small in relation to the size of their placentas. A rise in blood pressure with increasing placental weight has also been found in children in Salisbury, United Kingdom, and Adelaide, Australia, but in studies of children and adults the association between placental enlargement and raised blood pressure or ischaemic heart disease has been inconsistent.

As yet, we know little about the mechanisms which underlie the association between low rates of fetal growth and raised blood pressure. One suggestion is that retarded fetal growth leads to a reduced number of nephrons which in turn leads to increased pressure in the glomerular capillaries and the development of glomerular sclerosis. Another hypothesis which is being actively investigated is that fetal undernutrition leads to life-long changes in the fetus' hypothalamic–pituitary–adrenal axis and these in turn reset homeostatic mechanisms controlling blood pressure. Excessive cortisone production, as occurs in Cushing's syndrome, is associated with raised blood pressure and people who were small at birth have elevated plasma cortisol concentrations within the normal range. A third hypothesis derives from the observation that men and women in Sheffield who were small at birth had reduced elasticity in the large arteries of the trunk and legs, and raised blood pressure. The elasticity of larger arteries depends on elastin, which is laid down *in utero* and during infancy and thereafter turns over slowly: its half-life is 40 years. The amount of elastin laid down *in utero* increases with blood flow. 'Brain-sparing' diversion of blood to the brain could therefore lead to permanent loss of elasticity in the large arteries of the trunk.

Non-insulin dependent diabetes

Both insulin resistance and deficiency in insulin production are thought to be important in the pathogenesis of NIDDM. There is evidence that both may originate during fetal life. Men and women with low birthweight and a low ponderal index have a high prevalence of the 'insulin resistance syndrome', in which impaired glucose tolerance, hypertension, and raised serum triglyceride concentrations occur in the same patient. The patients are insulin resistant and hyperinsulinaemic. A number of studies have shown that people who had low birthweight are already insulin resistant in childhood. A study of men and women who were *in utero* during the war-time famine in Holland provides direct evidence that maternal undernutrition can programme insulin resistance and NIDDM in the offspring. The 'Dutch famine' began abruptly in November 1944 and ended with the liberation of Holland in 1945. The official rations varied between 400 and 800 calories per day. Men and women exposed to the famine *in utero* had higher 2-h plasma glucose concentrations after a standard oral glucose challenge than those born before or conceived after it. They also had higher fasting plasma proinsulin and 2-h plasma insulin concentrations, suggesting insulin resistance.

Figure 3 brings together some of the ideas and findings about the mechanisms through which ischaemic heart disease may be programmed *in utero*. It is a working hypothesis and will need to be re-evaluated as more information becomes available.

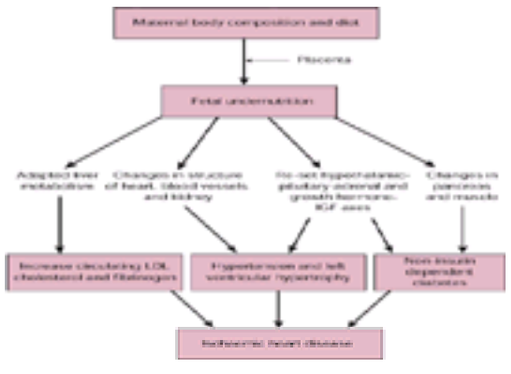

Fig. 3 Framework of possible mechanisms linking fetal undernutrition and ischaemic heart disease.

Ischaemic heart disease and childhood growth

As already described, babies that have low birthweight and are thin or short are at increased risk of ischaemic heart disease in adult life. We are beginning to learn how childhood growth modifies this risk. In the Helsinki study, ischaemic heart disease was commonest among men who were thin at birth, but who 'caught-up' in weight before the age of 7 years and had above average body mass index thereafter. Among women in the same cohort, those who developed ischaemic heart disease were short at birth but had accelerated growth in height in childhood. Table 2 shows that among men with the lowest ponderal indices at birth, but the highest

body mass indices in childhood, the risk of ischaemic heart disease was five times that of men with the highest ponderal indices but lowest body mass indices in childhood. It is not known why accelerated postnatal growth is detrimental. One speculation is based on the observation that restricted fetal growth leads to permanently reduced cell numbers in tissues such as the kidney, in which there is no further cell replication after birth. Accelerated postnatal growth could be deleterious either because overgrowth of a limited cell mass disrupts cell function or because large body size imposes an excessive metabolic demand on a limited cell mass.

Whatever underlies the association between death from ischaemic heart disease and accelerated growth in height and weight in early childhood, imbalances between prenatal and postnatal growth seem to be important in the genesis of adult disease. The effects of adult obesity are a further illustration of this. The highest prevalence of NIDDM is found in people who had low birthweight but become obese as adults. The Dutch famine had its greatest effect on the glucose tolerance of men and women who were overweight as adults.

Maternal nutrition

The nutrition of the fetus depends on the nutrition of the mother. In recent years 'maternal nutrition' has been equated with the diets of pregnant women. This is too limited a definition. Mellanby wrote in 1933 that 'it is certain that the significance of correct nutrition in child-bearing does not begin in pregnancy itself or even in the adult female before pregnancy. It looms large as soon as a female child is born and indeed in its intrauterine life'. Maternal nutrition defined in this way encompasses the nutritional experience of the mother from her own conception, through fetal life, childhood, and into adolescence and adult life. The Helsinki study shows that the mother's body composition before and during pregnancy is an important influence in programming the fetus. Figure 4 shows mortality from ischaemic heart disease according to the men's ponderal indices and their mothers' body mass indices (weight/height ^{2}) in late pregnancy. At any ponderal index, death rates were higher in men whose mothers had a high body mass, so that the highest rates were in men who were thin at birth but whose mothers had a high body mass. The effect of body mass was confined, however, to the offspring of mothers of below average stature (below 1.58 m). The processes by which high body mass in short mothers compounds the increased risk of ischaemic heart disease that is associated with thinness at birth are currently under investigation. The findings already described suggest that raised plasma glucose concentrations in overweight women, which necessarily lead to higher glucose intakes by the fetus, may be one influence.

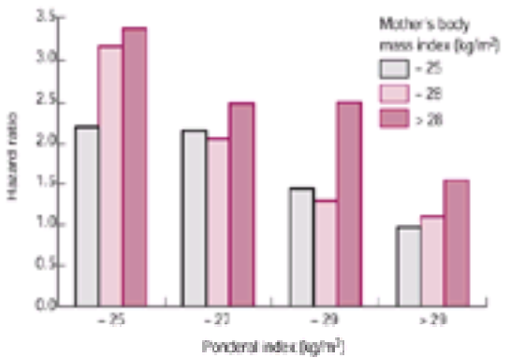

Fig. 4 Hazard ratios for ischaemic heart disease in Finnish men according to their ponderal indices at birth (birthweight/length ^{3}) and their mother's body mass indices (weight/height^2).

There is now a body of evidence suggesting that mothers who are thin also afford an unfavourable environment to their fetuses, leading to insulin resistance and raised blood pressure in the offspring. In the Dutch famine, for example, it was people born to mothers with the lowest weights in pregnancy who had the highest 2-h plasma glucose concentrations. Maternal thinness may have different consequences for the fetus depending on whether it is reflected in a low body mass index, low weight gain in pregnancy, or low skinfold thickness. Mothers' diet in pregnancy has been directly related to cardiovascular risk factors in the offspring during adult life in studies in Aberdeen, Scotland. The blood pressures of men and women were related to the balance of animal protein and carbohydrate in their mothers' diets in late pregnancy, while high intakes of fat and protein were associated with insulin deficiency. The findings of this small study are currently being examined in a larger study in Scotland.

Conclusion

Studies of programming in fetal life and infancy are now established in the agenda for medical research. They have refocused attention on maternal nutrition and fetal growth. The search for the environmental causes of ischaemic heart disease has hitherto been guided by a 'destructive' model. The causes to be identified act in adult life and accelerate destruction processes: the formation of atheroma, rise in blood pressure, and loss of glucose tolerance. There is now a 'developmental' model for the disease. The causes to be identified act on the baby. In responding to them the baby ensures its continued survival and growth at the expense of premature death from ischaemic heart disease.

15.4.1.2 The epidemiology of ischaemic heart disease

A. R. Ness and G. Davey Smith

Introduction

Ischaemic heart disease (IHD) is defined by a joint International Society and Federation of Cardiology and World Health Organization task force as 'myocardial impairment due to an imbalance between coronary blood flow and myocardial requirements caused by changes in the coronary circulation.' In this chapter we will focus on the epidemiology of the clinical manifestations of IHD. These include angina pectoris, myocardial infarction, and coronary death.

Atherosclerosis is clearly an important underlying pathological process in IHD. Other non-coronary manifestations of atherosclerotic disease include stroke, peripheral vascular disease, and aortic aneurysm. These different conditions share some epidemiological features but show distinct patterns in other respects. For example there is little correlation between IHD and stroke mortality across countries, and within Britain aortic aneurysm mortality correlates negatively with both stroke and IHD mortality. It therefore makes more sense to consider the epidemiology of these conditions separately rather than together.

The process of atheroma deposition and arterial narrowing in the coronary vasculature cannot be observed directly in life without the use of invasive clinical procedures such as coronary angiography. The thickness of carotid arteries measured ultrasonically is currently under evaluation and may prove to be a useful marker of atheroma. Even so, the study of symptomatic disease rather than the underlying process of atheroma deposition may actually be more appropriate. The clinical disease is, after all, what is experienced and may represent the culmination of a number of pathological processes. Indeed, the fact that changes in atherosclerosis at post mortem over time do not mirror changes in clinical IHD rates suggest that it would be unwise to concentrate on the epidemiology of a single pathological process.

IHD is a—or the—leading cause of death in most developed countries. The rates of such deaths in men and women from the populations participating in the World Health Organization MONICA (monitoring trends and determinants in cardiovascular disease) study, which established arrangements to monitor the mortality and incidence of coronary disease (using comparable coding criteria) over a 10-year period in 37 defined populations (in 21 countries), are shown in Fig. 1. Large differences in disease rates between countries, evidence that risk of disease changes on migration, large differences within countries according to socioeconomic position and area of residence, and relatively rapid changes (both increases and decreases in rates of IHD mortality and incidence over time) suggest that the disease is preventable. In this chapter as we describe the epidemiology of IHD we will attempt to relate these findings to the potential for IHD prevention, considering medical therapy only to the extent that it informs our understanding of disease aetiology and prevention.

Fig. 1 Male and female IHD mortality rates in men and women aged 35 to 64 in 35 MONICA populations in the 1980s. Source: Lawlor DA, Ebrahim S, Davey Smith G (2001). *British Medical Journal*, **323,** 541–5.

The burden of ischaemic heart disease

Around one-quarter of all deaths amongst men and one-fifth of all deaths of women in Britain are due to IHD. Among women the proportion is relatively stable throughout the adult years, whilst in men it peaks among 55 to 64-year-olds, for whom IHD accounts for a third of all deaths. Around 6 per cent of 55 to 64-year-old men and 3 per cent of 55 to 64-year-old women report experiencing angina; this increases to 13 per cent and 9 per cent respectively for those aged 75 and over. The National Health Service in England deals with around 200 000 inpatient episodes due to IHD for men and 100 000 for women each year, representing around 5 per cent of all hospital inpatient episodes for men and 3 per cent for women. In addition, there are around 30 million work days lost due to certified incapacity for IHD amongst men and over 4 million amongst women each year in Britain.

A historical perspective

Ischaemic heart disease was until recently viewed largely as a twentieth-century epidemic. In retrospect it seems clear that IHD and IHD deaths occurred before the formal medical description of myocardial infarction in the early years of the twentieth century. William Heberden described the typical symptoms of angina pectoris and the fact that sudden death occurred as a complication in 1768. Later in the eighteenth century, Dr Samuel Black of Newry, County Down, described many cases of angina pectoris and produced a list of factors associated with increased and decreased susceptibility to angina (Table 1). While angina pectoris was occasionally recorded as a cause of death, less than 2 per cent of all deaths attributed to heart disease in Britain fell into this category even by the early part of the twentieth century.

In the middle of the nineteenth century, Richard Quain described a condition he called 'fatty disease of the heart'. A retrospective review of his case series suggests that 52 out of 83 cases probably suffered from IHD. The pathologist Carl Weigert and clinician Carl Huber in Leipzig described the myocardial lesions induced by acute ischaemia and speculated that myocardial infarction and angina both reflected underlying coronary artery disease. Before the turn of the century myocardial infarction and coronary thrombosis were thought of as terminal events. The first diagnosis of acute coronary thrombosis in the living patient is generally attributed to two Russian doctors, Obrastzow and Straschesko, in 1910. By 1918 Herrick was able to link clinical information with electrocardiogram patterns shown to reflect myocardial infarction in experimental canine studies, making the antemortem diagnosis of myocardial infarction easier.

Atherosclerosis has retrospectively been demonstrated in Egyptian mummies, but the first contemporary descriptions occurred in the sixteenth century. As IHD is generally associated with advanced coronary atherosclerosis the dramatic increase in IHD mortality in the first half of this century would be expected to be accompanied by increasing evidence of severe atheroma. However, studies of post-mortem records of the London Hospital suggested that there was no such increase between 1908 and 1949; in fact the degree of coronary atheroma declined. This was interpreted as indicating that an increase in the risk of thrombosis was responsible for the increase in IHD incidence and mortality. Later data comparing the coronary arteries at post mortem of United States soldiers who died in the Korean and Vietnam War show a higher prevalence of atheroma in young men in the early 1950s (77 per cent with atherosclerosis, 15 per cent with clinically significant narrowing of vessels) than the 1960s (45 per cent and 5 per cent, respectively), while IHD mortality in the United States was high and stable over this period. A study in the United States covering the period 1980 to 89—when IHD mortality was declining rapidly—found no reduction in the prevalence of atherosclerosis. Hence the relative contribution of atherosclerosis and thrombotic tendency to trends over time and differences between countries in IHD mortality remain difficult to elucidate.

Trends in ischaemic heart disease in Britain

Despite problems of changing definition, IHD rates in Britain clearly increased from the beginning of the century until the 1980s for men, the pattern of change in women being somewhat different (Fig. 2, and see 'Gender', below). Since the late 1970s, IHD mortality has declined steadily in both men and women.

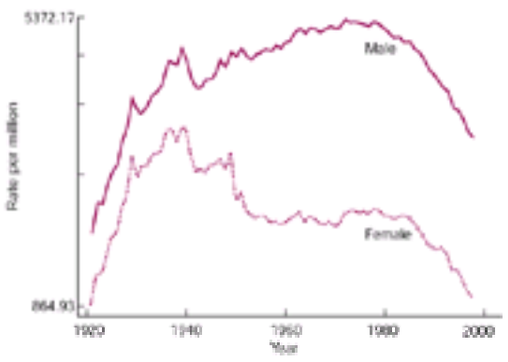

Fig. 2 Mortality from IHD, 1921 to 1998, ages 35 to 74, for England and Wales. Deaths per million population, age standardized to European population. Source: Lawlor DA, *et al*. (2001). *British Medicial Journal* **323**, 541–5.

In men, total circulatory disease mortality increased in the early decades of the century until the 1970s, although not as dramatically as IHD mortality. In women, total circulatory disease has tended to decrease over the century and the rise of IHD has been less consistent (with some decreases in the decades before the mid-century), and much less marked in women than men. Between the 1920s and 1960s the male to female ratio of IHD death rates increased from around 1.5 to around 6 for those under 55; males showed excess mortality at older ages but to a less extreme degree, with the ratio being around 2.5 for 65 to 74 year olds. Sex ratios have remained stable since the 1960s. The rapid rise and fall in rate of death attributed to IHD suggests that these differences were environmental rather than genetic and point to the scope for prevention.

International trends in ischaemic heart disease

Non-socialist, developed countries other than Britain have shown a similar pattern of rise and then fall in IHD mortality. Some, such as the United States and Australia, have experienced an earlier and more rapid fall in mortality than that seen in the United Kingdom. The United Kingdom (and in particular Scotland and Northern Ireland) has one of the highest death rates in the world from IHD, while rates in Japan and the Mediterranean countries of Europe, such as Greece, are low. These international time trends for men are illustrated in Fig. 3.

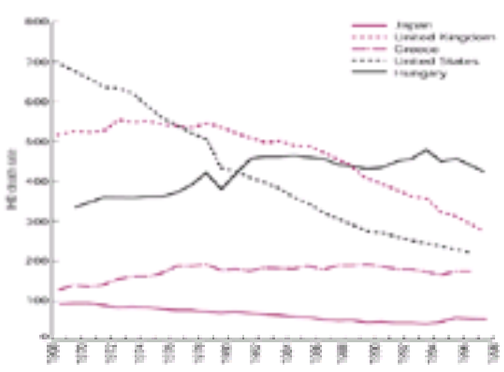

Fig. 3 Age-standardized death rates attributed to ischaemic heart disease from 1968 to 1997 in men aged 35 to 74 in selected countries. Source: Peterson S, Mockford C, Rayner M. *Coronary heart disease statistics 1999 edition.* British Heart Foundation, London, 1999.

More detailed data on recent trends in IHD incidence is available from the WHO MONICA study, which has shown that large differences between rates of death attributed to IHD do exist (Fig. 1), also that the recent trends in mortality are in part attributable to changes in event rates and in part to changes in case fatality. Other studies suggest that the recent falls in mortality attributed to IHD observed in the United States are largely due to reductions in case fatality rather than incidence. This suggests that interventions after myocardial infarction—such as aspirin, thrombolytics, b-blockers, and statin cholesterol lowering drugs—are reducing future mortality in groups with existing IHD.

Migrant studies

Studies of groups that migrate from a low-risk population to a high-risk population can provide valuable insights into the heritability of disease and the key stage of life at which risk is determined. Studies of Japanese migrants to Hawaii and mainland America suggest that as those of Japanese ancestry adopt Western lifestyles their risk of IHD increases. Thus the difference in risk between populations is at least in part environmental, rather than genetic. More puzzling is the fact that migrants to Australia from Greek islands, despite adopting many of the detrimental habits of their host country, are at lower risk of IHD. The acculturation process is clearly complex and it may be that Greek Australians adopt healthier lifestyles in other respects that counterbalance their increased fat consumption and smoking prevalence. Nevertheless, the experience of Greek migrants to Australia further emphasizes the ability of groups of individuals to modify their risk of subsequent IHD.

Overview of risk factors for IHD

There are a number of personal attributes, often described as risk factors, associated with the development of IHD. Some of these—such as age, sex, and family history—are fixed. Others, such as smoking and diet, are modifiable environmental exposures. Some, such as serum cholesterol and blood pressure, though modifiable, are really intermediate processes in the development of IHD and are a product of the interplay between an individual's genetic make-up and environmental exposures. A list of attributes associated with subsequent IHD, by no means exhaustive, is set out in Table 2. This list is not dissimilar to that proposed by Samuel Black over a 100 years earlier (Table 1).

Stamler suggests that the established major risk factors amenable to change are smoking, high blood pressure, high serum cholesterol, and diet. In a large study of middle-aged men in the United States, smokers in the highest quintiles for serum total cholesterol and systolic blood pressure were around 20 times as likely to die from IHD over the next 11.6 years as non-smokers in the lowest quintiles of serum cholesterol and blood pressure (Table 3). However, although these factors are powerful predictors of risk within a population, they only account for 23 per cent of the variance in IHD incidence in men and 14 per cent of the variance in women observed between 25 populations in the WHO MONICA study. Since these established major risk factors were described, many more risk factors have been suggested.

In the following sections we will discuss attributes associated with IHD, starting with fixed and relatively fixed risk markers, then covering the social environment and behavioural factors, finally considering physiological mediating processes.

Age

Age is the strongest risk indicator for IHD incidence and mortality. Compared to men aged 40, 50 year-old-men have five times the risk, 60 year-old-men have 15 times the risk, and 70-year-old men have over 40 times the risk of dying from IHD. A similar steep gradient with age is seen for women. Risk continues to increase into older age groups and recent evidence that the elderly benefit from risk factor control, blood pressure lowering, cholesterol lowering, and probably smoking cessation, combined with their much higher absolute level of risk than younger people, indicates that this is a group for whom sizeable absolute reductions in IHD risk can be achieved and therefore for whom therapies may be particularly cost effective.

Gender

Rates of death attributed to IHD in men are consistently three to four times higher than those in women across countries with differing background levels of disease. The rates of death attributed to IHD in women correlate closely with those in men, suggesting that environmental factors common to both sexes explain the international differences in ischaemic disease rates.

The temporal pattern of mortality attributed to IHD over the last 100 years in Britain has been different in women to that observed in men (Fig. 2). In men, mortality increased from the 1920s until the 1980s, when it began to decline. In women, the mortality rates have always been considerably lower than those observed in men. As with men, mortality in women increased in the early years of this century, but peaked around 1940. Mortality then declined until the 1960s, increased again until the mid-1970s, and has declined since then.

Despite the fact that women have been under represented in epidemiological studies of IHD, it nevertheless appears that classical risk factors such as serum total cholesterol, blood pressure, and smoking (shown to predict coronary disease in men) perform similarly in women. But as the disease is commoner in men the differences in absolute risk are much greater for men than for women.

Men are more likely to smoke than women are, but differences in smoking and other established coronary risk factor levels do not appear to fully explain the observed excess of IHD seen in men. The lower risk of coronary heart disease among women has understandably led to studies of sex hormones as potential protective or risk factors for IHD. There is, however, little empirical evidence to support an important role for sex hormones. It has often been stated that women are only protected against ischaemic heart disease premenopausally, and that their risk progressively increases towards that of men after the menopause. This supposition, which has recently been challenged, provided support for the notion that hormone replacement therapy taken after natural or artificial menopause would reduce the risk of IHD among women. Many observational studies (of women who had elected to take hormone replacement therapy) appeared to support this contention, but the preliminary findings of randomized, controlled trials (where women were allocated at random to hormone replacement therapy or placebo) suggest no such protection is given by hormone replacement therapy.

Further studies should allow more detailed study of the determinants of IHD in women. If these can also shed light on the reasons for the consistent sex difference in coronary disease they may, through uncovering important determinants of IHD risk, benefit both men and women.

Family history and genetic factors

A family history of IHD in first-degree relatives is associated with an increased risk of IHD over and above that produced by a shared environment. Currently identified, major, single gene conditions—for example familial hypercholesterolaemia—are of low prevalence, so that while they are associated with a large increase in relative risk for an individual, they contribute little to the overall population prevalence of IHD. Other polymorphisms with lower relative risks but greater prevalence are under investigation. The marked secular trends in IHD risk, change in risk on migration, and large differences between countries indicate that at the population level genetic factors must act in concert with environmental influences to produce population IHD rates, and that there is thus large scope for prevention. At the individual level, however, a strong family history of premature IHD means that an individual may have more to gain from intensive risk factor control than other members of the population.

Early-life influences

Until relatively recently the majority of epidemiological research on IHD focused on behavioural, physiological, socioeconomic, and psychological risk factors acting in adulthood. However, more recently it was noted that risk factors acting during adulthood could not account for all of the geographical and socioeconomic variation in IHD mortality, leading some to postulate that early-life influences could have a long lasting impact on IHD risk independent of adulthood risk factors. A series of studies have demonstrated that birth weight is inversely related to risk of IHD, suggesting that suboptimal intrauterine environments result in offspring who, many years later, are more likely to succumb to IHD. Furthermore, several conventional IHD risk factors have been shown to be related to birth weight—blood pressure, glucose tolerance, respiratory capacity, and (less consistently) haemostatic factors demonstrate associations with birthweight which would generate the observed inverse birthweight–IHD relationships. However, taking these risk factors into consideration does not appear to fully account for the influence of fetal development on IHD risk, which seems to involve other, as yet unspecified, pathways. It is possible that the birthweight–IHD associations, while they exist, are not causal and therefore not of public health significance. Genetic factors could underlie both low birthweight and increased disease risk in adulthood, and there is evidence that some polymorphisms could indeed act in this way. Whether modifying fetal development will modify later IHD risk is a matter that requires further investigation. These issues are discussed in detail in Chapter 15.4.1.1.

In addition to intrauterine influences, exposures acting in infancy, childhood, and adolescence may be of importance. A frequently replicated and long-standing observation is that taller individuals are at reduced risk of IHD. Growth occurs during infancy and childhood, being influenced by nutrition and infections, as well as genetic factors. Recently it has been shown that stature in childhood is inversely related to later IHD risk, indicating that the association between height and IHD mortality is not due to differential shrinkage occurring in adulthood amongst individuals most prone to IHD. Of the components of stature, leg length—rather than trunk length—is the one of importance, and this is particularly responsive to changes in nutrition and other environmental exposures acting during early childhood. Of the infections acquired in childhood *Helicobacter pylori* infection has been most widely investigated, but the overall evidence does not strongly point in the direction of a direct causal association between this infection and IHD risk. The role of nutrition and other infections acting in childhood requires more study if the intriguing associations between stature and IHD risk are to be understood.

Socio-economic position

In most industrialized countries, IHD risk is higher amongst people living in worse social circumstances. Whether the apparent gradients in the opposite direction seen during the early stages of the IHD epidemic in industrialized countries, and in newly industrialized countries currently, are genuine or due to differential classification of disease remains uncertain. Studies that have taken population samples and standardized measures of IHD prevalence or incidence—rather than simply using certified causes of death—have consistently shown a gradient of increasing risk with decreasing affluence. Social disadvantage can influence IHD risk in a wide

variety of ways, and act across an individual's entire lifetime. People born into worse social circumstances are likely to have lower birthweight, which appears to influence later IHD risk. Socio-economic deprivation in childhood is associated with poor nutrition and growth, and possibly higher incidence of childhood infections, which may increase later IHD risk. Behavioural patterns—in particular with relation to diet, physical activity, alcohol consumption, and smoking—are developed in childhood in a socially-patterned manner and track into adulthood. In most industrialized countries, smoking and dietary patterns associated with increased IHD risk are more common amongst poorer adults. Unemployment and job insecurity in adulthood may also increase IHD risk.

Given the wide array of exposures associated with socio-economic deprivation that could increase the risk IHD, it is not surprising that studies which have taken into account a limited number of these (generally smoking, blood cholesterol, body mass index, alcohol consumption, leisure time physical activity, and blood pressure) find they fail to account fully for the socio-economic distribution of IHD. The large (and in many countries increasing) socio-economic differentials in IHD risk provide both a model for testing aetiological hypotheses and also evidence of an important potential for public health interventions. Figure 4 shows the three-fold difference in IHD mortality between men in unskilled manual occupations in Britain compared to those in managerial and professional occupations, and the graded difference in risk between these occupational extremes. Clearly, reducing IHD risk amongst the less socio-economically advantaged to the same level as that of the most advantaged would have a dramatic influence on overall diseases rates in the population. A further implication is that since socio-economically disadvantaged people have a considerably increased risk of IHD, which is not purely dependent upon conventional risk factors, they have the most to gain from interventions, such as the statin cholesterol-lowering drugs that produce a consistent proportional risk reduction amongst different groups of people treated. A 30 per cent reduction in risk for an unskilled manual labourer in Britain is, in absolute terms, a considerably greater risk reduction than a 30 per cent risk reduction in a manager.

Diet

The association of diet and IHD can be thought of on three levels: the overall dietary patterns, the foods eaten, and the constituents of the diet. The dietary features thought to be associated with IHD are summarized in Table 4.

Overall dietary patterns

Certain regional dietary patterns are associated with low risk of IHD, for example the Mediterranean diet, which contains more fish, fresh fruit, fresh vegetables, and olive oil than the English diet. One small, randomized trial allocated people with a recent myocardial infarction to receive either advice to eat a Mediterranean diet (more bread, more vegetables, more fruit, more fish, and less meat) and to replace butter and cream with rapeseed margarine, or to usual dietary advice. After 27 months the trial was stopped early because there was a marked reduction in the relative risk of death in those given advice to eat a Mediterranean diet. Of particular interest is the observation that these dietary changes did not alter blood cholesterol levels, implying that the protective effect was not mediated through an effect on cholesterol. The results of this study require confirmation in further trials, and while it is unlikely that the very substantial reduction in IHD risk seen in this trial will be seen in future studies, it is clear that such dietary advice could produce a worthwhile influence on IHD rates.

The dietary patterns in East Asia (the pacific diet) are probably one reason for the low IHD rates there. The broad characteristics of the United States, Japanese, and Mediterranean diets are summarized in Table 5. These so-called traditional diets have changed considerably over recent years so that, for example, the Japanese diet now contains more meat and dairy products and less salted foods. Such changes make it difficult to interpret comparisons of dietary differences and time trends in IHD between countries. Within countries, vegetarians have a lower risk of IHD, but are different in a number of other ways that could influence IHD risk from non-vegetarians.

Foods eaten

Various foods have been linked to risk of IHD. These include alcoholic beverages, fish, fruits, and vegetables. Moderate consumption of alcoholic drinks appears to protect against IHD, with higher rates of IHD in teetotallers and heavy drinkers. Ecological comparisons suggest that wine may exert additional protection, but cohort studies appear to show that the type of beverage is unimportant. Recent studies have looked at the pattern of alcohol consumption as well as the average weekly consumption. People who indulge in sporadic- or binge-drinking appear to be at increased (rather than reduced) risk of IHD.

The low reported rates of IHD among the Inuit (formally known as Eskimos) led to work on the effect of eating fish on IHD risk. Some studies have shown that regular consumers of fish are at reduced IHD risk, while others have not. Two large trials of advice to eat more fish or fish oil capsules in people following a myocardial infarction suggest that intake of dietary fish or fish oil reduces total mortality by around 20 per cent.

The regular consumption of fresh fruit and vegetables is widely believed to be protective against IHD, but the exact size and nature of any beneficial effect is unclear. It is even possible that the observed protective associations represent residual confounding by other lifestyle factors, since people who eat more fruit and vegetables differ in many ways from those who eat less.

Dietary constituents

A number of dietary constituents have been associated with risk of IHD. These include energy intake, intake of various fats, antioxidants, and cereal fibre. The more energy consumed per day the lower the risk of IHD. Though obese people under-report food consumption, reported energy intake also reflects energy expenditure—that is level of physical activity. Hence this finding may reflect higher participation in exercise protecting against IHD.

The Seven Countries Study compared the diets of individuals from populations with different rates of IHD. It showed a strong association between IHD mortality and both total dietary fat and saturated fat consumption. The results of this study are shown in Fig. 5. Studies comparing individuals within cohorts have mostly failed to confirm this relationship, perhaps because of the problem of measuring diet accurately. The relationship between fats and IHD may also be more complex than first thought, with different fatty acids increasing, decreasing or having no effect on disease risk. There is some evidence that high intake of trans fatty acids, produced when oils are solidified by hydrogenation to form margarine, increases risk of IHD.

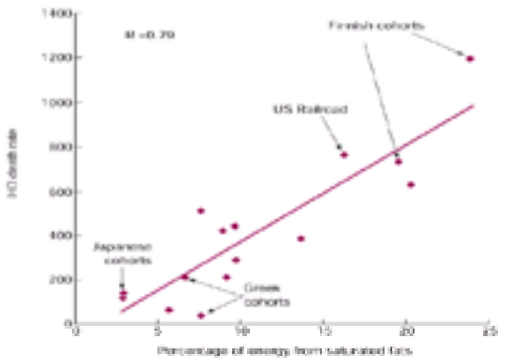

Fig. 5 Ecological comparison between percentage of calories from saturated fat consumed at baseline and IHD mortality over 15 years in 15 cohorts from seven countries recruited between 1958 and 1962. Source: Keys A, Menotti A, Karvonen MJ *et al*. The diet and 15-year death rate in the seven countries study. *American Journal of Epidemiology* 1986; **124**: 903–15

There is laboratory evidence that suggests that oxidation of cholesterol is an important step in atherosclerosis. This laboratory work has generated interest in the association between the intake of dietary antioxidants and rates of IHD. These include minerals such as copper, zinc, manganese, and selenium, vitamins (and provitamins) such as b-carotene, vitamin C, vitamin E, and other chemicals such as flavonoids. Though cohort studies have observed protective associations, the results of randomized trials—where they have been carried out—have not confirmed these observations.

Prospective observational studies of b-carotene intake showed a significantly lower pooled risk of cardiovascular death among those consuming more b-carotene. The results from the randomized trials, however, indicated a moderate adverse effect of b-carotene supplementation (Fig. 6). Various explanations have been put forward to account for these results, including the use of the wrong isomer of b-carotene, the wrong dose, and a detrimental effect of supplementation on levels of other carotenoids. It is more likely that the apparent protective association in observational studies represents confounding, as people who eat diets rich in b-carotene or who take supplements are more socio-economically advantaged and adopt a number of protective health-related behaviours.

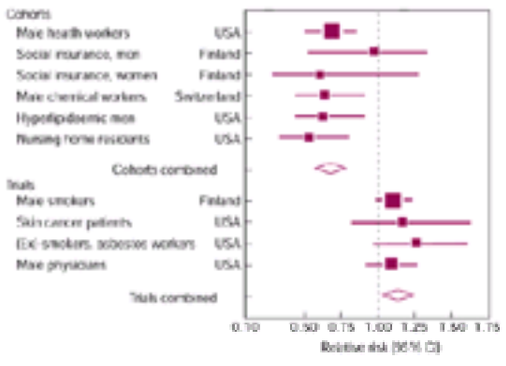

Fig. 6 Meta-analysis of the association between b-carotene intake and cardiovascular mortality: Results from observational studies indicate considerable benefit whereas the findings from randomized, controlled trials show an increase in the risk of death. Source: Egger M, Schneider M, Davey Smith G. Spurious precision? Meta-analysis of observational studies. *British Medical Journal* 1998; **316**: 140–144.

Similarly, most observational studies of vitamin E intake and IHD have reported a protective association, but cardiovascular mortality in trials is essentially unchanged in those receiving vitamin E (Fig. 7). In the case of b-carotene it was suggested that inappropriate supplements were used and that the trials were too short. These arguments are difficult to sustain for vitamin E, as the protective observational association was observed in people taking supplements and in people who had only taken supplements for a few years. As with b-carotene, it is more likely that the protective association in observational studies represents confounding, but with vitamin E there is little evidence that supplements are harmful.

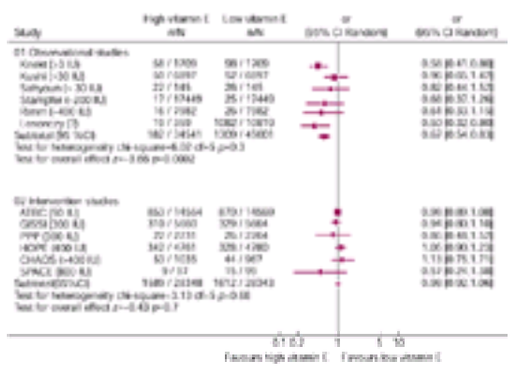

Fig. 7 Meta-analysis of the effect of high versus low vitamin E intake on cardiovascular mortality for observational and intervention studies. Source: Hooper L, Ness AR, Davey-Smith G (2001). *Lancet*, **357**, 1705. *n* = number of deaths; *N* = number at risk.

Cohort studies consistently report a protective association between increased intake of dietary fibre from cereals and reduced rates of IHD. One large trial randomized men with a recent history of myocardial infarction to receive advice to increase their dietary fibre intake (without making other changes to their diets) or no fibre advice. After 2 years there was no survival benefit in those randomized to receive fibre advice, indeed mortality was increased by about 20 per cent, though this increase was not statistically significant.

Summary of effect of diet on ischaemic heart disease

Dietary differences between populations and over time probably explain a considerable proportion of the temporal and geographical variation in IHD. The broad dietary patterns associated with reduced risk of IHD are not in dispute, but the relative importance of specific dietary features is less clear.

Smoking

Smoking was convincingly identified as a cause of lung cancer by German researchers in the 1930s and 1940s and suggestions about a detrimental effect on IHD were also made at this time, although backed by less elegant epidemiological evidence. Since the results of prospective epidemiological studies in the 1950s it has been clear that heavy cigarette smokers have an approximately two-fold elevation in risk of IHD incidence and death, which is reduced by giving up the use of cigarettes, the risk returning to close to that of non-smokers after about 10 years. Cigar smokers who have not previously smoked cigarettes do not have an increased risk of IHD, although amongst those who were previously cigarette smokers an increased risk is seen, presumably because cigarette smokers who switch to cigars continue to inhale some of the smoke.

The mechanism linking cigarette smoking and IHD remains unclear. Initially it was thought that nicotine was the important component of tobacco smoke, but the lack of elevated risk among primary cigar and pipe smokers who absorb nicotine through their buccal membranes suggests this is not the case. In Sweden (among other countries), raw or porous-bagged tobacco ('snuss') is widely used, applied to the buccal membrane this leads to high nicotine absorption but no increased risk of IHD.

Smoking accounts for some of the international variation in IHD rates, but it is noticeable that some countries with a high prevalence of smoking, such as Japan, have low IHD rates. This is borne out by data from the MONICA study that found that smoking alone (when included in models that adjust for cholesterol and blood pressure) accounts for only 5 per cent of the variance in rates of death attributed to IHD across countries. At a cross-national level a relatively high level of saturated fat intake and circulating cholesterol level may be required for smoking to translate into high population rates of IHD. Similarly some populations—for example women of Indian subcontinent family origin living in Britain—have high rates of IHD despite having low rates of smoking.

Obesity

For nearly 100 years insurance data have demonstrated that very obese individuals have an increased risk of death, including death from heart disease. However, studying the association between degree of overweight and IHD risk has produced conflicting findings. In most studies, body mass index (BMI) (weight (in kilograms) divided by height (in metres) squared) is used as the index of adiposity. A U-shaped association between BMI and all-cause mortality has been seen in many studies, with a similar pattern observed for IHD mortality. The reasons for this have been hotly debated, but it seems likely that the high mortality among thin individuals reflects a subset of people who have low BMI because they are ill, or because behavioural patterns—heavy smoking or heavy alcohol consumption—are associated with thinness. The greater the degree to which studies have been able to take this into account, the less evident is the elevated mortality amongst the thin.

Obesity is at least partially related to higher IHD risk because it is in turn associated with higher blood pressure and an unfavourable blood lipid profile (higher low-density lipoprotein (LDL) cholesterol and lower high-density lipoprotein (HDL) cholesterol). Reducing weight is accompanied by reductions in blood pressure and an improvement in blood lipid profile, therefore the risk factor profile associated with obesity should be considered to contribute to the mechanism linking overweight to IHD, rather than being seen as confounding factors. In some early epidemiological studies this issue was confused and investigators statistically adjusted the association between degree of overweight and IHD risk for these physiological measures, which is clearly inappropriate given that they are themselves influenced by the degree of overweight.

Obesity is associated with insulin resistance (which is covered in the next section) and this may also contribute to the elevated IHD risk amongst the obese. However, compared to a simple relative weight measure, such as BMI, the distribution of body fat is more strongly associated with insulin resistance. In epidemiological studies, the ratio of a waist measurement to a hip measurement (waist–hip ratio) has been used as an indicator of central adiposity. People with higher waist–hip ratios are at increased risk of IHD above and beyond the fact that people with high BMI tend to have higher waist–hip ratios; they also demonstrate adverse profiles of factors associated with insulin resistance. Prospective studies are currently examining other measures of adiposity such as impedance (which estimates percentage of body fat) and abdominal height (which estimates the amount of abdominal fat) to see if they are better predictors of IHD risk than BMI and waist–hip ratio.

Conventional hereditability models applied to studies of twins, adoptees, and siblings suggest that obesity is, to a remarkable degree, a genetic characteristic of individuals, with only a small proportion of the population variance being accounted for by environmental factors. This finding probably reflects the limitations of the methods available to study genetic contributions to population levels of risk factors. The substantial changes in the prevalence of obesity that have occurred within populations such as the United States or the United Kingdom over a relatively short period of time—during which there is essentially no genetic change of the population—indicate that environmental factors are of great importance. Low levels of physical activity and a high calorie intake to physical activity ratio are particularly implicated in the rising prevalence of obesity. Though mapping of the human genome may identify those at risk of obesity earlier and more precisely (and offers the possibility in the future of targeted treatments or genetic manipulation), tackling the current obesity epidemic requires measures to reduce population levels of physical inactivity and to encourage energy intake appropriate to activity levels.

Insulin resistance and diabetes

A spectrum of metabolic disorder running from frank diabetes to minor levels of glucose intolerance is of relevance when considering IHD risk. Examining fasting glucose levels or glucose levels after standardized intakes (e.g. in glucose tolerance tests) demonstrates this, with somewhat arbitrary cut-offs being used for 'impaired glucose tolerance (IGT)' and non-insulin dependant diabetes mellitus (NIDDM). This is not the case with insulin-dependant diabetes mellitus (IDDM), where in most instances people either have the disease or do not, but this is a considerably rarer condition that contributes substantially less to the population levels of IHD than NIDDM and IGT.

A cluster of physiological risk factors for IHD have been grouped into the insulin resistance syndrome (also known as the metabolic syndrome or syndrome X). These involve resistance to insulin-stimulated glucose uptake, high circulating levels of insulin, high triglyceride levels, low HDL cholesterol levels, and elevated blood pressure. The degree to which this truly constitutes a syndrome remains disputed, but it is clear that these risk indicators are correlated within populations and contribute to IHD risk.

The epidemiology of diabetes is discussed in detail elsewhere (see Chapter 12.11.1). By far the most important environmental factor influencing diabetes risk and level of glucose intolerance is obesity, in particular central obesity. Physical activity also appears to protect against NIDDM and IGT, while findings have been mixed with respect to alcohol intake and smoking, which have been both positively and negatively associated with disease risk.

Unlike risk factors such as circulating blood cholesterol or blood pressure, fasting glucose does not show a continuous association with IHD risk in prospective epidemiological studies. Only the top 5 or 10 per cent of the population levels of fasting glucose levels are associated with increased risk n studies in the United States and United Kingdom. Thus, the use of fasting glucose as a means of predicting risk in individuals is limited. The clear increased risk of IHD amongst people with frank NIDDM, which seems above and beyond their level of conventional IHD risk factors, indicates that these people have much to benefit from cholesterol and blood pressure lowering if they are eligible for these therapies.

Physical inactivity

In the early days of the coronary heart disease epidemic in industrialized countries it was thought that exercise may predispose to ischaemic heart disease through cardiac strain. However, research starting in the mid-twentieth century suggested that occupational physical activity was associated with reduced risk of IHD. With the increasingly sedentary nature of many occupations this has become a less important risk indicator for IHD and attention has shifted to physical activity in leisure time.

Clearly, health-related selection is a serious problem in studying the relationship between leisure time physical activity and ischaemic heart disease, since those with early signs of the disease will be less physically active. There is also considerable confounding as engagement in leisure time physical activity is associated with other important risk factors for IHD, such as smoking and socioeconomic position. However, the general picture suggests that increased physical activity does protect against IHD, although there is uncertainty about the type, intensity, and frequency of exercise that is required to confer such protection.

The key question has been whether the physical activity needs to be vigorous or not, with some studies suggesting that only vigorous exercise is protective, while others indicate that any form of increased physical activity is effective. This may reflect difficulties in measuring usual physical activity accurately, particularly at low levels. Differences in the findings between studies may also reflect the fact that the type of exercise that is vigorous for one group may not be vigorous for another. For example the elderly or unfit will find relatively low intensity physical activity results in increased cardiorespiratory fitness, while lower intensity activity will have no such training effect in fit young adults. A formulation that is consistent with the current data is that physical activity which is at a sufficient level to produce cardiorespiratory training reduces the risk of IHD, while the value of lower intensity physical activity is unclear.

Stress

Stress is widely considered by the general public to be an important cause of IHD. Indeed, several surveys of lay beliefs have shown that it is one of the most widely recognized risk factors for the disease. Stress is, however, difficult to define or measure. Epidemiological studies have examined a wide range of potential exposures that fall under the general heading of 'stress'. These include measures which are essentially of personality traits—such as the well-known Type A behaviour pattern—through to records of stressful life events or global measures of perceived stressfulness of daily activities. A broader conceptual category of 'psychosocial factors' is now widely used in the epidemiological literature. This includes aspects of social life such as the strength of social support networks or the level of control

that people have over their work.

The type A behaviour pattern was investigated from the 1950s, particularly in the United States, as a potential cause of IHD. Type A individuals—those who are involved in an incessant struggle to achieve more and more in less and less time—were found to have higher risk of IHD in several early prospective studies, and type A personality was included in official publications (produced by august bodies such as the American Heart Association) as a cause of IHD, along with smoking, high blood pressure, and high saturated fat diet. More recent studies have failed to find any association between type A behaviour and IHD. It may be that this association no longer exists because IHD is not now considered a disease of the wealthy, stressed, business man, who in the past was more likely to be diagnosed with the condition. Research on behavioural traits now focuses on those elements of the original type-A classification that are related to adverse social background, for example hostility: these may predict IHD risk because of this, rather than because of any causal link with the disease.

Measures of self-reported global stress and other self-reported indicators, such as low control at work or poor social networks, tend to be related to self-reported IHD symptoms (usually angina or severe chest pain indicative of a myocardial infarction). They less consistently relate to objective measures of IHD, such as ECG changes or IHD mortality. This may reflect an underlying reporting tendency, such that people who report higher levels of adversity in their lives also report higher levels of symptoms. Given the history of the association between type A behaviour and IHD it is also important to consider whether associations between stress and IHD are generated by confounding. People with low control over their work (e.g. shift workers in a factory) are, almost by definition, in less favourable social locations than those with higher control over their work (e.g. managers or senior academics). It is not surprising that the former have higher rates of IHD, given the strong social patterning of the disease. Whether these adverse psychosocial factors are one of the causes of the high IHD mortality in the less advantaged or merely another consequence of material inequalities is not clear.

More methodologically robust studies employing objective measures of both tress and IHD outcomes are required. In particular, it is remarkable that the supposed biological mediators between stress and disease (disturbed functioning of the hypothalamo–pituitary–adrenal axis and possible immune system outcomes of this) have not themselves been related to IHD risk in prospective observational studies, some 70 years after the basic concept was advanced by Hans Selye. The current controversy—with enthusiastic proponents of stress as a cause of IHD on one side (feeding into a popular propensity for accepting this view) lined up against the majority of academic and research cardiologists and epidemiologists who dismiss the association as spurious—will only be resolved when studies employing better methods report their findings.

Cholesterol

Circulating blood cholesterol is strongly and positively associated with ischaemic heart disease risk in men and women, both young and old. A series of large-scale, randomized, controlled trials of blood cholesterol reduction demonstrate that this process is reversible and risk reductions of the magnitude predicted from the observational data can be produced through lowering blood cholesterol.

One issue not directly relevant to ischaemic heart disease that led to controversy regarding cholesterol reduction was the suspicion that low circulating blood cholesterol caused an increased risk of morbidity and mortality from non-coronary causes, including cancer, psychiatric disease, and gastrointestinal and respiratory disease. Observational studies tended to report inverse associations between blood cholesterol and these conditions, though it was clear that these associations could be generated through early stages of ill-health or adverse health-related behaviours leading to lower circulating cholesterol levels. Findings from randomized, controlled trials of cholesterol reduction were initially ambiguous, in that there was evidence of elevation of non-coronary morbidity and mortality in some studies. This now appears to reflect specific adverse effects of certain cholesterol lowering drugs, in particular the fibrates. More recent studies in which circulating cholesterol levels were reduced more profoundly than in earlier studies, through the use of statins, suggest there are no detrimental effects of cholesterol lowering itself.

Early epidemiological studies only measured total circulating cholesterol, but it is evident that subfractions of cholesterol have differential effects on ischaemic heart disease risk. The adverse effects are restricted to the low-density lipoprotein cholesterol fraction, with high-density lipoprotein cholesterol (HDL) levels being inversely associated with ischaemic heart disease risk. Alcohol consumption increases HDL cholesterol and increased HDL levels are a potential mediator of the apparent protective effect of low to moderate alcohol consumption on IHD. Trials of raising HDL cholesterol are difficult to interpret as the agents employed also decrease trygliceride levels and, to an extent, LDL cholesterol. Current evidence suggests that there may be a protective effect of raising HDL cholesterol, but this requires confirmation.

Blood pressure

There is a strong, consistent dose–response relationship between increased casual blood pressure measured in middle age and increased risk of IHD. In observational studies a 10 mmHg increase in diastolic blood pressure is associated with a 37 per cent increase in the risk of coronary disease. Large, randomized trials of pharmacological blood pressure reduction in middle age have confirmed that blood pressure reduction reduces subsequent risk of coronary disease. Several observational studies have also shown that increased blood pressure in early adult life is associated with increased coronary mortality in later life, suggesting that risk trajectory may be set early.

Blood pressure is continuously distributed in populations and increases in blood pressure across the range of blood pressure measures are associated with increased risk of IHD. There is therefore no natural dichotomy between normotensives and hypertensives. Hypertension has to be defined by weighing up the risks of disease at a given level of blood pressure against the risks of treatment to lower blood pressure.

Blood pressure is determined both by environmental factors, such as increased sodium intake (increases blood pressure), increased alcohol intake (increases blood pressure), increased fruit and vegetable intake (lowers blood pressure), and genetic factors. While individual blood pressure response to environmental factors may be influenced by genetic factors, migrant studies illustrate the substantial and relatively rapidly acting effects of environmental factors. In one study of migrants from a rural community in western Kenya to urban Nairobi, mean diastolic blood increased by around 6 mmHg from that measured 10 months previously.

Not all environmental factors that increase blood pressure increase risk of coronary disease. For example increased alcohol intake results in increased blood pressure and people who drink heavily are at increased risk of coronary disease, but those that consume alcohol in moderation have lower risks of coronary disease than teetotallers. Though there are a number of explanations for this particular protective association, this example illustrates the more general point that effects on risk factors may not necessarily translate into changes in risk of IHD.

Haemostatic factors

Studies of changes in prevalence of atherosclerosis (discussed earlier) provide indirect evidence that another pathological process, such as thrombosis, influenced trends in symptomatic disease over the last century. Over the last 20 years a number of cohort studies have examined the association between haemostatic factors and coronary disease. There is a consistent, independent association between increased fibrinogen levels and increased risk of coronary disease. The subsequent risk of IHD comparing those in the highest third with those in the lowest third of the fibrinogen distribution at baseline is increased by around 80 per cent. Some prospective studies have reported increased coronary risk with factors VII and VIII but the data are less extensive and less consistent. Other studies have reported associations with tissue-type plasminogen activator (t-PA) and with plasminogen activator inhibitor-1 (PAI-1), while platelet function tests do not appear to predict subsequent coronary risk. These associations need to be confirmed. Smokers have higher fibrinogen levels than non-smokers and this may in part explain their excess coronary risk. Fibrinogen levels are also associated with higher levels of other acute phase reactants suggesting that chronic inflammatory or infective processes may increase fibrinogen levels and thus risk of symptomatic coronary disease. Alternatively, fibrinogen may merely be a marker for these underlying processes. These issues are discussed elsewhere.

The prevention of ischaemic heart disease

As we have seen, there are marked differences in the rate of death attributed to IHD over time, between countries, between regions, within countries, and between groups of individuals within countries. These differences point to the potential scope for prevention.

Attempts at prevention can be roughly classified as primary, secondary, or tertiary. Tertiary prevention is the treatment and rehabilitation of people with symptomatic disease: it clearly offers important opportunities for preventing further symptomatic episodes since many who experience an acute myocardial infarction will have known coronary disease. The recent results from the WHO MONICA study would seem to confirm that the widespread use of effective treatments can reduce the number of symptomatic episodes and deaths attributed to IHD. Secondary prevention is the identification and treatment of early, often asymptomatic, disease: this is

not currently (and may never be) a discrete option, because most people in Western populations have at least some atherosclerotic disease in their coronary arteries and there are no proven non-invasive tests that are able to detect reliably those with early disease before they develop symptoms. Primary prevention is the prevention of the onset of disease. In IHD the distinction between primary, secondary, and tertiary prevention is blurred: people identified as being at high risk of disease on the basis of risk factor profiles will comprise those with symptomatic disease, those with asymptomatic disease, and those without manifest disease.

There are two differing but complementary approaches to primary prevention: the high-risk approach and the population approach. The high-risk approach seeks to identify those at highest risk of developing disease with time to intervene to prevent disease. This approach has the advantage that it may be easier to encourage people at high risk to alter their lifestyles and to take tablets as these individuals have a considerable amount to gain personally from accepting change. Such an approach, however, requires that those at high risk be identified and ignores the many people who develop symptomatic disease who are at moderate rather than high risk. For example, in the Whitehall study, 42 per cent of the coronary deaths (and 36 per cent of all deaths) occurring over a 15-year follow-up occurred in the 20 per cent at highest risk (on the basis of smoking status, blood pressure, and plasma cholesterol). The majority of coronary deaths (58 per cent), however, occurred in those who were not at high risk (Table 6). Thus, even a universally effective package of interventions for people at high risk could only hope to prevent around 40 per cent of coronary deaths, and a (more plausible) package of interventions that halved coronary mortality in those at high risk could only hope to prevent around 20 per cent of coronary deaths. The alternative approach is the population approach, which seeks to alter risk-factor levels or behaviour across the whole population, its advantage being that for fairly modest changes in mean population risk-factor levels it is likely to produce larger overall improvements in the health of the population as a whole than the high-risk approach. The disadvantage is that the absolute benefit for each individual who makes a lifestyle change is likely to be small. This mismatch between the likely size of the benefits to the individual and population has been called the 'prevention paradox'.

In terms of IHD prevention, smoking cessation strategies are potentially of high impact. It has been shown that brief advice from physicians leads to small, but (in population terms) worthwhile reductions in smoking rates among their clients. Nicotine replacement gum can also aid smoking cessation. More problematic are attempts to reduce the initiation of smoking in adolescents. School-based antismoking programmes have shown disappointing results, which is perhaps not surprising given the nature of experimental behaviour among this age group. While smoking is an option it is likely that a high percentage of the population will experiment with the behaviour and strategies for early cessation—which also occurs amongst a high proportion of those who try the behaviour—should be built upon.

The detection and treatment of high blood pressure reduces the risk of IHD in the primary prevention setting and has the added benefit of also substantially reducing the risk of stroke. Similarly, lowering cholesterol levels with the statin drugs reduces IHD risk in primary prevention, although the absolute benefit is small for those who are not at increased risk of IHD for other reasons.

A series of multiple risk factor intervention trials have been carried out at both the community and individual participant level in which encouragement to modify diet, reduce smoking, increase physical activity, and (in some studies) increase medical treatment of elevated risk factors have been explored. Beyond the evident benefits of pharmacological reduction of blood pressure, the findings have been disappointing.

These results emphasize the degree to which health-related behaviours—such as dietary consumption, smoking, heavy drinking, and physical activity patterns—are strongly influenced by societal legislative and fiscal forces and are less to do with individual levels of knowledge and degree of willpower. This is clearly the pattern for smoking, where smoking levels in a country, smoking initiation rates, and the social distribution of smoking are all responsive to the profit-making incentives offered to tobacco companies. The diversification of tobacco companies to other products (within the 'home' advanced capitalist markets) and shifts to export to newly industrializing countries reflects the unfavourable economic environment that has been created for the companies in some countries. The prevention of smoking—one of the most important modifiable health risks globally—can only be ultimately successful if the world community accepts the need to restrict the profitability of growing and selling tobacco.

The differences between countries and over time in both behaviour and IHD disease rates clearly illustrate the capacity for populations to alter their behaviour and to adopt healthier lifestyles. While simple invocations to change have modest effects on behaviour and IHD risk, social change can result in profound improvements in health. Conversely, where cultures fail to adapt or social structures demise (as happened in Russia with the collapse of the Soviet Union) disease rates can increase. Effecting societal change is complex, but the potential public health benefits of even modest population change are profound. The concentration of IHD (and many other diseases) in those in society who are least advantaged suggest that policies will be more effective if they seek to improve the lot of the poor by improving their income, opportunities, and self-esteem. More inclusive and extensive programmes that seek to reduce inequalities in health and improve health for all offer real opportunities to reduce IHD incidence and mortality.

Summary

IHD is a globally important cause of morbidity and mortality. Epidemiological studies provide evidence that IHD is preventable and give some estimate of how much IHD might indeed be prevented. Current favourable trends in mortality in developed countries may not be maintained in the face of the current epidemic of obesity. Equally, the reductions in IHD case fatality (leading to reductions in mortality) achieved through use of effective treatments may not be viable solutions in less wealthy countries. While there are genuine areas of uncertainty that require further research, much is known about the aetiology and prevention of IHD. Invocations to individuals to adopt healthier lifestyles have produced disappointing results. At the population level, however, the will and capacity to modify behaviour exists. If coronary care units are to meet the same fate as sanatoriums, major societal and structural changes will be required to improve the material conditions of the least advantaged throughout their lives and to shape the diets, activity levels, alcohol consumption patterns, and smoking behaviour of us all.

15.4.2.1 The pathophysiology of acute coronary syndromes

Peter L. Weissberg

Introduction

An acute coronary syndrome arises when there is sudden total or partial occlusion of a coronary artery leading to myocardial ischaemia and its consequences. The syndrome therefore encompasses the clinical entities of unstable angina, acute myocardial infarction, and many cases of sudden cardiac death. In the vast majority of instances, an acute coronary syndrome is due to the thrombotic consequences of rupture or erosion of an atherosclerotic plaque. To understand the pathophysiology of acute coronary syndromes it is therefore important to understand the cellular and molecular events leading to the development and progression of an atherosclerotic plaque.

Atherosclerosis: stable and unstable plaques

Atherosclerosis

Endothelial function is crucially important in the development of atherosclerosis. Normal endothelial cells form a physical barrier between the thrombogenic matrix of the underlying vessel wall and the circulation. However, by producing a variety of antithrombotic and anti-inflammatory molecules the endothelium also protects against the development of atherosclerosis. In particular nitric oxide, which is constitutively produced from arginine by the action of endothelial nitric oxide synthase in normal endothelial cells, prevents accumulation of inflammatory cells and, along with prostacyclin, prevents activation and adhesion of platelets. Patients with established atherosclerosis have abnormal endothelial function, particularly if they smoke, as do apparently healthy individuals with high cholesterol levels.

Endothelial dysfunction is manifest in the coronary and peripheral circulations as reduced vasodilation in response to infused acetylcholine, a pharmacological stimulator of nitric oxide production, and in the brachial artery as reduced flow-mediated vasodilation in response to hyperaemic forearm blood flow. However, it remains unclear how these abnormalities of endothelial function relate to the development of atherosclerosis. Indeed, whilst it is accepted that the endothelium is abnormal in atherosclerosis, it is still unclear whether a primary endothelial abnormality predisposes to lipid accumulation and therefore the development of atherosclerosis, or whether endothelial dysfunction is secondary to hyperlipidaemia and/or the presence of subclinical atherosclerosis in apparently healthy subjects. The fact that the endothelium can respond to changes in shear stress by increasing or decreasing production of a number of molecules known to be involved in the atherogenic process suggests that subtle perturbations in endothelial function induced by local haemodynamic factors may contribute to the tendency of atherosclerosis to develop only at particular sites within the arterial tree.

The pathogenesis of the atherosclerotic plaque is discussed in detail in Chapter 15.1.2.1, but in brief, in the earliest atherosclerotic lesion, the fatty streak, there is subendothelial accumulation of oxidized lipid. This is associated with activation of the overlying endothelium and recruitment of inflammatory cells, predominantly monocytes and some T cells, into the subendothelial space. Once in the subendothelial space, the monocytes mature into macrophages and express a variety of surface molecules, in particular the scavenger receptors that allow them to bind and ingest lipid to become macrophage foam cells, the most abundant cell in the core of the atherosclerotic plaque. There is good evidence that oxidation of lipids is an essential step in the formation of foam cells and a mature atherosclerotic lesion. T cells are also activated and there is expression of major histocompatibility complex (MHC) molecules in surrounding vascular smooth muscle cells, some of which may also take up lipids to become foam cells. The activated inflammatory cells within the plaque produce a variety of cytokines that serve to recruit further inflammatory cells into the lesion. A crucial aspect is that some of these molecules also induce migration of vascular smooth muscle cells from the vessel media into the intima where they become incorporated into the atherosclerotic lesion. During the process of migration the vascular smooth muscle cells change from a contractile to a repair phenotype, as discussed in Chapter 15.1.1.3, which allows them to proliferate and elaborate the matrix proteins required to form a fibrous cap over the lipid core. Vascular smooth muscle cells are the only cells capable of synthesizing the fibrous cap, and their participation is therefore essential for plaque stability. Stable atherosclerotic plaques characteristically contain few inflammatory cells, large numbers of vascular smooth muscle cells, and have a thick fibrous cap that is resistant to rupture. They only cause symptoms if they are large enough to compromise flow through the artery, in which case they cause reversible ischaemia in the form of stable angina.

Plaque instability

Atherosclerotic plaques give rise to acute coronary syndromes when there is a sudden reduction in coronary blood flow. In most cases this is due to aggregation of platelets, with or without subsequent thrombosis. Spontaneous haemorrhage, presumably from immature microvessels within the plaque, causes rapid expansion of the plaque and a sufficient reduction in coronary blood flow to precipitate either myocardial infarction or unstable angina in a few cases. Most thrombotic events are due to rupture or fissuring of the fibrous cap with consequent exposure of the thrombogenic lipid core, but in some cases, variably reported to be between 25 and 44 per cent of thrombotic coronary events, thrombosis occurs because of accumulation of platelets at the site of endothelial erosion without obvious disruption of the fibrous cap or exposure of the lipid core.

Thrombosis due to endothelial erosion appears to be particularly common in female smokers dying suddenly with coronary disease, which may reflect a greater tendency to thrombosis in women than men rather than a difference in underlying plaque pathology. The mechanism of plaque erosion still remains to be determined, but it is possible that plaque inflammatory cells may produce cytokines that are toxic to the overlying endothelium, thereby inducing endothelial cell death and exposure of the underlying collagenous matrix of the atherosclerotic lesion. Alternatively, there may be a detrimental interaction between endothelial cells and underlying smooth muscle cells. Further studies are required to resolve the mechanism of endothelial erosion before therapies aimed at its prevention can be developed.

Plaque rupture, with the development of a thrombus that occludes the lumen and extends into the core of the lesion, is the commonest substrate for an acute coronary syndrome. In contrast to endothelial erosion, the pathophysiological mechanisms underlying plaque rupture are now beginning to be resolved. Modelling of the structural characteristics of atherosclerotic plaques has predicted that plaques with a large lipid core and a thin fibrous cap are subject to increased circumferential tensile stress, increasing the chance of rupture, whereas a thick fibrous cap confers structural stability by reducing tensile stress. The interaction between the physical properties of the plaque and local haemodynamic forces are therefore likely to play a part in determining stability and resistance to rupture, particularly in circumstances where the clinical event is related to physical activity, there being a well-recognized association between activities such as shovelling snow and the development of an acute coronary syndrome.

However, the most important determinant of plaque instability is the balance between the activity of inflammatory cells and the healing, fibrotic reaction of the smooth muscle cells in the fibrous cap. Plaque rupture occurs in lesions containing few vascular smooth muscle cells and abundant inflammatory cells, suggesting that inflammatory cells are responsible for the breakdown of the plaque: there are a number of ways in which they might weaken the fibrous cap. Firstly, they produce proinflammatory cytokines that inhibit vascular smooth muscle cell proliferation and matrix production. Secondly, inflammatory cytokines such as interleukin 1b, tumour necrosis factor-a, and interferon-g act synergistically to induce vascular smooth muscle cell death. Thirdly, activated macrophages can induce vascular

smooth muscle cell death by direct cell to cell contact. Fourthly, and probably most importantly, inflammatory cells, particularly macrophages, produce and activate a number of matrix metalloproteinases that digest the matrix of the fibrous cap. Thus inflammatory cells exert a potent negative influence on the turnover of matrix protein within the lesion. Furthermore, as discussed in Chapter 15.1.1.3, vascular smooth muscle cells in the fibrous cap become senescent and develop an inherent tendency to undergo apoptosis (programmed cell death). The overall effect is that inflammatory cell activity destroys the fabric of the fibrous cap and at the same time reduces the number and synthetic activity of intimal vascular smooth muscle cells, leading inevitably to weakening of the cap and eventual rupture under the stress of local haemodynamic forces (Fig. 1). The clinical importance of individual inflammatory cytokines and matrix metalloproteinases in the progression and rupture of plaque has yet to be established. However, evidence is beginning to emerge that subtle, genetically determined differences in production and activity of inflammatory mediators and matrix metalloproteinases, measured as polymorphisms in the genes coding for their production, may influence the rate of progression and outcome of atherosclerosis in different individuals.

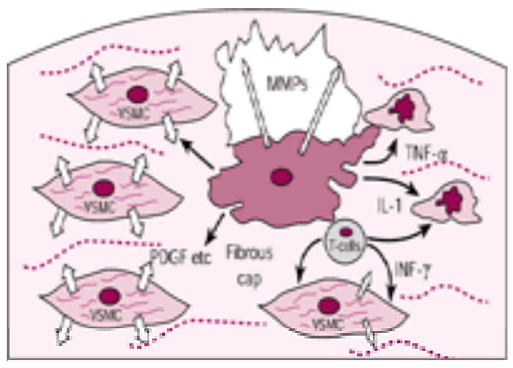

Fig. 1 Cellular interactions within the fibrous cap of an established atherosclerotic lesion leading to plaque rupture and an acute coronary syndrome. In early lesions cytokines produced by macrophages recruit vascular smooth muscle cells that produce the matrix proteins of the fibrous cap. In advanced lesions the cytokines produced by inflammatory cells inhibit vascular smooth muscle cell protein production and are cytotoxic. The vascular smooth muscle cells become senescent and die and macrophages produce matrix metalloproteinases that destroy the fibrous cap, leading to plaque rupture.

Modification of plaque stability

For many years symptomatic atherosclerosis was thought to represent the end stage of a slowly progressive, irreversible disease process that had developed over decades and which was therefore unlikely to be influenced favourably by medical therapy. Consequently, therapy for ischaemic heart disease focused either on abrogating the consequences of atherosclerosis, for example with antianginal, antiplatelet, and thrombolytic drugs, or relieving stenoses by interventions such as angioplasty or bypass surgery. However, as described above, it is now recognized that atherosclerosis is a dynamic inflammatory condition involving constant or cyclical recruitment and activation of inflammatory cells, with repeated subclinical episodes of plaque rupture and repair leading to episodic growth of individual plaques (Fig. 2). Encouragingly, results of several recently published large-scale trials of lipid-lowering agents, in particular the HMG CoA reductase inhibitors or 'statins', have shown that medical therapy can modify the pathophysiology of atherosclerosis.

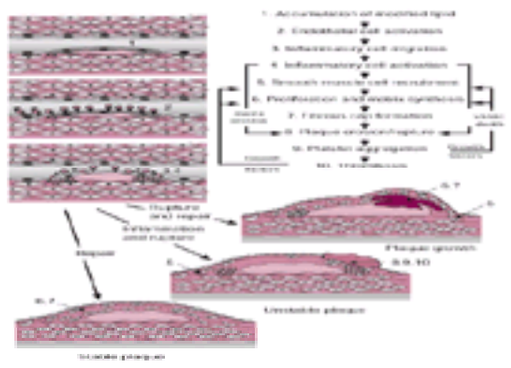

Fig. 2 Cellular interactions leading to the development and progression of atherosclerosis. (Reproduced from Weissberg PL (2000). *Heart* **83**, 247–52, with permission.)

Aggressive, sustained lipid lowering, by whatever means, reduces the risk of myocardial infarction. However, it is only since the introduction of statins that doctors have had access to powerful lipid-lowering drugs that are well tolerated and relatively free of toxicity. Angiographic studies in patients with angina have shown that statins reduce the rate of appearance of new lesions and reduce the incidence of spontaneous, clinically silent, vessel occlusions (occurring when there is plaque rupture and thrombosis in the context of a good collateral circulation that maintains viability of the tissue downstream of the occlusion). However, statin therapy has only a marginal and probably haemodynamically insignificant effect on the size of established stenotic atherosclerotic lesions. Despite this disappointing effect on plaque size, treatment with statins reduces mortality and the risk of a coronary event (unstable angina, myocardial infarction, or the need for surgical intervention) by about 30 to 40 per cent, both in asymptomatic individuals at high risk of a coronary event (primary prevention) and in patients who have already experienced a coronary event (secondary prevention). Results of theses studies suggest strongly that statins are stabilizing atherosclerotic plaques.

The inflammatory basis of atherosclerosis

The cellular and molecular interactions described above all point to an important role for inflammation in the development and progression of atherosclerosis. Evidence in support of this contention comes from recent clinical studies in which circulating levels of acute-phase proteins such as C-reactive protein, fibrinogen, and serum amyloid A have been shown to correlate closely with the risk of an acute coronary syndrome, or indeed stroke. This applies both in apparently healthy subjects without overt coronary disease and in those who have already survived a myocardial infarction. Recognition of this association led to the speculation that atherosclerosis or its consequences may be precipitated by infection, and several early studies demonstrated an association between serological evidence of recent infection with *Helicobacter pylori*, *Chlamydia pheumoniae*, and cytomegalovirus and coronary events. The case for *Chlamydia pheumoniae* was particularly plausible since these organisms can be found in vascular smooth muscle cells and macrophages within atherosclerotic lesions. However, recent more rigorous studies have suggested that these associations may be spurious, due to inadequate control for confounders, particularly for *Helicobacter pylori* infection, and do not indicate a strong association between infection and the development of coronary artery disease. The outcome of several ongoing studies on the effects of antibiotic therapy on coronary events should help resolve this important question. Evidence that elevated levels of C-reactive protein reflect inflammatory activity within atherosclerosis rather than infection comes from studies of inhibition of hepatic HMG CoA reductase with pravastatin. Compared with patients treated with placebo, whose C-reactive protein levels rose, patients treated with pravastatin, which lowers low-density lipoprotein cholesterol but has no known effect on bacteria, experienced a substantially reduced risk of a coronary event with an associated fall in level of circulating C-reactive protein.

The causes of acute coronary syndromes

Unstable angina versus myocardial infarction

The pathogenesis of unstable angina and myocardial infarction is similar in that both occur because of plaque erosion or rupture and subsequent aggregation of platelets. Lesions causing unstable angina are characteristically eccentric and ulcerated with associated non-occlusive thrombus, whereas angiographic studies have shown that myocardial infarction is usually due to complete thrombotic occlusion of the relevant vessel. Treatment of myocardial infarction therefore includes aspirin to prevent further platelet aggregation and a fibrinolytic drug to lyse the occluding thrombus. In unstable angina the accumulation and activation of platelets causes

local release of a number of peptides, such as thromboxane A2, 5-hydroxytryptamine, and platelet derived growth factor, all of which are potent vasoconstrictors. Thus, vasoconstriction superimposed on partial occlusion of the lumen is often responsible for myocardial ischaemia (Fig. 1). Although the thrombus in unstable angina may be non-occlusive, it provides the substrate from which embolization of platelet aggregates downstream can produce microinfarcts that are not apparent electrocardiographically, but which may be detectable through release of sensitive markers of myocyte necrosis, such as troponins I or T. Patients with unstable angina and an associated increase in circulating troponin levels are at particularly high risk of subsequent coronary events if not treated aggressively.

The logical result of this analysis is that the management of unstable angina includes inhibition of platelet aggregation with aspirin, heparin to prevent progression to a fibrin clot, and nitrates to offload the myocardium and relieve any local coronary artery spasm. Although aspirin continues to be the first-line antiplatelet drug, newer drugs such as ADP and glycoprotein IIb/IIIa antagonists are rapidly establishing their role in the management of unstable angina and other acute vascular syndromes such as transient cerebral ischaemic attack.

Plaque instability often occurs in small, haemodynamically insignificant atherosclerotic plaques that are clinically silent (not causing stable angina) and which may not be apparent at angiography. Approximately 70 per cent of coronary lesions that break down to cause thrombosis and subsequent myocardial infarction cause less than a 50 per cent stenosis of the relevant coronary artery. This is probably because arteries can remodel to accommodate large atherosclerotic lesions without reducing lumen diameter, but it explains why so many patients (about 50 per cent) suffer myocardial infarction without experiencing any prior symptoms of coronary disease. It also serves to emphasize the relatively greater importance of plaque composition than plaque size in determining the outcome of coronary disease.

Other causes of acute coronary syndromes

Not all acute coronary syndromes arise as a result of rupture of atherosclerotic plaque. Rarely, acute myocardial infarction can occur in the absence of significant coronary artery disease. Acute coronary artery dissection is a rare event that occurs more commonly in women than men and which can cause myocardial infarction and even sudden death. The underlying aetiology is unknown. Coronary artery spasm may also precipitate an acute coronary syndrome and even myocardial infarction, but the reasons for coronary spasm in the absence of atherosclerosis are poorly understood, although they almost certainly arise from endothelial dysfunction. Angina due to spasm, so-called Prinzmetal's variant angina, is characterized by marked ST segment elevation on the ECG, by contrast with ischaemia due to atherosclerotic plaque rupture or erosion that are characterized by ST segment depression. It usually responds to treatment with calcium channel blockers, particularly nifedipine. Finally, acute coronary syndromes can be precipitated by legitimate and illegitimate drug therapy. For example, symptoms of myocardial ischaemia can be provoked in some patients by the use of HT1 agonists to treat migraine or sildenafil for impotence, particularly when combined with nitrates. Recreational drug abuse, particularly cocaine derivatives, may also precipitate an acute coronary syndrome and should be considered when clinically appropriate.

Consequences of acute coronary syndromes

Sudden reduction in blood flow through a coronary artery inevitably leads to myocardial ischaemia unless the myocardium is supplied by an adequate collateral blood supply from another coronary artery. The three main clinical consequences of such ischaemia are arrhythmias, reduced contractile function, and, less commonly, myocardial rupture: these are discussed in Chapter 15.4.2.3. However, it is becoming clear that ischaemia has complex effects on the myocardium, and considerations of myocardial stunning and hybernation and of ischaemic preconditioning are likely to be increasingly important in the development of new therapies.

Myocardial stunning and hibernation

Contractile dysfunction after infarction does not always imply irreversible necrosis of myocytes. The myocardium may be either stunned or hibernating. Viable myocardium is said to be stunned when it fails to contract appropriately after the obstruction to coronary blood flow has been removed or bypassed. This may be due to what is called the 'no reflow' phenomenon in which there is a failure of flow through the previously ischaemic tissue, despite there being a patent feeding artery. The underlying mechanism for this phenomenon is unknown, but probably relates to local endothelial dysfunction. Stunned myocardium usually recovers normal or near normal function with time.

The term hibernating myocardium is used to describe viable myocardium that fails to contract properly because it has an inadequate blood supply. The importance of this concept lies in the fact that restoration of an adequate blood flow, by angioplasty or bypass surgery, usually results in recovery of contractile function. Identification of hibernating myocardium is crucial in determining which patients will experience an improvement in myocardial function if subjected to a revascularization procedure: revascularization of dead myocardium clearly confers no benefit. Techniques based on the echocardiographic measurement of left ventricular wall motion under pharmacological stress or which compare myocardial metabolism and blood flow with positron emission tomography (see above) can identify those with myocardial dysfunction due to hibernation.

Ischaemic preconditioning

Over recent years it has become clear that episodes of myocardial ischaemia may protect the myocardium from the consequences of a further ischaemic event. Thus it has been found that a transient interruption of myocardial blood flow delays the onset of infarction if blood flow is subsequently permanently interrupted. The biochemistry of this phenomenon is complex and incompletely understood and its clinical importance is currently unclear. However, its recognition heralds the possibility of future development of drugs that will protect the myocardium from the consequences of ischaemia.

15.4.2.2 Management of stable angina

L. M. Shapiro

Introduction

Coronary artery disease is the predominant cause of death in the developed world, causing 300 000 deaths per year in the United Kingdom, and is increasing in importance in developing countries and the previous Communist bloc. Coronary artery disease is also a major cause of hospital admission and clinic consultation.

The syndrome of stable angina pectoris is clinically defined as consistent exertional- or stress-related cardiac symptoms, usually of chest pain and, less frequently, shortness of breath. In the last decade there have been major advances in the management of patients with stable symptoms and coronary artery disease: particularly in the areas of lifestyle modification, medical treatment, and revascularization. The management of patients with stable angina is the subject of this chapter.

General patient management

The diagnosis of angina pectoris in a patient should be accompanied by a detailed explanation of the disorder. In particular, that angina pectoris has an unpredictable nature, with the possibility of deterioration as well as stabilization or an improvement with treatment. The treatments available include lifestyle modification, pharmacological intervention, and revascularization. These need to be individualized and usually ameliorate symptoms, and in most circumstances improve prognosis.

In the initial management of patients with chronic angina pectoris, a search should be made for treatable conditions which increase myocardial oxygen demand or reduce oxygen delivery—for example, marked obesity, thyrotoxicosis, fever, anaemia, tachycardia, or aortic stenosis.

The medical management of stable angina pectoris then depends upon consideration of the following options to improve symptoms and/or prognosis:

1. control of risk factors and lifestyle modification;
2. pharmacological management;
3. revascularization.

Risk-factor management and lifestyle modification

Lifestyle modification, if sufficiently rigorous, has the advantage of providing a modest degree of symptom relief and a reduction in the rate of further development of coronary artery disease.

Hypertension

The relationship between the development of coronary artery disease and hypertension is well established. Hypertension increases myocardial oxygen demand and leads to ischaemia in patients with obstructive coronary artery disease. Elevation of left ventricular mass is a strong predictor of mortality due to coronary artery disease. Treatment of hypertension, especially in the elderly, has been shown to reduce the mortality from cardiovascular causes by nearly one-third.

Cigarette smoking

Not only is smoking a powerful risk factor for the development of coronary artery disease, it also leads to more severe and premature atherosclerotic plaques. Cigarette smokers with documented coronary artery disease have an increased 5-year mortality risk, and cessation of smoking lessens the risk of adverse cardiovascular events. Smoking may also lead to exacerbation of angina pectoris by increasing myocardial oxygen demand and reducing coronary blood flow by a direct effect on coronary artery tone. Passive smoking may also be important.

Hyperlipidaemia

Reduction of cholesterol by diet, and more especially by drugs therapy, has been shown in primary prevention trials to reduce the risk of the development of coronary disease. Treatment with the statin group of drugs in patients with established coronary artery disease (secondary prevention) has only a modest effect on angiographically documented, coronary artery obstruction, but significantly reduces the number of new cardiovascular events. The Scandinavian Simvastatin Survival Study treated patients with a cholesterol level in excess of 5.5 mmol/l, but a value of 4.8 mmol/l or less is currently seen as a treatment threshold.

Recent evidence from the AVERT study (atorvastatin versus revascularization treatment) suggests that, in patients with mild and stable angina pectoris, aggressive cholesterol lowering with atorvastatin had a similar effect in reducing ischaemic events as treatment with percutaneous transluminal coronary angioplasty, although the latter group had better symptom control.

Antioxidants

Oxidized low-density lipoproteins (**LDL**) may play an important role in the pathogenesis of atherosclerosis. Agents that prevent lipid peroxidation of LDL particles might therefore influence the development of atherosclerosis and its clinical consequences. Epidemiological data suggests that high vitamin E levels are protective of coronary artery disease. Giving b-carotene does not appear to confer an advantage, whereas vitamin E may show some benefits in secondary prevention in doses of 400 or 800 IU per day.

Aspirin

Activated, aggregating platelets play an important role in the development of acute coronary events. A meta-analysis of 300 studies—including 140 000 patients with chronic coronary heart disease, stroke, or previous bypass surgery—has shown aspirin to have a prophylactic benefit. Aspirin is therefore widely used in the dose

range of 75 to 150 mg per day in patients with chronic angina pectoris.

Physical inactivity

Regular aerobic exercise allows a greater workload to be performed for any level of oxygen consumption, allowing patients with coronary heart disease to increase their exercise tolerance. The physiological benefits of exercise training have largely been described from postmyocardial infarction rehabilitation. However, smaller studies have confirmed significant benefits in improved quality of life, effort tolerance, and possibly morphology of coronary artery lesions, from a graded supervised physical exercise programme in those with chronic stable angina.

Obesity

The presence of obesity most probably acts via increased blood pressure and serum cholesterol as coronary artery disease risk factors. However, it may lead to symptom development in chronic angina and weight loss may have a profound influence on symptoms.

Diabetes mellitus

This is a powerful and independent risk factor for the development of coronary artery disease. Control of blood glucose levels is vital in the management of patients with stable angina pectoris.

Pharmacological management

Basic treatment includes the use of aspirin, sublingual glycerol trinitrate (**GTN**), and b-blockade. Other antianginal agents may also be helpful, including calcium antagonists, long-acting nitrates, and potassium-channel openers.

Nitrates

In 1867, Brunton first described the clinical benefit of organic nitrates. These are prodrugs and are biotransformed by denitration, thereby liberating nitric oxide. This endothelium-derived relaxing factor (**EDRF**) exerts a vasodilatory effect, even in the absence of the endothelium, and also reduces platelet aggregation and adhesion. The antianginal and haemodynamic effects are mediated predominantly by vasodilatation of the venous system, leading to a fall in left ventricular preload and cardiac work, but also by vasodilatation of arteries, including the coronary arteries.

GTN remains the most commonly used preparation. Single doses of tablets or spray rapidly relieve angina pectoris and may be repeated every 5 min if symptoms persist. GTN is particularly effective when used prophylactically 2 to 5 min before activity. Many patients need no other antianginal medication if their angina is predictable and not particularly severe. Adverse effects of GTN are common and include flushing, headache, and hypotension. GTN is best used in the sitting or lying position to avoid hypotensive syncope, particularly for the first few doses.

Various nitrate preparations are widely used in the chronic treatment of angina pectoris, but are all limited by the development of nitrate tolerance. The mechanism leading to a reduction in clinical efficiency is not well understood, but its clinical effects can be overcome by intermittent nitrate dosing.

Nitrates can be given transdermally. Dermal absorption from ointment and patches has been shown to improve exercise duration. The ointment is applied in strips, often to the chest, and is particularly useful in those with nocturnal angina, or in immobile patients with severe symptoms. Transdermal application is also subject to nitrate tolerance.

Isosorbide dinitrate has a low bioavailability and marked variations in plasma concentration occur. Isosorbide-5-mononitrate is the active metabolite of the dinitrate and has excellent bioavailability, with a standard preparation yielding clinical effects for 4 to 8 h. Long-acting preparations, given at doses of 20 to 60 mg, are beneficial for up to 12 h. Single daily dosing does not induce tolerance, but such dosing regimes can lead to rebound myocardial ischaemia during the nitrate-free period. However, this is uncommon in clinical practice, particularly if the timing of the dose covers the period when the patient is physically active.

b-Blocking agents

These are the cornerstone of the pharmacological management of chronic angina pectoris. b-Blocking agents are well tolerated and reduce the frequency and duration of anginal episodes and improve exercise tolerance. They are also effective antihypertensive agents and prevent some arrhythmias. They act by competitively inhibiting catecholamine effects on the b-adrenergic receptor. This reduces heart rate and improves coronary perfusion (by prolonging diastole), thereby reducing an exercise-induced rise in blood pressure and contractility.

There are increasing numbers of b-blocking agents available. Factors that influence their usage include selectivity, elimination half-life, intrinsic sympathomimetic activity, and vasodilatory properties. However, for the standard treatment of patients with chronic angina pectoris, most agents will have a similar beneficial effect.

The b-receptor has two major subtypes: b1 and b2. The former predominates in the heart and the latter in the lungs. Non-selective b-blocking agents (propanolol, nadolol, pindolol, sotalol, and timolol) block both receptors, whereas selective agents (atenolol, bisoprolol, metoprolol) predominantly influence b1 receptors. These effects are relative and as doses rise selectivity becomes less prominent, so that bronchoconstriction may occur at effective antianginal doses.

Acebutolol, celiprolol, and pindolol have intrinsic sympathomimetic activity, inducing low-grade stimulation when sympathetic activity is low. The clinical significance of this is uncertain. Lipid-soluble agents such as propranolol and metoprolol are readily absorbed and have shorter half-lives.

Most agents are started in relatively small doses which are titrated against symptoms and markers of b-blockade such as heart rate, particularly on exercise. They are generally well tolerated, but bradycardia, atrioventricular block, heart failure, central nervous system effects (fatigue, depression, and nightmares) are often seen. Cold hands and feet, sexual dysfunction, and lethargy are also common. If b-blockers are to be stopped, this should be done gradually. Abrupt cessation can lead to worsening of angina pectoris with reflex tachycardia and anxiety.

The most appropriate recipient of b-blockade is an individual with exercise-induced angina, possibly with coexisting hypertension or arrhythmias. These patients should commence treatment with, for example, atenolol 50 to 100 mg once daily, metoprolol 50 to 100 mg twice daily, or propanolol 80 mg twice or three times per day. There is additional benefit after myocardial infarction. However, such agents are best avoided in the presence of reversible airways obstruction, diabetes, and impaired left ventricular function. Depression is often worsened, as is peripheral vascular disease.

Calcium antagonists

Calcium antagonists constitute a heterogeneous group of compounds with various degrees of effect on heart muscle, atrioventricular conduction, and peripheral and coronary vessels. They act by inhibiting calcium ion movement through slow channels in cardiac and smooth muscle membranes by non-competitive blockade of voltage-sensitive calcium channels. The effect of calcium antagonists in angina pectoris is related to a reduction in myocardial oxygen demand with some increase in oxygen supply. The latter is particularly important in patients with a vasoconstrictor component to their disease. While calcium antagonists may be effective on their own, some can be particularly useful when taken in combination with b-blocking agents. There are three main first-generation, calcium-channel blocking agents (verapamil, diltiazem, and nifedipine), which have quite diverse physiological actions and clinical effects.

Verapamil

This acts by slowing the heart rate and reducing myocardial contractility as well as dilating systemic and coronary vessels. It is markedly negatively inotropic, but this rarely causes clinical effects. Verapamil is started orally in the range of 40 to 80 mg three times daily. Adverse effects are hypotension, facial flushing, and constipation.

Diltiazem

The cardiac depressant effect of diltiazem is rather less than that of verapamil, but rather more than that of nifedipine. It is well tolerated. Although it causes little vasodilatation of coronary arteries, it does block exercise-induced coronary vasoconstriction and reduces afterload. It is usually started at a dose of 60 mg three times daily, but a number of long-acting preparations are now available (200–300 mg once daily).

Nifedipine

Nifedipine is a dihydropyridine derivative and there are a number of second-generation agents of a similar type (nicardipine, isradipine, and amlodipine). It is a more potent vasodilator than verapamil or diltiazem. Its beneficial effect in angina is due to its capacity to reduce myocardial oxygen requirement by afterload reduction and increase oxygen delivery through coronary vasodilatation. Nifedipine is usually started as 10 mg three times daily, but there are number of long-acting preparations that deliver 30 to 90 mg per day. Adverse effects are quite prominent and relate to vasodilatation, including headache, dizziness, palpitations, flushing, hypertension, and leg oedema. The adverse effects of nifedipine are reduced by the use of sustained-release preparations and short-acting formulations should probably not now be used. Nifedipine may increase in mortality. Second-generation dihydropyridine derivatives may have some advantages in side-effect profiles.

Other pharmacological agents

The potassium-channel opener nicorandil has been show to have effective antianginal properties. It is currently prescribed to patients with persisting symptoms despite 'maximal' medical therapy. Whether patients would benefit from an earlier introduction of nicorandil is yet to be determined.

Revascularization

Coronary angiography, with a view to revascularization, is recommended in patients who remain symptomatic or have documented ischaemia, despite maximal medical therapy. Other indications include the results of non-invasive testing suggesting poor prognosis despite milder symptoms (exertional hypotension, arrhythmias, and marked ischaemia), or for occupational reasons. While in younger, more active, patients, revascularization may be considered earlier in the disease course, age itself is not a restriction. However, whilst percutaneous transluminal coronary angioplasty can be performed safely in the elderly, the mortality from bypass surgery will rise unacceptably in very old patients with coexisting disease (see later). Coronary angiography is underutilized but clinically very useful in patients with diagnostic doubt as to the cause of chest pain, as normal findings considerably simplify management.

Exercise electrocardiography (or similar tests of ischaemia) give positive results in only 60 to 80 per cent of patients with coronary artery disease. The remainder are false-negative tests. Also, some normal individuals have an ischaemic response—these are false-positives. Such lack of sensitivity and specificity makes these tests too unreliable for screening normal individuals for coronary artery disease (for a fuller discussion of these important issues see Chapter 15.3.2).

Summary of the medical management of patients with chronic stable angina

1. Confirm the diagnosis by demonstrating myocardial ischaemia.
2. Control risk factors and modify lifestyle: in particular, weight loss may improve symptoms.
3. Treat with aspirin and GTN for both symptom relief and prophylaxis.
4. Add a b-blocking agent.
5. If angina is not controlled, add a long-acting nitrate or calcium-channel blocker.
6. If angina persists, and there are no contraindications, consider coronary revascularization.

15.4.2.3 Management of acute coronary syndromes: unstable angina and myocardial infarction

Keith A. A. Fox

Introduction

Acute coronary syndromes comprise a clinical spectrum of conditions that extend from new-onset angina through unstable angina and minimal myocardial injury (enzyme release without diagnostic changes of infarction) to myocardial infarction based upon ECG and enzyme criteria. These different clinical presentations share important pathophysiological features. They occur in patients with underlying symptomatic or occult coronary artery disease and flow-limiting or non-flow-limiting atheromatous plaques in the coronary arterial wall.

The acute coronary syndrome is precipitated in an abrupt change in an atheromatous plaque, resulting in increased obstruction to perfusion and ischaemia or infarction in the territory supplied by the affected vessel. For discussion of the mechanisms involved, see Chapter 15.4.2.1. The clinical manifestations are dependent not only upon the degree of obstruction to perfusion, but also on the presence or absence of collateral perfusion, the extent and distribution of fragmented microthrombi, and myocardial oxygen demand in the perfused territory. Thus, the clinical consequences of plaque rupture can range from an entirely silent episode through to a development of abrupt occlusion with profound ischaemia and infarction or sudden death.

Rational management, including pharmacological treatment and percutaneous or surgical revascularization strategies, are critically dependent on the underlying pathophysiological mechanisms and on the extent and severity of myocardial ischaemia. Despite sharing key pathophysiological mechanisms with ST-segment elevation, acute myocardial infarction (**MI**), unstable angina, and non-ST elevation MI demand special attention. Whereas acute reperfusion strategies (thrombolysis or primary percutaneous coronary intervention, **PCI**) are of proven benefit in ST-segment elevation infarction (or that associated with new bundle-branch block), there is no evidence that thrombolytic treatment improves outcome in the remainder of the syndrome. For this reason a pragmatic division is made between acute coronary syndromes with ST-segment elevation, and those without.

Unstable angina/non-ST elevation MI

Outcome based upon trial data and large-scale observational registry studies

Imprecision in the definition and characterization of unstable angina or non-ST elevation MI has previously resulted in underestimation of the risk of this syndrome. The inclusion of patients with chest pain, but without diagnostic features of acute ischaemia, masked the true hazards of the syndrome.

Patients with acute coronary syndrome (without persistent ST elevation) are at substantial risk of subsequent cardiac events despite current therapy. Based on data from randomized trials and prospective registry studies, about 9 to 11 per cent suffer death or myocardial infarction at 6 months, with almost half of this risk within the first 7 days (GUSTO IIb, OASIS Registry, GRACE Registry). Between one-quarter and a third of patients suffer death, myocardial infarction, or readmission for unstable angina within 6 months (GRACE Registry, PRAIS Registry).

Clinical presentation and definition of the syndrome

Unstable angina may present *de novo* (new-onset angina) with episodes of typical ischaemic discomfort at rest (rest angina) or on minimal exertion. Alternatively, a previously stable pattern of angina may deteriorate abruptly or progressively, resulting in episodes of typical rest angina or angina provoked by minor exertion (crescendo angina). Although new-onset exertional angina is not generally recognized as part of the acute coronary syndrome, the outcomes are similar (7 per cent develop non-fatal MI and 4 per cent die, and a further 19 per cent require revascularization within 15 months) (Table 1).

As a clinical syndrome, unstable angina is conventionally diagnosed by the presence of new-onset angina or angina of worsening severity in terms of frequency or duration. The syndrome must be distinguished from non-cardiac pain, stable angina, and infarction. To improve the specificity of the diagnosis, and for the purposes of clinical trials, a more restricted definition has been employed which requires at least 15 to 20 min of typical, ischaemic discomfort, or two 5-min episodes at rest. The specificity is further improved when the definition requires objective evidence of ischaemia or evidence of underlying coronary artery disease. ST-segment depression on the electrocardiogram, especially in association with typical pain, is highly predictive, whereas the less specific ECG abnormalities including T-wave inversion are less strong predictors. Markers of myocardial damage (troponins or cardiac enzymes) are powerfully predictive. The ECG changes and the markers also indicate an adverse prognostic outcome. In the absence of such markers, documented evidence of underlying coronary artery disease (prior infarction or angiographically demonstrated coronary disease) helps to confirm the diagnosis.

Minimal myocardial damage—infarction without ST elevation or Q-wave development ('including non-Q-wave MI')—lies between unstable angina and Q-wave myocardial infarction in its prognostic significance (Fig. 1). It is best considered as part of the continuous spectrum of acute coronary syndromes rather than as a separate entity (Fig. 2). Management strategies are the same as for other higher risk patients with unstable angina. Minimal myocardial injury arises as a result of episodes of transient occlusion and/or embolization of thrombus into the distal circulation of the affected coronary vessel. Injury to myocytes results in the release of enzymes from the contractile apparatus (troponins) and cardiac enzymes, indicating irreversible injury (creatine kinase (CK) or CK-MB (**CK-MB**)). Thus, although the management of ST-*segment-elevation MI* differs, the remainder of the acute coronary syndrome should be managed as a continuous spectrum, but influenced by risk stratification.

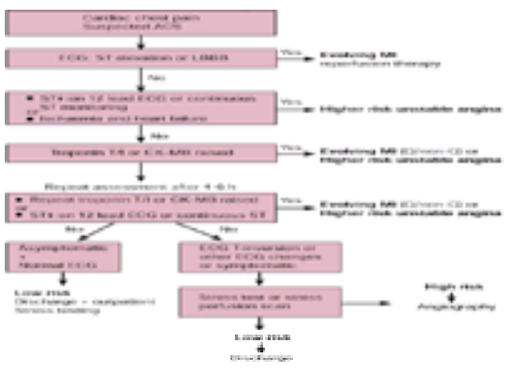

Fig. 1 Diagnostic triage for suspected acute coronary syndromes. Flow chart to illustrate the key diagnostic features for evolving myocardial infarction, for higher risk unstable angina and for low-risk patients.

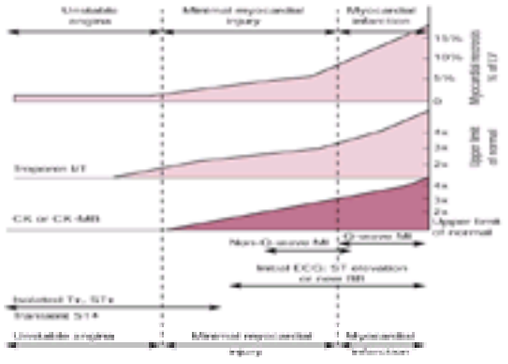

Fig. 2 Schematic of the spectrum of acute coronary syndromes. The relationship between the extent of myocardial necrosis (upper panel) and the release of cardiac enzymes (troponin I or T, or CK or CK-MB) and electrocardiographic changes. The schematic illustrates that unstable angina is associated with minor myocardial necrosis without the release of CK or CK-MB but with the release of troponin in approximately one-third of cases. With minimal myocardial injury, more extensive myocardial necrosis is associated with the release of cardiac enzymes and ECG changes (non-ST elevation-wave MI). With Q-wave MI the most extensive myocardial necrosis and release of cardiac enzymes occurs in association with the electrocardiographic changes.

Variant angina

A condition characterized by recurrent episodes of angina at rest, often accompanied by ST-segment elevation, was originally described by Prinzmetal. Such patients may have relatively a well-preserved exercise capacity and specific diurnal periodicity to the symptoms, with occasional clustering of symptomatic episodes and symptom-free periods. Coronary vasospasm has been implicated in the syndrome, and in some instances the coronary arteries appear angiographically normal, or with only minor occlusive disease. However, the vast majority of patients with symptomatic ischaemia and ST-segment elevation or depression have occlusive coronary artery disease with superimposed thrombosis, and they should be managed as such. Indeed, vasospasm very frequently accompanies plaque rupture and thrombosis. With the use of modern cardiac enzyme studies and coronary angiographic techniques, variant angina is a rare diagnosis that should only be considered if atherosclerotic acute coronary syndromes have been excluded. It is possible that erosion of a minor plaque, superimposed thrombosis and embolization may be responsible for a number of such clinical cases.

Risk characterization and outcome

In patients with acute coronary syndromes, risk can be separated into two components: prior risk and acute ischaemic risk. Based upon large observational studies it is possible to derive univariate and multivariate predictors of outcome. Prior risk is determined by patient characteristics (age and gender), prior ischaemic heart disease (myocardial infarction, heart failure, prior angina), and systemic factors that influence risk (hypertension, diabetes, and other life-threatening systemic disorders). These are largely unchangeable and can be considered as the background level of risk that the patient brings with them to the point of presentation. The extent of underlying coronary artery disease and prior heart failure require assessment and management.

The second component of risk, 'acute ischaemic risk' is determined by the severity of ischaemia induced by plaque rupture and thrombosis and the extent of the territory affected. Collateral perfusion and myocardial oxygen demand both influence the extent of ischaemia. Patients may experience transient complete occlusion, or severe subtotal occlusion complicated by distal embolization of fragments of a platelet-rich thrombus, also by changes in vascular tone in the distal territory. Clinical markers of acute ischaemic risk include electrocardiographic changes, enzyme release into the systemic circulation, and mechanical and arrhythmic complications of the ischaemic episode.

The first priority in the management of patients with acute coronary syndromes is to deal with acute ischaemic risk. Assessment of the extent of underlying coronary artery disease (for example with stress testing and/or angiography) and assessment of left ventricular function can take place later in the management of these patients. Simplistically, 'prior risk' can be regarded as the 'baggage' that the patient carries with them, and 'acute ischaemic risk' as an 'acquired hazard' arising from the new ischaemic event. The distinction is important because management strategies for prior risk aim to treat heart failure, underlying coronary and systemic disease, and risk factors. The management of acute ischaemic risk aims to reverse the impact of acute coronary obstruction and thrombosis.

The clinical syndrome and outcome

The Braunwald classification categorizes unstable angina according to the mode of onset and time course (Table 2). It was empirically based but has been validated by prospective studies. Patients with unstable angina at rest (Braunwald Class 3) have the highest risk of an adverse cardiac event (approximately 11 per cent in hospital event rate). Similarly, those with unstable angina following acute myocardial infarction are at an increased risk. Although useful, many of the patients that present with acute coronary syndromes are in Braunwald Class 3B and additional methods of risk characterization are required to optimize management.

A diagnostic triage system can be developed for patients with suspected acute coronary syndromes (Fig. 1). This is based upon electrocardiographic changes, enzyme release, and stress or perfusion testing. As a result, those with evolving infarction are identified and those with higher risk unstable angina are separated from those with lower risk. These categories of patients require different management strategies.

The electrocardiogram and outcome

The 12-lead electrocardiogram (performed on admission) provides direct prognostic information (Table 3).

The greatest risk of death and subsequent MI is seen in patients with simultaneous ST elevation and depression. The next highest risk is seen in those with transient ST-segment elevation or ST-segment depression. Isolated T-wave inversion carries a lower risk (Table 3). The number of leads demonstrating ST deviation also yields prognostic information: among those with ST deviation in the anterior leads a rate of death or myocardial infarction of 12.4 per cent was seen at 1 year, higher than seen with similar changes in other locations (TIMI III trial). Patients with a left main and three-vessel coronary artery disease may show a combination of ST-segment elevation and depression.

Holter ST-segment recording can identify patients with unstable angina and either silent or symptomatic myocardial ischaemia with an increased risk for major subsequent cardiac events. However, they provide off-line analysis and are not suitable for the prediction of imminent events. Computer-assisted, continuous,

multi-lead, ECG monitoring techniques have become available for real-time ECG and ST-segment monitoring. The occurrence and extent of ischaemic territory identified by such continuous recordings can provide additional prognostic information over and above the admission ECG. They can be combined with serial enzyme markers; recent studies have indicated that together they provide additional prognostic information (FRISC study).

Biochemical markers and outcome

Enzymes are gradually released into the systemic circulation following complete or transient occlusion of the coronary artery, or fragmentation of a thrombus and embolization. Following total occlusion of the vessel, creatine kinase (or more specifically CK-MB) will be released and detectable at clearly abnormal levels about 6 to 8 h after the event, unless there is extensive collateral perfusion. By convention, CK values greater than twice the upper limit of normal are associated with infarction, and this is categorized into those with Q-wave development and those without. However, a continuous spectrum of injury exists from unstable angina through non-Q-wave myocardial infarction to Q-wave infarction. The evolution of Q waves on the ECG (or none) provides prognostic information by the time of hospital discharge, but cannot be used to guide early treatment.

The measurement of myocardial isoforms of troponins in the blood are more sensitive markers of injury. The cardiac isoforms of troponin I and troponin T are exclusively expressed in cardiac myocytes and provide specific evidence of myocardial damage. Only a few patients with renal dysfunction will have falsely elevated troponin measurements. Following marked ischaemia or infarction, troponins are released from the cytosolic pool and first appear in the circulation in detectable concentrations between 3 and 4 h after the ischaemic event and reach diagnostic concentrations at 6 to 8 h. Troponin release may be regarded as evidence of myocardial injury and it carries a prognostic significance worse than that of patients without troponin release but less severe than those with acute infarction diagnosed by by a rise of more than twofold in CK-MB (Fig. 3) unless the concentrations in the blood are markedly elevated. The greater the troponin release the greater the risk of subsequent myocardial infarction and death.

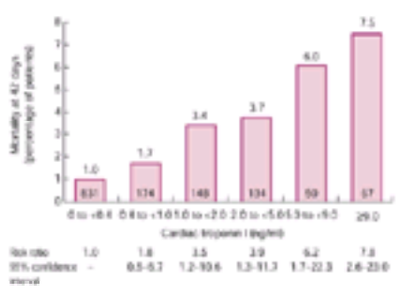

Fig. 3 Cardiac troponin I and subsequent risk of death among patients with unstable angina or non-ST-elevation MI. Mortality rates at 42 days (without adjustment for baseline characteristics) are shown for ranges of cardiac troponin I levels measured at baseline. The numbers at the bottom of each bar are the numbers of patients with cardiac troponin I levels in each range, and the numbers above the bars are percentages. p <0.001 for the increase in the mortality rate (and the risk ratio for mortality) with increasing levels of cardiac troponin I at enrolment. (Reproduced with permission from Antman *et al*. *New England Journal of Medicine* 1996, **335**, 1342–9.)

When should the cardiac enzymes be measured? The time course of the release of enzymes from myocardium is such that diagnostic concentrations may not be achieved until between 6 and 8 h after an ischaemic event. Thus, normal values for a patient on arrival do not exclude infarction or unstable angina. However, elevated values on arrival are highly predictive of subsequent infarction (for CK, or CK-MB, or troponins). The CK and CK-MB measurements should be repeated between 8 and 12 h later and also after any suspected ischaemic event. Troponins should be measured on arrival and at approximately 8 h: these provide the highest predictive accuracy.

Among those with persistently negative troponins and without significant ECG changes there is a very low risk of subsequent infarction and death (provided that severe underlying coronary artery disease is excluded). Ideally such patients should undergo predischarge stress testing; the most accurate test being that accompanied by myocardial perfusion scanning or stress echocardiography. Treadmill electrocardiograms on exercise are less accurate but more widely available (see Chapter 15.3.2).

Among patients in whom myocardial infarction is excluded by standard criteria, about one-quarter will have elevated troponin levels (minor myocardial damage) and these patients have the same frequency of cardiac events during follow-up as seen for conventionally diagnosed infarction.

Markers of inflammation

Inflammatory changes in the vessel wall promote plaque fissuring or erosion, and inflammatory changes also follow episodes of minor myocardial damage. In unstable angina there is evidence that inflammatory markers (C-reactive protein (**CRP**), interleukin-6, and interleukin-1) are independent predictors of adverse outcome. Only 50 to 70 per cent of patients with Braunwald class IIIB unstable angina have elevated CRP levels. After the acute phase, continuing inflammation—with, for example, elevated CRP—occurs in half of those whose levels are acutely elevated and identifies a category of patients at increased risk. Although inflammatory mechanisms are implicated in plaque growth and plaque destabilization, specific anti-inflammatory therapy of surface integrins (including the inhibition of surface integrins or inhibition of polymorph infiltration with anti-CD11/CD18 antibodies) has not yet been demonstrated to improve outcome.

Treatment

Antiplatelet therapy

Aspirin

Exposure of the contents of atheromatous plaque to circulating blood triggers platelet activation by several different pathways. Aspirin is a potent and irreversible inhibitor of platelet cyclo-oxygenase, blocking the formation of thromboxane A_2 and inhibiting platelet aggregation. Although the effects of aspirin can be overcome in the presence of potent thrombogenic stimuli, nevertheless the benefits of aspirin treatment in unstable angina are clearly defined and substantial. The Antiplatelet Trialists Collaboration demonstrated a reduction of 36 per cent in death or MI with antiplatelet treatment (predominantly aspirin) versus placebo in unstable angina trials. Aspirin treatment significantly reduces subsequent myocardial infarction, stroke, and vascular death, with the largest reductions seen amongst patients at highest risk. In patients with unstable angina, four key studies have demonstrated that aspirin significantly reduces the risk of cardiac death or non-fatal MI by approximately 50 per cent.

The efficacy of lower dose aspirin (75 mg day) therapy has been demonstrated in several studies, including those of Wallentin and colleagues where long-term effects were evaluated in men under 70 years of age with unstable coronary artery disease. After 6 and 12 months of aspirin treatment the risk of myocardial infarction or death was reduced by 54 per cent and 48 per cent, respectively (risk ratio 0.52 with 95 per cent confidence intervals 0.37–0.72). The strength of evidence and magnitude of benefit demonstrated with aspirin treatment in unstable angina or non-ST- *segment-elevation MI* is such that aspirin forms the reference standard against which alternative or adjunctive antiplatelet therapies are judged.

- Aspirin treatment is indicated in all patients with acute coronary syndromes unless there is good evidence of aspirin allergy.

Nevertheless, patients with acute coronary syndromes are at significant risk despite aspirin therapy. In prospective registry studies of unstable angina/non-ST-*segment-elevation MI*, and in spite of aspirin treatment in more than 80 per cent of patients, the risk of death or myocardial infarction is approximately 10 per cent at 6 months and the risk of death/myocardial infarction or refractory angina is approximately 22 to 33 per cent over the same period (OASIS Registry,

PRAIS Registry).

ADP antagonists (thienopyridines)

Ticlopidine and clopidogrel reduce thrombotic events following angioplasty and stenting. Clopidogrel has now replaced ticlopidine as it lacks the side-effect of thrombocytopenia.

Clopidogrel has now been tested in a large-scale trial of patients with unstable angina/non-ST-elevation MI (*N*=12 562 CURE trial). The agent was used on top of existing therapy and in addition to aspirin. It reduced death, non-fatal MI and stroke from 11.4 per cent to 9.3 per cent (95 per cent CI 0.72-0.90 *P* = <0.001). For every 1000 patients treated there were 28 fewer major cardiovascular complications but six more transfusions. Importantly, benefits were seen across risk groups (diabetics, hypertensives, CK or troponin elevation or not, revascularization or not). In a sub-study (PCI-CURE) clopidogrel also reduced death and myocardial infarction in those undergoing percutaneous revascularization (2.9 per cent clopidogrel versus 4.4 per cent for placebo). Thus, with the combination of clopidogrel and aspirin there is evidence of early and sustained reductions in the risks of death and myocardial infarction in patients that present with acute coronary syndromes, irrespective of their risk group and irrespective of baseline conditions. New guidelines are likely to incorporate this treatment in the management of the syndrome.

Glycoprotein IIb/IIIa inhibitors

Platelet adhesion is the initial step in haemostasis after disruption of an atheromatous plaque. It is triggered by damage to the vessel wall and exposure of the subendothelium, and is followed by platelet activation and aggregation. Regardless of the agonist, the final common pathway leading to the formation of a platelet aggregate is mediated by the glycoprotein (**GP**) IIb/IIIa receptor (up to 80 000 per platelet). GPIIb/IIIa receptor antagonists inhibit platelet aggregation irrespective of the agonist, and they prevent binding of fibrinogen to its receptor on the platelet surface.

To date, three GPIIb/IIIa inhibitors have been tested in large-scale randomized clinical trials. Abciximab is a chimeric human–murine monoclonal antibody that binds with high affinity to the receptor: it has a long biological half-life of 6 to 12 h, and low levels of receptor occupancy are detected even 2 weeks after treatment. Eptifibatide is a synthetic cyclic heptapeptide with high affinity for the arginine–glycine–aspartic acid ligand adhesion site of the IIb/IIIa receptor. It inhibits platelet aggregation in a dose-dependent manner and is readily reversible due to competitive binding and a short half-life of approximately 2.5 h. Tirofiban is a non-peptide tyrosine derivative which also binds to the arginine–glycine–aspartic acid site with high specificity. It inhibits platelet aggregation in a dose- and concentration-dependent manner and is rapidly reversible, with platelet function approaching normal levels in 90 per cent of patients within 4 to 8 h.

Although it is convenient to group glycoprotein IIb/IIIa receptor antagonists together, and undoubtedly there is evidence of a class effect, there are nevertheless biological and pharmacological differences between the agents.

Trials of GPIIb/IIIa inhibitors

More than 32 000 patients have been randomized in clinical trials involving GPIIb/IIIa inhibitors (16 trials). A highly significant (*p* <0.001) benefit is observed for the combined endpoint of death or MI at 48 to 96 h, 30 days, and 6 months. At 30 days the odds ratio is 0.76, or 20 fewer events per 1000 patients treated. Similarly, a highly significant benefit is observed for the combined endpoint of death/MI or revascularization at all time points. By contrast, mortality benefits are seen only at 48 to 96 h with no significant benefit at 30 days or 6 months. However, a pooled analysis of abciximab trials has revealed a net mortality benefit.

The effects of GPIIb/IIIa inhibitors may be greater in higher risk groups: trials involving percutaneous intervention (angioplasty with or without stent) have demonstrated significantly greater reductions in events with GPIIb/IIIa inhibitors in comparison with trials where angiography or intervention were not a prerequisite. In the interventional trials, death or MI was reduced by 27 fewer events per 1000 patients treated (odds ratio 0.64; confidence interval (95 per cent CI 0.51–0.80). In trials of GPIIb/IIIa inhibitors in acute coronary syndromes without mandatory intervention, there were 13 fewer events per 1000 patients treated (with an odds ratio of 0.88; 95 per cent CI, 0.81–0.97).

Subsequent analyses have been performed for those patients with elevated troponin levels and data from the CAPTURE study, the PRISM PLUS, and the PRISM study indicate that almost all the benefit is seen amongst those higher risk patients demonstrating troponin release.

Indications for treatment with GPIIb/IIIa inhibitors

Because of the variability in trial design, it is not yet feasible to assess differences, if any, in clinical benefit among the GPIIb/IIIa inhibitors. Head-to-head trials in acute coronary syndromes would be needed to resolve this issue. Nevertheless, robust evidence supports the following conclusions:

- Treatment with glycoprotein IIb/IIIa inhibitors results in improved outcome in unstable angina or non-Q-wave MI patients treated with aspirin and heparin. Most benefit is seen in high-risk patients (ST depression and/or troponin-elevation).
- Glycoprotein IIb/IIIa inhibitors result in improved outcome in patients requiring urgent percutaneous intervention for unstable angina or non-ST-*segment-elevation MI*.

Antithrombins

Unfractionated heparin

Unfractionated heparin has been adopted as standard antithrombin therapy in guidelines for the treatment of unstable angina/non-ST-elevation MI. However, the evidence upon which this is based is less robust than for other widely adopted treatment strategies. In practice, unfractionated heparin is difficult to control due to its unpredictable levels of binding to plasma proteins, and this may be amplified by the acute-phase response. In addition, heparin has reduced effectiveness against platelet-rich and clot-bound thrombin. In the absence of aspirin, heparin treatment is associated with a lower frequency of refractory angina/myocardial infarction and death (as a combined endpoint) compared to placebo.

Oler and colleagues have conducted a meta-analysis of the influence of adding heparin to aspirin in the treatment of patients with unstable angina. Only six randomized trials were available: there were 55 deaths or myocardial infarctions out of 698 in the aspirin plus heparin arm and 68 out of 655 in the aspirin-alone arm, giving a risk reduction of 0.67 and a 95 per cent confidence interval of 0.44 to 1.02. Thus, these results do not produce conclusive evidence of benefit from adding heparin to aspirin, but it must be stressed that appropriately powered, larger scale trials have not been conducted. Nevertheless, clinical guidelines have adopted unfractionated heparin treatment with aspirin as a pragmatic extrapolation of the available evidence.

Low-molecular-weight heparins versus placebo

The 1996 FRISC trial tested dalteparin against placebo in aspirin-treated patients with unstable angina/non-ST-elevation MI. Some 1506 patients were randomized to receive dalteparin (twice daily for the first 6 days and then once daily at a lower dose for approximately 6 weeks), and the trial showed a highly significant reduction in the frequency of death or new myocardial infarction at 6 days (1.8 per cent versus 4.8 per cent, with a risk ratio of 0.37). The effects were sustained to 42 days but were attenuated at 6 months, the differences no longer maintaining significance. Nevertheless, this trial clearly showed the benefit of low-molecular-weight heparin over placebo, in the presence of aspirin, and the feasibility of administering such treatment over a prolonged time.

Low-molecular-weight heparins possess enhanced anti-Xa activity in relation to anti-IIa (antithrombin) activity compared with unfractionated heparin. They also exhibit decreased sensitivity to platelet Factor 4, have more predictable anticoagulant effect, and lower rates of thrombocytopenia. In view of their enhanced bioavailability they offer the substantial practical advantage of subcutaneous administration, based on a dose per kilogram of body weight, and without the need for laboratory monitoring.

Low-molecular-weight heparin versus unfractionated heparin

Acute-phase treatment (approximately 2 to 8 days)

In the FRIC trial dalteparin was tested against unfractionated heparin in 1400 patients with unstable angina: it had limited power to show a difference, and no significant difference was seen between unfractionated heparin and dalteparin.

The ESSENCE trial was double-blinded and placebo-controlled and tested enoxaparin against unfractionated heparin. The treatments were given for 2 to 8 days (median 2.6 days) and the primary endpoints were death, myocardial infarction, or recurrent angina. Enoxaparin reduced the primary endpoint from 19.6 per cent to 16.6 per cent at 14 days (odds ratio 0.80 and confidence intervals 0.67–0.98). A similar and significant odds ratio was maintained at 30 days and 1 year. At 1 year there were 3.7 fewer events/100 patients (p = 0.022). The study was not powered for death/myocardial infarction alone but demonstrated corresponding trends for these endpoints.

The TIMI 11b trial was also double-blinded and tested enoxaparin *versus* unfractionated heparin, but additionally it examined 72 h of treatment *versus* 43 days of treatment. The results up to 14 days mirrored those seen in the ESSENCE trial: at 14 days the primary outcome occurred was 16.6 per cent (heparin) *versus* 14.2 per cent (enoxaparin), risk ratio 0.85 (p = 0.03). A combined analysis of ESSENCE and TIMI 11b in 1999 indicated an absolute reduction of 3.1 per 100 for death/MI/refractory angina, and showed a similar risk ratio of 0.79 (CI 0.65–0.96) for death and myocardial infarction. Taken together, these findings indicate that short-term treatment with enoxaparin results in about 3 per 100 fewer major cardiac endpoints compared to unfractionated heparin treatment, and this is achieved without additional major bleeding.

Prolonged outpatient treatment

The FRAXIS trial reported in 1999 tested fraxaparin, for 6 or 14 days, against unfractionated heparin. A total of 3468 patients were randomized within 48 h of symptom onset; no difference was seen at 6 days, 14 days, or 43 days, but there was a significant excess of major bleeds with longer term outpatient treatment. In TIMI 11b the curves remained separated over the succeeding treatment interval: at 43 days there were 19.6 per cent events (heparin) *versus* 17.3 per cent (enoxaparin) (p = 0.049), with no evidence of a further separation of the curves. However, only about 60 per cent of the patients entered the chronic-treatment phase of the study and it must be recognized that the study does not exclude a moderate treatment for more prolonged treatment. There was 1.4 per cent absolute excess in major bleeds over the chronic phase.

One component of the FRISC II trial compared long-term *versus* short-term low-molecular-weight heparin (dalteparin) treatment. After 5 days of open-phase treatment with dalteparin, patients were randomized to placebo or weight-adjusted dalteparin for a period of 3 months. The primary endpoint of death/MI occurred in 6.7 per cent of patients at 90 days in the dalteparin arm and 8 per cent in the placebo arm (a non-significant difference). The risk ratio was 0.82 but confidence intervals were between 0.6 and 1.11. The secondary analysis at earlier time points indicated a difference in favour of the low-molecular-weight heparin but this diminished by 3 months.

Conclusions from the low-molecular-weight heparin studies

There is convincing evidence in aspirin-treated patients that low-molecular-weight heparin is better than placebo (FRISC trial). The two trials using enoxaparin have provided consistent data in favour of low-molecular-weight heparin over unfractionated heparin when administered as an acute regimen. The other trials have produced a similar outcome for the acute phase of treatment and it can be concluded that acute treatment is at least as effective as unfractionated heparin. To date, the evidence to support longer term treatment with low-molecular-weight heparin is less convincing. Low-molecular-weight heparins offer significant practical advantages with simplicity of administration, more consistent antithrombin effects, lack of the need for monitoring, and a safety profile similar to that of unfractionated heparin. Evidence supports the following conclusions:

- Low-molecular-weight heparin is superior to placebo in aspirin-treated patients.
- Low-molecular-weight heparin is at least as effective as unfractionated heparin.
- Low-molecular-weight heparin can be used in place of unfractionated heparin and has practical advantages over unfractionated heparin.

Hirudin

Hirudin is a more potent and specific antithrombin than heparin, and large-scale trials have been conducted against unfractionated heparin. A combined analysis of the OASIS-1, OASIS-2, TIMI 9b, and GUSTO IIb trials indicates a 22 per cent relative-risk reduction in cardiovascular death or MI at 72 h, 17 per cent at 7 days, and 10 per cent at 35 days. This combined analysis is significant at 72 h and 7 days and the p value at 35 days is 0.057. Hirudin has specific indications for patients with heparin-induced thrombocytopenia. None of the hirudins are currently licensed in the United Kingdom for the treatment of acute coronary syndromes.

Anti-ischaemic therapy

Specific antithrombotic treatment will have an impact on limiting the progression of occlusion and improving perfusion, hence such treatment has an anti-ischaemic impact. In addition, other pharmacological treatments reduce myocardial oxygen demand and may induce coronary vasodilatation, thus reducing ischaemia. Mechanical revascularization (percutaneous intervention and coronary bypass surgery) also aims to relieve obstruction and reduce a patient's susceptibility to ischaemia and these interventions will be considered separately (see below).

Nitrates

Nitrates act by venodilatation, and in higher dose arteriolar dilatation, and hence reduce preload and afterload, thereby decreasing oxygen demand (see Chapter 15.4.2.2). In addition, nitrates can also induce coronary vasodilatation. They are effective in relieving symptoms of ischaemia. In the acute phase of the syndrome, where dose titration is required, they are most conveniently administered intravenously. Once dose titration is no longer required, buccal, oral, or topical administration is feasible.

The main limitation of continuous administration is the development of tolerance. Increased doses of nitrates may be required, with the dose adjusted on the basis of heart rate, blood pressure response, and relief of symptoms.

Large outcome trials have been conducted with nitrates in acute myocardial infarction but not in the remainder of acute coronary syndromes. However, patients without ST-segment elevation or bundle-branch block were randomized within the ISIS-4 trial. Their mortality was 5.3 per cent for nitrate treatment and 5.5 per cent for placebo treatment, a non-significant difference.

Following acute-phase treatment, patients may be switched to an outpatient oral administration of nitrates. However, if tolerance has been induced in the acute phase, such treatment may have reduced efficacy. Nevertheless, on the basis of current evidence:

- nitrates are effective in reducing ischaemia in the inhospital management of unstable angina/non-ST-elevation MI.

b-Blockers

b-Adrenoceptor antagonists reduce heart rate and blood pressure and myocardial contractility. They are primarily employed to reduce ischaemia in acute coronary syndromes. Large-scale trials have not been conducted in patients with unstable angina or non-Q-wave myocardial infarction. However, in the context of acute myocardial infarction b-blockers reduce mortality by approximately 10 to 15 per cent. They may act be reducing ventricular arrhythmias, reinfarction, and myocardial rupture. A meta-analysis of five trials involving 4700 patients with threatened MI (treated with intravenous b-blockers followed by oral therapy for approximately 1 week) resulted in a 13 per cent reduction in the risk of MI.

b-Blockers may exacerbate acute heart failure. By contrast, recent trials have produced strong evidence of a benefit for the gradual introduction of b-blockers in

ambulant patients with heart failure (see Chapter 15.2.2).

On the basis of current evidence:

- Patients with suspected acute coronary syndromes should be initiated on b-blocker therapy unless contraindicated in the individual case.

Calcium-entry blockers

These agents inhibit the slow inward current induced by the entry of extracellular calcium through the cell membrane, especially in cardiac and arteriolar smooth muscle. They act by lowering myocardial oxygen demand, reducing arterial pressure, and reducing contractility. Some agents induce a reflex tachycardia (nifedipine, nicardipine, amlodipine) and are best administered in combination with a b-adrenoceptor antagonist. By contrast, diltiazem and verapamil are suitable for patients who cannot tolerate a b-blocker because they inhibit conduction through the atrioventricular (**AV**) node and tend to cause bradycardia. All calcium antagonists reduce myocardial contractility and may aggravate heart failure. Calcium-entry blockers have been demonstrated to reduce the frequency of angina in patients with variant angina.

A meta-analysis of calcium-entry blockers in acute coronary syndromes indicates a non-significant trend towards a higher mortality in treated *versus* control patients (5.9 per cent *versus* 5.2 per cent, in 7551 patients). In individual trials, diltiazem has been compared with propranolol and both agents produced a similar reduction in anginal episodes. Subgroup analysis suggests that diltiazem is efficacious in the group with rest angina, but the clinician should always be cautious in extrapolating from subgroup analyses.

- Dihydropyridine calcium-entry blockers should be employed with b-blockers in acute coronary syndromes to avoid reflex tachycardia. In patients unable to tolerate b-blockers, a heart rate-slowing calcium antagonist may be appropriate. Short-acting dihydropyridines should not be used in isolation in acute coronary syndromes.

Potassium-channel activators

These agents (for example, nicorandil) have arterial and venous dilating properties but do not exhibit the tolerance seen with nitrates. They have been shown to be better than placebo in relieving the symptoms of angina, but little convincing evidence exists in comparison with other antianginal agents. Nicorandil possesses both potassium channel and nitrate properties and may be considered as an alternative to nitrate administration.

Conclusions: anti-ischaemic therapy

The following strategy is based upon available clinical and trial evidence:

- Patients with suspected acute coronary syndromes should be initiated on nitrate and b-blocker therapy unless there are contraindications to the use of b-blockers.
- In patients with contraindications to b-blockers, heart rate-slowing calcium antagonists should be employed.
- The combination of a calcium antagonist and b-blocker is superior to either agent alone.
- Angiography and revascularization should be considered in patients with recurrent ischaemia (with ECG abnormalities) or patients with troponin elevation (including non-ST elevation MI).

Revascularization

In chronic, stable angina strong evidence supports the use of surgical revascularization for the relief of symptoms and also for improved prognosis in patients with left main or three-vessel coronary artery disease (especially with left ventricular impairment). Percutaneous revascular *iza*tion (percutaneous intervention, PCI) is primarily employed for the relief of symptoms in chronic stable angina and in patients with one- or two-vessel coronary artery disease. By contrast, until 1999 evidence to support revascular*iza*tion in the acute coronary syndrome was inconclusive. The feasibility of PCI or coronary artery bypass grafting (**CABG**) had been established, but they were associated with an increased risk of complications in comparison with equivalent procedures performed in patients with chronic stable angina.

Observational studies

Large-scale observational studies have demonstrated wide variations between countries in the use of cardiac catheter *iza*tion and revascular*iza*tion for patients with acute ischaemic syndromes (OASIS Registry 1998, GRACE Registry 2001). Unsurprisingly, a direct correlation was demonstrated between the availability of revascular*iza*tion facilities and the frequency with which such procedures were performed. Thus, highest revascularization rates were demonstrated in the United States, with lower rates in Poland and Hungary. By contrast, no significant differences in the rates of death or myocardial infarction were seen, despite rates of invasive procedures of 59 per cent in high revascularization countries *versus* 21 per cent in low revascularization countries. Furthermore, the higher rates of revascularization were associated with an increased frequency of procedural complications, including stroke and major bleeding. These observational data highlighted the importance of performing randomized trials to resolve the role and timing of revascularization in patients with acute coronary syndromes, and to test the impact of adjunctive antithrombotic therapy.

Randomized trial data

Early comparisons of CABG and medical therapy for patients admitted with unstable angina were performed in two studies in the 1970s and 1980s, but these produced inconclusive results. The TIMI IIIB trial was conducted in the early 1990s: 1473 patients were randomized to an early invasive strategy or an early conservative strategy. Unfortunately, the trial was rather underpowered in size and was further underpowered by the high crossover rate from the conservative to invasive strategy (61 per cent revascularization in the invasive arm *versus* 49 per cent in the conservative arm). Mortality or myocardial infarction occurred in 7.2 per cent of patients randomized to the invasive strategy *versus* 7.8 per cent in those randomized to conservative strategy (at 6 weeks), and the corresponding rates at 1 year were 10.8 per cent *versus* 12.2 per cent. These differences were not significant, but the revascularization strategy was supported by a low frequency of hospital readmission. On the basis of this trial, guidelines have suggested that either strategy is acceptable.

The **VANQWISH** study (Veterans Affairs Non-Q Wave Infarction Strategies in Hospital) randomized 916 patients with evolving non- *ST-segment* elevation myocardial infarction. These patients had a high prevalence of comorbidity; moreover, the rate of death or reinfarction at 1 year was 24 per cent in the surgical group *versus* 19 per cent in the medical group (risk ratio of 1.29, $p = 0.05$). There was a high 30-day mortality in those undergoing surgical revascularization, but most of the deaths occurred amongst those randomized to revascularization but in whom the procedure was not performed. Furthermore, the study had a significant crossover rate, with 29 per cent crossing from the conservative to the revascularization arms within 30 days.

The FRISC-II trial compared an invasive strategy with a conservative strategy in patients who were initially stabilized with approximately 6 days of treatment with low-molecular-weight heparin. Coronary angiography was performed within the first 7 days and revascularization performed in 71 per cent of those in the invasive arm and 9 per cent of those in the non-invasive arm within 10 days. This was therefore the first trial to achieve substantial separations in strategy and to include an appropriately powered population. After 6 months, death or myocardial infarction occurred in 9.4 per cent of the invasive group compared with 12.1 per cent of the non-invasive group (a risk ratio of 0.78, $p = 0.031$) and the results remained significant at 1 year. Greatest benefits were demonstrated in higher risk patients.

Can the apparently discordant findings be resolved?

Early trials of revascularization predated modern techniques, and stenting was not performed in the TIMI IIIB study. The VANQWISH trial had no deaths among those undergoing percutaneous revascularization; however, it did demonstrate a high postoperative surgical mortality and a substantial death rate in those assigned revascularization but in whom the procedure was not performed. In addition, the strategy in the 'conservative arm' was more aggressive than in many other studies, in that it aimed to detect ischaemia with nuclear perfusion scanning and undertake revascularization where such tests revealed significant ischaemia. The FRISC-II trial demonstrated the feasibility of a revascularization strategy and a low surgical complication rate. It must be interpreted in the context of an initial stabilization of several days' infusion with low-molecular-weight heparin. Up until 30 days the invasive arm had an excess rate of death or myocardial infarction due to periprocedure

complications. Such complications may be reduced with the use of glycoprotein IIb/IIIa receptor antagonists (used in only 10 per cent of cases in FRISC-II). This strategy was tested in the TACTICS trial where all patients received a GPIIb/IIIa inhibitor (tirofiban) and no early excess hazard was observed in the intervention arm of the trial. The results support the findings of FRISC-II. As discussed above, GPIIb/IIIa antagonists reduce the frequency of peri and postprocedure myocardial infarction in patients with acute coronary syndromes and therefore their use is indicated, especially in those high-risk patients with positive troponins or marked *ST-segment* depression.

In conclusion, an invasive strategy of revascularization can result in a lower frequency of major cardiac complications when performed in patients who are initially stabilized with low-molecular-weight heparin treatment. The FRISC-II trial should not be interpreted as supporting very early revascularization in the absence of an initial stabilization period. The results of FRISC-II are supported by TACTICS indicating that an early invasive strategy is preferable to a conservative strategy in treating higher risk patients with acute coronary syndromes. Although very unstable patients have not been randomized in these trials (for example, those with profound ischaemia or haemodynamic complications) and emergency revascularization may provide their best therapeutic option. It is also important to note that the vast majority of patients in FRISC-II had evidence of ischaemia on the electrocardiogram and most had a positive troponin test: the results should not be extrapolated to low-risk patients, including those without clear-cut ischaemia or without troponin release.

An integrated approach to the patient with unstable angina/non-ST-elevation MI

The at-risk patient
