The clinical manifestations first appear around the age of 4 years and consist of polyuria, secondary enuresis, and polydipsia, reflecting a urinary concentration defect. Renal failure, metabolic acidosis, anaemia, and growth retardation subsequently develop, and endstage renal failure is usually reached at the age of 10 to 13 years. More or less severe renal salt wasting is a common finding. In approximately 10 to 15 per cent of cases renal involvement is associated with retinal changes: tapetoretinal degeneration with or without retinitis pigmentosa, leading to blindness early or later in life (this association is referred to as the Senior–Loken syndrome; in most of these cases, no deletion of the *NPH1* gene has been detected). Other extrarenal features (skeletal changes, cerebellar ataxia, and liver fibrosis) are rare.

Familial nephropathy with juvenile hyperuricaemia and gout (or familial juvenile hyperuricaemic nephropathy)

This disease is characterized by its autosomal dominant inheritance, juvenile onset of gout, hyperuricaemia disproportionate to the age, sex, or degree of renal dysfunction, which is due to low renal fractional excretion of urate, and renal failure often recognized between 20 and 40 years of age. Renal biopsy shows non-specific tubulointerstitial changes. Allopurinol is indicated to prevent gout and perhaps to slow the progression of renal disease.

Genetic disorders with nephrolithiasis

Pertinent clinical data on these disorders are summarized in Table 3. Additional information can be found in Chapter 20.13, Chapter 20.8, Chapter 11.10, and Chapter

11.4.

Other genetic diseases with kidney involvement

Phakomatoses

Two diseases of this group have significant renal involvement: von Hippel–Lindau's disease and tuberous sclerosis.

In von Hippel–Lindau's disease, renal cysts and bilateral multifocal renal cell carcinomas are found in 70 per cent of the patients. Carcinomas are often asymptomatic, should be screened for regularly (Fig. 2), and occur at a mean age of 45 years. Nephron-sparing surgery (tumorectomy) is advocated when technically feasible. The other clinical features of von Hippel–Lindau's disease are described in Chapter 14.8.

Fig. 2 Computed tomography of the kidneys in a patient with von Hippel–Lindau's disease. In the right kidney, a solid tumour is found as well as cystic changes. In the left kidney, a voluminous multilocular tumour is detected with thick walls, corresponding to renal clear cell carcinoma, associated with other cystic lesions.

The most typical renal lesion encountered in tuberous sclerosis is angiomyolipoma, which is a benign tumour, often multiple and bilateral. By ultrasonography, this tumour is hyperechogenic and by CT is characterized by its fat content (Fig. 3). Bleeding is the main complication of renal angiomyolipoma. Multiple angiomyolipomas may severely reduce renal mass and lead to renal failure, but this is rare. The development of segmental glomerulosclerosis may accelerate the progression to endstage. Renal cysts may also be found in *TSC2* forms (see below). The incidence of renal cell carcinoma is slightly higher than in the general population. The other features of tuberous sclerosis involve the skin and the central nervous system (Chapter 24.8).

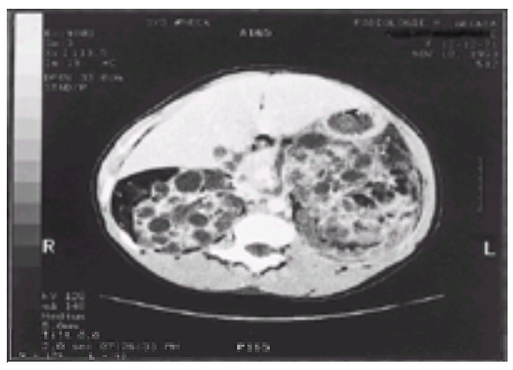

Fig. 3 Multiple bilateral renal angiomyolipomas in a patient with tuberous sclerosis (CT scan). Note the voluminous angiomyolipoma (with high content of fat that is black) at the periphery of the right kidney.

The genes mutated in von Hippel–Lindau's disease and tuberous sclerosis are tumour-suppressor genes. Two mutations ('two-hit' phenomenon) are required to trigger tumour formation: the first one germinal, inherited, and the second one somatic. The *VHL* gene has been cloned and located on 3p. Two somatic mutations of the same gene are involved in sporadic renal cell carcinoma. Two genes are identified in tuberous sclerosis: *TSC1* on chromosome 9q encoding for hamartin, and *TSC2* on chromosome 16p, encoding for tuberin.

Cystinosis

Cystinosis results from defective carrier-mediated transport of cystine through the lysosomal membrane. The disease is transmitted as an autosomal recessive trait with an incidence of about 1 in 200 000 live-born babies. The gene has been mapped on chromosome 17, has been identified, mutations have been characterized, and it encodes for a protein named cystinosine. The diagnosis is based on the findings of cystine crystals in tissues, such as the eyes, and on the elevated cystine content in leucocytes. It should be clear that cystinosis is completely different from cystinuria, which is due to a defective reabsorption of cystine in the proximal tubule.

The clinical manifestations are due to progressive intralysosomal accumulation of cystine. In the infantile form, the first symptoms are related to the clinical consequences of Fanconi syndrome (salt and water depletion, hypokalaemia, acidosis, rickets) appearing before 6 months of age. Renal failure develops later, reaching endstage generally before 12 years. Cystine accumulates in other tissues, before and after kidney transplantation: eyes (photophobia due to corneal deposits, then retinal depigmentation and visual impairment), thyroid gland (hypothyroidism), liver and spleen (portal hypertension), pancreas (diabetes mellitus), muscles, testis, and central nervous system (encephalopathy) (see Chapter 11.3).

In addition to symptomatic management, cysteamine has proved to be effective in cystinosis. It accumulates within lysosomes, promotes cystine outflow, and thus reduces tissue cystine content. Administration of this drug should be started as soon as the diagnosis is made. It may slow the rate of progression of renal failure and prevent most extrarenal complications. Despite recent progress, tolerance of the drug is not good because of its offensive taste and odour: compliance may therefore be poor. Topical cysteamine prevents corneal crystal deposition.

Juvenile cystinosis presents in late childhood or early adult life. Renal involvement occurs. By contrast, in the adult form only corneal crystals are found. Both forms are very rare.

Malformation syndromes with kidney involvement

The most frequent of these rare syndromes is Bardet–Biedl syndrome. This is a heterogeneous autosomal recessive condition for which six different genetic loci have been identified. Clinical features comprise obesity, hypogonadism (in males), polydactyly or dystrophic extremities, retinal dystrophy (leading to blindness), and renal abnormalities. The last have only been recognized recently as a cardinal feature in the syndrome. Renal imaging often shows the following abnormalities: calyceal clubbing and pronounced diverticulas, and lobulated renal outlines of the fetal type. These changes are probably dysplastic in nature, and are characteristic when associated. Renal cortical and medullary cysts have also been found by ultrasonography, but the latter may be difficult to differentiate from calyceal diverticulas. Approximately 25 per cent of patients develop chronic renal failure, progressing to endstage, which is probably the major cause of death. The most important treatment is the provision of specialized education with low-vision aids. Symptomatic management of diabetes mellitus (found in 30 per cent), hypertension, and renal

failure is required.

Renal hypoplasia or unilateral renal agenesis is found in other malformation syndromes, such as the following.

1. Kallmann's syndrome—with hypogonadism and hyposmia or anosmia.
2. Branchio-oto-renal syndrome—where laterocervical fistulas or cysts and otic abnormalities, involving the outer, middle, or inner ear are found, and the *EYA1* gene, on the long arm of chromosome 8, is mutated. This gene is the homologue of a gene present in drosophila, the mutation of which leads to eye absence.
3. Renal–coloboma syndrome—with optic nerve coloboma and sometimes hearing defect, and where the *PAX2* gene, located on 10q, is mutated.
4. Alagille's syndrome—characterized by paucity of intrahepatic bile ducts leading to cholestasis, vertebral abnormalities (butterfly vertebra), and heart defects. The gene has been identified.

All these genes implicated in malformation syndromes are involved normally in the control of kidney development.

20.12 Urinary tract infection

C. Tomson

Introduction and definitions

Infection of the urinary tract is important for different reasons in different age groups. In infants and children, ascending infection is thought to be a preventable cause of renal parenchymal scarring and eventual renal failure, although (as discussed below) it is controversial how frequently this occurs. In adult women, recurrent lower urinary tract infection ('cystitis') is a common cause of misery and time off work. In all age groups, persistent or relapsing infection is an important indicator of abnormal host defences, usually due to abnormal anatomy or function of the urinary tract, and may result in irreversible renal damage unless the underlying cause is dealt with. Urinary tract infections are the cause of over 50 per cent of Gram-negative septicaemic episodes. In the elderly, non-specific symptoms including toxic confusional states are often due to occult urinary tract infection, and asymptomatic bacteriuria is associated with increased mortality.

'Urinary tract infection' refers to bacterial or fungal infection of the kidneys, pelvis, ureters, or bladder (viral infections may involve the urinary tract, as in Hantaan virus infection, but viruria more commonly reflects systemic viral infection). Infections primarily involving the urethra are nearly lways sexually acquired and are dealt with elsewhere (see Section 21). 'Pyelonephritis' refers to infection primarily involving the kidneys and collecting systems. 'Cystitis' refers to infections localized to the urinary bladder. 'Recurrent' urinary tract infections are due to repeated reinfection, whether by similar organisms on each occasion or by different species; 'relapsing' and 'persistent' infections are due to the continued presence of the same organism, suppressed or not suppressed during antibiotic therapy. 'Uncomplicated' urinary tract infection occurs in an anatomically and functionally normal urinary tract; 'complicated' infection refers to all infections occurring in patients either with impaired host defence (e.g. diabetes) or with abnormal urinary tract anatomy (e.g. urinary tract obstruction).

Epidemiology

Symptomatic bacterial urinary tract infection is one of the commonest bacterial infections. Around 1 per cent of boys and 3 per cent of girls will develop a urinary tract infection during childhood, and 50 per cent of women have a history of at least one episode of urinary tract infection, with recurrent infections in a significant minority. Urinary tract infection is rare in men until after the age of 60, when the rising prevalence of prostatic bladder outflow obstruction leads to an increased risk of infection. Asymptomatic bacteriuria is found in about 10 per cent of elderly men and in 20 per cent of elderly women. Each year in the United Kingdom around 60 women per 1000 population visit their general practitioner with urinary tract infection. Urinary tract infection is responsible for over 25 per cent of all community-acquired bacteraemias, more than any other source of infection, and accounts for over 40 per cent of hospital-acquired infections, often as a result of bladder catheterization.

Causative organisms

The commonest causative organisms in bacterial urinary tract infection are Gram-negative gut organisms, particularly *Escherichia coli* (Table 1). This reflects the fact that most infections reach the urinary tract via the urethra from the perineum. However, as discussed below, only some subtypes of *E. coli* and only some of the other species of gut organisms have the necessary virulence characteristics to enable infection of the normal urinary tract.

Pathophysiology

The great majority of urinary tract infections are acquired by ascent of the infecting organism up the urethra; only a very small minority result from haematogenous spread or—even loss commonly—from vesicoenteric fistulas. The pelvis, ureters, bladder, and urethra possess a highly specialized epithelium, which normally maintains complete impermeability to all components of urine, including toxins and water. This is maintained by tight junctions between the surface layers of epithelial cells, with a very high transepithelial electrical resistance. In the bladder, this impermeability has to be maintained despite repeated large changes in surface area as the bladder fills and empties. This is maintained by unfolding and refolding of the large, highly folded 'umbrella' cells that form the uppermost layer of the epithelium, together with insertion and endocytosis of vesicles, ready-lined with uroplakin, a hexagonal transmembrane protein found only on the surface of umbrella cells. In experimental models, infection is associated with a marked reduction in transepithelial resistance and loss of tight junctions, allowing components of urine to stimulate pain fibres and inflammatory cytokine release.

Ascending infection takes place in a series of steps, at each of which defective host defence increases the chance of successful establishment of infection (Fig. 1).

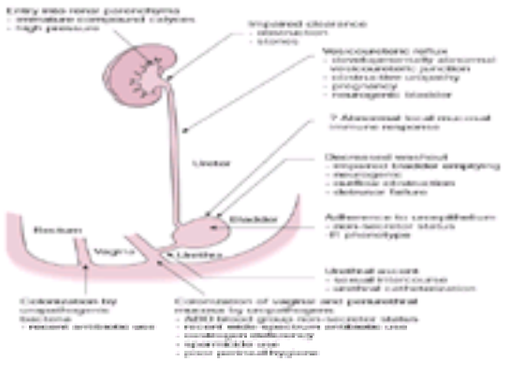

Fig. 1 Mechanisms allowing ascent of infection up the urinary tract.

The ability of a bacterium to colonize the gut and periurethral mucosa, and subsequently to adhere to the uroepithelium, is a major determinant of its ability to cause clinical infection, particularly if other host defences are intact. This ability to adhere is governed by specific interaction between bacterial adhesins, located on the tips of thin filaments ('pili' or 'fimbrias'), with genetically determined glycoproteins on the cell surface of the host cell. Type 1 fimbrias bind to mannose-containing glycoproteins that are present on the surface of uroepithelial cells, but also to Tamm–Horsfall protein, which is present in urine and can competitively inhibit binding of bacteria to cell surface glycoproteins. Type P pili bind the a-galactosyl-1,4-b-galactose disaccharide sequence present in some glycoproteins and glycosphingolipids, including the human P blood-group antigen system and also on the cell surface of uroepithelial cells as well as red cells. Some uropathogens are particularly adapted to colonizing foreign surfaces, particularly those coated by biofilm or mucin; for example, *Proteus* spp. are able to transform into a swarming phenotype with massive flagellas, organize into rafts, and move very rapidly against the flow of urine—they are therefore important causes of infection in patients with indwelling urinary catheters and those with ileal conduits.

Following adherence, fimbriae appear to retract, drawing the organism closer to the surface of the uroepithelial cell. Adherence is followed by apoptosis, exfoliation, and excretion of infected superficial cells and replacement by less differentiated cells, a process that may also contribute to host defence.

Bacterial adherence results in the local production of interleukin 8, which results in neutrophil migration through the uroepithelium into the bladder. Inflammatory cytokine release may also be promoted by soluble bacterial stimuli, such as lipopolysaccharide.

Variability in host defence

Frequency and completeness of bladder emptying

For an ascending infection to become established in the bladder, the number of organisms needs to reach a critical mass. The chance of this happening is reduced by increased urine flow rate, causing dilution of organisms within the bladder, and by frequent voiding, which also flushes the urethra and helps to prevent ascent of organisms into the bladder. This is termed 'hydrokinetic' defence. Habitual infrequent voiding is thought to be a risk factor for recurrent urinary tract infection for this reason. Patients with recurrent urinary tract infections are routinely advised to increase fluid intake and frequency of voiding, and some women report that a high fluid intake alone is enough to clear symptomatic infection. Incomplete voiding, which may be present in both sexes and is not necessarily due to outflow obstruction (Table 2) is an important cause of increased susceptibility to urine infection.

Vesicoureteric reflux

During normal micturition urine is expelled into the urethra, while retrograde flow ('reflux') of urine into the ureters is prevented because muscular contraction of the bladder wall results in closure of the vesicoureteric junctions. Reflux of urine into the ureters can occur if this mechanism is defective, sometimes as far as the renal pelvis, followed by return to the bladder once bladder contraction has finished. The most common cause of reflux is abnormal insertion of the ureters into the bladder: this occurs as a relatively frequent developmental anomaly, the other major cause being abnormally high intravesical pressure, for instance in high-pressure chronic retention of urine due to bladder outflow obstruction, or in neurogenic bladder in patients with partial spinal cord lesions. Whatever the cause, reflux of urine results in failure to expel all bladder urine during micturition, and therefore significantly impairs host defence against infection, as well as being associated with a greatly increased risk of infection ascending to the kidneys and causing acute pyelonephritis. Vesicoureteric reflux is frequently found in children with urinary tract infection. The question of whether ascending infection is a cause of renal damage in children with reflux is discussed later in this chapter.

Foreign bodies, stones, and privileged sites

The presence of a foreign body, such as a urinary catheter or ureteric stent, or of a stone within the urinary tract, creates a protected site where uropathogenic organisms can adhere and multiply, relatively immune to both hydrokinetic and mucosal defence mechanisms. In this situation it is often impossible to eradicate urine infection unless the foreign body or stone is removed completely, and prolonged use of antibiotics often results in the acquisition of resistance by the infecting organism. Urinary infection is nearly inevitable after a few weeks of bladder catheterization, which has led to attempts to develop catheter materials that are less easily colonized by bacteria and might thereby reduce the risk of infection. Meta-analysis shows that silver alloy urinary catheters may be cost-effective in preventing urinary infection in patients catheterized for a short time. Other 'privileged' sites include renal cysts (as in polycystic kidney disease, discussed below) and bladder diverticulas.

Sexual behaviour

Many women first experience acute cystitis shortly after becoming sexually active. Most women have transient bacteriuria after sexual intercourse, which develops into symptomatic cystitis only in a minority. In case–control studies of young women, the risk of urinary tract infection was associated with vaginal intercourse, and increased further by condom use. These findings are explained by the mechanical effect of intercourse encouraging ascent of organisms up the urethra, an effect that may be exacerbated by condom use, particularly without lubricants. The risk of urinary tract infection is also increased by a change in sexual partner, which may reflect male to female transmission of uropathogens. Use of spermicides as an adjunct to barrier contraceptive methods is also associated with an increased rate of periurethral colonization with *E. coli* and other uropathogens and with an increased risk of symptomatic urinary tract infection, probably because the active component in spermicides (nonoxynol-9) is bactericidal against lactobacilli. The protective effect of micturition soon after intercourse, based on the supposition that washout of recently introduced bacteria will prevent establishment of infection, remains unproved.

Vaginal and periurethral flora

Vaginal secretions are normally colonized by lactobacilli that appear to protect against colonization by uropathogenic bacteria such as *E. coli*. The mechanism of this protection is uncertain but may in part be related to the maintenance of an acidic pH, which suppresses growth of some uropathogenic bacteria. Suppression of this normal vaginal colonization by antibiotic treatment or by spermicide use increases the risk of colonization of the periurethral mucosa by uropathogenic bacteria and subsequent ascending urinary tract infection. In addition, atrophic vaginitis caused by oestrogen deficiency is associated with the absence of lactobacillus colonization, which may be part of the reason for the increased risk of urinary tract infection in postmenopausal women. However, attempts to prevent recurrent urinary infection by re-establishing colonization by lactobacilli have so far not yielded convincing results.

Genetic factors

In laboratory studies, adherence of *E. coli* to both vaginal and buccal cells is greater in women with recurrent urinary tract infection than in healthy controls, and women with recurrent urinary tract infection more frequently have gut colonization by uropathogenic strains of *E. coli*, suggesting that they experience more frequent urinary tract infections because they are more susceptible to colonization of the periurethral area by uropathogenic bacteria. It appears that this difference in susceptibility to colonization and infection, especially in patients in whom there is no other defect of host defence (such as vesicoureteric reflux), is due to genetically

determined differences in the extracellular antigens to which bacteria adhere, in particular in the expression of blood group antigens. The density of glycosphingolipids is higher in patients with the P1 blood group than those with the P2 blood group, and the P1 blood group is a risk factor for acute pyelonephritis among girls without vesicoureteric reflux. Expression of the large oligosaccharide A, B, H blood group antigens on the cell surface partially or completely obscures the smaller glycosphingolipids, preventing them from being bound by type P pili, which is why women with the secretor phenotype, in which these antigens are both expressed on the cell surface and secreted, are less prone to most *E. coli* infections than non-secretors. Non-secretors also have an increased inflammatory response (fever and acute-phase response) to urinary infection compared with secretors, and non-secretors are over-represented among patients with urographic evidence of reflux nephropathy. However, some *E. coli* strains only bind to cells from subjects who are secretor-positive blood group A.

Local immunity

Another aspect of host defence is the local production of antimicrobial peptides, secreted by uroepithelial cells into the urine, and the secretion of immunoglobulin A into the urine. However, there is little convincing evidence that impaired local IgA secretion is responsible for increased susceptibility to urinary tract infection. Patients with inherited or systemic defects in systemic immunity, whether cellular or humoral, do not appear to be at greatly increased risk of urinary tract infection; the increased risk of urinary tract infection in homosexual men with the acquired immune deficiency syndrome is associated with anal intercourse.

Pathogenicity

A few species of bacteria, collectively known as 'uropathogenic' bacteria, together account for most urinary tract infections (Table 1); the presence of non-uropathogenic species suggests an abnormality of host defence. Within uropathogenic species there are strains that are capable of causing infection and other strains that are far less likely to do so: uropathogenicity is determined by expression of cell surface molecules determining adhesion to receptors on uroepithelial cells, toxin production, factors conferring resistance to the membrane attack complex, and virulence factors. The factors determining pathogenicity of *E. coli* have been studied extensively, but much less is known about the determinants of pathogenicity of other uropathogenic bacteria, although motility may be an important determinant of the ability of *Proteus* spp. to ascend the urinary tract and cause infection; and *Staphylococcus saprophyticus*, an important cause of urinary tract infection in sexually active young women, is probably better able to cause urinary tract infection than *Staphylococcus aureus* or *Staphylococcus epidermidis* because of its possession of a lactosamine adhesin permitting adherence to uroepithelial cells.

Clinical presentation of uncomplicated urinary tract infection

Frequency and dysuria

The commonest presentation of urinary tract infection is with 'cystitis', a symptom complex associated with lower urinary tract infection in which many of the symptoms are directly attributable to increased bladder irritability caused by local infection. Classic symptoms include:

1. severe dysuria, often described as 'scorching' or 'like peeing barbed wire', worse towards the end or immediately after micturition;
2. increased urinary frequency, including nocturia—which helps to distinguish cystitis from other causes of daytime frequency;
3. urgency—the feeling of having to pass urine straight away to avoid incontinence;
4. urge incontinence—leakage of urine associated with the desire to pass urine;
5. strangury—the feeling of needing to pass urine despite just having done so;
6. offensive-smelling urine, often described as 'strong' or 'fishy';
7. macroscopic haematuria—particularly in women under 50, less commonly in girls or older women;
8. constant lower abdominal aching, not just in the genital area but also in the back, flanks, and lower abdomen; and
9. non-specific malaise, aching all over, nausea, tiredness, irritability, and cold sweats.

Not all of these symptoms are specific for lower urinary tract infection. Dysuria may be due to cystitis, urethritis, or vaginitis, but the latter two conditions are usually not associated with urinary frequency, and may be associated with vaginal discharge or itching and with specific findings on vaginal examination. Symptoms of cystitis may be due to causes other than lower urinary tract infection, for instance drug-induced cystitis.

Genuine inflammation of the bladder wall may or may not be present, and it is important to remember that there may be non-infective causes of increased bladder irritability, such as chemical- or drug-induced cystitis. Most patients with cystitis do not have fever, nor is there evidence of an acute-phase response.

Asymptomatic bacteriuria

By definition, this is an incidental finding in patients whose urine is cultured despite the absence of urinary tract symptoms. It is seldom justified to send a urine sample from an asymptomatic patient for culture, so this diagnosis should only rarely be made in clinical practice. An important exception is during pregnancy. Pregnant women with bacteriuria are at increased risk of acute pyelonephritis (occurring in 20 to 30 per cent of untreated women), of delivering low birth-weight babies, and of premature delivery, and antibiotic treatment significantly reduces these risks. Elderly patients with asymptomatic bacteriuria are also at increased risk of death, but this is probably because bacteriuria is a marker of poorer general health, and antibacterial treatment has not been shown to improve survival in this situation.

Acute pyelonephritis

The term acute pyelonephritis denotes infection within the renal pelvis, with or without active infection within the renal parenchyma. The diagnosis is usually made on the basis of the presence of flank pain (usually unilateral), fever, rigors, raised C-reactive protein (or erythrocyte sedimentation rate or plasma viscosity), neutrophilia, and evidence of urine infection on culture of a mid-stream urine sample. However, rigorous tests to localize the site of infection (discussed below) show that the correlation between the presence or absence of bacteriuria in the upper urinary tract and the presence or absence of flank pain, systemic symptoms, and an acute-phase response is dismally poor; many patients with infection confined to the bladder have flank pain and fever, whereas over 60 per cent of elderly women with asymptomatic bacteriuria have upper tract infection. The symptoms and signs of so-called 'acute pyelonephritis' are therefore in reality those of a marked host response to urinary tract infection, irrespective of whether organisms are multiplying in the renal pelvis or in the bladder.

Diagnosis

Inspection and dipstick testing

In a 'classic' case of established urinary tract infection the urine is cloudy, has an offensive smell, and is positive for blood, protein, leucocyte esterase, and nitrite on dipstick urinalysis. In this situation it is reasonable to make a diagnosis of urinary tract infection without further delay, and to institute empirical treatment. Whether a midstream urine sample should also be sent to the laboratory for confirmation and identification of the causative organism depends on the clinical situation, as discussed below. However, in many situations the diagnosis is not so obvious, and the diagnostic accuracy of inspection and dipstick testing less good.

1. Cloudy urine may be caused by bacteria and pyuria, but may also be caused by amorphous phosphate crystals that form in normal urine as it cools. Low concentrations of bacteria and white cells will not cause sufficient turbidity to be detected on visual inspection.
2. An offensive, fishy smell is highly suggestive of urinary tract infection, but relatively infrequent.
3. Macroscopic haematuria can certainly occur as a result of severe cystitis, but is frequently absent in genuine urinary tract infection and is more often due to glomerular bleeding or urothelial bleeding as a result of tumours or stones. Dipstick detection of haematuria is neither sensitive nor specific for the detection of urinary tract infection.
4. Proteinuria can occur in urinary tract infection as a result of the release of proteins from white cells, but is neither specific nor sensitive.
5. Leucocyte esterase is an enzyme released by white cells and a reliable test for pyuria, which is in most situations a major diagnostic criterion for urinary tract infection, as discussed in the next section. A positive test indicates 10 white cells/ml. Transport of urine samples in containers containing boric acid can result in false-negative leucocyte esterase tests, as the boric acid inhibits the enzyme.
6. Nitrite is produced by most uropathogens, which reduce urinary nitrate to nitrite, but not by Gram-positive organisms. A positive test for nitrite is highly

suggestive of urinary tract infection. False negative tests can be seen in patients with low dietary nitrate and in those taking high-dose ascorbic acid.

A combination of visual inspection and dipstick testing is therefore a reasonable screening test for patients in whom uncomplicated urinary tract infection is suspected on clinical grounds: in this situation, crystal clear urine and negative dipsticks for nitrite and leucocyte esterase make the diagnosis of urinary tract infection very unlikely (Table 3). The worst that is likely to happen if the diagnosis is missed is that the patient will re-present with more obvious abnormalities due to progression of the urinary tract infection to a more severe stage. However, in situations in which it would be important not to miss the opportunity to start treatment early, for example in patients with known abnormalities of host defence, pregnancy, or previous acute pyelonephritis, or in suspected atypical infections, formal microscopy and culture of the urine is required.

Microscopy and culture of urine

At first sight, the diagnosis of bacterial infection in the urinary tract should be straightforward, relying on culture of freshly voided urine. However, urine samples are very easily contaminated during voiding by bacteria from the perineal skin (or, to a lesser extent, the foreskin in males), resulting in false-positive results. The only certain way to circumvent this problem is to take urine directly from the bladder, either by suprapubic needle aspiration of urine from the bladder, which is invasive and seldom performed in clinical practice, or by urethral catheterization, which carries a 1 to 2 per cent risk of introducing infection into the bladder. In men, contamination of the voided urine sample can largely be avoided by retraction of the foreskin prior to voiding. In women, the reliability of urine culture can be improved by instructing women to part the labia with one hand and ensuring collection of a midstream sample, without either the initial portion or the 'afterdrip', but is not improved further by perineal washing or antiseptic use. These precautions only reduce the risk of contamination, rather than abolishing it altogether.

Microscopy of urine samples allows quantification of pyuria—the presence of white blood cells in the urine. However, the methodology used to report pyuria varies enormously: microscopy of urine that has been centrifuged and resuspended, with reporting of the number of cells per high-power field, gives results which bear little relation to leucocyte excretion rate or to counting cells from unspun urine in a counting chamber, when significant pyuria is usually defined as a urinary white cell count of 10 leucocytes/μl or more.

Bacterial urinary tract infection is by far the commonest cause of pyuria, and symptomatic patients with pyuria whose urine cultures are reported as showing no significant pathogens should be suspected either of having 'low-count' bacteriuria due to early infection or infection with a slow-growing organism, chlamydial infection, or one of the causes of sterile pyuria (Table 4). However, vaginal leucorrhoea can also result in 'false-positive' pyuria.

Microscopy also gives information on whether the urine sample is contaminated by cells from the periurethral area. Squamous cells are five to seven times larger than red cells and are easily recognized on microscopy: their presence in a midstream urine sample has conventionally been taken to indicate contamination, but they may originate from the urethra as well as from the epithelium of the vulva and vagina, as well as from areas of squamous metaplasia in the bladder, which is a common finding; and squamous cells are frequently seen in urine obtained by bladder catheterization, showing that their presence is not an absolute indicator of contamination.

Once a urine sample is obtained, the conditions under which it is cultured determine whether any organisms present grow. Standard laboratory culture conditions are designed to encourage the growth of recognized urinary pathogens (if present), but may not be optimal for the growth of atypical organisms or of those not usually recognized as urinary pathogens. Because small numbers of organisms are frequently cultured from urine as a result of contamination, growth of an organism is conventionally reported as a 'significant growth' if it meets several criteria:

1. there is a pure growth, i.e. of a single organism;
2. the organism grown is a 'recognized' urinary pathogen;
3. quantitative urine culture results in greater than 10^5 colony-forming units per millilitre (**cfu/ml**); and
4. there is significant pyuria on urine microscopy, and few if any squamous cells.

However, there are important exceptions to these criteria.

1. Genuine mixed growth of two or more bacteria may occur in complicated urinary tract infection (Table 5), as may the growth of an organism not usually associated with the urinary tract.
2. The spectrum of organisms recognized as capable of causing genuine urinary tract infection is widening. *Staphylococcus saprophyticus* was only fairly recently recognized as a cause of urinary tract infection in sexually active women, and it is possible that other true urinary pathogens are yet to be identified, perhaps accounting for some cases of the so-called urethral syndrome (see below).
3. 'Low-count' bacteriuria may reflect genuine bladder infection, particularly in early urinary tract infections, and may occur in patients who have increased their fluid intake and are 'diluting' their bacterial counts by generating a high urine output; also in patients infected with slow-growing organisms such as *Staph. saprophyticus*. The criterion of 10^5 cfu/ml was originally validated in asymptomatic women, but subsequent studies showed that nearly 50 per cent of women presenting with frequency and dysuria had genuine bladder infection but with counts between 10^2 and 10^5 cfu/ml on culture of a midstream urine sample. If symptomatic women with counts of between 10^2 and 10^4 cfu/ml are left untreated, most have persistent symptoms and counts of more than 10^5 cfu/ml 2 days later.
4. In men, bacterial counts of 10^3 cfu/ml or more are very likely to reflect significant infection, as the potential for significant contamination is lower.
5. The presence of pyuria further increases the likelihood that low counts are significant, although pyuria is not always present in proven bladder infection, particularly if the sample is taken early after the onset. The traditional method of expressing urinary white cell counts as cells per high-power field is very poorly reproducible as the volume in a high-power field is extremely variable. If a counting chamber or equivalent is used, then a criterion of 10 white cells/mm^3 separates patients with genuine bacteriuria from those without.

Localization to upper or lower urinary tract

It is sometimes important to discover whether infection is confined to the bladder or whether it has spread to involve one or both kidneys. The 'gold standard' for diagnosis of upper urinary tract infection is culture of urine obtained from each ureter by direct catheterization during cystoscopy, but such an invasive procedure can only be justified in exceptional circumstances, and even then may be difficult to interpret due to contamination of ureteric samples by bladder urine during passage of the catheters. An alternative, the Fairley test, involves a bladder washout using neomycin and fibrinolytic enzymes. Urine is cultured following completion, to confirm eradication of bladder bacteria, and then at 10, 20, and 30 min after completion of the washout. Bacteriuria returns slowly, if at all, in patients with infection confined to the bladder, but because the washout procedure has no effect on bacteria in the upper urinary tracts, rapid reappearance of bacteriuria indicates upper urinary tract infection. Using this test it has been shown that both upper and lower urinary tract infection are frequently asymptomatic and that flank pain and fever are extremely unreliable indicators of the presence of upper urinary tract infection.

Detection by immunofluorescent staining of immunoglobulin-coated bacteria is suggestive of tissue invasion, and has been advocated as a test to distinguish upper from lower urinary tract infection. However, compared with ureteric catheterization or Fairley tests, tests for antibody-coated bacteria are not reliable. This may be partly because tissue invasion can also occur in severe lower urinary tract infection, such as that complicating urethral catheterization. Antibody-coated bacteria may indicate a higher risk of treatment failure after standard antibiotic courses, but this remains uncertain.

Tubular damage due to ascending infection may be detected by measurement of urinary b_2-microglobulin, although this is also raised in patients with chronic renal disease and is therefore not specific for acute pyelonephritis. Renal excretory function usually remains unchanged during acute pyelonephritis unless obstruction is present, but acute renal failure is occasionally seen, often associated with coincident use of non-steroidal anti-inflammatory drugs. Abnormal appearances on contrast CT scanning and/or dimercaptosuccinyl acid (**DMSA**) scanning have been reported, including generalized renal swelling, focal areas of decreased parenchymal enhancement, and perirenal abscess formation, with the development of cortical scars and calyceal diverticulas if imaging is repeated on follow-up. In general, the more severe the infection is clinically (assessed by acute-phase response, duration of fever, etc.), the more marked the scarring. However, significant loss of renal excretory function following acute pyelonephritis in patients without diabetes, obstruction, or pre-existing reflux nephropathy/dysplasia is remarkably uncommon, and the significance of such scars is therefore uncertain.

Culture-negative syndromes

Occasionally patients may present with symptoms and signs highly suggestive of urinary tract infection, with or without pyuria, but with negative urine cultures. These

patients may have 'false-negative' urine cultures, for instance a low growth of a genuine pathogen; infection with a 'fastidious' organism, the presence of which is not detected by routine laboratory cultures; or may have a non-infectious cause. It is dangerous to label symptoms in such patients as psychogenic without careful thought and investigation; prolonged symptoms combined with numerous unsuccessful trials of antibacterials or with different explanations from different doctors may result in psychological stress, which in turn may amplify symptoms, whereas there is little evidence that psychological disease is the primary problem even in a subgroup.

'Urethral syndrome'

The term 'urethral syndrome' was used in the past as a synonym for the typical symptoms of cystitis, namely frequency, urgency, and dysuria. More recently it has been applied to the subgroup of women with typical symptoms but in whom a recognized urinary pathogen cannot be cultured from the urine. A significant proportion of these patients, particularly those with pyuria, have chlamydial urethritis, which can be diagnosed by urethral swab or by detection of chlamydial antigens in a first-pass urine sample. Chlamydial infection can be treated with tetracyclines, but as the infection may be sexually transmitted it is also important to treat the patient's sexual partner(s), who may be asymptomatic. Other patients have 'low-count' infection with a true bacterial urinary pathogen. Vaginal infection or atrophy should be excluded, as these can cause similar symptoms.

The pathogenesis and optimal management of the remaining patients with frequency and dysuria with no identifiable bacterial infection remains controversial. There is controversy over the role of 'fastidious bacteria' that are difficult to grow in the laboratory, particularly lactobacilli. Empirical antiobiotic treatment is equally successful in eradicating symptoms in women presenting to primary care whether or not urinary pathogens are found on urine culture, suggesting that the syndrome is frequently due to bacterial infection that is not detected by routine laboratory urine culture. However, a few women with persistent symptoms do not respond to antibiotics, and in these women repeated courses of antibiotics are likely to lead to the emergence of antiobiotic-resistant organisms, which may later cause true infection that is difficult to treat. Psychological distress is common in patients with persistent lower urinary tract symptoms, but the prevalence of emotional or psychiatric disorders is no higher in women presenting to general practitioners with dysuria and frequency whose urine cultures are negative than in those with proven cystitis. Urologists often offer such women urethral dilatation on the assumption that the symptoms are due to urethral spasm or stricture, but there is minimal evidence beyond clinical anecdote that this procedure is of any benefit; one randomized, controlled trial showed no difference in outcome between urethral dilatation and cystoscopy alone. Urethral dilatation may itself cause periurethral fibrosis, resulting in the later formation of genuine urethral strictures.

Women with recurrent episodes of frequency and dysuria, with or without pyuria, whose urine cultures remain sterile should be carefully evaluated for the presence of vaginitis (either infective or atrophic) and for sexually acquired urethritis (where relevant). It is justified in this situation to obtain urine direct from the bladder during an episode, preferably by suprapubic aspiration or alternatively by urethral catheterization, and ensure that this is cultured in conditions permitting the identification of fastidious or low-growing organisms. In urine obtained direct from the bladder, any growth of organisms is clinically significant. Any infection so detected should be treated, preferably with a prolonged course of an appropriate antibiotic to ensure complete eradication. If no infection can be detected, cystoscopy is required to exclude non-infective causes of cystitis. Patients should be treated with compassion and their symptoms believed: attributing the symptoms to psychiatric disease is almost certain to be incorrect and likely to alienate the patient.

Interstitial cystitis

Interstitial cystitis causes chronic suprapubic pain, dysuria, and frequency despite, by definition, sterile urine. Urine microscopy shows pyuria. Cystoscopy shows variable inflammation, sometimes with ulceration. Bladder biopsies show a chronic inflammatory infiltrate; mast cell infiltration is common, but is also seen in infective cystitis. The condition may progress to cause contracture of the bladder. Many of the features would be explained by an acquired defect in the barrier function of the uroepithelium, but the cause of such a defect remains unclear. It remains possible that infection by a fastidious organism is responsible for initiating the disease in some patients. Numerous therapies have been tried, including intravesical instillation of glycosoaminoglycans.

Drug-induced cystitis

This presents similarly, although often more acutely and with macroscopic haematuria. It may be caused by acrolein, a metabolite of cyclophosphamide and ifosfamide, and also by non-steroidal anti-inflammatory drugs, particularly tiaprofenic acid, and by danazol.

Investigation of patients with urinary tract infection

Most women with uncomplicated cystitis do not require investigation other than urine culture, and may even be treated empirically, the choice of antibiotic being based on locally prevalent sensitivity patterns of the most common uropathogens, rather than waiting for the results of culture and sensitivity. The yield in such women of investigation with cystoscopy and/or intravenous urography is low. Because minor abnormalities such as duplex collecting systems are common in the general population, these will often be found in women presenting with cystitis, but detection of such abnormalities does not lead to any change in treatment. Investigation of women should therefore be reserved for those with atypical features (Table 6). In men, urinary tract infection is nearly always associated with an underlying abnormality of host defence, and all men with proven urinary tract infection should therefore be offered investigation. If investigation in either sex is thought necessary, the important abnormalities being looked for are:

- diabetes
- urinary tract stones
- anatomical abnormalities of the upper urinary tract (e.g. papillary necrosis, reflux nephropathy)
- urinary tract obstruction (anywhere from the renal pelvis to the tip of the urethra)
- bladder diverticulas
- impaired bladder emptying.

The choice of investigation of the upper urinary tract depends on local facilities, and usually lies between plain abdominal radiography with ultrasound, on the one hand, and intravenous urography on the other. Both may need to be supplemented by cystoscopy and by bladder voiding studies, using urinary flow rate and measurement of pre- and post-void bladder volumes.

Whether adults should be investigated for vesicoureteric reflux is open to doubt, as there is no good evidence that antireflux surgery (e.g. ureteric reimplantation, injection of Teflon around the ureteric orifice) is of benefit in preventing either ascending infection or renal damage.

Treatment of uncomplicated 'cystitis'

Rational treatment of urinary tract infection requires the physician to balance the costs and dangers of treatment (including cost of the drug, risk of unwanted side-effects, and the induction of resistance) with benefit.

Is treatment necessary at all? Many women with recurrent uncomplicated cystitis report that they can clear their own infections by increased fluid intake and frequent voiding. Many buy alkalinizing agents (e.g. potassium citrate) to ameliorate the symptoms, which work by reducing bladder irritability. Placebo-controlled studies have confirmed that infection may clear spontaneously, although this may take several weeks or even months, and a small percentage of women remain infected until given antibiotics. There is therefore no justification in insisting on antibiotic treatment in those who wish to try to do without.

Choice of antibiotic

It is usually impracticable to await the results of culture and sensitivity testing, if these tests are justified at all. The choice of antibiotic is therefore usually empirical, based on the likelihood that the drug will clear the infection (efficacy), cost, side-effect profile, and the risk of selection of resistant organisms, both in the patient being treated and in the community. The efficacy of antibiotics is not fully predictable from *in vitro* sensitivity testing, which is probably part of the reason why trimethoprim (with or without sulphamethoxazole) remains the first-line choice in many areas, despite resistance rates on *in vitro* testing of up to 20 per cent. This is at least in part because many antibiotics are concentrated in the urine to levels far greater than those found in tissues, and at these concentrations may remain active against organisms that are reported to be resistant to the concentrations found in tissues, which are usually used to define resistance *in vitro*. However, increasing resistance *in vitro* to trimethoprim is sure to lead sooner or later to increased clinical failure rates, as has already been observed for b-lactam antibiotics. Some of the properties of the most commonly used antibiotics are reviewed in Table 7. The most recent recommendations of the Infectious Diseases Society of America are summarized in

Table 8.

Duration of treatment

A single high dose of an antibiotic will cure many women and is simple, cheap, and may reduce the risk of side-effects and bacterial resistance. Single-dose treatment is thought to be popular amongst patients, although those paying for prescription medications may feel 'short-changed' by paying a full prescription fee for a single tablet. However, cure rates after single-dose treatment are lower than for longer courses of antibiotics, this difference being more marked for b-lactam antibiotics, which in general need to be given for 7 days, than for trimethoprim (with or without sulphonamide) and for quinolones. Fosfomycin given as a single dose gives higher cure rates than single doses of other antibiotics, but is less effective and more likely to cause adverse effects than 3-day courses of trimethoprim (with or without sulphonamide) or quinolones. The rate of adverse reactions also increases with duration of therapy, particularly for trimethoprim–sulphonamide combinations, which should therefore be given for no more than 3 days. Cure rates of urinary tract infections caused by *Staph. saprophyticus* and in elderly women are low with 3-day regimens, and these infections should be treated with 7-day courses.

Alternatives to antibiotic therapy

Fructose, present in many fruit juices, inhibits binding of type 1 fimbrias of *E. coli* to the uroepithelium. Cranberry juice also contains proanthocyanidin, which inhibits adherence of P-fimbriated *E. coli*. Cranberry juice is popular as an alternative treatment for urinary tract infection, but the evidence for its effectiveness in clinical practice remains uncertain.

Treatment of uncomplicated 'acute pyelonephritis'

Choice of antibiotic

The antibiotic chosen in this situation needs good tissue penetration as well as high urinary excretion, and must be fully active against the infecting organism at typical serum concentrations. It is therefore much more important to identify the infecting organism and its antibiotic sensitivity pattern by sending urine (or blood from patients in hospital) for culture. However, empirical treatment must be started while awaiting culture and sensitivity results, as acute pyelonephritis can evolve rapidly into a life-threatening illness. Oral therapy with a quinolone antibiotic (ciprofloxacin, ofloxacin, norfloxacin) is probably the best choice, although trimethoprim or trimethoprim–sulphamethoxazole are alternatives if local rates of resistance among uropathogens remain low. Treatment with b-lactam antibiotics, even if the infecting organism is fully sensitive *in vitro*, is associated with a high rate of recurrence compared with treatment by other agents. Patients with septicaemia should receive a quinolone (for which oral administration is as effective as intravenous) or a combination of an aminoglycoside with ampicillin plus b-lactamase inhibitor, or an extended-spectrum cephalosporin with or without an aminoglycoside. Once-daily administration of aminoglycosides is as effective as thrice-daily and reduces the risk of toxicity.

Duration of therapy

It is widely recommended that acute pyelonephritis is treated with a significantly longer course of antibiotics than acute cystitis. Since, as discussed above, the clinical distinction between acute pyelonephritis and cystitis relies on the presence of fever, flank pain, and an acute-phase response, and since all of these may be present in acute cystitis with no involvement of the upper urinary tract and entirely absent in acute pyelonephritis, what these recommendations really mean is that those patients demonstrating a more marked host response should be treated more aggressively and for longer. It is therefore reasonable to suggest that in a patient with systemic symptoms (including flank pain), fever, or leucocytosis, or a raised C-reactive protein, plasma viscosity, or erythrocyte sedimentation rate, antibiotic treatment should be continued until these abnormalities have disappeared. A 14-day course is as effective as a 6-week course in uncomplicated acute pyelonephritis, and a 7-day course may be sufficient for patients with mild illness.

Treatment of asymptomatic bacteriuria

The only situation in which treatment of asymptomatic bacteriuria is mandatory is during pregnancy (see Chapter 13.5). Eradication of asymptomatic infection in children with or without proven vesicoureteric reflux is widely practised in the hope that this will prevent ascending infection and renal damage. However, prophylactic treatment for 2 years of covert bacteriuria in schoolgirls without renal scarring has no effect on glomerular filtration rate at age 18, but is associated with lower fractional reabsorption of glucose and with a smaller increment in glomerular filtration rate and greater degrees of glycosuria during subsequent pregnancy. Screening for asymptomatic bacteriuria with the aim of preventing these minor abnormalities is not currently thought justified. Treatment of asymptomatic bacteriuria in patients with anatomically abnormal urinary tracts or with indwelling urinary catheters is unjustified and is likely only to lead to the emergence of antibiotic-resistance urinary infection. Treatment of asymptomatic bacteriuria in the elderly has been shown to be of no benefit.

Prophylaxis of recurrent urinary tract infection

Some women with recurrent cystitis choose to have antibiotic treatment for each infection as it arises, particularly if they are allowed to self-administer treatment as soon as symptoms start. Others may opt for prophylactic treatment. Long-term low-dose antibiotic treatment has been shown to be effective in reducing the rate of infection in such women, but no regimen offers 100 per cent protection. Prophylactic treatment should be considered in women with at least two symptomatic infections per year and probably works by preventing colonization of periurethral tissues by uropathogens. Trimethoprim (100 mg at night) is widely used for prophylaxis because it achieves very high concentrations in vaginal fluid and may therefore remain active against organisms that are resistant to the concentrations used in *in vitro* sensitivity testing. Nitrofurantoin (100 mg at night) has also been widely used, and may be more effective, but can cause rare but serious adverse effects (pulmonary and hepatic toxicity) with long-term therapy, making regular monitoring of liver enzymes and lung function tests necessary. Because both are well absorbed they do not reach high concentrations in the colon, hence emergence of resistant strains in colonic flora is uncommon, whereas this problem does arise with long-term use of b-lactam antibiotics. Long-term use of quinolones is expensive and associated with a significant risk of selection of resistant strains. There is no proven advantage in 'rotating' antibiotic prophylaxis. A number of dosage regimens have been used, including nightly treatment, thrice-weekly treatment, and postcoital treatment, with no convincing evidence of the superiority of one regimen over another. Treatment should be continued for at least 6 months, because, for reasons that are not clear, this results in a lower relapse rate once treatment is stopped than shorter periods of prophylaxis.

Cranberry juice, as discussed above, contains substances that inhibit adherence of uropathogenic bacteria to the uroepithelium, and has become popular as an alternative treatment to prevent recurrent urinary tract infection. However, the evidence that regular use of cranberry juice reduces the risk of recurrent symptomatic infections remains poor, and there is no consensus on what dosage and regimen, if any, is effective.

Complicated urinary tract infection

'Complicated' urinary tract infections are those occurring in a patient with abnormal host defence, and as a result are often more severe.

Urinary tract infection in men

Cystitis

In the first year of life, urinary tract infection is commoner amongst boys than girls; circumcision reduces the risk. Urinary tract infection in men is uncommon, as the length of the urethra and the fact that the penile mucosa is seldom colonized with faecal organisms including uropathogens confer major protection against ascending infection. The occurrence of urinary tract infection in a man therefore suggests an abnormality of host defence, which may predispose to more severe infection and should be investigated unless the cause is immediately obvious (e.g. the presence of a urinary catheter). Risk factors that may be identified by investigation include:

- bacterial prostatitis and prostatic calcification
- lack of circumcision
- impaired bladder emptying (particularly if this has resulted in bladder catheterization or instrumentation)
- anal intercourse
- urinary tract stones

- reflux nephropathy.

The symptoms of urinary tract infection in men are similar to those in women. The risk of bacterial contamination of voided urine is low apart from in elderly men with foreskins, in whom precautions should be taken to minimize contamination by retraction of the foreskin and collection of a midstream sample. Colony counts of 10^3/ml or higher usually indicate significant infection.

Acute prostatitis

Acute bacterial prostatitis causes fever, rigors, backache, and dysuria, and may result in acute urinary retention. Symptoms and signs of epididymitis may also be present. Rectal examination reveals an enlarged, tender prostate. Untreated, acute prostatitis may culminate in prostatic abscess formation. The causative organism can be identified on urine culture: an antibiotic which has good tissue penetration (e.g. trimethoprim, a tetracycline, or a quinolone) should be used and continued for 4 weeks, as it is thought that this reduces the risk of chronic prostatitis.

Chronic bacterial prostatitis

This is an uncommon syndrome caused by the persistence of a uropathogen within the prostate, with repeated episodes of acute infection caused by the same organism on each occasion, and few if any symptoms between episodes. Obtaining bacteriological proof that the infecting organism is 'hiding' in the prostate gland between acute episodes is difficult. The 'textbook' method described by Stamey and Mears involves culture of four specimens obtained during voiding of the bladder. The first 10 ml voided and a midstream sample are collected. The patient then interrupts the flow of urine, bends forward, and digital prostatic massage is performed, resulting (sometimes) in the collection of a few drops of 'expressed prostatic secretions'. Finally, voiding is completed and a fourth sample collected. Prostatitis is diagnosed when bacterial counts are highest in the expressed prostatic secretions and the final voided urine sample; urethritis, by contrast, results in high counts in the first sample. Due to its complexity and the unpleasantness of performing digital prostatic massage *per rectum* during interrupted micturition, this test is very rarely performed in practice, and many patients are treated with a prolonged course of a quinolone antibiotic. a-Blockers have been shown to reduce recurrence rate, possibly by reducing reflux of urine into prostatic ducts during micturition.

Culture-negative pelvic pain in men

Patients may complain of chronic pelvic pain, dysuria, strangury, urinary frequency, and pain during sexual intercourse but have no evidence of bacterial infection on cultures of prostatic secretions, semen, or post-massage urine specimens. Patients with this symptom complex may be further subclassified as having chronic abacterial prostatitis or non-inflammatory pelvic pain syndrome according to the presence or absence of leucocytes in semen. There is no gold standard for diagnosis, no clear understanding of the pathophysiology, no correlation between symptoms and prostatic histology, and no satisfactory treatment for this ill-understood group of conditions. Occasionally, patients are found to have evidence of prostatic inflammation on biopsy, or to have leucocytes in prostatic fluid in the absence of symptoms. As in the urethral syndrome in women, some cases may be caused by persistent infection by fastidious bacteria, such as *Chlamydia* or *Mycoplasma*; a prolonged trial of a tetracycline is therefore often used. Other treatments include regular prostatic massage, non-steroidal anti-inflammatory drugs, a-blockers, and 5-a reductase inhibitors. a-Blockers have been shown to be of some benefit in all types of symptomatic chronic prostatitis in one randomized study.

Urethral catheterization

P>Urinary tract infection occurs after 2 per cent of in/out urethral catheterizations, after 10 to 30 per cent of 5-day indwelling catheterization, and is nearly inevitable in patients with long-term indwelling catheters. It is an important cause of hospital-acquired infection, increasing the risk of Gram-negative septicaemia fivefold and carrying a threefold increase in mortality after adjustment for age, severity and type of underlying illness, duration of catheterization, and renal function. Organisms enter the bladder either by migration between the catheter and the urethral mucosa or by ascent up the column of urine in the lumen after entry into the drainage system following contamination at disconnection or drainage points. Although most infections are probably caused by ascent of the patient's own faecal flora, there is evidence from investigation of clusters of infections by highly antibiotic-resistant organisms that inadequate handwashing by hospital staff may also cause some infections. A sample obtained directly from the catheter (not from the drainage bag) represents bladder urine, when any bacterial growth should be considered as evidence of urinary tract infection; low-count infection (e.g. less than 10^2 cfu/ml) usually progresses within days to higher counts. Mixed growths are common in patients with long-term catheterization and may be associated with mixed-growth bacteraemia.

Risk factors for the acquisition of infection include increasing duration of catheterization, increasing age, female sex, renal impairment, diabetes mellitus, and the nature of the underlying illness. Use of prophylactic antibiotics is associated with a delay in the onset of infection and may be justified in high-risk patients requiring catheterization for 3 to 14 days, whereas in those with long-term catheters, antibiotic use simply increases the risk of emergence of antibiotic-resistant pathogens. Use of silver alloy-coated catheters also reduces the risk of infection and may be justified in high-risk patients. Progress is being made in the development of new catheter materials that may provide further resistance against colonization by micro-organisms.

Urethral catheters should not be inserted unless absolutely necessary (is knowledge of hourly urine output really going to change your management?) and removed as soon as they are no longer needed. Consideration should always be given to methods of urine collection that may carry lower risks, such as condom drainage in men, intermittent catheterization in patients with abnormal bladder empyting, and suprapubic catheterization.

Abnormal bladder emptying

Incomplete bladder emptying, removing the 'washout' part of host defence, greatly increases the risk of urinary tract infection, as in patients with prostatic bladder outflow obstruction and those with neurogenic bladder due to spinal cord injury. Long-term catheterization only increases these risks. Where possible, the cause of incomplete bladder emptying should be treated. However, patients shown on urodynamic study to have underactive detrusor activity will not benefit from prostatectomy or a-blockade and may require long-term intermittent self-catheterization. Bladder dysfunction in patients with neurogenic bladder, for instance due to spina bifida or spinal cord injury, depends on the level of injury. Patients with lesions above T-11 have hyperreflexic bladder activity, often with sphincter dyssynergia (failure of the sphincter to relax during detrusor contraction), resulting in a high-pressure system, often with high-pressure reflux, combined with impaired emptying. In combination with urinary tract infection, this frequently results in progressive renal damage. Those with lesions below L-1 have decreased detrusor activity with large amounts of residual urine, which also increases the risk of urinary tract infection. Diabetic neuropathy may also cause decreased detrusor activity. The aim of treatment in both situations is to achieve a low-pressure bladder with low residual volumes. This may involve teaching patients to utilize reflexes to induce bladder contraction and sphincter relaxation, condom drainage for incontinence, anticholinergics to reduce detrusor overactivity, sphincterotomy, augmentation cystoplasty, and intermittent self-catheterization. Urethral catheterization should be avoided wherever possible. There is no evidence that regular use of antiseptics to wash the perineum and urethral meatus are of benefit. Bladder washouts with saline or boiled water may be of benefit in eliminating mucus in patients with augmentation cystoplasties: antiseptic bladder washouts are of minimal value in prevention, probably due to the fact that uropathogens become embedded in a biofilm adherent to the bladder wall. Methenamine, a drug that releases formaldehyde into acidic urine, may be of some benefit in preventing infection.

Treatment of urinary tract infection in patients with abnormal bladder emptying should be reserved for those with evidence of invasive infection. The diagnosis is obvious in those with cloudy urine combined with fever, rigors, and flank pain, but it is important to remember that symptoms and signs, particularly flank pain, dysuria, urgency, and frequency may be absent in those with neurological dysfunction.

Urinary diversion

Ileal or colonic conduits have been used for many years in patients requiring cystectomy for malignancy, and occasionally (although increasingly less frequently) for non-malignant conditions such as neurogenic bladder. Such conduits are frequently complicated by urine infection as the bowel mucosa and the mucus it produces readily permits adherence of uropathogens. Upper urinary tract dilatation is common, irrespective of whether the ureteric anastomoses are designed to be non-refluxing or not, and there is a high incidence of recurrent 'acute pyelonephritis' with flank pain, fever, and rigors. Diagnosis of urinary tract infection in patients with a conduit requires insertion of a catheter to the far end of the conduit and collection of urine via the catheter, rather than culture of urine collected from the conduit bag. Preventive measures include ensuring that the ileal segment is as short as possible at the time of surgery and ensuring a high fluid intake. The belief that cranberry juice reduces the incidence of urinary tract infection by reducing bacterial adherence is as yet unproven, although it seems likely that treatments designed to interfere with bacterial adherence or with mucin production are more likely than antibiotic treatment to help prevent symptomatic infection in these patients.

Renal tract stones

Renal tract stones are an important cause of persistent or relapsing urinary tract infection, as they provide a 'hiding place' in which organisms are protected from antibiotics. Management of such patients is complicated, as it may be impossible to eradicate infection without aggressive stone management (which may involve extracorporeal shock-wave lithotripsy, percutaneous and ureteroscopic stone removal). Attempts at stone removal may be complicated by septicaemia unless combined with antibiotic treatment, yet prolonged antibiotic therapy may encourage the emergence of resistance in the infecting organism.

Infection stones are caused by chronic infection with urease-producing organisms, usually *Proteus mirabilis*, and account for around 5 per cent of urinary tract stones. These stones are made of 'struvite' ($MgNH_4PO_4.6H_2O$), which forms as a result of the action of the alkaline pH caused by the production of ammonium and hydroxyl ions from the breakdown of urea by urease. Pure struvite stones may result from *de novo* urinary tract infection by a urease-producing organism, and are commoner in women and, probably, in patients with pre-existing anatomical abnormalities of the upper urinary tract such as reflux nephropathy, pelviureteric junction obstruction, or urinary diversion. Sruvite stones may also form as a secondary complication of metabolic stones. Struvite stones often expand to fill the entire renal pelvis, forming 'staghorn' calculi, but such calculi should not be assumed to be due to infection (rather than a metabolic cause) without demonstration of chronic infection by a urease-producing organism and/or biochemical analysis showing that the stone is made of struvite. The usual presentation is with symptomatic 'acute pyelonephritis' and alkaline urine; renal colic is unusual due to the large size of the stones. Treatment is with a combination of antibiotic and stone removal, which is imperative to prevent stone recurrence, and may require a combination of extracorporeal shock-wave lithotripsy and percutaneous nephrolithotomy, aided by dissolution therapy for larger stones. Urease inhibitors (acetohydroxamic acid, propionhydroxamic acid) may reduce stone recurrence but are too toxic for clinical use. See Chapter 20.13 for further discussion.

Encrusted cystitis and pyelitis occur as a result of chronic infection by urease-producing organisms, including *Corynebacterium* spp., in immunosuppressed patients, causing deposition of struvite in the bladder wall.

Autosomal dominant polycystic kidney disease

Cystitis is common in women with polycystic kidney disease, and in 20 per cent it is the presenting clinical finding, but there is no evidence that host defence in the lower urinary tract is abnormal. However, the risk of upper urinary tract infection is increased, and its diagnosis and treatment complicated. Acute parenchymal infection presents as acute pyelonephritis with flank pain, fever, and infected bladder urine, and usually responds to conventional therapy. Infection of cysts is more difficult to diagnose: the urine may be sterile and there may be no pyuria if the infected cyst does not communicate with the urinary space. Presentation is with fever and a discrete area of tenderness in the affected kidney. Blood cultures are the most reliable way of making a bacteriological diagnosis. Imaging studies, looking for cysts with increased fluid density, septations, and thick walls, are seldom conclusive, as similar appearances may occur normally or after previous cyst haemorrhage. The spectrum of causative organisms suggests that ascending infection rather than haematogenous spread is the usual route of infection. Hydrophilic antibiotics, including aminoglycosides and b-lactam antibiotics, penetrate poorly into those cysts which maintain large ionic gradients, whereas quinolones, trimethoprim–sulphamethox-azole, doxycycline, and clindamycin achieve better penetration. Prolonged courses of antibiotics are usually needed to eradicate infection, with surgical resection a last resort.

Renal transplantation

Urinary tract infection is the commonest bacterial infection after renal transplantation. Risk factors include urethral catheterization in the early postoperative period, the use of ureteric stents, pre-existing abnormalities of bladder emptying (such as diabetic autonomic neuropathy, previous bladder outflow obstruction, small contracted bladders in anuric patients on dialysis), anatomical abnormalities in the upper urinary tract (such as reflux nephropathy), contamination of the transplanted organ during retrieval and storage, abnormal drainage of urine from the transplanted kidney, vesicoureteric reflux into the transplant, areas of renal infarction, and immunosuppression. The commonest causative bacteria are those found in the general population with urinary tract infection, but many organisms not usually considered as urinary tract pathogens may also cause significant infection in these patients. Many infections are asymptomatic. Prophylactic antibiotics may reduce the early postoperative risk and many centres use co-trimoxazole as it also reduces the risk of *Pneumocystis* pneumonia. Antibiotic treatment must be chosen with care because of the risk of interactions with immunosuppressive treatment and of nephrotoxicity.

Infections with the polyomaviruses BK virus and JC virus may cause cystitis, ureteric stenoses, and interstitial nephritis (easily mistaken for acute rejection) in renal transplant recipients. The diagnosis may be suggested by recognition of infected transitional uroepithelial cells on urine cytology or by histological recognition of inclusion bodies on renal biopsy. Treatment is by reduction of immunosuppression, but this is often complicated by further rejection.

Pregnancy

Asymptomatic bacteriuria early in pregnancy is associated with the development of acute pyelonephritis in up to 30 per cent of patients if left untreated. It is commoner in women of lower socio-economic status and is associated with an increased incidence of preterm delivery and low birth weight, particularly if the pregnancy is complicated by acute pyelonephritis towards term. The increased risk of pyelonephritis is attributed to ureteric dilatation caused primarily by progesterone-induced smooth muscle relaxation. Antibiotic treatment of infection reduces the risk of acute pyelonephritis and of preterm delivery and low birth weight. Similar benefit is seen from a short course of treatment and from continued antibiotic prophylaxis. (See Chapter 13.5 for further discussion.)

Reflux nephropathy

As discussed above, vesicoureteric reflux (retrograde flow of urine up into the ureters and, in severe cases, as far as the renal pelvis) is often found in children with recurrent urinary tract infection. At the time of first diagnosis of urinary tract infection or subsequently, a small proportion of such children are found to have a characteristic pattern of renal parenchymal scarring at the upper and lower poles, with underlying clubbing and distortion of calyces. This pattern of scarring has become known by a variety of terms including 'reflux nephropathy' and 'chronic pyelonephritis'. Patients with reflux nephropathy have an increased risk of recurrent urinary tract infection, may develop infection stones, and a proportion develop hypertension, proteinuria, and progressive renal impairment with an inexorable progression to endstage renal failure. Under the age of 1 year, when only relatively severe cases come to clinical attention, slightly more boys than girls are affected; in older children the disease is diagnosed up to 5 times more frequently in girls, possibly because the disease is often discovered during investigation of urinary tract infection, which is commoner in females. Reflux nephropathy is commonly familial, best modelled by an autosomal dominant pattern of inheritance with variable penetrance. Linkage has been demonstrated to an area of chromosome 1 in some large pedigrees.

The diagnosis is conventionally made in adults by intravenous urography, which permits the detection both of focal parenchymal scarring and of the underlying calyceal abnormality (Fig. 2). Ultrasound scanning can show focal scarring but does allow visualization of the calyces. DMSA isotope scanning is the most sensitive test for the detection of parenchymal scars, and is widely used in children, as there are few alternative causes of focal scarring in this age group. Lateral displacement of the ureteric orifices can be demonstrated by Doppler ultrasound in most patients with reflux nephropathy. Demonstration of vesicoureteric reflux by direct or isotopic micturating cystography is commonly used to confirm the diagnosis in children, but is rarely justified in adults, as the absence of reflux could be due to spontaneous resolution of reflux with age (it often resolves in childhood), and its presence seldom justifies a change in clinical management. The histological appearances of 'chronic pyelonephritis' are well described and may occasionally be seen in patients with no scarring on urography or even DMSA scanning, probably because the scars are too small in these patients to be detected radiologically.

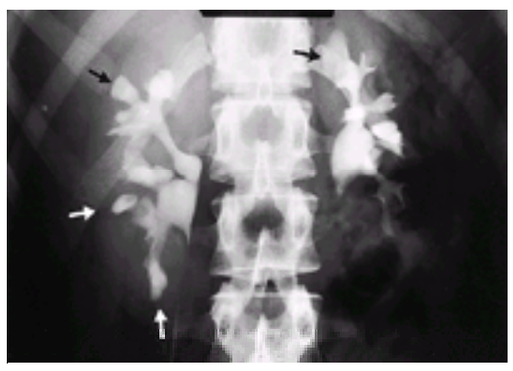

Fig. 2 Reflux nephropathy on intravenous urography, more marked on the right side than the left. Several focal scars (arrowed) involving the full thickness of the renal parenchyma and associated with calyceal clubbing are most obvious in the polar regions (reproduced from Bailey, 1993, with permission).

The conventional view is that reflux nephropathy is 'postinfectious focal renal scarring' and caused by the ascent of infected urine into the renal pelvis and then into the collecting ducts and renal parenchyma via compound papillas (papillas in which more than one collecting duct opens into the pelvis), which are found at the upper and lower poles but not in the middle calyces—explaining the polar distribution of scars. Sequential radiological imaging studies in children with urinary tract infections appear to support this theory, with the emergence of new scars up until the age of around 5 years, after which it is thought that maturation of the papillas prevents entry of infected urine into the renal parenchyma. Experimental infection in pigs causes a pattern of scarring very similar to that seen in human reflux nephropathy.

An alternative hypothesis is that at least a proportion of children with the radiological diagnosis of reflux nephropathy have congenital renal dysplasia, caused by abnormal nephrogenesis *in utero*, and associated with abnormal embryogenesis of the ureterovesical junction leading to vesicoureteric reflux. Vesicoureteric reflux is often found in the rare genetic syndromes that include renal dysplasia, and in non-syndromic renal dysplasia or aplasia, vesicoureteric reflux in the contralateral ureter is commonly seen. This theory would explain the presence of classic reflux nephropathy in neonates and in children with no documented history of urinary tract infection. Even the emergence of new scars during the first 5 years of life could be due to differential growth around areas of renal dysplasia. The rarity with which acute pyelonephritis in adults results in renal impairment, even in the presence of radiological evidence of scar formation, is perhaps further evidence that progressive loss of renal function is more likely to be due to 'remnant nephropathy' in dysplastic kidneys rather than the result of postinfectious scarring alone.

These two theories have different implications for the prevention of reflux nephropathy. Proponents of the 'postinfectious focal renal scarring' theory believe that diagnosis in infancy and treatment to prevent the ascent of infected urine into the renal pelvis until at least the age of 5 years should prevent the emergence of renal scarring and the later sequelae of hypertension, proteinuria, and progressive renal failure; by contrast, such treatment will not prevent these sequelae if reflux nephropathy is a disease of embryogenesis. Of course, the two theories are not mutually exclusive: in an individual patient reflux nephropathy may be due to the interaction of dysplasia and ascending infection during infancy. Antireflux surgery (ureteric reimplantation) and long-term prophylactic antibiotic treatment have been compared in several large randomized trials. Surgery is more effective at preventing episodes of acute pyelonephritis than medical treatment, but no other major differences in outcome were observed, and potential complications of antireflux surgery include ureteric obstruction, itself a potent cause of renal parenchymal damage.

The confusion over the pathogenesis of reflux nephropathy probably explains the lack of hard clinical evidence to guide the management of children with urinary tract infection. Current United Kingdom guidelines are summarized in Table 9.

Whatever the cause of reflux nephropathy, there is little doubt that women with it are more prone to recurrent acute pyelonephritis than those with anatomically normal upper urinary tracts, particularly during pregnancy.

Invasive/destructive renal parenchymal infection

As discussed above, ascending infection may cause the clinical syndrome of 'acute pyelonephritis' but seldom causes significant renal parenchymal damage. However, this is not the case if there is further impairment of host defence against infection, particularly by diabetes or urinary tract obstruction.

Acute papillary necrosis

This is an unusual complication of acute pyelonephritis, but more likely to occur in the elderly and especially those with diabetes. It should be suspected, as should urinary stones, in the patient with symptoms and signs of acute pyelonephritis who also has pain suggesting renal colic. This situation requires immediate imaging, usually with ultrasonography, to exclude urinary obstruction, and if obstruction is present then it must be relieved urgently, most often by antegrade nephrostomy.

The use of non-steroidal anti-inflammatory drugs is associated with an increased incidence of chronic renal papillary necrosis, perhaps because they compromise the renal medullary circulation. It therefore seems reasonable to say that these agents should be discontinued, at least temporarily, in the presence of acute pyelonephritis.

Renal carbuncle

Renal carbuncle is the formation of renal cortical abscesses, often only in one kidney, caused by bloodborne infection, usually associated with untreated *Staph. aureus* septicaemia. It is most commonly seen in intravenous drug abusers and patients with diabetes. There is usually a significant time delay between the initial infection and presentation with renal carbuncle, typically 6 to 8 weeks. Presenting symptoms include fever, malaise, and abdominal or flank pain, and are often non-specific. Because the infection is limited to the renal cortex and does not communicate with the collecting system, the urine is sterile and acellular. Blood cultures are usually negative. Radiological studies show a semisolid, thick-walled mass, percutaneous aspiration of which yields pus.

Pyonephrosis

Pyonephrosis is bacterial infection within a completely obstructed collecting system, for instance due to an obstructing ureteric stone. Patients usually present with fever, rigors, and flank pain, and have a marked neutrophilia and acute-phase response. Radiological differentiation from hydronephrosis relies on the presence of echogenic material and/or septas in the pelvicalyceal system, and confirmation is by percutaneous aspiration; as with other localized urinary tract infections, the voided bladder urine may be sterile. Untreated pyonephrosis rapidly results in complete destruction of the renal parenchyma, followed by death from complications of sepsis if nephrectomy is not performed; correction of obstruction and aggressive intravenous antibiotic therapy may prevent this if instituted soon enough.

Perinephric abscess

Perinephric abscess may complicate renal carbuncle or, more commonly, acute pyelonephritis—particularly if complicated by an anatomical or functional abnormality of the urinary tract. Typical presenting symptoms are those of acute pyelonephritis, with flank pain, fever, and rigors. If the abscess does not communicate with the collecting system, for instance in abscesses caused by haematogenous spread or complicating obstruction or renal cysts, there may be no lower urinary tract symptoms, no pyuria, and the urine may be sterile. Response to antibiotic treatment is much less rapid than in patients with uncomplicated acute pyelonephritis. Diagnosis is by ultrasound, urography, or CT scanning, followed by percutaneous (or occasionally surgical) aspiration, drainage, and culture of the aspirate. Prolonged antibiotic treatment of the organism identified is needed, stopping only when there is evidence that the infection has resolved, based on defervescence, resolution of the acute-phase response, and repeated radiological studies. This may take as long as 8 weeks.

Xanthogranulomatous pyelonephritis

Xanthogranulomatous pyelonephritis is an atypical form of chronic infection of the renal parenchyma in which bacterial infection, usually in the presence of obstruction or staghorn calculi, results in formation of granulomas with the accumulation of lipid-rich foamy macrophages. The process may be multifocal and can be complicated by extension into the perinephric fat, causing perinephric abscess. Patients are typically febrile and ill, with a history of progressive weight loss, anaemia, and malaise, without lower urinary tract symptoms, and have a mass in the flank on examination. Radiologically, the multifocal mass crossing tissue planes may be indistinguishable from a renal cell carcinoma, which may also cause systemic symptoms such as fever, anaemia, and weight loss. Although both require surgical excision, radical surgery can be avoided if the diagnosis is made preoperatively.

Emphysematous pyelonephritis

Emphysematous pyelonephritis is a rare and life-threatening form of acute pyelonephritis in which there is tissue necrosis together with formation of hydrogen and

carbon dioxide, which accumulate in pockets in the renal parenchyma, perinephric space, and collecting systems—'gas gangrene of the kidney' (Fig. 3). The typical patient is an obese, elderly woman with type 2 diabetes; urinary tract obstruction is another important risk factor. Presentation is with fever, vomiting, and abdominal pain. The patient is often extremely ill with hypotension, neutrophilia, and renal impairment. The commonest causative organism is *E. coli*; clostridial infection has not been reported. Even with aggressive medical treatment the mortality is high, and although occasional successes with antibiotics combined with percutaneous drainage have been reported, the standard treatment is nephrectomy.

Fig. 3 Gas-forming infection, seen as the three black holes in the single remaining (right) kidney of a patient with diabetes. The left kidney had been removed 2 years earlier for a similar gas-forming infection. This infection was successfully treated by intravenous antibiotics and percutaneous drainage.

Malakoplakia

Malakoplakia (Greek: 'soft plaque') is a rare disease characterized by destructive tumour-like granulomatous infiltrates in the urinary bladder, kidneys, and occasionally other organs. Bladder involvement usually presents with haematuria, frequency, and dysuria; renal involvement presents with fever, flank pain, and renal enlargement, and may frequently be bilateral. The diagnosis may be suspected at cystoscopy or on renal imaging, but is confirmed histologically by detection of large eosinophilic granular macrophages containing characteristic intracellular lamellated 5- to 10-µm inclusion bodies. It is caused by bacterial urinary tract infection, commonly *E. coli*, together with an ill-understood acquired defect of microtubule assembly within phagocytic cells, resulting in the accumulation within the cytoplasm of bacterial remnants that subsequently calcify. Treatment with bethanechol (to stimulate intracellular cGMP and thus microtubule assembly) and ascorbic acid (to stimulate the intracellular hexose monophosphate shunt, which is involved in phagocytosis) have been recommended on theoretical grounds, but seldom arrest the disease. The best chance of avoiding nephrectomy comes from the use of long-term quinolone antibiotics such as ciprofloxacin, which penetrate macrophages well.

Unusual infections

Tuberculosis

Genitourinary tuberculosis is an uncommon late manifestation of tuberculosis, and is often clinically silent, with few if any systemic symptoms. Most cases of renal tuberculosis probably result from haematogenous spread, although unilateral disease is common. Seeding of infection from above leads to ulceration and distortion of the collecting system, pelvis, and ureter, followed by stricture formation and calcification. Obstruction and parenchymal infection may eventually lead to 'autonephrectomy' (Fig. 4). The disease is usually detected either during investigation of asymptomatic sterile pyuria or during investigation of irritative lower urinary tract symptoms or haematuria due to bladder involvement. Reactivation of disease may result from acquired deficiency of 1,25-dihydroxyvitamin D. Occasionally, renal tuberculosis may present with a cold abscess in the flank. Chronic renal failure due to bilateral diffuse interstitial renal tuberculosis may occur, and may account for some of the excess of chronic renal failure in Asian immigrants in the United Kingdom.

Fig. 4 Calcified 'autonephrectomy' as a result of long-standing tuberculous infection. (Reproduced by permission of Professor P. W. Mathieson.)

Diagnosis of renal tuberculosis is by culture of early morning urine samples. Treatment is with rifampicin, isoniazid, pyrazinamide, and ethambutol for 2 months, followed by rifampicin and isoniazid for a further 4 months, and should be supervised by a physician experienced in the chemotherapy of tuberculosis, and with adjustment of the dose of ethambutol in the presence of renal impairment. Corticosteroids may help to prevent or reverse ureteric obstruction, which may otherwise require stent insertion or surgery to prevent renal destruction. Nephrectomy is seldom necessary.

Schistosomiasis

Schistosoma haematobium infection in the venules of the urinary bladder may cause irritative symptoms and terminal haematuria, starting 2 to 3 months after the initial infection. Eosinophilia may be present. The diagnosis is made by detection of ova in a midday terminal urine specimen or by cystoscopy and biopsy. Treatment is with systemic anthelmintic drugs, currently praziquantel.

Fungal infections

Fungal urinary tract infections typically occur in patients whose host defence is compromised by indwelling urethral catheters or ureteric stents, previous wide-spectrum antibiotic therapy, immunosuppressive drugs, or diabetes. Most infections are caused by *Candida* spp. Many patients with funguria have asymptomatic colonization, but some develop life-threatening ascending disease. Severity of infection does not correlate with pyuria. It is important to differentiate funguria from contamination of voided urine by *Candida* in patients with vaginal candidiasis. Many infections clear spontaneously on removal of the urethral catheter, although this can take many months. Treatment options for patients thought to be at high risk of invasive infection (for instance patients with diabetes with indwelling catheters, renal transplant recipients) include continuous bladder irrigation or antegrade perfusion via a nephrostomy tube with amphotericin B at 50 mg/l, and oral fluconazole. Patients with clinical features of acute pyelonephritis require parenteral antifungal treatment, adjusted to *in vitro* sensitivities.

Fungaemia is often complicated by renal parenchymal infection, possibly because the hypertonic and hypoxic conditions in the renal medulla favour transformation of *Candida* from the yeast to the mycelial phase. Infection starts with multiple cortical abscesses and progresses to invasion of the renal pelvis and ureter, with eventual obstruction by fungus balls.

Prospects for the future

Current methods for prevention and treatment of uncomplicated and complicated urinary tract infection are unsatisfactory, with persisting high morbidity and mortality from complicated infection and increasing rates of antibiotic-resistant organisms. Development of new antibiotics is likely only to remain half a step ahead. We hope to see major advances in the prevention of urinary tract infection, perhaps with the development of substances designed to inhibit bacterial adherence to the uroepithelium, the development of new catheter materials and of alternatives to urethral catheterization, and the possibility of vaccines against the virulence determinants of uropathogenic bacteria.

20.13 Urinary stones, nephrocalcinosis, and renal tubular acidosis

Robert J. Unwin, William G. Robertson, and Giovambattista Capasso

Nephrocalcinosis and urinary stone disease

> 'No stretch of chemical or physical imagination will permit so heterogeneous a group of compounds (as renal stones) to be ascribed to a common origin, or their disposition in the kidney, ureter or bladder to be uniformly charged to an identical cause'
>
> (Howard Kelly)

Nephrocalcinosis and uro-(nephro-)lithiasis frequently coexist and the terms are often loosely combined when describing patients with urinary stone disease. Whether they are aetiologically distinct is unclear, although it is generally believed that nephrocalcinosis represents one end of the spectrum of urinary stone disease. However, although nephrocalcinosis is often associated with urinary stones, most patients with urinary stones do not have macroscopic nephrocalcinosis.

Urolithiasis

Introduction

Urolithiasis has no geographical, demographic, or genetic boundaries: patterns of stone formation have changed in the past and are continuing to change today. The earliest evidence of the disorder is the stones found in mummies entombed in the predynastic Egyptian era, around 4000 BC. In Western countries before 1900, stones occurred commonly in children, particularly boys, and were formed mainly in the bladder. These stones consisted of ammonium urate and/or calcium oxalate and were associated with poor nutrition. Although this form of stone disorder is still found today in rural areas within the so-called 'endemic stone belt' (which stretches from Jordan, through Iraq, Iran, and the Indian subcontinent to the furthest reaches of South-East Asia), it is gradually disappearing with improving standards of nutrition, as it did in most developed countries 100 years ago.

By contrast to the gradual decrease in the occurrence of bladder stones in children, the incidence of upper urinary tract stones (mainly renal) in adults has steadily increased in most countries over the last century. Kidney stones are more common in the industrially developed nations and less so in countries whose economies are more dependent on agriculture. Overall, upper tract stone disease seems to be a disorder associated with affluence, presumably through effects on diet and lifestyle.

Epidemiological factors in the formation of urinary stones

Although stones generally occur more frequently in men than in women (male:female ratio about 2.5:1), recent studies in the United Kingdom and Portugal have shown that, within the past 25 years, there has been a progressive decrease in the age at onset of stone formation in both men and women, particularly women. Within the population of stone formers as a whole, the male:female ratio is now 1.7:1 among patients who formed their first stone before the age of 20 years; but in patients currently aged less than 20 years, the ratio has fallen to 1.1:1. These changes have been attributed to alterations in diet and lifestyle over the last 25 years.

Epidemiological factors important in the formation of urinary stones are summarized in Table 1. Each has been shown to increase the risk of stone formation through effects on the balance between supersaturation and inhibitors and promoters of crystallization in urine (see later).

Calcium oxalate stones

Most (80 per cent) urinary calculi contain calcium oxalate, often on its own, but frequently mixed with calcium phosphate or, occasionally, uric acid. In about 90 per cent of these cases (the so-called idiopathic or primary stone formers), there is no obvious metabolic cause for stone formation. In the remainder, calcium-containing stones form as a result of some disorder of calcium metabolism, oxalate metabolism, or acid–base balance.

For idiopathic calcium stone formation the main epidemiological factors are age, gender, season, climate, stress, occupation, affluence, diet (including fluid intake), and genetic/metabolic factors. The role of diet, in particular, has been studied in detail and appears to explain much of the changing pattern of stone incidence over the past 100 years. As the diet becomes 'richer' in a given population (with an increased consumption of protein, particularly animal protein, refined sugars, and salt), the incidence of stones increases. This often follows periods of economic expansion, whereas the incidence of stones decreases during periods of recession in parallel with a return to a diet containing more fibre and less energy-rich foods. The recent increase in consumption of soft drinks, especially in the young, is becoming an important 'new' factor in the risk of urinary stone formation. These contain phosphoric acid, providing a small acid load, but one that may become significant if large volumes are drunk. Paradoxically, potential sources of oxalate, such as beer, may be associated with a reduced stone risk, perhaps because a minimum ingestion of oxalate is necessary to bind dietary calcium and limit calciuria. Antacid ingestion (as distinct from 'milk-alkali syndrome') may also reduce stone risk by increasing urine pH, binding oxalate, and providing a source of magnesium.

Infection stones

So-called 'infection stones', composed of magnesium ammonium phosphate, usually in conjunction with calcium phosphate, are more common in women and now constitute between 4 and 15 per cent of stones, depending on the country of origin. They are caused by urinary tract infection with urea-splitting organisms that secrete the enzyme urease. This converts urea to ammonium (NH_4^+) and bicarbonate, making the urine more alkaline (urinary NH_4^+ concentration is normally low in sterile alkaline urine). As a result, phosphate-containing salts, such as calcium phosphate and magnesium ammonium phosphate, precipitate and increase the risk of stone formation. Infection stones can also form secondary to most other types of stone. The relative incidence of infection stones has decreased over the past 25 years in most Western countries, presumably as a result of better clinical diagnosis and earlier treatment of urinary tract infections.

Uric acid stones

Stones consisting of uric acid constitute between 4 and 25 per cent of published series, depending on the relative consumption of animal and vegetable protein in the population studied. There are three factors that promote formation of uric acid stones: (i) low urine volume, (ii) acid urine pH, and (iii) high uric acid excretion. For a given diet, these stones are more common in elderly men, at least in part because of the decline in urine pH with age. Because the pK of uric acid/urate is approximately 5.7, a more acid urine pH favours the less soluble undissociated form of uric acid. 'Pure' uric acid stones are infrequent in most developing countries and are most common in the oil-rich states of the Arabian Gulf, or in countries where there is a cheap local source of meat, fish, or poultry protein. Most uric acid stones are idiopathic; a small number form secondary to some disorder of purine metabolism (such as Lesch–Nyhan syndrome), or to a condition in which there is high tissue turnover (such as tumour necrosis following chemotherapy).

'Rare' stones

In all series of stones analysed, between 1 and 2 per cent consist of a range of 'rare' constituents derived from either some hereditary or congenital inborn error of metabolism, such as cystinuria (not to be confused with cystinosis), xanthinuria, or 2,8-dihydroxyadeninuria, or from a prescribed drug or metabolite, which is relatively insoluble in urine. Examples are silica (from excess ingestion of the antacid magnesium trisilicate, or from the use of pectin and silicium to thicken milk for infant feeding), sulphonamides, indinavir, and triamterene. All stones contain a small percentage by weight of mucoproteinaceous matrix. Some 'stones' consist almost entirely of mucoprotein, and usually result from inflammation of the urinary tract in patients whose urine is not sufficiently supersaturated to mineralize the organic matrix.

Causes of urinary stone formation

Insolubility of mineral components

The overriding factor that is common to all types of stone is the relative insolubility of their respective mineral component(s) in the urine. However, whether or not this is the only factor responsible for the formation of stones is still open to debate. There are two possible models (which are not mutually exclusive) for the initiation of stones. The 'free-particle' model is that stones are initiated when urine becomes so excessively supersaturated with one of the salts or acids occurring in kidney stones that crystals spontaneously precipitate in urine. If this happens frequently, and if the crystals grow or aggregate sufficiently within the transit time of urine through the kidney, then the risk increases that one of these particles will become trapped at some narrow point along the urinary tract and act as a focus around which a stone can form. The other model of stone formation, which is currently favoured, requires chemical 'fixation' of a crystal, or aggregate of crystals, to the renal epithelial cell lining. This fixed particle may result from injury to the cell wall (caused either by the crystals themselves or by viruses or bacteria) and/or from some 'gluing' material—present only in the urine of stone formers—that causes crystals to adhere to these sites and then results in stone formation.

Both models require urine to be supersaturated to some degree with respect to the stone-forming salt or acid concerned, sufficient to cause crystals to be formed by nucleation that is either homogeneous (spontaneous) or heterogeneous (on a pre-existing nucleus of some foreign material). The factors causing urine to become supersaturated with one or more of the various constituents of stones are shown in Table 2.

Modifiers of crystallization

One factor that might affect the kinetics of the processes involved is the presence or absence in urine of so-called modifiers of crystallization, claimed to be of particular importance in the formation of calcium-containing stones. One group of crystallization modifiers is said to retard the rate of growth and/or aggregation of crystals, or the binding of calcium-containing crystals to cell walls. These are known as inhibitors of crystallization and include magnesium, citrate, pyrophosphate, ADP, ATP, at least two phosphopeptides, glycosaminoglycans, Tamm–Horsfall protein, nephrocalcin, calgranulin, fibronectin, various plasma proteins, osteopontin (uropontin), a_1-microglobulin, b_2-microglobulin, urinary prothrombin fragment 1, and inter-a-trypsin inhibitor. Of these, urinary citrate is probably the most important. The second group of modifiers is claimed to promote one or more of the processes involved in crystallization. These are known as promoters of stone formation and include matrix substance A, various uncharacterized urinary proteins and glycoproteins, and the polymerized form of Tamm–Horsfall protein (uromucoid). However, the clinical importance of these compounds in the pathogenesis of stone formation remains unclear.

In the final analysis, stone formation is probably due to an abnormal combination of factors that affect either the thermodynamic (supersaturation driving force) or kinetic (rate-controlling) processes involved in the crystallization of the various stone-forming minerals. For some types of stone formation (cystine, xanthine, 2,8-dihydroxyadenine, uric acid, and probably magnesium phosphate ammonium stones) the thermodynamic factors predominate; in others (calcium oxalate and calcium phosphate) both sets of factors may be involved.

Idiopathic hypercalciuria

This is often familial, accounts for the majority (more than 50 per cent) of patients with renal stones, and can be divided into three types: absorptive, resorptive (or fasting), and renal. The most common is absorptive, due to increased intestinal absorption of calcium, the cause of which remains unknown. Resorptive hypercalciuria is associated with reduced bone mineralization, although primary hyperparathyroidism must be excluded. Renal hypercalciuria is distinct from that seen in tubular disorders such as the Fanconi syndrome (see under renal tubular acidosis). Although the underlying mechanism is not known, there may be a primary defect of renal phosphate reabsorption, suggested in some cases by an increase in plasma calcitriol (1,25-OH vitamin D) levels, which will enhance intestinal absorption of calcium.

Hypocitraturia

This is an important risk factor for renal stone disease. The blood citrate pool is maintained by delivery from bone and the gastrointestinal tract and by removal by hepatic and renal metabolism. High urinary citrate prevents calcium stones by encouraging formation of soluble calcium citrate; it also reduces formation of urate stones by alkalinizing the urine. Hypocitraturia is present in about 40 per cent of calcium stone formers, but in most cases the reason for this is unknown.

Low urinary citrate excretion results from metabolic acidosis in conditions such as chronic diarrhoea, urinary diversion, and distal renal tubular acidosis. The hypocitraturia of distal renal tubular acidosis is due to increased reabsorption of citrate in the proximal tubule as a result of intracellular acidosis (see section on renal tubular acidosis below for more detail). Citrate excretion is also reduced because of acid retention in subjects on a high protein diet. The widely prescribed angiotensin-converting enzyme (**ACE**) inhibitor enalapril has been shown to decrease citrate excretion in rats, although the effect is small in humans. It is not known whether this is true of all ACE inhibitors, or if it is of any significance in patients at risk of renal stones (particularly given the increased prevalence of hypertension in renal stone disease).

Hyperuricosuria

The contribution of increased uric acid excretion to uric acid stone formation occurs mainly in patients on a high protein (purine) diet, which leads to the production of more acid urine and increases the risk of urate precipitation. Hyperuricosuria is less commonly due to a defect of urate metabolism *per se*.

Up to a fifth of patients with gout also have urinary stone disease (urate, calcium oxalate, calcium phosphate, or mixed). Hypertension is commonly associated with both conditions; hence, as already mentioned, it may be important to consider the effect of antihypertensive therapy on the risk of urolithiasis. The angiotensin receptor blocker Losartan lowers plasma urate concentration and increases uric acid excretion by an unknown mechanism, although this does not seem to increase the risk of uric acid stones.

Hyperoxaluria

The excretion of oxalate is often mildly elevated in idiopathic stone formers. Most oxalate is derived from the metabolism of glycine and ascorbic acid, vitamin C intoxication being a rare cause of hyperoxaluria (vitamin C can be non-enzymatically converted to oxalate in urine; this can be prevented by collecting urine in acid or EDTA; up to 4 g/day of vitamin C has no significant effect on urinary oxalate excretion). Intestinal absorption of oxalate is normally low, but rises when dietary calcium content is reduced. It is also increased following small bowel resection and in Crohn's disease (so-called enteric hyperoxaluria), when saponification and the action of bile salts increase the permeability of the large bowel to oxalate. In these conditions diarrhoea and malabsorption can lead to chronic dehydration, low urinary volumes and metabolic acidosis, with the risk of interstitial oxalate deposition causing acute or chronic renal failure.

Recent research suggests that normal bowel colonization with the bacterium *Oxalobacter formigenes* is an important determinant of urinary oxalate excretion, because this organism digests dietary oxalate, thereby reducing its absorption. This might be relevant to the association between renal stones and long-term antibiotic use in patients with cystic fibrosis, although their high protein intake from pancreatic enzyme supplements may also be a factor.

The two genetic types of primary hyperoxaluria are autosomal recessive and cause oxalate overproduction. Type 1 (PH1) is the more severe form, producing widespread tissue deposition of oxalate (oxalosis), early renal failure, and nephrocalcinosis. It is due to a defect of the liver transaminase that converts glyoxylate to glycine, resulting in glyoxylate oxidation to oxalate and reduction to glycollate. The rarer type 2 (PH2) is due to a deficiency of liver D-glycerate dehydrogenase and is

characterized by glyceraturia. Since pyridoxine (vitamin B_6) is a cofactor for the defective enzyme in PH1, high doses of this vitamin can sometimes help to reduce oxalate production; more modest doses are sometimes also effective in patients with mild 'idiopathic' hyperoxaluria.

Cystinuria, xanthinuria, and 2,8-dihydroxyadeninuria

A small number of stones are found in patients with cystinuria, xanthinuria and 2,8-dihydroxyadeninuria arising from inherited or congenital errors of metabolism. Cystine is normally excreted in very low concentrations, well below the limit of solubility of cystine in urine (1 to 1.5 mmol/l). In cystinuria, due to a defect in the tubular reabsorption of cystine, the urinary concentrations are 200-fold higher than normal, leading to precipitation of cystine and stone formation. Only homozygotes form stones; the excretion of cystine in heterozygotes is higher than normal, but insufficient to cause crystal formation in most cases. The basic amino acids ornithine, lysine, and arginine share the same amino acid transport mechanism as cystine and their excretion is also increased.

Xanthinuria results from a deficiency of the enzyme xanthine oxidase, such that xanthine is not converted to uric acid. Radiolucent stones form in acid urine. Secondary xanthinuria producing xanthine stones is an unusual complication of allopurinol therapy.

A deficiency of the enzyme adenine phosphoribosyl transferase, inherited as an autosomal recessive trait, is associated with an increased urinary excretion of 2,8-dihydroxyadenine and this sometimes leads to stone formation.

Clinical features

Calculi can occur at any point in the urinary tract, although they are more often located in the kidney and ureter than in the bladder. Upper urinary tract stones can occur on either side and are often bilateral. Over 60 per cent are small enough to be passed spontaneously. Within the kidney itself, concretions may be found in the calyces, in the renal pelvis, or extending from the calyces into the pelvis. They may be attached to the epithelial surfaces of the pelvicalyceal system, be encapsulated within the renal parenchyma, or lie free within the pelvis or lower pole of the kidney. Occasionally, they may occupy the entire pelvicalyceal space to form a so-called 'staghorn' calculus. The clinical presentation of calculi depends primarily upon their position in the urinary tract, and whether or not they cause obstruction to urinary flow.

Pain from urinary stones

The commonest presentation of urinary calculi is with pain. Stones can become lodged at any point in the ureter, but most commonly do so at the upper and lower ends, where there are constrictions at the pelviureteric and vesicoureteric junctions. A stone in the renal pelvis typically causes dull loin pain with occasional colic. The most problematic differential diagnosis is from musculoskeletal pain arising in the back, lower ribs, or their muscular and ligamentous attachments. Such pain is common, and it can be very difficult to decide whether a stone seen on a radiograph is 'incidental' (see later) or the cause of symptoms. Musculoskeletal pain is more likely to be precipitated by bad posture, exercise, or movement, to come on suddenly, to last for a few seconds or minutes only, and to be associated with a localized 'superficial' point of tenderness. Renal pain is less likely to be brought on by exercise or movement and more likely to be felt 'deeper inside', last for hours, and be associated with diffuse loin tenderness and no comfortable position.

Partial or total obstruction of the pelviureteric junction or ureter gives rise to the agonizing pain of renal colic, described by many sufferers as the 'worst pain they have ever had'. The patient can be in absolute agony, rolling around and crying out as the waves of colic strike them. If the stone is at the pelviureteric junction, the pain is felt in the loin. If it moves down the ureter, the pain radiates into the groin and (sometimes) into the scrotum or labia. The patient sweats profusely with the waves of pain and often vomits. Treatment with non-steroidal anti-inflammatory agents may be helpful, but the physician should not refrain from giving prompt and adequate doses of powerful analgesics (pethidine, morphine) and will certainly gain the undying gratitude of their patient if they do so. The diagnosis of renal colic is often straightforward from the history alone, but in some cases differential diagnoses need to be entertained, which include biliary colic, small bowel obstruction, appendicitis, and diverticulitis. Children and pregnant women are less likely to present with characteristic symptoms and a high index of suspicion is sometimes required to make the diagnosis.

The patient with stones in the upper urinary tract may have macroscopic haematuria and frequently will have microscopic haematuria, together with episodes of frequency and dysuria caused by the passage of 'sand' or 'gravel'.

'Staghorn' calculi are associated with infection, as described previously, but urinary infection is probably more common in any individual with urinary stones, and the combination of urinary obstruction with sepsis can be particularly dangerous. Added to symptoms arising from obstruction are those from infection, with high fever (often 39°C or higher), rigors, and (in severe cases) circulatory collapse. These cases are medical emergencies requiring resuscitation, intravenous antimicrobial therapy, and urgent relief of obstruction.

Another circumstance worthy of note is the patient with a single functioning kidney. Obstruction by a stone, or any other cause, will lead to acute obstructive renal failure, demanding urgent relief of obstruction.

Calculi may be found in the bladder, either lying free or lodged in a diverticulum in the vesical wall. Most probably they originate in the upper urinary tract and continue to grow in their new location, although others may be initiated in the bladder. They occur almost exclusively in elderly men and usually consist of uric acid, or are associated with infection due to chronic prostatic obstruction. Stones in the bladder may be asymptomatic, but can cause discomfort in the suprapubic and perineal regions, and also the dramatic symptom of sudden and painful cessation to urine flow.

Imaging

Diagnosis is usually confirmed by a combination of ultrasound, plain abdominal radiography (kidney, ureters, and bladder), and particularly in the case of radiolucent stones (i.e. those composed of uric acid, 2,8-dihydroxyadenine, or xanthine), an intravenous urogram. The place of the intravenous urogram is still hotly debated, although there is really no better means of defining the anatomy of the renal drainage system and at the same time providing some index of renal function, which an ultrasound examination cannot do. Occasionally, a computed tomographic (CT) scan (especially spiral) can provide useful additional information, particularly if there is associated nephrocalcinosis or lucent stones. Magnetic resonance imaging is poor at showing calcium deposits.

Recurrence

If patients are not provided with proper preventative management, the risk of recurrence is high—40 per cent within 3 years, rising to 74 per cent at 10 years, and 98 per cent at 25 years. The rate of recurrence appears to be higher after the use of minimally invasive techniques for the disintegration and/or removal of stones than it was in the days of open kidney surgery. This is particularly noticeable in patients treated with extracorporeal shock-wave lithotripsy, which by the nature of the technique tends to leave behind fragments of stone that may act as foci for subsequent stone formation. Percutaneous nephrolithotomy is slightly less of a problem in this respect, because it is usually easier to ensure that most of the stone fragments are removed during this procedure: it is usually preferred to lithotripsy for treatment of a stone present in the lower pole of the kidney, or greater than 2 cm in diameter. It is important to remember that sole reliance on surgical procedures for the overall management of stone formers is inadequate: stones tend to recur unless dietary and/or medical treatment is also instituted.

Asymptomatic urinary stones

About 3 per cent of patients undergoing abdominal ultrasound or radiographic investigations for other indications are found to have 'silent' kidney stones (Fig. 1(a)). If the stone is greater than 4 mm in diameter and of uncertain location, an intravenous urogram should be performed to determine this in relation to the renal pelvis and ureter and to assess the risk of future obstruction (Fig. 1(b)). A simple metabolic screen (see later) is also required. If the patient remains asymptomatic, no specific abnormality is found, and no intervention deemed necessary, then a follow-up radiograph or ultrasound at 2 years is probably advisable, depending on the size of the stone.

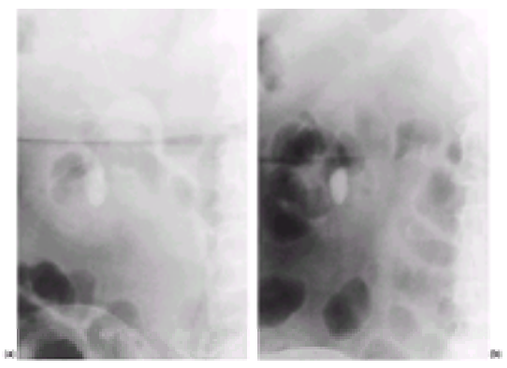

Fig. 1 A plain radiograph (a) and intravenous urogram (b) of an adult woman showing an incidental right kidney stone. The stone is in a lower pole calyx or calyceal diverticulum and measures 8 by 15 mm.

Biochemical screening to determine risk of urinary stones

Once the presence of a stone is confirmed and a decision is reached on the most appropriate urological intervention (if any), the patient should be screened for a biochemical cause. It is usually best to do this when the patient is eating and drinking 'normally', but not when there is haematuria or immediately prior to stone removal or lithotripsy. After such treatment it is sensible to wait for 2 to 3 months, because during this period patients often consume a diet that is very different from their 'normal'one. If they do not form another stone within 3 months of the presenting episode, then they will frequently return to former dietary habits and an increased risk of stone formation.

There are several published biochemical screening procedures for assessing the risk of stone formation, most of which require a stone analysis, a metabolic screen, a 24-h urine screen, and in some instances, a dietary history. These should not be carried out when the patient is in hospital, because the diet is usually very different from that consumed at home. In addition to the routine clinical history from the patient, which should include occupation and family history of stones, the screen includes the following.

1. Analysis of a simultaneous blood and spot urine sample. The blood sample should be analysed for urea, creatinine, calcium, magnesium, sodium, potassium, bicarbonate, phosphate, urate, alkaline phosphatase, albumin, and oxalate (where necessary). The urine sample should be analysed for urea, creatinine, pH, calcium, sodium, potassium, phosphate, and urate.
2. Analysis of two 24-h urine samples collected on consecutive days at home: the first in a container with 50 ml of 2.2 mol hydrochloric acid as a preservative and analysed for volume, creatinine, calcium, magnesium, sodium, potassium, phosphate, oxalate, and citrate; the second in a plain container and analysed for volume, creatinine, pH, protein, urate, and a qualitative test for cystine.
3. Dietary assessment carried out using the diet diary system during the week leading up to, and including, the 2 days of the 24-urine collections. The patient is asked to complete a diet diary of everything that he or she consumes each day. This is analysed for fluid intake, calories, calcium, magnesium, sodium, potassium, phosphate, oxalate, purine, protein (and its various fractions, including animal protein, meat plus fish plus poultry protein, dairy protein, and fruit plus vegetable plus cereal protein), fibre, fat, and refined sugars.
4. Quantitative stone analysis (whenever possible). All patients should be encouraged to retain their stones or stone fragments for quantitative analysis by infrared spectroscopy. This is an important tool, often providing the first clue as to the cause of the stone(s) in a given patient.

From the combined analyses, a number of algorithms can be used to assess the overall biochemical risk of forming stones containing uric acid, calcium oxalate, or calcium phosphate, or various mixtures of these constituents (details of several such algorithms that are currently used in various specialist urinary stone clinics can be found in chapter 2 of Coe *et al.*1996). These are used to give an indication of the risk of stone formation in an individual patient. High risk is rarely caused by a single abnormal urinary constituent (except in the case of primary hyperoxaluria), but usually due to a combination of several lesser abnormalities, depending on the stone type. Indeed, it is possible to be at high risk with every single individual risk factor within its 'normal range', but with several lying towards the upper or lower limits of these ranges. This is an important feature of these models because they allow a risk assessment to be made in the patient who would otherwise be described as 'having normal urine', yet has an abnormal combination of the variables that lead to crystalluria and stones. The models can be used both to assess the patient's probability of stones before treatment, and also to follow progress during preventative management.

Prevention of stone recurrence

The main aim in the prevention of stone recurrence is to decrease the likelihood of crystals forming in the urinary tract by reducing the supersaturation of urine with respect to the particular constituent(s) that occurs in a patient's stone.

A summary of the available dietary and medical treatments for the various types of urinary calculi is shown in Table 3. The injunction to 'drink more' is crucially important for all at risk of urinary stones, and patients should aim to maintain a urinary volume of at least 2.5 litres per day. Those with recurrent stones will certainly benefit from maintaining a higher urinary volume than this, and also from making a point of drinking when they get up at night to micturate. This is undoubtedly an inconvenience, but recommended to ensure that the urine is as dilute as possible throughout the 24 h, and does not become concentrated at night. Patients taking treatment to modify their urinary pH should be given appropriate sticks to measure this, instructed how to use them, and how to modify their treatment to achieve the desired effect.

Some patients will benefit from alteration of their diet, in particular those who eat excessive amounts of animal protein and purine from meat, fish, and poultry; those who consume large quantities of oxalate-containing foods; and those who not only consume high amounts of calcium but also hyperabsorb calcium from the intestine. Too low an intake of calcium, on the other hand, may increase the intestinal absorption and hence urinary excretion of oxalate. It is important, therefore, not to advise patients to cut out all dairy produce to correct their hypercalciuria, as they may end up with a higher risk of forming stones than when they started. Other dietary excesses that may increase the risk of stones include a high intake of salt, which leads to a renal leak of calcium, and a high intake of refined sugars, which increase the intestinal absorption of calcium. When taken together, gross hypercalciuria often results. A list of foods that should be avoided in excess and taken only in moderation is contained in Table 4.

Although most of the treatments listed in Table 3 and Table 4 are effective in reducing the risk of stone recurrence, the main problem in the long-term management of patients with stones is compliance. Stone formers typically feel well for most of the time, except when experiencing an attack of renal colic. It is therefore often difficult to maintain co-operation and motivation to adhere to preventative treatment for long after a first stone episode, particularly since this is socially intrusive, with drinking of large volumes leading to urinary frequency. If patients do not have a recurrent stone within a few months, they will generally return to their original abnormal pattern of urine biochemistry by 3 to 6 months and eventually produce another stone. Once they have had several episodes of renal colic, compliance with treatment is usually better.

Figure 2 illustrates how the important urinary risk factors for stone formation can be represented visually to encourage understanding, compliance, and motivation. The patient can see immediately how changes in diet and urine composition affect his/her stone risk, which can be an incentive to try and reduce the combined risk by moving it from outside (high risk) toward the central (low risk) 'bull's eye'. It is important to review the patient regularly as an outpatient and to repeat the relevant screening tests, preferably annually but at least biennially, to encourage adherence to the recommended treatment.

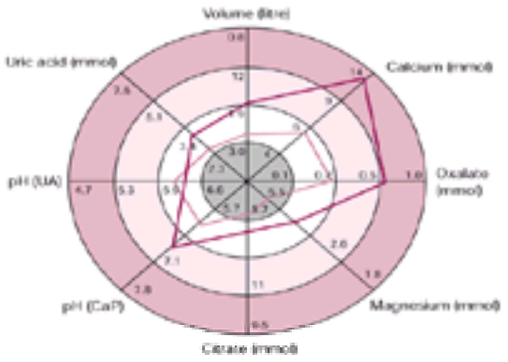

Fig. 2 A radar plot ('target diagram') showing the baseline urinary risk factors for stone formation (purple lines) and the corresponding data during preventative treatment (pink lines) in a patient with 'mixed' calcium oxalate and calcium phosphate stones. The individual urinary risk factors are plotted such that abnormal values fall in the dark pink outer ring and normal values in the grey bull's eye. Intermediate values fall in the white and light pink areas. The objective for the patient is to aim to get his/her risk factors in the 'bull's eye'. Units of axes are urinary volumes or amounts per 24 h. UA, refers to a patient with uric acid stones; CaP, refers to a patient with calcium phosphate-containing stones.

Economics of management of urinary stones

The undoubted success of lithotripsy, less invasive surgery (such as percutaneous nephrolithotomy), and ureteroscopy for the disintegration and removal of calculi has lulled some into the belief that urinary stone disease can be managed solely by these interventions. Although these minimally invasive techniques are often the procedures of choice for the removal of stones, they do not prevent their recurrence. Without biochemical screening and appropriate dietary and/or medical management, the patient will often return for further stone removal in the future, which can be uncomfortable for the patient and is expensive to perform. Failure to provide proper prophylactic treatment and follow-up can also result in missed infections and eventually compromised renal function. Financial analysis has shown that the projected costs of treating patients with stones by only removing their stones as they form is much more costly than removing the initial stone(s) and then screening to identify risk factors to provide appropriate advice and long-term management.

Nephrocalcinosis

Nephrocalcinosis is the deposition of calcium salts (mainly phosphates and oxalates) within the kidney, but the term is usually reserved for those conditions in which there is a generalized increase in kidney calcium content, rather than any localized intrarenal calcification, as may occur in some tumours, cysts, tuberculous granulomas, and areas of renal infarction.

Microscopic, or mild, nephrocalcinosis is a common incidental finding at autopsy, but macroscopic nephrocalcinosis is uncommon. It is diagnosed by radiography or ultrasound, although there is still some debate amongst radiologists as to whether radiography or ultrasound is more sensitive in detecting early disease. Plain radiographs have the advantage that they can more readily be used to judge progress from one year to the next, and they are better at detecting associated urinary stone disease. It is useful to have both tests, except in children and women of childbearing age.

Cortical nephrocalcinosis is seen following extensive acute cortical infarction, and in chronic glomerulonephritis or pyelonephritis. It can occur in the transplanted kidney and in severe oxalosis, conditions that also produce a medullary distribution. An example of the more common (and clinically more important) medullary form of nephrocalcinosis is shown in Fig. 3. There are many causes of medullary nephrocalcinosis: it is usually associated with disordered calcium homeostasis and can, like urolithiasis, be broadly divided into hypercalcaemic, hypercalciuric/non-hypercalcaemic, and non-hypercalciuric forms. However, the presence of nephrocalcinosis is more likely to signify an underlying metabolic disturbance than is isolated urinary stone disease.

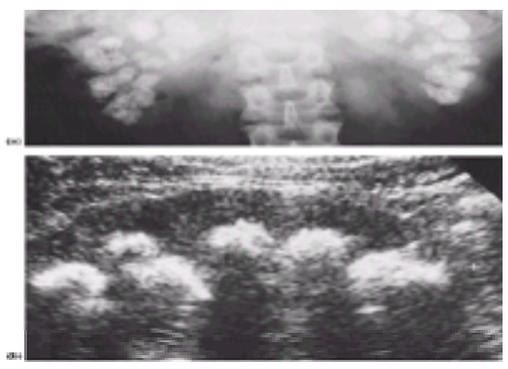

Fig. 3 A plain radiograph (a) and renal ultrasound scan (b) of a man with familial distal renal tubular acidosis and severe medullary nephrocalcinosis. Note the striking medullary distribution of calcification in the radiographic picture and the increased medullary reflections and acoustic shadows 'behind' in the ultrasound picture.

The most important risk factors for nephrocalcinosis are the same as those for urolithiasis:

1. hypercalcaemia (leading to an increased filtered load of calcium), which is linked to diet;
2. enhanced intestinal absorption of calcium, increased parathyroid hormone activity, or vitamin D excess;
3. altered renal tubular handling of calcium resulting in hypercalciuria; and
4. absence of factors in urine (such as citrate) that help to maintain calcium salts in solution.

Nephrocalcinosis associated with hypercalcaemia

Hyperparathyroidism is a common cause, accounting for approximately a third of cases in the large series of Wrong and Feest. Skeletal breakdown due to neoplasia or bone loss from chronic immobilization and severe osteoporosis can also be associated with nephrocalcinosis, although the latter, especially when the result of steroid therapy, usually only causes hypercalciuria. Vitamin D intoxication is often iatrogenic, a consequence of treating combined hypophosphataemic and hypocalcaemic states with vitamin D, calcium, and phosphate supplements. Sarcoid-induced hypercalcaemia is also related to increased activity of vitamin D, due in this circumstance to increased synthesis in granulomas, and sometimes causing significant hypercalciuria without overt hypercalcaemia. Nephrocalcinosis in association with hypothyroidism has been reported. By contrast, nephrocalcinosis is not seen in thyrotoxicosis, which can cause hypercalcaemia, except when there is an autoimmune basis and may therefore be associated with autoimmune distal renal tubular acidosis (see later in this section). A rare cause is the idiopathic hypercalcaemia of infancy (William's disease).

Nephrocalcinosis associated with hypercalciuria without hypercalcaemia

The commonest cause in this category is distal renal tubular acidosis, which is associated with low urinary excretion of citrate. Hypercalciuria is a consistent finding in patients with the complete form of this disease and systemic acidosis (see under renal tubular acidosis). Although hypercalciuria is also a feature of the Fanconi syndrome and proximal renal tubular acidosis, these conditions are less commonly associated with nephrocalcinosis, presumably because of supranormal excretion of citrate in many cases.

The next most common cause of nephrocalcinosis is medullary sponge kidney. The cause of this condition is unknown. The collecting ducts are dilated and become

the site of crystal formation and precipitation, probably related to stasis. The diagnosis can only be made reliably on an intravenous urogram, which shows grape-like clusters of ectatic medullary collecting ducts filled with contrast dye. Medullary sponge kidney can run in families and in some cases is associated with hemihypertrophy affecting the face, an arm, or a leg. Because damage to the collecting ducts can affect acid excretion, medullary sponge kidney can also be associated with a 'secondary' form of distal renal tubular acidosis, as well as mild nephrogenic diabetes insipidus.

Absorptive hypercalciuria is another cause: this may be idiopathic, but is also seen with vitamin D excess and in sarcoidosis. 'Milk-alkali syndrome' as a cause, due to excess calcium ingestion from calcium carbonate, is now rarely seen. Hypercalciuria and nephrocalcinosis can also occur in inherited tubular disorders like Bartter's syndrome and familial magnesium-losing nephropathy, and may follow intensive loop diuretic treatment in premature infants.

Non-hypercalciuric

Hyperoxaluria and oxalosis have been described earlier (see under urolithiasis). Various chronic hypokalaemic states have been associated with nephrocalcinosis. Hypokalaemia causes an intracellular acidosis, which reduces citrate excretion and may cause unspecified tubular damage. Reported examples are the hypertensive syndromes of apparent mineralocorticoid excess, due to a defect in the enzyme 11b-hydroxysteroid dehydrogenase, and Liddle's syndrome, due to an activating mutation of the collecting duct sodium (Na^+) channel (ENaC). Other conditions in which hypokalaemia may be a contributory factor include Bartter's syndrome and loop diuretic use in infancy. These and other causes are listed in Table 5.

Clinical approach to the patient with nephrocalcinosis

In most patients with nephrocalcinosis, a clinical diagnosis can be made and contributory factors identified. However, as with urinary stones, it is still poorly understood why changes in important risk factors (such as urinary calcium or citrate excretion) occur, and why or how calcium is deposited. The impact of nephrocalcinosis on health varies and its presentation can range from incidental, when detected on abdominal radiographs or ultrasounds performed for another reason, to life threatening. It may result in uncontrolled hypertension, renal infection, scarring, renal colic, defects of renal tubular function (impaired urinary concentrating ability and acid excretion—mild diabetes insipidus and secondary distal renal tubular acidosis), and even renal failure, although this is unusual.

Treatment

A metabolic cause must always be sought and treated if found. Treatment and management are otherwise very similar to those for macroscopic renal stone disease, and are mainly symptomatic. Assessment of dietary risk factors may be of some help if the underlying cause, such as distal renal tubular acidosis, cannot be easily corrected. Surgical intervention is only required if significant stones form, are passed frequently, or cause obstruction and infection. There is no place for lithotripsy, which may actually do harm, as the calcium deposition is largely parenchymal.

Renal tubular acidoses

The term 'renal tubular acidosis' is used to describe a group of clinical disorders in which net renal excretion of acid (hydrogen ions, H^+) is impaired as a result of renal tubular dysfunction. Strictly speaking, this definition could also include chronic renal failure, but by convention a reduced glomerular filtration rate as the cause of failure of acid excretion is excluded. Primary abnormalities of urinary acidification, renal tubular acidosis, are responsible for approximately 20 per cent of cases of medullary nephrocalcinosis with stones (see under nephrocalcinosis). To understand the pathogenesis of the renal tubular acidoses, an understanding of the role of the kidney in acid–base balance is required.

Role of the kidney in acid–base balance

Normal H^+ excretion depends on the ability of the renal tubule to reabsorb filtered bicarbonate (HCO_3^-) in the proximal nephron, followed by net H^+ secretion (approximately 50 mmol/day) by excretion of titratable acid and ammonium (NH_4^+) in the distal nephron (distal tubule and collecting duct) (see Fig. 4).

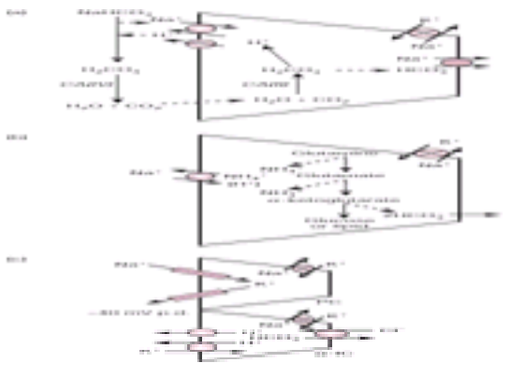

Fig. 4 Diagram showing cellular mechanisms of bicarbonate (HCO_3^-) reabsorption, ammonium (NH_4^+) generation and secretion, and hydrogen ion (H^+) secretion along the nephron. (a) Reclamation of filtered HCO_3^-, also mechanism of titratable acid; (b) generation and secretion of NH_4^+; (c) H^+ secretion. CA, carbonic anhydrase; PC, principal cell; a-IC, a-intercalated cell. See text for further details.

Reclamation of filtered bicarbonate

Normally, almost all filtered HCO_3^- is reabsorbed, the bulk of it in the proximal tubule (about 80 per cent), the remainder in the loop of Henle (about 15 per cent) and distal nephron (about 5 per cent). The mechanism of reabsorption is indirect: H^+ and HCO_3^- are generated in renal tubular cells (with the aid of carbonic anhydrase type II, **CA-II**), and the H^+ are secreted apically into the lumen, while the HCO_3^- enters the plasma via the basolateral cell membrane. In the proximal tubule and loop of Henle, most of the H^+ secretion is via Na^+/H^+ exchange in the apical (luminal) membrane, although there is also a contribution from primary active H^+-ATPase. The secreted H^+ reacts with filtered HCO_3^- to produce carbonic acid (H_2CO_3), which is rapidly converted to CO_2 and H_2O by carbonic anhydrase type IV (**CA-IV**) present on the luminal membrane, and the CO_2 and H_2O diffuse into the cell. The net result is that for every filtered HCO_3^- removed from tubular fluid, another replaces it in plasma.

Addition of 'new' bicarbonate to plasma

The bulk of H^+ generated within tubular cells is involved in reclaiming filtered bicarbonate (more than 4000 mmol/day). However, under normal conditions, because of the excess acid produced from food metabolism (about 50 mmol/day), it is necessary to add 'new' (extra) HCO_3^- to the plasma to replace that which has buffered this acid load. This is achieved by the generation of H^+ (and HCO_3^-) within tubular cells in addition to those needed to effect HCO_3^- reabsorption. The extra HCO_3^- enters the plasma, thus making the bicarbonate content of blood in the renal vein slightly higher than that in the renal artery. What happens to the H^+ produced simultaneously is a little more complicated. It would seem simplest to secrete these H^+ directly and independently into the tubular lumen and excrete them in the urine. However, the excretion of around 50 mmol of free H^+ per day in urine would lower urine pH to approximately 1.5 ($[H^+]$, ? 31 mmol/l), which the tubular epithelium cannot do, because it is only able to sustain a maximum pH gradient between plasma (pH ? 7.4; $[H^+]$? 40 nmol/l) and tubular fluid of 3 pH units (minimum urine pH ? 4.5; $[H^+]$? 31 600 nmol/l). The extra H^+ are excreted in two different ways: as titratable acid and as NH_4^+.

Excretion of titratable acid

Some of the extra H^+ are secreted into the lumen, where they can react with buffer anions in the tubular fluid (principally filtered HPO_4^{2-}); any buffer that is not reabsorbed will therefore excrete acid. The total amount of H^+ lost in the urine in this way can be determined by back-titrating the urine with a strong base, such as NaOH, until the urine pH is raised to 7.4 (that of arterial plasma); hence the term 'titratable acid'. It usually amounts to about 20 mmol/day. Approximately half the titratable acid production occurs in the proximal tubule, where tubular fluid pH falls to around 6.8 (equal to the pK of the $HPO_4^{2-}/H_2PO_4^-$ buffer system). The remainder occurs in the collecting duct, where H^+ can be secreted against a higher concentration gradient and consequently, as indicated above, urine pH can fall to approximately 4.5.

Excretion of ammonium

The proximal tubular cells are capable of taking up the amino acid glutamine and deaminating it to form NH_4^+ and a-ketoglutarate. NH_4^+ is secreted into the tubular lumen (substituting for H^+ on the Na^+/H^+ exchanger—Fig. 4) and eventually excreted, whereas a-ketoglutarate is converted to glucose, through reactions that consume H^+. The secreted H^+ (in NH_4^+) is generated from CO_2 and H_2O, and the HCO_3^- that is formed at the same time is added to plasma. It is important that the NH_4^+ produced from glutamine enters the tubular fluid and not the plasma: if it did so it would be taken up by the liver and combined with bicarbonate to produce urea ($CO(NH_2)_2$) and CO_2, effectively neutralizing the bicarbonate generated in the proximal tubule thus: $2NH_4^+ + 2HCO_3^- \rightarrow CO(NH_2)_2 + CO_2 + 3H_2O$. In severe liver disease, metabolic alkalosis occurs because urea synthesis is impaired and bicarbonate consumption in this way is reduced. The converse of this is that when whole kidney NH_4^+ production and 'new' bicarbonate generation are impaired (as in chronic renal failure), continuing synthesis of urea by the liver will generate unneutralized H^+ (from CO_2), which may contribute to the metabolic acidosis of uraemia. This renal NH_4^+ system for the generation of 'new' bicarbonate is adaptable: the activity of the glutaminase enzyme that deaminates glutamine is enhanced during acidosis (including intracellular acidosis due to chronic hypokalaemia).

The elimination of NH_4^+ in the urine occurs only after a complicated process that involves active NH_4^+ secretion in the proximal tubule, NH_4^+ reabsorption in the thick ascending limb of the loop of Henle (which can be blocked by the loop diuretic frusemide—see under urinary acidification and the diagnosis of renal tubular acidosis), and finally, NH_3 secretion by diffusion into the collecting duct. The reabsorption of NH_4^+ in the thick ascending limb leads to accumulation of NH_4^+ in the medullary interstitium, which is increased further by countercurrent multiplication (similar to generation of the corticomedullary osmotic gradient for urinary concentration). At the pH of interstitial fluid, and with a high medullary concentration of NH_4^+, some dissociates and increases the local level of NH_3. This can then diffuse into the collecting duct, where owing to the lower pH it is converted to NH_4^+ again, trapped in the tubular lumen, and excreted. This conversion maintains a concentration gradient for further NH_3 diffusion into the collecting duct ('diffusion trapping'). Anything that interferes with H^+ secretion in the collecting duct, as in distal renal tubular acidosis, would be expected to reduce diffusion trapping and thereby cause not only a higher urine pH (which depends on the presence of free H^+), but also a reduction in NH_4^+ and titratable acid (net acid) excretion; in fact some authorities advocate defining renal tubular acidosis in terms of reduced NH_4^+ excretion. The converse of this is decreased availability of NH_3 (as in hyperkalaemia, which suppresses NH_3 synthesis), but relatively normal tubular H^+ secretion per nephron. In this situation, urine pH will be low (because of less NH_3 to buffer H^+) and net acid excretion reduced. Like distal renal tubular acidosis, in chronic renal failure (uraemic acidosis), urinary excretion of NH_4^+ and titratable acid (mainly phosphate) is decreased; however in contrast to renal tubular acidosis, urine pH is usually low, and when the amounts of excreted phosphate and NH_4^+ are corrected for the reduced glomerular filtration rate (i.e. excretion per nephron), they are both normal or even increased.

What determines the presence of acidosis?

The following factors are important:

1. H^+ intake and endogenous generation;
2. Net H^+ excretion in urine = urinary [titratable acid] + $[NH_4^+]$ – $[HCO_3^-]$;
3. [titratable acid] in urine is dependent on urine pH and the amount of buffer available;
4. $[NH_4^+]$ in urine is dependent on NH_3/NH_4^+ generation and delivery (proximal tubule secretion, thick ascending loop reabsorption, and diffusion trapping in the collecting duct); and
5. $[HCO_3^-]$ in urine is dependent on urine pH and pCO_2.

Specific transport proteins differentially located on the apical and basolateral membrane of tubular cells mediate the processes described above. They are either responsible for H^+ or HCO_3^- transport. The Na^+/H^+ exchanger and H^+-ATPase, together with a small and uncertain contribution from a renal H^+/K^+-ATPase (similar to that found in the stomach) are responsible for H^+ secretion. Six isoforms of the Na^+/H^+ exchanger have been identified (NHE-1 to NHE-6), but so far none has been linked to a clinical form of renal tubular acidosis. The H^+-ATPase is not a single protein, but composed of at least nine distinct subunits. It is found mainly in the distal nephron, although it is also present in the proximal tubule and loop of Henle. The role of the H^+/K^+-ATPase in normal urinary acidification is still debated, although it seems to be upregulated along the distal nephron in potassium deficiency.

To generalize, it can be said that the main exit pathway for bicarbonate from tubular cells of the proximal tubule and loop of Henle is the Na^+-HCO_3^- cotransporter, while from cells of the distal nephron it is the Cl^-/HCO_3^- exchanger. The latter transporter can also mediate HCO_3^- secretion when present in the luminal cell membrane.

Nomenclature of the renal tubular acidoses

The 'old' numbered classification of renal tubular acidosis is a chronological one and reflects historical description of clinical disease. The numbering is often a source of great confusion to students and doctors alike, since it is not based on any functional understanding of acid excretion by the nephron. It is easier to subdivide renal tubular acidosis into proximal ('old' type II) and distal ('old' type I) nephron types (which may be inherited, or due to a variety of drugs or systemic diseases) and to consider underlying mechanisms. What is now emerging is that we can begin to subclassify these two main types according to the transport defect of acid excretion. The fact that several of the transporters involved in the renal handling of H^+ and HCO_3^- have now been cloned means that our classification of renal tubular acidosis is likely to change in the future, to one based on underlying and specific molecular transport defects.

Tests to diagnose renal tubular acidosis

From the above, it is apparent that in the presence of a normal glomerular filtration rate, renal tubular acidosis can result from (alone or in combination): (1) failure to reclaim filtered bicarbonate in the proximal tubule; (2) failure to generate and excrete NH_4^+; and (3) impaired H^+ secretion along the distal nephron. The finding of a low serum bicarbonate concentration in an appropriate clinical context should raise the possibility of renal tubular acidosis, but to make the diagnosis, specialized tests are usually required. A variety of such tests have been described, some of which we find to be more useful than others, as indicated below.

Measurement of urinary pH and HCO_3^- excretion

Dipstix urine pH values are unreliable: pH should be measured in a freshly passed specimen of urine with a glass pH electrode. The pH of a urine sample that has been left to stand, and has not been covered with a film of oil, will rise as CO_2 is lost; this is usually the reason for a measured urine pH of higher than 8, unless it is infected (high NH_4^+ from urea-splitting organisms).

Whilst a high urinary pH might lead one to diagnose renal tubular acidosis in an acidotic patient with normal glomerular filtration rate and uninfected urine, especially if they had nephrocalcinosis and/or urinary stones, the diagnosis of renal tubular acidosis cannot be based on the measurement of urine pH alone. For example, even in the presence of systemic acidosis, and excluding chronic renal failure, a low urine pH may not rule out a diagnosis of renal tubular acidosis, since renal acid excretion can still be impaired if the generation and delivery of NH_3/NH_4^+ are reduced. In addition, in proximal renal tubular acidosis, when bicarbonate reabsorption is impaired, urine pH can be low (rather than high) if previous loss of bicarbonate has lowered plasma $[HCO_3^-]$ to such a level (less than 18 mmol/l) that the filtered load of bicarbonate is then decreased, resulting in low urinary bicarbonate excretion. In this situation, failure of the proximal tubule to reabsorb bicarbonate can only be demonstrated by showing a high fractional (as a proportion of the amount of filtered bicarbonate) excretion (urinary $[HCO_3^-]$/plasma $[HCO_3^-]$ × plasma

[creatinine]/urinary [creatinine]) × 100 per cent), although to do this plasma [HCO_3^-] must be increased to approximately 24 mmol/l by intravenous infusion of bicarbonate. Fractional bicarbonate excretion is normally less than 5 per cent, but in proximal renal tubular acidosis it exceeds 15 per cent. Ammonium generation can also be reduced in proximal renal tubular acidosis (as part of more generalized proximal tubular dysfunction), which may be another reason for the finding of a low urine pH.

Urinary net negative charge and osmolal gap

The difficulty in interpretation of urinary pH in isolation is why some have argued for the calculation of the urinary net charge, or anion gap ([Na^+] + [K^+] – [Cl^-]), which is usually negative (because Cl^- is balanced by unmeasured NH_4^+), to estimate urinary NH_4^+concentration indirectly. Because a non-renal cause of metabolic acidosis will increase NH_4^+ generation and excretion (making the net charge more negative), reduced NH_4^+ excretion is evident as a positive net charge, which would indicate a renal cause for acidosis, including uraemic acidosis (chronic renal failure). However, an increase in the excretion of ketoacid anions (such as in diabetic ketoacidosis) will also make the net charge positive, despite increased NH_4^+ excretion, because excreted NH_4^+ accompanies unmeasured ketoacid anions (A^-), rather than measured Cl^-.

To get around the problem of unmeasured anions, calculation of the urinary osmolal gap (urine osmolality-(2 × ([Na^+] + [K^+]) + [urea] + [glucose])) has been proposed. Assuming that NH_4^+ and its accompanying anion constitute the main unmeasured osmotically active particles in the urine, then urinary [NH_4^+] is approximately half the osmolal gap. A low osmolal gap suggests low NH_4^+ excretion and thus a defect of renal acidification. However, to determine where the defect might lie, urine pH must still be measured: if it is high (more than 6), there may be reduced distal H^+ excretion or increased distal delivery of HCO_3^-, that is, distal or proximal renal tubular acidosis, respectively; if urine pH is low (less than 5), there may be chronic renal failure (low glomerular filtration rate) or hyperkalaemia (inhibiting NH_4^+ generation); an intermediate urine pH of 5 to 6 is said to indicate renal interstitial disease.

However, despite the sound theory, there are too many confounding variables, and both estimation of urinary net negative charge and osmolal gap fail to distinguish reliably between the acidosis of chronic renal failure and renal tubular acidosis. In our opinion these measurements often seem confusing and are of limited practical value in the diagnosis of renal tubular acidosis.

Urinary pCO_2/blood difference

Since the distal nephron H^+ secretory mechanism is intact in proximal renal tubular acidosis, measurement of the urine–blood pCO_2 (U–B pCO_2) difference has been proposed as a means of distinguishing proximal from distal renal tubular acidosis. In the presence of adequate bicarbonaturia and alkaline urine (pH greater than 7.4; intravenous bicarbonate may be necessary to achieve this) this difference is high (around 30 mmHg (4 kPa) or more), whereas it is low (less than 25 mmHg) when distal H^+ secretion is defective. This test is also said to distinguish between reduced distal H^+ secretion due to a primary secretory ('pump') defect and that due to increased cell membrane permeability and backleak of H^+ (see Table 5). Whilst there are theoretical reasons why this may be so, our incomplete understanding of the factors that determine urinary pCO_2 make interpretation difficult; moreover, in practice the test is not easy to perform and results can be variable. Like the urinary anion and osmolal gaps, we do not find it clinically useful.

Acid loading

The most straightforward and reliable means of making the diagnosis of impaired distal nephron acidification is an acid load test. The easiest and best-established method is the short oral ammonium chloride (0.1 g/kg) test of Wrong and Davies. The criterion for a diagnosis of a distal acidification defect is a failure to lower urine pH to less than 5.5, making measurements as urine is passed for at least 6 h (and up to 8 h) after the ingestion of NH_4Cl.

A simpler test, which compares well with the NH_4Cl test in normal subjects, although it has not been formally validated in patients with renal tubular acidosis, is the frusemide/fludrocortisone test. In this much more palatable test, a single dose of fludrocortisone (1 mg) is given orally, followed 1 h later by oral frusemide (40 mg), and urine pH measured for up to 5 h; again the threshold pH is 5.5. Frusemide works by enhancing H^+ secretion through increased delivery of Na^+ (from the thick ascending limb) to the distal tubule and collecting duct, where increased Na^+ reabsorption facilitates H^+ secretion; fludrocortisone directly stimulates both distal Na^+ reabsorption and H^+ secretion. Frusemide may also promote NH_4^+ excretion by blocking its reabsorption in the thick ascending limb, which could be used to demonstrate that impaired NH_4^+ generation *per se* is not the primary cause of reduced distal acidification. In distal renal tubular acidosis secondary to a defect of H^+ secretion, frusemide should still increase NH_4^+ excretion, although it may be less than normal.

The clinical features of renal tubular acidosis

A hyperchloraemic (normal anion gap) metabolic acidosis is a feature of both proximal and distal forms of renal tubular acidosis.

Proximal renal tubular acidosis

As already mentioned, urine pH in this form of renal tubular acidosis (also known as type 2) is often within the normal range; plasma bicarbonate concentration can range between 10 and 20 mmol/l. This type of renal tubular acidosis is uncommon and an isolated failure to reabsorb bicarbonate is unusual. Most cases are associated with other proximal tubular transport defects, as in the Fanconi syndrome, which may have many causes (see Table 5). Thus, it is likely that other clues to a primary abnormality of proximal tubular function will be present, such as glycosuria, hyperphosphaturia (hypophosphataemia), hyperuricosuria (hypouricaemia), aminoaciduria, and tubular (low molecular weight, e.g. retinol-binding protein) proteinuria. Osteomalacia (rickets and growth retardation in children) is common and due to impaired synthesis of active metabolites of vitamin D and urinary loss of 25-OH vitamin D.

Although hypercalciuria and hyperphosphaturia occur, nephrocalcinosis or urinary stones are rare, probably because of the associated increase in urinary citrate excretion. However, nephrocalcinosis is sometimes seen as a consequence of treatment with vitamin D, calcium, and phosphate supplements, and is often attributable to periods of iatrogenic hypercalcaemia.

Hypokalaemia is common and probably a consequence of osmotic diuresis due to reduced solute reabsorption (mainly bicarbonate) in the proximal tubule, leading to increased flow rate in the distal nephron, the site of potassium secretion. For this reason, bicarbonate supplementation tends to exacerbate hypokalaemia.

The molecular basis of a particular form of inherited non-cystinotic Fanconi syndrome, now known as Dent's disease, has been defined. This condition is X-linked (Xp11.22) and recessive, typically (about 80 per cent) presenting with nephrocalcinosis and urolithiasis, hypercalciuria, and progressive renal failure. A proportion of cases are initially thought to have a proximal or distal type of renal tubular acidosis. The reason for is that the underlying defect is a mutation of an intracellular membrane-associated chloride channel (ClC-5) found in cells of the proximal tubule, thick ascending loop, and collecting duct (a-intercalated cells) (Fig. 5). This channel appears to be involved in normal endosomal function (acidification), which affects both the reabsorption of low-molecular weight-proteins in the proximal tubule and perhaps the normal turnover and recruitment (recycling) to the luminal membrane of transport proteins, like the H^+-ATPase of the a-intercalated cell. Tubular proteinuria is a characteristic feature, distinguishing it from distal renal tubular acidosis proper.

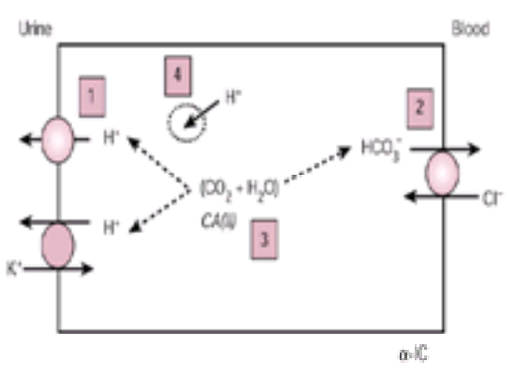

Fig. 5 Diagram of the a-intercalated cell (a-IC) of the collecting duct, showing the sites of ion transport defects that have been linked to distal renal tubular acidosis (dRTA). In boxes: **1**, H^+-ATPase mutations in recessive dRTA with and without deafness; **2**, Cl^-/HCO_3^- exchanger mutation in dominant (and recessive) dRTA; **3**, CA-II (carbonic anhydrase) deficiency in inherited mixed pRTA and dRTA; **4**, Cl^- channel (ClC-5) mutation in Dent's disease (pRTA/Fanconi with some dRTA features).

Because the proximal tubule is the dominant site of bicarbonate reabsorption, and this is ultimately dependent on CA-II activity, lack of this enzyme produces a predominantly proximal form of renal tubular acidosis, although it is widely expressed along the nephron. This type of proximal renal tubular acidosis is very rare and associated with increased bone mineralization (osteopetrosis), deafness, and cerebral calcification. Interestingly, a recent publication describing a *CA-II* 'knockout' mouse with renal tubular acidosis (but without bicarbonaturia) demonstrated that the condition could be partially corrected by gene therapy (retrograde injection of *CA-II* cDNA in liposomes), which restored *CA-II* function to the distal nephron.

Distal renal tubular acidosis

The most common form of renal tubular acidosis is 'classic' (or type 1) distal renal tubular acidosis and is due to an underlying defect of H^+ secretion ('pump defect'). The key feature of this form of renal tubular acidosis is an inability to lower urine pH below 5.5. In the absence of systemic acidosis, a patient who cannot reduce their urine pH to less than 5.5 in the face of an acid load is said have the 'incomplete' form. In patients with 'complete' distal renal tubular acidosis, plasma bicarbonate concentration usually ranges between 15 and 20 mmol/l, but can fall to less than 10 mmol/l in severe cases. In patients with 'incomplete' distal renal tubular acidosis, NH_4^+ excretion is normal (in relation to glomerular filtration rate) and this may be why these patients are not acidotic and their plasma bicarbonate concentration stays within the normal range. The causes of distal renal tubular acidosis are listed in Table 5.

Hypokalaemia can occur, especially in the autoimmune form (such as Sjögren's syndrome) and when there is systemic acidosis, but it is not as consistent a feature as it is in proximal renal tubular acidosis. Nephrocalcinosis is common and present in 70 to 80 per cent of adults, whether or not they have a systemic acidosis. Osteomalacia (rickets in children) is seen only in acidotic patients with 'complete' distal renal tubular acidosis. Hypercalciuria is said to be a feature of this form of renal tubular acidosis, but it is not a consistent finding and may depend on the presence of systemic acidosis and resulting calcium loss from bone.

A characteristic of distal renal tubular acidosis, which can be useful in screening for this condition in children, is a low urinary excretion of citrate, which in alkaline urine is normally increased. The probable explanation for reduced citrate excretion in distal renal tubular acidosis is that it is reabsorbed in the proximal tubule by a mechanism dependent on intracellular pH: intracellular acidosis (due to systemic acidosis or chronic hypokalaemia) increases mitochondrial metabolism of citrate and thus its reabsorption. In addition, trivalent citrate buffers H^+ in systemic acidosis and is converted to the more readily reabsorbed divalent form. Because it inhibits the precipitation of calcium salts (mainly phosphate), reduced citrate delivery to the distal nephron is a key factor in the development of nephrocalcinosis and urinary stone disease in distal renal tubular acidosis.

The main site of H^+ secretion along the distal nephron is the H^+-ATPase in the luminal cell membrane of the a-intercalated cell (Fig. 5). As already described, H^+ and HCO_3^- are generated from intracellular hydration of CO_2, the latter exiting the basolateral cell membrane in exchange for Cl^- by an anion exchanger (AE1). This basolateral exchanger is essential for normal apical H^+ secretion in the a-intercalated cell and it has been established that a mutation of the gene encoding this transport protein is the cause of dominantly inherited distal renal tubular acidosis and some cases of the recessive form without deafness. Recessive distal renal tubular acidosis with deafness is due to a mutation of the B1 subunit of the H^+-ATPase (and recently another H^+-ATPase subunit mutation in some cases without deafness). However, unlike the dominant form, the recessive form appears to be genetically heterogeneous. Expression of both these transport proteins is decreased in the collecting duct a-intercalated cells of patients with autoimmune distal renal tubular acidosis.

A rare drug-related form of distal renal tubular acidosis with hypokalaemia is that due to amphotericin B. This drug accumulates in the kidney and increases the permeability of the tubular cell membrane, resulting in a back-leak of secreted H^+ ('permeability' or 'gradient' defect) and failure to maintain the plasma–urine pH gradient across the tubular epithelium.

Distal renal tubular acidosis with hyperkalaemia is also known as type IV renal tubular acidosis, or voltage-dependent renal tubular acidosis. It occurs in situations in which the lumen negative potential difference along the distal nephron (Fig. 4) is reduced. This normally facilitates potassium and hydrogen ion secretion, depends on sodium reabsorption, and is stimulated by aldosterone. Thus, when sodium reabsorption through the epithelial Na^+ channel is reduced by drugs like amiloride and trimethoprim, or when the Na^+ channel is inactive (autosomal recessive pseudohypoaldosteronism type 1a), there is a decrease in both potassium and hydrogen ion secretion, leading to hyperkalaemia and metabolic acidosis. Because of the stimulatory effect of aldosterone, this form of renal tubular acidosis is also seen in states of hypoaldosteronism.

Another rare and inherited form of hyperkalaemic renal tubular acidosis is autosomal dominant pseudohypoaldosteronism type II, or Gordon's syndrome. The transport defect underlying this condition remains unknown, although it has been proposed that an abnormal increase in collecting duct permeability to Cl^- is responsible, leading to a decrease in the lumen negative potential difference. In contrast to patients with the type 1 variant of pseudohypoaldosteronism, these patients are usually hypertensive, and their blood pressure and hyperkalaemia are particularly responsive to thiazide diuretics.

In all forms of hyperkalaemia, renal NH_3/NH_4^+ generation is reduced, which also impairs acid excretion and exacerbates systemic acidosis.

Treatment

Administration of oral bicarbonate, which can also be given as citrate, is the mainstay of treatment in all forms of renal tubular acidosis, unless the underlying defect can be corrected (for instance drug withdrawal or aldosterone replacement). It can prevent the long-term complications of rickets and growth retardation, and may also limit the progression of nephrocalcinosis and ephrolithiasis in distal renal tubular acidosis by increasing citrate excretion. In both proximal renal tubular acidosis and 'classic' distal renal tubular acidosis, a potassium supplement may also be necessary, since oral sodium bicarbonate tends to increase urinary potassium loss.

Treatment that is more specific to proximal renal tubular acidosis may include vitamin D, calcium, and phosphate supplementation; a thiazide diuretic can also be tried, so as to increase bicarbonate reabsorption (secondary to mild extracellular volume contraction), but this may also exacerbate the tendency to hypokalaemia.

In distal renal tubular acidosis, plasma bicarbonate concentration should be maintained above 20 mmol/l. Morbidity in classic distal renal tubular acidosis is due to calcium phosphate renal stones; endstage renal failure is a rare complication and is usually the result of unrecognized urinary tract obstruction and recurrent infection. In hyperkalaemic distal renal tubular acidosis, a loop diuretic plus fludrocortisone, or an ion exchange resin, can be used to control the hyperkalaemia, and improve NH_3/NH_4^+ generation and thus acid excretion.

A seeming contradiction in the treatment of distal renal tubular acidosis with nephrocalcinosis and urolithiasis is the use of alkali therapy. On the one hand, this treatment will correct acidosis-related hypercalciuria and increase urinary citrate excretion, which should reduce or arrest nephrocalcinosis and stone formation. On the other hand, calcium phosphate precipitation (the main component of nephrocalcinosis and stones related to distal renal tubular acidosis) is favoured by an alkaline urine pH, and if bicarbonate is given as the sodium salt, this will also tend to increase urinary calcium excretion. It is possible that these opposing effects are why amelioration of nephrocalcinosis is often not seen in treated patients followed long-term.

20.14 Urinary tract obstruction

L. R. I. Baker

Introduction

If the flow of urine is impeded at any point in its course from the renal calices to the exterior, urinary tract obstruction is present. The terms 'obstructive uropathy', 'obstructive nephropathy', and 'hydronephrosis' are frequently used interchangeably and are taken to have the same meaning as the term 'urinary tract obstruction'. A more rigorous approach is preferable: 'obstructive uropathy' should be taken to mean pathological change occurring in the urinary tract and kidney consequent upon urinary tract obstruction. 'Obstructive nephropathy' is present when pathological change in the kidney resulting from urinary tract obstruction is associated with prolongation of the transit time of glomerular filtrate down the nephron. The term 'hydronephrosis' should be taken to denote dilatation of the renal pelvis and calyceal system.

Intraluminal obstruction between the commencement of the proximal tubule and the distal end of the collecting duct, such as occurs in uric acid nephropathy, as a result of sulphonamide crystal deposition, and in multiple myelomatosis, falls outside the definition of urinary tract obstruction employed here and will not be considered further.

Although dilatation of the outflow system proximal to the site of obstruction is a characteristic finding, widening of the ureter and/or pelvicalyceal system does not necessarily indicate the presence of obstruction. Causes of such anatomical abnormality in the absence of obstruction are listed in Table 1.

Obstruction may be partial or complete, unilateral or bilateral. Bilateral obstruction, or obstruction of a single kidney, is a greater threat to the patient than unilateral obstruction. Obstruction associated with infection is a greater threat to kidney function and to life than obstruction in the absence of infection. Since it is common, and often reversible, obstruction of the urinary tract should be considered in every uraemic patient, whether acute or chronic.

Incidence

Urinary tract obstruction occurs most frequently in the young and the old. Hydronephrosis is the most common cause of an abdominal mass in neonates, and obstruction, usually due to congenital abnormalities, is also relatively common in children. Its incidence declines after the age of 10 and is at its lowest in middle age, but begins to rise again after the age of 60, particularly in males, in whom the commonest cause is prostatic enlargement. Although the overall frequency of urinary tract obstruction is the same in both sexes, between 20 and 60 years of age it is more frequent in women, and over the age of 60 years the reverse is true. Urinary tract obstruction has been found in 3.8 per cent of a large series of routine autopsies and 25 per cent of autopsies carried out upon uraemic patients.

Causes

Obstructing lesions may lie within the lumen or the wall of the urinary tract, or may cause obstruction by pressure from outside, the major causes in each group being listed in Table 2.

Calculi and neuromuscular malfunction at the junction of the renal pelvis and ureter are common causes of unilateral obstruction. Prostatic obstruction, stone disease, and bladder tumours account for approximately 75 per cent of cases of bilateral obstruction in developed countries. Wide geographical variations occur in the relative incidence of some causes of obstruction, for example schistosomiasis. To the clinician, the most important questions are whether urinary tract obstruction affects the upper or the lower urinary tract, and whether it is of recent onset (acute obstruction) or is long-standing (chronic obstruction).

Pathophysiology

Acute upper tract obstruction

Urine flows from the kidney to the bladder as a result of ureteric and pelvic peristalsis, the effects of gravity, and the pressure of glomerular filtration. Peristalsis normally generates high pressures within the ureteric lumen, sufficient to propel urine down the ureter without the transmission of the increased pressure to the renal parenchyma. Initially, an upward movement occurs in the ureter: thereafter, proximal contraction of ureteric circular muscle, with eventual complete occlusion of the lumen, forms a bolus of urine. Contraction of longitudinal smooth muscle then propels the bolus along the ureter. Baseline ureteric pressure is similar to that in the renal pelvis, but during this process rises to values between 10 and 25 mmHg. These pressures are not transmitted to the renal pelvis, where pressure seldom rises above 4 mmHg.

Any change in blood flow or glomerular filtration rate resulting from ureteric obstruction would have important effects on tubular pressures and flows. In humans, the time of onset of obstruction is seldom known with any precision, and methods of measurement of renal blood flow or filtration rate using clearance techniques are indirect and depend upon tubular function, which is affected by urinary tract obstruction; hence pathophysiological explanations must depend on animal experiments. In the normal dog, pressure within the ureter more than doubles when the ureteric lumen is occluded during peristalsis, and similar changes occur in ureteric wall tension. Baseline and peak pressure and wall tensions are about twice as high as control values 3 min after acute ureteric obstruction; at 5 to 20 min they

approximate to peak values; and at 1 h there is a threefold increase. At this point, occlusion of the ureter fails to occur and pressures generated by ureteric wall tension are transmitted to the renal pelvis and parenchyma. Any further increase in pressure results in dilatation of the ureter.

The effect of an increase in pressure within the ureter transmitted to the nephron depends upon the degree of obstruction (whether complete or incomplete), whether obstruction is unilateral or bilateral, and the duration of obstruction. In the dog, renal blood flow falls to 50 per cent of control values 3 or 4 days after induction of complete ureteric obstruction and at 4 weeks it is about one-third that of the contralateral unobstructed kidney. Three phases, which are not well understood, are discernible in the relationship between changes in ureteral pressure and renal blood flow with time (Fig. 1). Phase I occurs during the first hour after induction of obstruction. Renal blood flow increases, presumably owing to a reduction in intrarenal vascular resistance, associated with a gradual increase in ureteric pressure. In phase II, which takes place over the next 2 to 5 h, ureteric pressure continues to rise and renal blood flow begins to fall. Thereafter, in phase III, renal blood flow continues to fall and ureteric pressure returns towards or to normal.

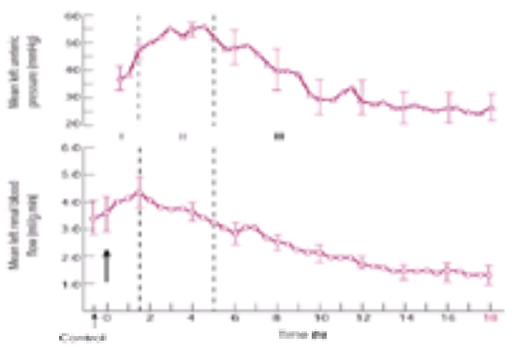

Fig. 1 The relationship between ipsilateral renal blood flow and ureteric pressure during experimental ureteric occlusion in the dog. In phase I, renal blood flow and ureteric pressure rise. In phase II, blood flow declines while ureteric pressure continues to rise. In phase III, both renal blood flow and ureteric pressure decline. The arrow indicates the time of ureteric occlusion. Mean ± standard error; $n = 5$. (Reprinted with permission from Moody *et al.* 1975.)

Chronic upper tract obstruction

Three months after the production of experimental obstruction in dogs, baseline ureteric wall tension is increased and there is no difference between baseline and peak values of wall tension, the latter being measured during ureteric occlusion. By contrast, baseline and peak pressures within the ureteric lumen are not significantly different from control values. This is a consequence of the relationship between pressure and wall tension expressed in Laplace's law, which states that $P = K(T/R)$, where P is the transluminal pressure, K is a constant, T is wall tension, and R is the radius of the ureter. In chronic obstruction, therefore, normal intraluminal pressures are maintained as a consequence of ureteric dilatation.

These experimental findings suggest that the major component of damage to the kidney due to obstruction occurs soon after its onset. In humans the highest measured ureteric pressures have been found during acute obstruction (as high as 50 mmHg during passage of a stone) and there appears to be an inverse relationship between pressure within the renal pelvis and time of measurement in patients with complete obstruction. The notion that chronic obstruction with dilatation of the ureter may be relatively benign is supported by the observation that patients with incomplete urinary tract obstruction due to congenital anomalies lose renal function only slowly.

Acute lower tract obstruction

The mechanical efficiency of smooth muscle fibres is reduced when they become overstretched. As obstruction to bladder outflow increases, a point is reached when acute urinary retention will result. Factors which may precipitate acute retention include a sudden diuresis, such as occurs after diuretic therapy (particularly loop agents) for heart failure, urinary infection, and drugs that have pharmacological effects upon the bladder, provoking retention, such as those with antimuscarinic and calcium channel blocking activity.

Chronic lower tract obstruction

In adults, chronic obstruction of the outflow from the bladder is most commonly due to benign prostatic hypertrophy. Prostatic malignancy and urethral strictures may also be responsible. In children, posterior urethral valves and urethral strictures are most often the cause. Such organic causes are easy to understand, but functional obstruction may occur at the bladder neck and at the level of the distal sphincter owing to a failure of co-ordination between bladder contraction and sphincter relaxation. The bladder wall may become increasingly compliant or non-compliant: this is of significance to the urologist, since patients with poorly compliant bladders fare much better after removal of the obstruction than those with highly compliant bladders. The highly compliant bladder tends not to be associated with upper tract dilatation, whereas the high pressure that exists within a bladder of low compliance may be transmitted to the upper tracts and may be the cause of renal impairment, which on occasion will be severe.

Histopathological changes

Acute obstruction results in increased ureteric pressure and decreased renal blood flow, and may be complicated by bacterial infection. The rise in intraluminal pressure and dilatation of the system proximal to the site of obstruction both result in compression of the renal substance. In the early phase of obstruction, the kidney becomes oedematous and haemorrhagic; tubular dilatation initially affects mainly the collecting duct and distal tubular segments; and Bowman's space may be dilated. The ducts of Bellini are first affected by dilatation of the system proximal to the site of obstruction. Subsequently, other papillary structures are affected, and ultimately compression of renal cortical tissue occurs with thinning of the renal parenchyma. Enlargement of the kidney occurs in association with dilatation of the renal pelvis.

Atrophy of the renal parenchyma with reduction in size of the kidney (obstructive atrophy) is believed to result from the effects of compression of the renal parenchyma and from prolonged renal ischaemia. Slowly progressive increasing resistance to outflow tends to result in gross dilatation of the collecting system, dilated calyces, and the renal pelvis being surrounded by only a thin rim of renal parenchyma. In acute complete obstruction dilatation tends to be less marked.

In patients with long-standing obstruction there is flattening of the renal tubular epithelium, periglomerular fibrosis, interstitial fibrosis, and mononuclear cell infiltration. These changes are thought to result in part from renal ischaemia and in part to reflect the effects of bacterial infection (Fig. 2).

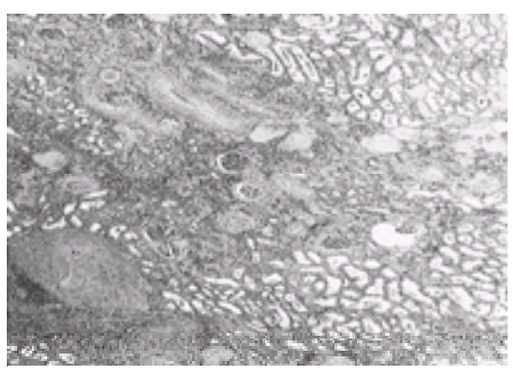

Fig. 2 Histological appearances in long-standing obstruction. Note dilated tubules, interstitial fibrosis, vessel wall thickening, and global sclerosis of some glomeruli.

Effects of obstruction upon renal function

Little detailed information is available about the effects of urinary tract obstruction on the glomerular filtration rate in humans, but it is clear that ureteric obstruction results in a marked fall in glomerular filtration rate, and that incomplete bilateral obstruction causes progressive renal failure. Glomerular filtration must continue to some extent even after development of complete acute obstruction since a nephrogram (albeit a delayed one) can be obtained after injection of intravenous contrast medium during urography.

Distal tubular function is more strikingly disturbed than proximal tubular function in chronically increased resistance to outflow, as would be expected from the histopathological findings. A characteristic feature of patients with such pathology is an impaired ability to concentrate urine. The concentration defect is resistant to administration of antidiuretic hormone and is thus an example of nephrogenic diabetes insipidus. Such patients may present with polyuria, dehydration, and hypernatraemia secondary to a reduction in free water reabsorption. Animal experiments indicate that production of cyclic AMP in response to vasopressin is reduced in chronic partial obstruction and this may, in part, explain the concentration defect. The extent to which the need to excrete an increased solute load in bilateral ureteric obstruction contributes to the concentration defect is unclear. Chronically increased bilateral resistance to outflow in humans may be associated with a salt-losing state, although the frequency with which this occurs has not been defined.

Since ureteric obstruction preferentially affects distal segments of the nephron, an acidification defect is associated with chronically increased resistance to outflow in humans. In many patients with obstructive nephropathy, urinary pH is inappropriately high for any associated degree of metabolic acidosis. This distal renal tubular acidosis is present in both unilateral and bilateral ureteric obstruction, and may be associated with hyperkalaemia.

Renal function after relief of obstruction

The relationship between duration of obstruction and recovery of function has been defined in experimental animals. In dogs subjected to unilateral ureteric ligation the ipsilateral glomerular filtration rate was 25 per cent of the ipsilateral control value and 16 per cent of that concurrently measured in the contralateral kidney when a ligature causing complete obstruction was removed after 1 week. This discrepancy resulted from a compensatory increase in function of the non-obstructed kidney during the week of complete obstruction of its partner. Improvement in the glomerular filtration rate of the previously obstructed kidney continued up to, but not beyond, 2 months after release of the obstruction, but complete recovery never occurred, maximum improvement being to only 50 per cent of the glomerular filtration rate of the non-obstructed kidney.

In humans, renal blood flow increases after relief of obstruction and the glomerular filtration rate either remains the same or increases, but no large study has been performed in which the duration of obstruction has been correlated with the degree of recovery of glomerular filtration rate. However, there is no reason to doubt that the extent of recovery depends upon whether the resistance to outflow is mild or severe, the duration of obstruction, and whether or not obstruction is complicated by bacterial infection.

After relief of prolonged bilateral obstruction or obstruction of a functionally or anatomically single kidney, there may follow a pronounced salt and water diuresis and kaliuresis, requiring appropriate oral or intravenous replacement. This is usually attributed to damage to the renal tubules and collecting ducts induced by the resistance to outflow, resulting in failure of sodium, water, and potassium conservation. However, this cannot be the sole explanation because a salt, water, and potassium diuresis is not seen as a clinical problem in humans following relief of unilateral obstruction. The osmotic diuretic effect of uraemia, hypervolaemia owing to salt and water retention, and perhaps retention in renal failure of natriuretic factors may play a part.

Hormonal changes induced by obstruction

Erythropoietin

Levels of erythropoietin are low in humans with renal failure due to obstructive uropathy, but neither the degree of anaemia nor the degree of depression of erythropoietin concentration is known to differ from that occurring in chronic renal failure of similar severity and different aetiology.

Erythraemia is a recognized association of chronic upper urinary tract obstruction and correction after relief of obstruction has been recorded. Erythropoietin concentrations in such patients have rarely been documented.

Vitamin D metabolism

Anatomical considerations suggest that renal 1a-hydroxylase activity might be particularly severely affected in chronic obstruction, but scant data are available in respect of levels of vitamin D metabolite and vitamin D metabolism in renal failure associated with obstruction, compared with renal failure of similar degree but of different aetiologies. There is an impression that osteomalacia may be more common in patients with chronic renal failure due to obstruction, but the fact that such renal failure is very slowly progressive may account for this. Among patients about to start dialysis, radiological evidence of hyperparathyroid bone disease is most common in those whose renal failure is a consequence of obstruction, even when a correction is applied for duration of renal failure and gender.

Hypertension and the renin–angiotensin system

Hypertension is more common in patients with bilateral urinary tract obstruction than in normal individuals matched for age and sex. The prevalence of hypertension resulting from unilateral obstruction is unknown.

An increase in total exchangeable sodium has been demonstrated in chronic bilateral upper tract obstruction, and blood pressure frequently returns to normal with correction of obstruction. Patients of this sort appear to have a volume-dependent form of hypertension consequent upon salt and water retention. Concentrations of renin in renal and peripheral veins are normal.

Patients with chronic unilateral ureteric obstruction and hypertension have been described in whom renal vein renin concentrations were elevated on the side of obstruction and in whom both blood pressure and renal vein renin concentration returned to normal after the relief of obstruction, but there are no clinical features or preoperative investigations that will predict outcome.

Atrial natriuretic peptide

Release of atrial natriuretic peptide is augmented in patients with bilateral ureteric obstruction and uraemia, probably owing to salt and water overload, and this may contribute to the postobstructive diuresis and natriuresis which occurs after surgical correction of the problem.

Clinical features

Acute upper tract obstruction

Typically, this gives rise to pain in the flank that may radiate to the iliac fossa, inguinal region, testis, or labium. The pain may be dull or sharp, intermittent or persistent, though waxing and waning in intensity. A high fluid intake, alcohol, or diuretics—all measures that increase urinary volume and distend the collecting system—may provoke it, which is particularly noticeable when obstruction occurs at the pelviureteric junction. Loin tenderness may be detected and an enlarged kidney felt. Upper urinary tract infection with malaise, fever, and symptoms and signs of septicaemia may dominate the clinical picture.

Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney. The differential diagnosis includes bilateral total renal cortical necrosis, acute anuric glomerulonephritis, and bilateral renal arterial occlusion. Intermittent anuria indicates the presence of intermittent complete

obstruction.

Chronic upper tract obstruction

Patients may present with flank or abdominal pain, renal failure, or both, and the symptoms and signs of urinary tract infection and septicaemia may be superimposed. Rarely, presentation is with erythraemia or hypertension and their complications. Some patients are asymptomatic, obstruction being found during investigation of another condition.

Polyuria often occurs when there is chronic resistance to outflow owing to impairment of the concentrating capacity of the renal tubules. Intermittent anuria and polyuria indicate intermittent complete and partial obstruction.

Acute lower tract obstruction

Acute urinary retention is often preceded by a history of symptoms of obstruction of bladder outflow. It is typically associated with severe suprapubic pain, but this may be absent if acute retention is superimposed on chronic retention or if there is an underlying neuropathy. A potential clinical pitfall is failure to recognize that patients who have had an epidural anaesthetic may develop painless acute retention of urine. Most modalities of bladder sensation are mediated via sacral parasympathetic nerves. The pain from overdistension of the bladder is sympathetically mediated and will be abolished by a high epidural reaching to D10. Obstetricians need to be particularly alert to this problem.

Pre-existing obstruction may have provoked changes in the bladder, such as muscle wall hypertrophy, sacculation, and diverticulum formation; these in turn predispose to persistence of lower urinary tract infection once acquired and occasionally to bladder stones. Epididymo-orchitis may occur.

Chronic lower tract obstruction

Symptoms may be minimal or may be accepted by the patient as within normal limits. Hesitancy, narrowing, and diminished force of the urinary stream, terminal dribbling, and a sense of incomplete bladder emptying are typical features. If a large volume of residual urine remains in the bladder after urination, the frequent passage of small volumes of urine may be a prominent symptom even in the absence of infection. Incontinence of such small volumes of urine is termed overflow incontinence or retention with overflow.

There are no pathognomonic clinical features that differentiate high-pressure and low-pressure chronic retention. In each the bladder may be palpably distended if the volume of residual urine is sufficient. The size and consistency of the prostate is variable.

Acute complete retention of urine, usually with severe suprapubic and perineal pain, may complicate chronic retention and is commonly precipitated by lower urinary tract infection. Frequency, urgency, urge incontinence, dysuria, strangury, suprapubic pain, haematuria, and cloudy, smelly urine may be present. Asymptomatic bacteriuria is common.

Examination of the abdomen and genitalia, and rectal and vaginal examination are essential. It should be noted that the apparent size of the prostate is a poor guide to the presence of prostatic obstruction. Median lobe enlargement of a palpably normal prostate may give rise to severe obstruction, whereas an apparently grossly enlarged gland may cause little or no obstruction.

Investigation

Acute upper urinary tract obstruction

The range and specificity of imaging techniques available for the investigation of possible upper urinary tract obstruction is continually expanding. The decision as to which method of investigation to use will be influenced by local expertise and availability, but new developments seem certain to alter the optimum plan of investigation in the future. At present ultrasonography, excretion urography, and computed tomography (**CT**) scanning compete for the role of first-line investigation in this field, each having its advantages and disadvantages. Magnetic resonance urography is an alternative investigation that is currently very little used but shows considerable promise.

Ultrasonography

Ultrasonography appears to be completely safe and is relatively inexpensive. It is non-invasive, no intravenous injection, exposure to radiation, or exposure to contrast medium being involved. It has become the first-line imaging procedure in many centres, but an ultrasound report saying 'normal kidneys and urinary tract' should not be taken as meaning 'obstruction is excluded'. A relative disadvantage is its dependence on the operator: the ultrasonographer sees much more during the course of an examination than the clinician examining the few images produced. Relatively minor degrees of upper tract dilatation may be missed, indicative in some cases of clinically important obstruction. Ultrasound may visualize a few centimetres of dilated upper ureter and can show a dilated distal ureter posterior to the bladder, but it does not visualize most of the mid ureter. Calculi are easily missed: those in a dilated upper or lower ureter may be detected, but since much of the ureter is not visualized, ultrasonography cannot diagnose many ureteric calculi and hence should be accompanied by a full-length plain abdominal radiograph and, if necessary (usually owing to bowel gas overlying the renal areas), plain tomograms. Ultrasonography is less sensitive for detection of opaque renal calculi than either plain films and plain renal tomography or CT. The site and nature of obstruction often cannot be defined by ultrasonography, and upper tract dilatation on ultrasound (Fig. 3) is not synonymous with urinary tract obstruction since ultrasound cannot differentiate a baggy, low-pressure, unobstructed system from a tense, dilated, obstructed one. Ultrasound has advantages compared with intravenous urography, although not with CT, in patients with severe impairment of renal function (see below). In contrast with urography, but again not with CT, it does not exacerbate pain due to obstruction, caused in excretion urography by the diuretic effect of intravenous contrast medium employed.

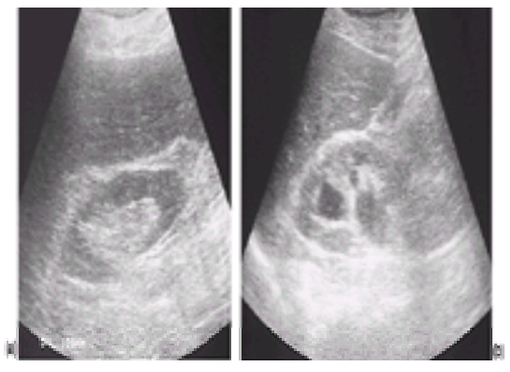

Fig. 3 Ultrasound showing (a) a normal kidney, and (b) a kidney with a dilated pelvicalyceal system in urinary obstruction.

Intravenous urography

Intravenous urography will usually demonstrate the site, cause, and degree of obstruction and is much less operator dependent than ultrasound since the number of images checked by the clinician is equal to the number of images reported by the radiologist. Its major disadvantage is that the technique carries a mortality owing to contrast hypersensitivity reaction of perhaps 1 in 200 000. It also involves an intravenous injection, exposure to radiation (of particular concern in pregnant women and children), worsening of pain due to the diuretic effect of contrast medium when an upper tract (or tracts) is obstructed, and the potential for contrast nephrotoxicity. Patients with impaired renal function, particularly those with diabetes and perhaps patients with myelomatosis, are at particular risk. Such risk is

minimized by employment of low osmolality contrast medium and the avoidance of prior dehydration. As with ultrasound, upper tract dilatation does not necessarily indicate the existence of obstruction, but this is much less often a diagnostic problem in urography than with ultrasonography because of the better ureteric visualization and the ability to assess drainage of the upper tracts. Ultrasonography has replaced high-dose urography as the first-line method for detecting obstruction in renal failure.

The initial sequence of radiographs must include sufficient films to identify calcifications in the urinary tract, a good combination being a full length and a coned renal area plain film. The plain films must be examined carefully for opaque calculi along the line of the ureter—calculi overlying bone are easily missed (Fig. 4(a) and Fig. 4(b)). Some obstructing calculi are very small and only faintly calcified or non-opaque. Ureteric calculi within the bony pelvis are often impossible to distinguish from calcified phleboliths on the plain film.

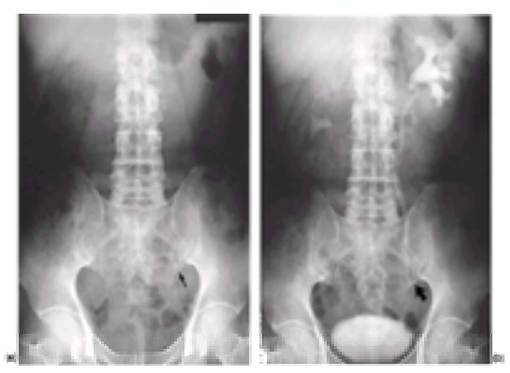

Fig. 4 (a) Plain abdominal radiograph. Opaque calculus (arrowed) medial to the left lower sacroiliac joint is easy to overlook. (b) Same patient as in (a) after contrast radiograph. Note dilatation of collecting system and ureter to the level of the calculus.

A large dose of contrast, preferably of low osmolality, should be given to those who may have acute obstruction to compensate for the lack of preparation of the patient and the probability of a low glomerular filtration rate. After contrast injection, the recently obstructed kidney is typically enlarged and smooth in outline. There is an immediate nephrogram, but the calyces and pelvis fill with contrast later than normal and the nephrogram becomes increasingly dense over time owing to the prolonged nephron transit time, which allows greater than normal concentration of contrast medium within the tubules (Fig. 5). In time, the site of obstruction may become obvious owing to dilatation of the system to the level of the block (Fig. 6). A full length film should be taken 20 min after contrast injection and after the patient has been asked to empty their bladder, since contrast in a full bladder may cause spurious upper tract dilatation and may obscure the lower end of the ureter and make it impossible to confirm that a ureter is dilated down to an opacity seen in the line of the ureter in the bony pelvis.

Fig. 5 Acute left ureteric obstruction. Note the increased density of the nephrogram and the absence of a pyelogram on the left side 15 min after injection of contrast.

Fig. 6 Same patient as in Fig. 5. A later radiograph showing a persistent dense nephrogram on the left. The pelvicalyceal system and ureter, which have now filled, are only slightly dilated due to the fact that obstruction is of very recent onset. The obstructing calculus at the left ureteric orifice is not visible.

Since contrast medium enters the pelvicalyceal system and ureter slowly, opacification of the system and ureter may never be seen in severe acute obstruction. However, in most instances filling of the pelvicalyceal system and ureter to the level of obstruction can be demonstrated on delayed films. In acute ureteric obstruction the pelvicalyceal system and ureter are typically only slightly dilated. Occasionally the only abnormality may be a ureter that remains full throughout its length to the level of the vesicoureteric junction, with this finding persisting on the full length postmicturition film. Acute obstruction is also characterized by increased excretion of contrast medium by the liver, leading to opacification of the gallbladder on delayed films.

When typical obstructive changes are present, with a ureter dilated down to a calcified opacity, diagnosis is simple. If there is an obstructive nephrogram or dilatation of the pelvicalyceal system and/or ureter but no radiodense calculus is seen, diagnosis is more difficult. If the history is of pain of recent onset, the likely diagnostic possibilities are a small low-density stone not detected by urography, recent passage of an opaque stone, a uric acid stone, acute pelviureteric junction obstruction, a blood clot, or sloughed papillae. Ultrasonography can often demonstrate small low-density stones at the vesicoureteric junction not shown by urography. The presence of a uric acid stone may be suggested by a previous history of such stones, a personal or family history of gout, or clinical circumstances associated with uric acid stone formation, such as cytotoxic drug therapy or chronic small bowel disease. Urography shows uric acid stones as lucent filling defects (Fig. 7); similar filling defects may also occur with transitional cell tumours, sloughed papillae, or blood clots. Since most ureteric stones pass spontaneously, investigation of a possible transitional cell tumour or blood clot should be delayed. If a persistent lucency is present, CT scanning may be very helpful (Fig. 8).

Fig. 7 Uric acid stones seen on intravenous urography as lucent filling defects in the collecting system on the left.

Fig. 8 Same patient as in Fig. 7. The CT scan clearly shows uric acid stones as opacities within the collecting system.

Acute idiopathic pelviureteric junction obstruction should be suspected if there is a large, soft tissue density inferomedial to the kidney on the plain film produced by the distended pelvis. This usually fills on delayed films of the urogram, with no filling of the ureter.

Clot colic is always associated with macroscopic haematuria. When it is suspected, the urogram should be repeated after 2 weeks, by which time the clot should have lysed and any underlying lucent filling defect can be seen. Such patients require further investigation to define the cause of bleeding.

Sloughed papillae result from papillary necrosis. Typically, abnormal calyces are seen in both kidneys, but papillary necrosis may occasionally be unilateral, usually as a result of a previous episode of infection associated with unilateral obstruction, especially in diabetics. Occasionally, calcified papillae may mimic stones (Fig. 9).

Fig. 9 Bilateral papillary necrosis with papillary calcification mimicking stones.

CT scanning

CT scanning carried out without the use of oral or intravenous contrast medium offers obvious safety advantages compared with intravenous urography, since no intravenous injection is required. The radiation dose is, however, significantly higher (four to 10 times) than with urography. Unenhanced CT is well established as a second-line method for detecting pelvicalyceal and ureteric dilatation when ultrasonography is non-diagnostic in patients with suspected obstruction. CT also has an established role in demonstrating the cause of obstruction when this is not shown by ultrasonography (for example ureteric calculus, retroperitoneal mass). With the advent of helical (spiral) CT, this method is being increasingly widely used, especially in the United States, in patients with suspected ureteric colic where it has a sensitivity and specificity (in expert hands) of over 95 per cent.

A major advantage of helical CT scanning over both ultrasonography and intravenous urography is that it is capable of diagnosing non-urological conditions presenting with flank pain and not associated with urinary tract obstruction, as well as conditions causing obstruction by extrinsic compression of the ureter. These include appendix abscess, diverticular perforation, torsion of an ovarian mass, a leaking abdominal aortic aneurysm, and pancreatitis.

Other techniques

Magnetic resonance imaging

A number of magnetic resonance urography techniques are available. In suspected obstruction when irradiation and/or contrast exposure are contraindicated (for example pregnancy, contrast allergy, impaired renal function) and ultrasonography is inconclusive, heavily T_2-weighted sequences may be used to generate a magnetic resonance urogram. The dilated pelvicalyceal system and ureter show increased signal and can be delineated without using contrast medium. However, since magnetic resonance does not demonstrate calculi, it may be difficult to be sure that the obstructing lesion is a stone.

Antegrade and retrograde pyelography and ureterography

If the site of obstruction is not demonstrated by intravenous urography or other imaging techniques, antegrade or retrograde examination may be helpful. Both have the advantage that they can be initiated as a method of diagnosis and then extended to provide a therapeutic role by providing drainage.

Radionuclide imaging

There is no role for the use of radionuclides in the investigation of acute urinary tract obstruction.

Which imaging technique to use?

The time taken for each of the examinations described above is not a major consideration. With appropriate equipment, unenhanced helical CT is very quick (approximately 5 min), ultrasonography takes approximately 15 min, and standard urography 30 min. If there is an obstruction, delayed films up to 24 h after contrast injection may be necessary with urography. The cost of ultrasound is approximately half that of intravenous urography but neither is expensive by the standards of the developed world. It has been claimed that the cost of helical CT scanning is equivalent to that of urography, although the initial cost of providing the necessary equipment is high.

The plan and sequence of investigation in suspected upper tract obstruction is dictated by the mode of presentation and the presence or absence of uraemia. If there is suspected chronic urinary tract obstruction, ultrasonography is the method of choice. Uraemia, if present due to urinary tract obstruction, must indicate bilateral obstruction or obstruction of a functionally or anatomically single kidney. Renal ultrasonography (plus plain films to screen for the presence of calculi) is the investigation of first choice. The same is true if a palpably enlarged kidney or kidneys are present in the absence of pain or flank tenderness. Where signs of sepsis are present and pyonephrosis (an infected and obstructed system) is suspected, ultrasound is also the investigation of first choice. However, many patients with acute urinary tract obstruction present with pain and without uraemia or signs of sepsis. In this situation, intravenous urography (or unenhanced spiral CT, if available) remains the investigation of first choice for reasons given above. Magnetic resonance urography may be of value in the minority of patients in whom ultrasonography is inconclusive and irradiation and/or contrast exposure are contraindicated.

Chronic upper urinary tract obstruction

Obstruction must be excluded in all patients with unexplained renal failure. In patients with known renal disease, rapid deterioration in renal function unexplained by the primary renal problem also demands investigation. Relapsing urinary tract infections should also raise the possibility of an associated obstructing lesion. The diagnosis of chronic resistance to outflow should not be discounted simply because the volume of urine is normal or even increased.

The history should include questions relating to analgesic abuse (associated with papillary necrosis, transitional cell tumours, and periureteric fibrosis) and vitamin D consumption (associated with calculus formation). Ingestion of methysergide and other drugs may be associated with retroperitoneal fibrosis. A history or family history of gout, diabetes, or renal stone formation should be sought.

Ultrasonography

In suspected chronic upper tract obstruction, including the initial investigation of patients with unexplained impairment of renal function, ultrasonography is usually the imaging method of choice. Plain films should also be obtained, often with plain renal tomography to check for low-density calculi if the bowel overlies the renal area. Ultrasonography has a high sensitivity for the detection of pelvicalyceal dilatation but cannot distinguish between dilatation caused by obstruction and other types of pelvicalyceal abnormality—caused for example by a distensible system, extrarenal pelvis, vesicoureteric reflux, or dilated calyces due to reflux nephropathy (Table 1). To avoid missing the relatively minor dilatation that may occur with some causes of severe functional obstruction (for example in retroperitoneal fibrosis and tumours), all questionable pelvicalyceal visualization on ultrasonography must be evaluated further. This, together with the difficulty in differentiating dilated obstructed from dilated non-obstructed systems, leads to a significant false positive rate when ultrasonography is used to exclude obstruction. Further evaluation with intravenous urography or CT may be necessary depending on renal function. Intravenous urography is the method of choice in patients with loin pain since it best diagnoses the more common causes—calculous obstruction and idiopathic pelviureteric junction obstruction. Scintigraphy is not recommended as the first investigation in suspected obstruction but is useful in defining whether dilatation shown by other methods is obstructive (see below).

Intravenous urography and CT scanning

Intravenous urography may be helpful when ultrasonography yields equivocal results in a patient with suspected obstruction, especially when renal function is normal.

Unenhanced CT is used as a secondary method of diagnosing obstruction when the results of ultrasonography are equivocal. On CT the dilated collecting system appears as a multiloculate fluid collection with the density of water in the renal sinus. It is possible to distinguish the intrarenal collecting system from the extrarenal portion of the pelvis; this is important since obstruction can only be diagnosed on CT when there is dilatation of the intrarenal collecting system since a prominent extrarenal pelvis may be a normal variant. The whole dilated ureter is well shown on CT.

The main value of CT in the investigation of chronic upper tract obstruction is in defining the cause (Fig. 10). It is particularly helpful for diagnosing retroperitoneal masses causing obstruction, since the retroperitoneum is often obscured by the bowel at ultrasonography. CT also demonstrates calculi causing obstruction, including 'lucent' calculi such as urate stones that appear with a high density on CT.

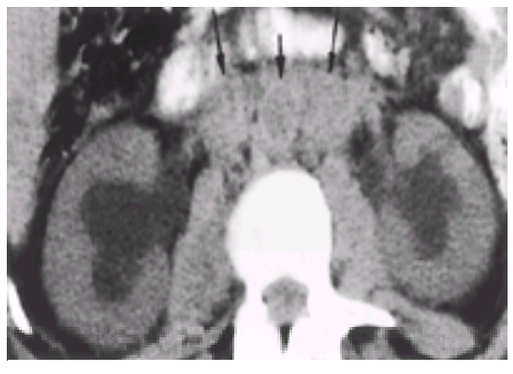

Fig. 10 CT scan in a patient with bilateral urinary tract obstruction due to prostatic cancer. Tumour tissue is clearly delineated on the scan (arrowed).

Scintigraphy

Renal scintigraphy (also called renography) provides functional evidence of obstruction. A radioactive tracer is injected, its passage through the kidney and pelvis is recorded by serial images, and the data are computerized for further analysis (see section 20.4 for further discussion). A rise in resistance to flow in the pelvis or ureter, sufficient to result in impaired renal function, prolongs the parenchymal transit of tracer and there is usually a delay in emptying the pelvis. On whole-kidney renograms, the activity–time curve fails to fall after an initial peak, or continues to rise (Fig. 11). These activity–time curves alone do not enable a distinction to be made between obstructive nephropathy, in which parenchymal transit time is prolonged, and retention of tracer within a large, baggy, low-pressure unobstructed pelvis, where the parenchymal transit time is normal. Parenchymal transit times must therefore be measured through renographic data analysis to make this distinction. Whereas obstructive nephropathy is associated with prolonged transit of tracer through the renal parenchyma, a normal parenchymal transit time with delayed outflow indicates a non-obstructed dilated pelvis.When the possibility of obstruction is suspected, a dynamic renal scintigram is performed with diuresis. Frusemide (furosemide) (0.5 mg/kg, adult dose 40 mg) is given intravenously about 18 to 20 min into the study. Activity–time curves show an immediate fall in the normal kidney after the injection of frusemide (furosemide): in the presence of obstructive uropathy activity persists in the pelvis, the activity–time curve fails to fall, or falls to a lesser extent than its previous rate of increase (an 'inappropriate' response). The half-time of the descending part of the activity–time curve is prolonged, meaning that 'outflow efficiency' is impaired, which compares the amount of activity taken up by the kidney with that excreted within 30 min (the normal value is greater than 78 per cent). However, this test is not infallible: a poor response to frusemide (furosemide) may result from poor renal function or blood volume depletion rather than from obstruction and in the presence of massive pelvic or ureteric dilatation washout may not be observed on the images. Under these circumstances this part of the test is uninterpretable. However, the parenchymal transit time index will indicate whether obstructive nephropathy is or is not present.

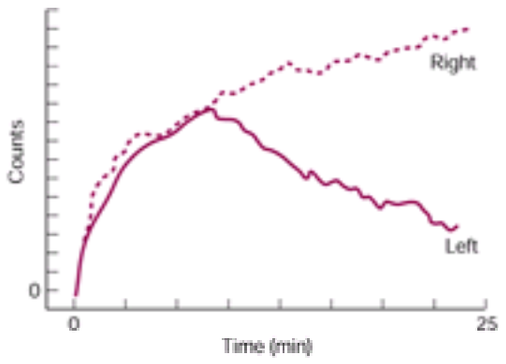

Fig. 11 Dynamic diethylene-triamine penta-aceticacid (DTPA) scintigram. Note the progressive rise of the right kidney curve to a plateau in contrast to the normal left kidney curve.

In conclusion, radionuclide scintigraphy methods are of particular value in differentiating obstructive nephropathy from a baggy, dilated, but unobstructed system and in defining the contribution of each kidney to overall uptake function. A decision as to whether conservative surgery or nephrectomy should be carried out in unilateral obstruction may be much facilitated by the latter assessment.

Antegrade pyelography and ureterography

Percutaneous introduction of contrast medium directly into the renal pelvis or a calyx via a needle, with subsequent radiographic examination of the pelvicalyceal system and ureter (antegrade pyelography and ureterography) is used increasingly to define the site and cause of chronic upper tract obstruction. Diagnostic antegrade examination can be combined with therapeutic drainage of an obstructed system.

Retrograde ureterography

Cystoscopy and catheterization of one or both of the ureters from below, followed by retrograde injection of contrast medium (retrograde ureterography), is indicated if antegrade examination cannot be carried out, or if there is a prospect of dealing with ureteric obstruction from below at the time of retrograde examination. The technique carries the risks of introducing infection into an obstructed urinary tract and of septicaemia, and should be performed only when absolutely necessary. In obstruction due to neuromuscular dysfunction at the pelviureteric junction and in retroperitoneal fibrosis, the collecting system may fill normally from below.

Pressure flow studies

This investigation provides a quantitative assessment of the effect of obstruction on the outflow tract. The technique involves the insertion of a needle transparenchymally into the upper collecting system. Local anaesthetic is sufficient in adults, but general anaesthesia is required in children. The bladder is catheterized and the intravesical pressure measured. The pressure differential between the kidney and the bladder is monitored while the collecting system is perfused with dilute contrast at a rate of 10 ml/min. Perfusion must be maintained for long enough to ensure that the upper urinary tract is filled.

Normal systems can accommodate a flow rate of 10 ml/min without a pressure differential of more than 15 cm of water. If an obstruction is present, there will be a pressure differential of more than 22 cm of water. An equivocal range exists when the differential pressure is between 15 and 22 cm of water, but such a result occurs in only a small proportion of patients.

This diagnostic technique is relatively simple and can readily be extended into a therapeutic one by leaving a catheter *in situ*, to provide drainage of an obstructed system. The disadvantages are that it is an invasive test with a risk (albeit small) of provoking haemorrhage or infection, that the technique investigates the collecting system and gives no information on parenchymal function, and that it is not readily repeatable. Leakage around the needle can invalidate the pressure measurements.

With the advent of more sophisticated renography, pressure flow studies are rarely performed, but they still have a place in the investigation of obstruction in patients with very poor renal function, in whom radioisotope techniques are less reliable, in equivocal obstruction, particularly at the pelviureteric junction, and intraoperatively in patients with retroperitoneal fibrosis undergoing ureterolysis.

Difficult clinical situations

Significant incomplete chronic upper urinary tract obstruction

It may be very difficult to tell whether a given degree of resistance to outflow or intermittent obstruction is impairing, or potentially impairing, renal function or causing symptoms. Symptoms may be present in the absence of deleterious effects upon renal function and the converse may also be true. Different methods of diagnosing obstruction define subtly different pathological features of the condition and a valid correlation between the results of different investigations cannot invariably be made. Incomplete obstruction is clinically important if it causes deterioration in kidney function that can be halted or corrected by intervention, or symptoms that are improved thereby. In patients with one kidney, or in those with bilateral partial obstruction, a decline in serial measurements of glomerular filtration rate attributable to obstruction may define the situation. There may be a similar change in uptake of radionuclides in unilateral obstruction. Other proposed methods of detecting significant incomplete obstruction are given in Table 3. Strict validation of these methods would require them to be carried out in patients with supposed obstruction who would then be allocated randomly to intervention or no intervention. Deterioration in function predicted by each of the methods by comparison with matched controls would provide validation. This study is never likely to be done.

Differential diagnosis of non-obstructive dilatation of the collecting system

A number of non-obstructive conditions may cause dilatation of the collecting system (Table 1).

Extrarenal pelves may mimic pelviureteric junctional obstruction. If intravenous frusemide (furosemide) is administered after the 20-min full length contrast radiograph in this condition, contrast medium will have washed out of the affected side on a full length film 15 min later. In the presence of obstruction of the pelviureteric junction the contrast is retained and the pelvicalyceal system increases in size.

Megacalyces are readily identified on urography. The renal cortex is normal and the calyceal infundibula, pelvis, and ureter are normal with no evidence of obstruction.

Vesicoureteric reflux may be associated with dilatation of the ureters and in severe cases dilatation of the pelvicalyceal system too. The presence of reflux on urography is suggested by the degree of dilatation varying at different times during the examination, by dilatation which is greatest from the vesicoureteric junction upwards, and by a postmicturition film which shows a large volume of residual urine in the bladder composed of urine that has refluxed into the ureters during voiding and drained back thereafter.

A decision as to whether or not significant obstruction is present at the pelviureteric junction and whether operation is indicated may be facilitated by frusemide (furosemide) urography (Fig. 12) or frusemide (furosemide) scintigraphy. In some patients the urographic findings are unremarkable during asymptomatic periods, while emergency intravenous urography during an episode of pain may define the condition.

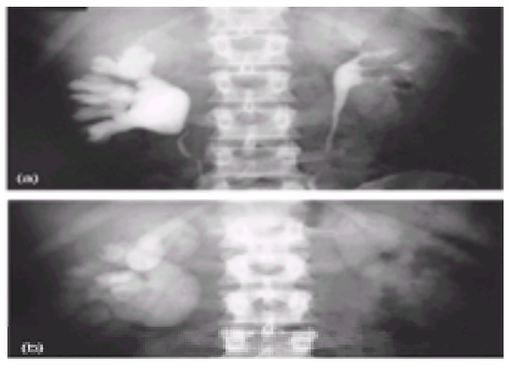

Fig. 12 (a) Right-sided pelviureteric obstruction. (b) Same urogram as in (a) 15 min after intravenous injection of frusemide (furosemide). Note the increase in size of the pelvicalyceal system, indicating significant pelviureteric junction obstruction.

In women who have been pregnant, particularly those who have suffered pregnancy bacteriuria, one or both upper ureters (more often the right) may be dilated to the pelvic brim, but the system is seen to empty on a full length postmicturition film and there is no dilatation of the pelvis and calyces (see Chapter 13.5 for further discussion).

Acute lower urinary tract obstruction

Most patients presenting with acute urinary retention require no investigation before treatment. Suprapubic pain coexisting with a bladder that is palpably or percussibly distended above the level of the symphysis pubis is sufficient evidence for immediate catheterization.

If there is doubt about the diagnosis, an ultrasound examination will confirm or refute the presence of a distended bladder. Transrectal ultrasound of the prostrate can demonstrate both the size of the gland and, to some extent, the benign or malignant nature of any enlargement. Such an investigation is not indicated in the acute situation but is of potential benefit after the relief of obstruction.

An ascending urethrogram may be indicated if an attempt at urethral catheterization proves unsuccessful. This is done as an elective procedure after bladder drainage has been achieved by suprapubic catheterization.

Chronic lower urinary tract obstruction

In one series of patients presenting with acute retention of urine, approximately half had bladders of low compliance and half of high compliance. Investigation is aimed at demonstrating associated pathology such as urinary tract infection, upper tract dilatation, stones, and renal impairment, and also at defining the severity of obstruction of bladder outflow.

Urine culture is essential. In most centres, ultrasonography of the upper and lower urinary tract, together with a plain abdominal radiograph and measurement of urinary flow rate have replaced the intravenous urogram. Full urodynamic investigations, with combined videopressure cystourethrography may be necessary. Serum biochemistry and routine haematology are also required, as is measurement of the level of prostatic-specific antigen in men.

Management

Acute upper tract obstruction

Stones

Most patients presenting with renal and ureteric colic will have a stone in the lower third of the ureter, often in that portion of the ureter lying within the bladder wall. Such patients can be managed conservatively, since the stone has already passed through two areas of relative ureteric narrowing—the pelviureteric junction and the site at which the ureter crosses the bifurcation of the common iliac artery. A conservative policy is likely to prove successful if the stone is 5 mm or less in its maximum diameter. It is unusual for acute episodes of colic to persist for more than 72 h.

Patients with ureteric colic are usually admitted to hospital, although this is unnecessary in many cases since the only medical requirement is the provision of regular analgesia, which can be given parenterally, orally, or rectally. There is a time-honoured recommendation that patients with colic should be encouraged to maintain a very high fluid intake to induce a diuresis. An antimuscarinic drug such as propantheline is also often prescribed. There is no reason to think that these measures are of benefit, and they may even be harmful since both encourage ureteric dilatation and would be expected to reduce forward peristalsis of the ureter, which is the very effect needed to encourage spontaneous passage of the stone. A diuresis will also tend to increase intratubular pressure and may increase the risk of forniceal rupture. It might be argued that forniceal rupture may, by decompressing the system, encourage the return of peristalsis but few would regard this as an appropriate approach to management.

Although it has long been argued that morphine should be avoided as an analgesic as it may provoke prolonged ureteric constriction, there is no evidence that therapeutic doses of morphine have this adverse effect. Pethidine may provoke nausea and vomiting, particularly when administered parenterally, but since nausea and vomiting frequently accompany colic it is difficult to disentangle the effects of such treatment from the effects of colic alone. Very satisfactory pain relief can often be obtained using non-steroidal anti-inflammatory agents administered orally or rectally.

With the advent of new, less invasive methods of surgical management of ureteric stones, there is a temptation to intervene earlier. Stones in the intramural ureter can be treated readily with most lithotripters, whether imaging is by ultrasound or radiology. Since most stones at that site will pass spontaneously, the extent to which lithotripsy will hasten the process is difficult to establish. Lithotripsy may be worthwhile for stones in the upper third of the ureter since, by disintegrating the stone into small fragments, spontaneous passage will be encouraged. However, the availability of lithotripsy for patients with acute colic varies very markedly between countries and the precise role and benefits of the technique have yet to be established. Endoscopic manoeuvres, which are usually performed under general anaesthesia, are reserved for those patients with persistent colic.

Drainage of an obstructed system

If there is clinical evidence of infection above an obstruction, drainage must be established as a matter of urgency. The diagnosis is a clinical one, made on the basis that the patient is pyrexial, often with a very high fever and rigors, and the degree of loin tenderness is greater than when obstruction is not associated with infection. Examination of bladder urine may be unhelpful since ureteric obstruction may prevent red and white blood cells and organisms from reaching the lower urinary tract. Leucocytosis may be present but this is not invariably the case, especially in the elderly.

The choice between antegrade and retrograde intervention will depend on the facilities and expertise available. In most specialist centres there is a clear preference for the percutaneous insertion of an antegrade needle to provide a nephrostomy under local anaesthesia. In a dilated high-pressure system the procedure is usually easy, and such a system may be used to provide drainage for weeks or even months if necessary. If excretion of intravenous contrast has outlined renal anatomy, renal puncture may be guided radiographically; if not, the initial puncture may be better directed under ultrasound control using a fine needle. The collecting system is then outlined with contrast and an accurate transparenchymal calyceal puncture can be placed, usually through a lower calyx. By contrast, a retrograde ureteric catheter can be relied on to provide drainage for only for a matter of days at best. Occasionally a retrograde catheter cannot be passed beyond the obstruction and the diagnostic role of retrograde ureterography cannot then be extended to a therapeutic one.

Other causes of acute obstruction

Aside from urinary stone, the two other most common causes of acute obstruction are sloughed papillae and blood clots. The principles of management vary little from those already outlined for ureteric stones, but greater attention must be paid in the acute phase to the underlying cause. In the patient with papillary necrosis, infection is a more common accompaniment of obstruction, and intervention, usually with a percutaneous needle nephrostomy, is required more often. When colic results from a blood clot, treatment of the underlying cause may be necessary at an early stage. Renal parenchymal tumours and transitional cell tumours of the collecting system may both cause persistent bleeding and colic, and ablative open surgery is usually required. More difficulty is encountered when bleeding occurs from a non-malignant cause. An arteriovenous fistula, whether spontaneous or traumatic, may be embolized with every prospect of success. The most difficult case of recurrent bleeding to manage is that associated with papillary necrosis in sickle cell trait or disease. Antifibrinolytic agents may be of value, but administration of such treatment during active bleeding may produce hard, rubbery clots that fill the collecting system and require surgical removal.

Chronic upper tract obstruction

The aim of management is to relieve symptoms, improve or conserve renal function, and avoid complications such as septicaemia. Important surgical advances in the past decade include the increasing use of ureteric stents to provide short-term, or even long-term, relief of obstruction. Recently a means of avoiding problems associated with endoluminal stenting has been described, in which a stent is used to drain urine from the renal pelvis through a subcutaneous tube directly into the bladder, bypassing the ureter.

Obstruction is the most readily reversible cause of chronic renal failure. Acute obstruction caused by ureteric stones commonly resolves spontaneously; but the longer a stone remains in the same position within the ureter the less likely it is that a conservative policy will be successful.

Probably the second most common cause of chronic obstruction in adults is obstruction of the pelviureteric junction. The Anderson–Hynes pyeloplasty gives very satisfactory results and provides the gold standard against which other open and endoscopic techniques (such as endopyelotomy) must be assessed.

Idiopathic obstruction at the pelviureteric junction may present in childhood, when obstructed megaureter and ureteric obstruction secondary to a ureterocele are also more common. Since all three congenital anomalies cause pelvicalyceal dilatation, it is becoming increasingly common for obstruction to be diagnosed *in utero*. Treatment of the obstruction *in utero* by the insertion of a nephrostomy tube has been reported: it is too early to know whether such early intervention will prove to have long-term benefits, but at the moment it seems, on balance, best to wait until immediately after delivery to investigate and relieve the problem.

Ureteric obstruction can occur in a transplanted kidney, most commonly at the site of the ureteroneocystostomy, but sometimes more proximally in the ureter. Vesicoureteric stenosis is caused by ischaemia of the ureter, but it is never possible to define whether this ischaemia is associated with rejection or is a result of poor vascularization following donor dephrectomy. More proximal ureteric obstruction may be due to mechanical kinking of the ureter or, occasionally, to extrinsic compression by a lymphocele. Irrespective of the site and cause of the obstruction, the diagnosis presents special problems. The possibility of obstruction is raised either because of deteriorating renal function or because ultrasound during routine follow-up demonstrates increasing dilataton of the collecting system. The differential diagnosis includes rejection, cyclosporin nephrotoxicity, and arterial insufficiency. An obstruction may be demonstrated by intravenous urography and/or antegrade pyelography. Retrograde studies are usually difficult and not infrequently impossible, and since, in the case of stenosis at a ureteroneocystostomy, they involve passing a catheter across the segment of ureter under suspicion, the investigation is only indicated if intravenous urography and antegrade pyelography prove unsatisfactory.

Minimally invasive stone surgery

The past decade has seen a revolution in the management of urinary tract stones, due to the adoption of minimally invasive techniques including percutaneous surgery and extracorporeal shock wave lithotripsy. Open operation for renal stones can now be avoided in many cases by creating a nephrostomy track to the calculus, dilating the track, and then either removing the calculus endoscopically via the track or causing it to disintegrate by direct application of an ultrasound probe. It is possible to extract ureteric stones endoscopically with the assistance of a ureteroscope, and bladder calculi may be disintegrated by the endoscopic application of electrohydraulically produced shock waves.

Externally delivered shock waves can be used to shatter calculi into many fragments which are then passed spontaneously, hence extracorporeal shock wave lithotripsy offers a solution to the problem of the presence of a calculus or calculi within the kidney without the need for a surgical operation. This carries the promise of a reduction in morbidity and perhaps mortality, a much shorter hospital stay for the patient, a more rapid return to work, and may also be suitable for those who are unfit for conventional surgery. The technique is unsuitable for hard uric acid and cystine stones, for very large stones (which must be debulked percutaneously before lithotripsy), and for some ureteric stones (although a proportion of these can be manoeuvred into the upper collecting system endoscopically and then dealt with by this method). Other disadvantages include the high capital cost of the necessary equipment and the need for further intervention in 10 to 15 per cent of patients in whom stone fragments do not pass. Such fragments can, in general, be removed endoscopically. Despite these difficulties, non-operative dissolution of calculi is being increasingly used. The recurrence rate of stones in the long term seems to be no higher than after open surgery and to date no unforeseen long-term complications have emerged.

Large staghorn calculi are still usually removed by a cutting procedure. Surface cooling of the kidney at the time of operation allows time for more complete clearance of stones with the renal artery clamped, and protects against the development of ischaemic damage to the kidney.

For details of other aspects of diagnosis and management of urinary stones see Chapter 20.13.

Other causes of urinary obstruction

Pelviureteric junction obstruction

This often appears to result from a functional disturbance in peristalsis of the collecting system in the absence of mechanical obstruction. A percutaneous procedure for managing pelviureteric junction obstruction was first described in 1983 (endopyelotomy): this involves a full thickness incision through the stenosed region with a stent left *in situ*; healing occurs by re-epithelialization from either side of the incision and very little new scar tissue is formed. There is no consensus on the indications: patients with secondary pelviureteric junction stenosis in association with stones, infection, or previous surgery tend to be offered the percutaneous operation, whereas those with primary idiopathic obstruction are usually treated by open pyeloplasty.

Malignant obstruction

A wide variety of tumours may cause ureteric obstruction, either by local spread (cervix, prostate, bladder), or secondary to para-aortic nodal enlargement (lymphoma, testicular tumours). The diagnosis rests upon the same investigations as for any other cause of chronic obstruction, but the treatment will vary widely, depending on the cause. An aggressive or radical approach is almost always indicated in a patient who has received no previous treatment for the underlying malignancy. Unilateral or bilateral ureteric stenting or percutaneous nephrostomies may be necessary to cover the period of time during which chemotherapy or radiotherapy is given with the expectation of controlling the tumour. More difficulty arises when ureteric obstruction is due to recurrent tumour, when the potential benefits of chemotherapy and radiotherapy are significantly less and patients may be facing debilitating treatment for an advancing malignant disease, the prognosis of which is poor. To be confined by nephrostomy drainage for what is left of life significantly diminishes its quality, but may be right in certain circumstances. A percutaneously placed pigtail nephrostomy, which can be inserted under local anaesthetic, has a tendency to fall out or to be pulled out. Open surgery can be avoided by the use of a ring nephrostomy inserted percutaneously under general anaesthesia: this provides secure long-term drainage, for years if necessary.

Obstruction in patients with urinary diversion

There are many reasons for diverting the urine into an isolated loop of ileum or colon. One of the recognized complications is stenosis at the site of anastomosis between the bowel and ureter(s).

The thin muscle wall of the ileum means that it is not possible to fashion an antireflux anastomosis between the bowel and the ureter when diverting the urine into an ileal conduit, hence a loopogram (a radiograph carried out after injection of contrast into an ideal loop) will normally show bilateral ureteric reflux, and the absence of such reflux is strong evidence of a stenosis at the ureteroileal junction.

The operation of ureterosigmoidostomy, in which the ureters are anastomosed to sigmoid colon, has fallen into disfavour owing to the associated complications of infection, metabolic acidosis (caused by reabsorption of hydrogen ions from the gut), and osteomalacia.

Idiopathic retroperitoneal fibrosis (peri-aortitis)

In this condition the ureters become embedded in dense fibrous tissue, with resultant unilateral or bilateral obstruction, usually at the junction between the middle and lower thirds of the ureter. The condition is progressive: initially, the fibrous tissue is fairly cellular, later becoming relatively acellular. The mechanism by which obstruction occurs is unclear, not least because of the frequent observation that contrast medium injected into the lower ureter may pass freely up to the pelvicalyceal system despite the presence of clinical, radiological and isotopic evidence of functional urinary tract obstruction.

Pathogenesis

'Retroperitoneal fibrosis' is an unfortunate term, since there are many causes of fibrosis in the retroperitoneal area, for example malignant disease of the breast, colon, or prostate, and because it is anatomically misleading and says nothing about pathogenesis.

The location, long known to surgeons and pathologists, and further emphasized by the advent of CT scanning (Fig. 13), is around the aorta, hence the term peri-aortitis is preferable to retroperitoneal fibrosis. The histological appearances are of aortic atheroma, medial thinning, splits in the media, and an increase in the adventitia, which contains an inflammatory infiltrate. These findings are present to some extent in the aortas of some patients with advanced atherosclerosis who have not suffered a clinical illness and may reasonably be classified as having 'subclinical peri-aortitis'. The fibrous tissue itself contains macrophages and plasma cells but not polymorphs, and it now seems likely that this is due to an autoimmune response to leakage of material derived from atheromatous plaques in the diseased aorta.

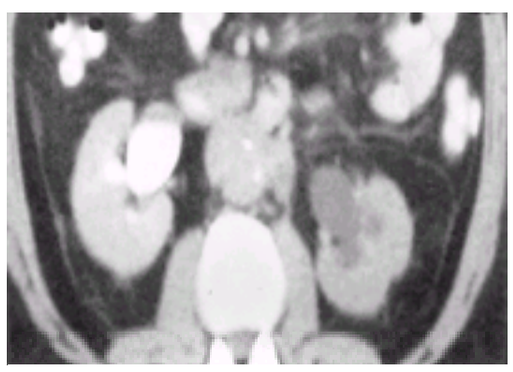

Fig. 13 A CT scan of idiopathic retroperitoneal fibrosis (peri-aortitis) causing urinary tract obstruction. Note the aortic calcification and peri-aortic nature of the mass.

The substance ceroid, an insoluble polymer of oxidized lipid and lipoprotein, which can be synthesized artificially by oxidizing low-density lipoprotein, may be involved in generating the fibrotic reaction. It is found in atheromatous plaques and is identified by staining with oil red O. Examination of sections of aorta containing such plaques incubated with mouse monoclonal antibody to human IgG localizes the antibody to the region of the plaque where ceroid has been identified by oil red O staining. Identical findings are obtained on incubation with polyclonal rabbit antihuman IgG. Moreover, IgG and some IgM, but not IgA or IgE, can be identified in plasma cells in the fibrotic tissue where there are splits in the adjacent media. Circulating antibodies to oxidized low-density lipoprotein and to ceroid extracted from human atheroma are detected in patients with peri-aortitis in much higher concentrations than in normal individuals and in those with ischaemic heart disease. Stored sera obtained from individuals subsequently shown at autopsy to have had subclinical peri-aortitis also show significantly increased antibody titres compared with controls. It thus seems likely that chronic peri-aortitis has an autoimmune aetiology in which the allergen is a component of ceroid, probably oxidized low-density lipoprotein, produced in human atheroma, and that a specific immune response involves T cells and plasma cells, which secrete IgG. Oxidized low-density lipoprotein is known to be highly immunogenic.

This concept clarifies some issues that were previously difficult to explain. For example, the definite, although uncommon, association between mediastinal fibrosis and idiopathic retroperitoneal fibrosis has always been difficult to understand. If one regards at least some cases of mediastinal fibrosis (see below) as a peri-aortitis, occurring in this instance around the thoracic aorta, the association becomes comprehensible. Surgeons operating on aortic aneurysms quite often see fibrosis around the aneurysm. Sometimes the surgeon encounters technical difficulties in adhesions between the aorta and duodenum, and a dense, fibrotic, chronic inflammatory infiltrate is present around the aorta: the term 'inflammatory aneurysm' is used to describe this condition. The unifying hypothesis of an autoimmune peri-aortitis accounts for this finding. Certainly so-called idiopathic retroperitoneal fibrosis, idiopathic mediastinal fibrosis, perianeurysmal fibrosis, and inflammatory aneurysm have much in common. The hypothesis also accounts for the well-known association between aortic disease, including aneurysm and aortic wall calcification, and retroperitoneal fibrosis. Finally, it may be no coincidence that carcinoid tumours and drugs such as methysergide and ergot derivatives which are sometimes responsible for the condition all have well described effects on the vasculature.

Clinical features

The condition is three times as common in men as in women. Patients' ages range from the third to the ninth decade, but peak incidence occurs in the sixth and seventh decades; in one series of 60 patients the mean age of the group was 56 years. The early clinical manifestations are not distinctive. Most commonly there is pain in a girdle-like distribution from the low back to the lower abdomen, occasionally spreading to the buttocks or thighs. Examination is usually unremarkable apart from hypertension, which is found in over 50 per cent of patients. Oedema of the legs, a palpable kidney, or hydrocele is found in fewer than 10 per cent of patients. There is usually a normochromic, normocytic anaemia and a raised erythrocyte sedimentation rate and plasma C-reactive protein, but a significant minority are normal in one or both of these respects. Proteinuria is uncommon and significant bacteriuria rare.

Diagnosis

Peri-aortic fibrosis is clearly more common than hitherto appreciated, particularly if one takes subclinical forms of the condition into account. Diagnostic delay is the rule: in one series 6 to 12 months, or even longer, elapsed from the onset of symptoms to diagnosis. Perhaps for this reason, bilateral rather than unilateral upper tract obstruction was present in the majority of patients.

When taking the history, enquiry should be made regarding consumption of relevant drugs, including methysergide, b-blockers, methyldopa, and bromocriptine, another ergot-like drug.

Ultrasonography, radionuclide methods, and the intravenous urogram will reveal findings typical of urinary tract obstruction, and the last technique may show medial deviation of the ureters, although this may also be present in normal subjects and is an unreliable guide to diagnosis. CT scanning will show the peri-aortic mass (Fig. 13). The differential diagnosis includes lymphoma (in which case splenomegaly and lymphadenopathy may be seen on CT scanning) and various forms of cancer, including particularly those of the bladder, bowel, and cervix.

A histological diagnosis should be obtained if at all possible, and laparotomy is required in order to obtain a sufficiently large sample to exclude lymphoma and cancer with certainty. Conversely, a CT-guided needle biopsy may be sufficient to make a definitive diagnosis of malignancy.

Management

Management of the idiopathic and probably autoimmune syndrome is empirical and controversial since controlled trials of treatment are lacking. Corticosteroid therapy, with or without temporary relief of obstruction by insertion of ureteric stents, ureterolysis alone, and ureterolysis followed by steroid therapy to shrink the peri-aortic mass and maintain remission are all employed. Corticosteroid therapy alone may correct obstruction, but is not invariably effective. Ureterolysis alone may also correct obstruction in the long term but is sometimes associated with recurrence or the development of a further obstruction in a previously unaffected kidney. Surgical relief of obstruction by ureterolysis followed by corticosteroid therapy (initial dose of prednisolone 20 mg daily, begun when sutures are removed) has proved to be a reliable and successful strategy. Corticosteroid dosage is reduced progressively thereafter according to clinical response. When bilateral obstruction is present, bilateral ureterolysis followed by steroid therapy is preferable to unilateral ureterolysis with reliance upon corticosteroid therapy to free the contralateral side, since this is sometimes unsuccessful. Ureterolysis of kidneys shown to be non-functioning on high-dose excretion urography or by appropriate radionuclide techniques is usually unsuccessful in restoring useful renal function. A reasonable policy for management would seem to be to perform unilateral or bilateral ureterolysis, as appropriate, followed by corticosteroid therapy in patients fit for operation and able to take steroids safely. Surgery alone should be employed in those with a particular contraindication to corticosteroid treatment, such as the presence of a peptic ulcer or severe osteoporosis. Steroid therapy alone (methylprednisolone 500 mg intravenously daily for 3 days, followed by prednisolone 20 mg daily), with or without insertion of ureteric stents, should be reserved for patients unfit for ureterolysis. A dramatic response to parenteral steroid treatment sometimes occurs, a marked diuresis being seen within 24 h of commencing treatment.

In the United Kingdom in recent years there has been an increasing tendency to avoid operation, even in patients fit for ureterolysis, whether unilateral or bilateral. Reliance is placed upon the insertion of a ureteric stent or stents plus corticosteroid therapy. This approach has the advantage of avoiding operative mortality and morbidity, of providing a rapid solution to the problem of urinary tract obstruction, and a much reduced hospital stay. Disadvantages include difficulties in stent insertion, incomplete relief of obstruction by stents, the need for periodic (say 6-monthly) change of stents if steroid therapy is unsuccessful, and the potential for urinary tract sepsis in the presence of a stent, which is a foreign body. To these must be added, in 'real life' clinical practice, the potential for patients to be lost to follow-up and the presence of a stent to be forgotten. No completely reliable method has ever been devised to render this last occurrence impossible. By contrast, when the ureter or ureters are displaced surgically, well away from the periaortic mass, the patient and the patient's urinary tract are secure, and a further advantage of open surgery is the potential it offers to obtain adequate tissue to permit a firm histological diagnosis to be made. Patients judged fit for operation should in general undergo ureterolysis unless or until prospective controlled trials are published showing equivalent or better results from alternative approaches.

Peri-aortitis in the absence of ureteric obstruction

The use of CT scanning in the investigation of abdominal pain has revealed an increasing number of patients to have peri-aortitis before the onset of urinary tract obstruction. Management of these cases is controversial. The development of bilateral ureteric obstruction with severe uraemia within 3 months of diagnosis (at which time renal function was normal and the ureters unobstructed) has occurred in at least one patient. Until more is known of the natural history of the disease in such patients, it would seem prudent to obtain a histological diagnosis at open operation and to consider corticosteroid therapy to shrink the mass. Whether an attempt to reduce the risk of ureteric obstruction by insertion of stents or displacement of the ureters from the mass at the time of the operation should be carried out is not known.

Prognosis

The older and the more uraemic the patient at the time of presentation, the worse is the prognosis. Nevertheless, if treated appropriately, most patients do well.

Follow-up

In some patients long-term remission is achieved by surgery alone. In those receiving maintenance prednisolone, the dose can be reduced progressively, and in some patients long-term remission occurs after complete withdrawal of corticosteroid therapy. In one series of 60 patients, 10 relapsed more than 5 years after the time of diagnosis when steroid therapy had been stopped, in that their erythrocyte sedimentation rates rose to an abnormal level, and obstruction and diminished renal function redeveloped. Five patients relapsed as late as 10 years after the onset of the disease. Lifelong follow-up is therefore mandatory, but the best way to monitor such patients is not certain. Clinical assessment, serial measurement of erythrocyte sedimentation rate and C-reactive protein, and assessment of renal function, together with imaging to detect redevelopment of obstruction, is appropriate. Reduction in size of the peri-aortic mass can be detected on serial CT scanning, but residual peri-aortic tissue is seen frequently, even after steroid therapy, and the usefulness of CT in monitoring disease activity is limited.

Associated fibrotic conditions

Mediastinal fibrosis

The pathological process described in connection with retroperitoneal fibrosis can also develop in the upper mediastinum where it tends to be located around the bronchi, the cardiac atria, the pulmonary arteries and veins, the superior vena cava, and the azygos vein; rarely, it also envelops the oesophagus. Symptoms vary according to the structures principally affected. There may be cardiopulmonary manifestations because of scar tissue about the atria, pulmonary vessels, or bronchi, and dysphagia can result from oesophageal constriction. One of the commonest clinical manifestations results from obstruction of the superior vena cava, with distension of veins in the neck and upper extremities. When mediastinal fibrosis appears without discernible cause, it may be associated with retroperitoneal fibrosis and then probably has the autoimmune origin described above. There are, however, other causes to consider. The condition is encountered most commonly in people who reside in places where histoplasmosis is endemic, notably in the central parts of the United States, and most of the case reports have come from clinics located in the Mississippi river valley (see Chapter 7.13.1 for further information). Studies of some of these patients have revealed the existence of large granulomas due to histoplasmosis, with eventual rupture into the superior mediastinum and subsequent growth of the dense masses of scar tissue characteristic of the fibrosing syndromes. A curious anomaly in this context is that tuberculosis rarely, if ever, causes the syndrome.

The diagnosis is suggested by radiographic demonstration of the fibrous tissue in the affected areas. CT scanning may be of great value in this context, and histological verification of the diagnosis can be made by CT-guided needle biopsy or by mediastinoscopy. Surgical treatment of mediastinal fibrosis is much more hazardous than of retroperitoneal fibrosis and is much less likely to be beneficial. Despite this, some experienced thoracic surgeons recommend that attempts be made to remove large granulomatous masses of histoplasmosis when this is the diagnosis. Chemotherapy for histoplasmosis has not been very effective. In view of the tendency of this fibrosing process to burn out eventually, it may be possible to ameliorate the manifestations by steroid therapy and thus gain time for a collateral circulation to develop. However, there is little experience of the effects of steroid treatment or other forms of immunosuppression, but there is obvious potential for this approach if the origin of the disorder is autoimmune.

Other rarer fibrosing syndromes

In association with retroperitoneal fibrosis and mediastinal fibrosis, other fibrotic processes have been reported to involve the thyroid gland (Riedel's thyroiditis), the pancreas, the salivary glands, and orbital tissue. The last mentioned can cause severe proptosis and damage to the optic nerve leading to loss of vision, some cases of which may be due to undiagnosed Wegener's granulomatosis. Peyronie's disease is characterized by the deposition of fibrous plaques in the corpora cavernosa of the penis. These plaques, which can be detected by palpation, may cause discomfort and angulation during penile erection.

Chronic inflammatory bowel disease

Chronic inflammatory bowel disease is associated with chronic and unsuspected urinary tract obstruction in 10 to 15 per cent of patients. The obstruction is nearly always right-sided in patients with Crohn's disease, and a valuable clue to its existence is pain radiating down from the right iliac fossa into the right leg. The ureter is usually involved in an inflammatory mass. By contrast, in patients with ulcerative colitis the problem may occur on either side and nearly always follows colectomy. There should be a low threshold for ultrasound examination of the urinary tract to detect obstruction in patients with chronic inflammatory bowel disease.

20.15 Tumours of the urinary tract

P. H. Smith, H. Irving, and P. Harnden

Introduction

Tumours of the kidney, bladder, prostate, and testis are grouped together only because of their association with the genitourinary tract. Each has, over the years, inspired surgeons to prove that ever more complex operations may be undertaken, but patients have not always benefited from this approach and surgeons now rely increasingly upon physicians working in radiotherapy and medical oncology. Recent emphasis has focused on earlier diagnosis and population screening in the hope that overall mortality will fall as more and more localized tumours are detected. Such an approach carries considerable economic consequences.

Transitional cell carcinoma of the bladder and upper urinary tract

Aetiology and incidence

Risk factors include: tobacco smoking; several chemicals related to the dye, rubber, leather, painting, and organic chemical industries; chronic irritation involving *N*-nitrosamine production; and therapeutic pelvic irradiation in women. Genetic factors modulate individual responses to environmental carcinogens, partially explaining variations in incidences between ethnic groups. The slow *N*-acetylation genotype and inherited defects of the glutathione- *S*-transferase M1 gene are susceptibility factors in occupational and smoking-related bladder cancer. Occupational exposure is thought to account for up to 25 per cent of cases in the United States, but less than 5 per cent of patients with bladder cancer are eligible for prescribed disease benefit in the United Kingdom.

The incidence in males and females is 32.5 and 12.9 per 100 000 population, respectively. The changes in industrial practice (and in supervision of workers) ver the last 50 years has reduced the incidence of bladder cancer due to industrial carcinogens and it is now believed that over 40 per cent of all bladder tumours arise primarily as a consequence of cigarette smoking. The recent changes in attitude to smoking, both in the workplace and socially, may well result in a significant fall in the incidence of bladder cancer in the years to come.

The peak age at presentation is 65 to 69 years for men and 75 to 79 years for women, with less than 5 per cent of tumours occurring in patients younger than 60 years.

Clinical features

Though most bladder tumours present because of haematuria, less frequent presentations include bladder irritability, difficulty with micturition, and symptoms of uraemia or backache. Tumours of the renal pelvis and ureter may bleed or may silently obstruct the relevant kidney and ureter.

Investigation and diagnosis

Urinary cytology and high quality ultrasound is usually adequate to make the diagnosis of bladder cancer (Fig. 1). The flexible cystoscope allows the nature and extent of the lesion within the bladder to be seen. Tumours of the upper tract are revealed by intravenous pyelography or by ultrasound.

Fig. 1 Bladder ultrasound scan showing small (1 cm diameter) transitional cell carcinoma arising from the posterior wall.

Patient categories and treatment

The TNM classification of bladder tumours is unique in that it recognizes a category of papillary carcinoma that is non-invasive (invasion through the basement membrane is the hallmark of malignancy in other tumour types, otherwise the lesion is regarded as premalignant or ' *in situ*'). This evolved because of the difficulties in using standard microscopical techniques to distinguish urothelial papillomas (implying a benign lesion with no associated cancer risk) from the 70 per cent of tumours which recur and may progress. Understanding the biological behaviour of urothelial tumours has been further hampered by the tendency until recently to group together non-invasive tumours (pTa) and the tumours invading the lamina propria (pT1) under the umbrella of 'superficial disease' for treatment purposes, despite

evidence that tumours with lamina propria invasion are at higher risk of progressing further.

Tumours not invading the lamina propria (pTa)

The now accepted primary treatment of the superficial lesion is by transurethral resection with a single instillation of an intravesical agent. Once the tumour has been resected, continuing supervision by check cystoscopy is mandatory as 70 per cent of lesions recur at some stage, whilst approximately 10 per cent will subsequently show progression of grade or stage requiring additional therapy.

Tumours involving the lamina propria (pT1)

These tumours have already demonstrated their invasive potential and require more intensive treatment. Intravesical BCG is commonly used.

If there is associated carcinoma *in situ*, or if the tumour is poorly differentiated, approximately half of the patients will develop invasive disease within 5 years. Many urologists believe that early cystectomy is better for this small subgroup, comprising perhaps 5 to 6 per cent of the whole.

Muscle invasive disease of the bladder (pT2 and above)

For the patient with disease invading the bladder muscle, cystectomy or radiotherapy will be necessary. Cystectomy is well established, but is a major procedure that still carries a mortality of between 2 and 4 per cent in different institutions and in different trials. In addition, the patient must accept the need for some form of urinary diversion or bladder replacement. Both are inconvenient to a greater or lesser extent, and the large segments of bowel needed for bladder replacement or a continent diversion bring with them the risks of metabolic problems associated with impaired absorption from the bowel, of diarrhoea, and of electrolyte imbalance. Radiotherapy may be thought to be a more attractive option, especially for the elderly patient. It must be accepted, however, that radical radiotherapy causes troublesome proctitis in 10 per cent of patients and, if survival is prolonged, telangiectases within the bladder that lead to haematuria. In addition, bladder contracture due to ischaemic fibrosis can necessitate secondary cystectomy for intractable symptoms.

As the two forms of radical treatment, cystectomy and radiotherapy, have not been adequately compared in randomized trials, comparisons of outcomes are limited as cystectomy may only be offered to fitter, younger patients. However, both treatment types offer similar overall 5-year survival rates related to the depth of invasion (which can only be accurately assessed in surgical series). This ranges from 60 to 70 per cent for tumours involving superficial muscle only, to 0 to 10 per cent for tumours which have spread beyond the bladder.

Adjuvant chemotherapy appeared to be very promising 10 years ago, but randomized trials have shown no survival advantage for single agent therapy or for combinations including cyclophosphamide, methotrexate, and vinblastine (CMV). The addition to this combination of adriamycin (M-VAC) may have marginally greater benefit but is also more toxic.

In the United Kingdom it is increasingly being suggested that patients with muscle invasive bladder cancer be managed in cancer centres in which there is surgical, radiation, and medical oncological expertise to advise the patient of the options and to supervise effectively the treatment that is chosen.

Transitional cell tumours of the upper urinary tract

Radical nephro-ureterectomy excising a cuff of bladder mucosa remains the treatment of choice in most patients whose other kidney is normal, since accurate staging of tumours of the ureter and pelvis is often impossible because of difficulties in obtaining biopsies of adequate depth endoscopically. Similarly, the possibility of regular assessment of the upper tracts for evidence of recurrence or progression is limited. Unifocal small lesions may be treated endoscopically or by local excision. In the patient in whom overall renal function is impaired or in whom there is only one kidney a conservative approach is desirable. Such lesions may be treated endoscopically or by local excision in certain cases.

Other tumours

Squamous and adenocarcinomas may be found in the bladder and, more rarely, in the upper urinary tract in association with long-standing stone disease, schistosomiasis, or spinal cord injury. The management of these tumours is surgical and the prognosis is poor.

Screening for transitional cell tumours of the bladder and upper urinary tract

Routine urinary cytology in workers in the chemical and dye industries is well established. The situation in relation to the general public is more debatable: screening by dipstick for microscopic haematuria in the elderly yields a positive test in up to 20 per cent, but a tumour incidence of only 1 per cent. Whilst a single positive dipstick test may not merit full urological investigation, if the test is repeatedly positive, formal investigation (urinary cytology, ultrasound of the urinary tract, and perhaps flexible cystoscopy) becomes inevitable, even in patients taking aspirin or anticoagulants, to reassure the physician, the patient, (and his lawyer). Unfortunately there is no evidence that 'screening' picks up invasive bladder cancer more effectively than the superficial tumour, nor that—in patients known to have bladder cancer—screening and early diagnosis will prevent invasion in the 10 per cent of patients in whom this subsequently recurs. For further discussion of the approach to microscopic haematuria, see Section 20.7.

Carcinoma of the prostate

Aetiology and incidence

There is some relationship between the number of sexual partners or extent of sexual activity and prostate cancer. The condition is less common in those who are celibate. The tumour does not occur in those who are castrated before puberty. Dietary factors are also of importance. The incidence is high at 50.7 per 100 000 men.

Clinical features

Patients may present themselves with symptoms of bladder outflow obstruction, bladder irritation, or the effect of some secondary deposit. Increasingly, however, the diagnosis is made as a result of a prostate-specific antigen (**PSA**) test. PSA is a glycoprotein of molecular weight 33 000 containing 7 per cent carbohydrate. It is a serine protease and an esterase with chymotrypsin-like and trypsin-like activity. It is found almost exclusively in the epithelial cells of the prostate.

Investigation and diagnosis

The introduction of the PSA test has led to increasing public awareness of prostate cancer, whilst the introduction of the nerve-sparing technique of radical prostatectomy by Walsh in the early 1980s offered the hope of effective cancer surgery with preservation of sexual function for the patients whose disease proves to be localized. As a consequence, diagnosis is increasingly made before metastases in lymph nodes or bone are evident. Bony metastases are very unlikely unless the PSA exceeds 20 ng/ml and a bone scan at diagnosis is probably an unnecessary luxury in patients whose PSA is below 20. Repeated bone scans during the course of treatment are unnecessary in the absence of clinical indications since repeated PSA tests are as effective and much cheaper.

Large numbers of cancers are now diagnosed following a PSA test at a stage before they are palpable (category T1c) by sextant biopsies under transrectal ultrasound control. The usual indication for biopsy is a PSA exceeding 4 ng/ml, but there is logic in taking a biopsy from all patients whose PSA exceeds 3 ng/ml (see below). As a consequence, large numbers of patients without symptoms and with no clinical findings are discovering that they have prostate cancer and are having to consider the form of therapy that they are prepared to accept. The situation is further complicated by the difficulty in staging the disease when it is not advanced. There is no true prostatic capsule. The prostate merges with the muscle of the bladder above and with the fibres of the levator ani below.

Radical therapy is appropriate for patients whose disease is confined to the prostate—a particularly important point with this disease since the surgeon has little opportunity to excise any normal tissue around the prostate because of its close association with the rectum and the base of the bladder. Surgical studies reveal that

up to 50 per cent of prostatic tumours are understaged clinically, implying the need for even earlier diagnosis if surgical treatment is to be effective.

Treatment

'Localized disease'

In patients whose PSA is less than 20 ng/ml bone metastases are hardly ever seen and many patients have no involvement of their lymph nodes. Such early diagnosis will be of help only if existing therapy is curative or provides improved survival or quality of life. Unfortunately, 30 to 40 per cent of patients, despite early diagnosis, are found to have tumour extending beyond the prostate at the time of surgical intervention, suggesting that recurrence is likely if not inevitable. This is typically discovered as a rising level of PSA during follow-up ('PSA failure'): following radical prostatectomy or radiotherapy the PSA is expected to fall—to zero after operation or to less than 0.5 after radical radiotherapy since the prostate remains *in situ*. PSA failure is more common in those with higher stage and less well differentiated disease. It is seen in half of patients whose PSA at diagnosis is 10 ng/ml or more and in the vast majority of those with lymph node involvement at the time of treatment. None the less, it is possible that the reduction of tumour bulk by operation or radiotherapy may have affected the natural course of events such that the death rate from prostatic cancer will fall significantly, but this will not be clear for at least another 5 to 10 years.

'Advanced disease'

The dramatic change in outlook following the introduction of oestrogen therapy and orchidectomy in the 1940s was followed 20 years later by a search for agents that were more effective and without cardiotoxicity. Unfortunately, neither the steroidal nor non-steroidal anti-androgens, estramustine phosphate, nor the luteinizing hormone releasing hormone (LHRH) analogues used alone or in combination have been shown to prolong life to any clinically significantly extent, and many have concluded that little progress has been made in hormone therapy in the last 50 years. It is true, however, that sexual function may be preserved somewhat longer if the patient takes a non-steroidal anti-androgen and that the modern compounds have a lower rate of cardiovascular complications than stilboestrol.

Screening for prostate cancer

This topic creates great emotion in urological circles. The debate is polarized between those who believe that screening and radical therapy (prostatectomy) will cure the condition and those who are less certain that screening will identify only those patients whose cancers are likely to be life-threatening during the remaining years of the individual's life.

Post-mortem studies of victims of road accidents reveal that histological changes of prostate cancer can be found at increasing frequency with age from 30 per cent of 40-year olds to 50 per cent of 80-year olds. Of 1000 men in their 50s to 70s approximately 400 will have histological changes of prostate cancer, but only 100 will develop symptoms of the disease in the remaining years of their lives, whilst the 'forces of competing mortality' result in only one-quarter of these dying of the condition. Those anxious to prove that radical prostatectomy will cure the condition are naturally in favour of population screening. Epidemiologists are less convinced of its benefits to society as a whole.

A recent report of a working party of the British Association of Urological Surgeons recommends the following.

1. There is a need for scientifically valid controlled trials. These are currently being undertaken in the United States and Europe by the International Prostate Study for Treatment and Evaluation Group (IPSTEG) and by the European Randomized Study for Screening of Prostate Cancer (ERSPC).
2. Diagnostic tests, particularly prostate-specific antigen (PSA) measurements, should not be used in those for whom they are inappropriate, particularly the very elderly and those with diseases severely limiting their life expectation.
3. No asymptomatic man who requests PSA testing should undergo tests for prostate cancer without adequate counselling as to the possible consequences.
4. The role of PSA as part of a routine protocol for investigating men with lower urinary tract symptoms is controversial.
5. Transurethral ultrasound and biopsy must be carried out by trained operators with appropriate equipment.
6. The diagnosis of early prostate cancer will identify those who need or desire treatment for confined disease.
7. Early prostate cancer should be managed in designated clinics where the patient has access to a urologist and an oncologist.

The approach to a patient who has symptoms or has a genuine fear of having prostate cancer must be different from that adopted towards the population as a whole. Even here, however, it must be remembered that approximately half the men subjected to radical prostatectomy whose PSA at diagnosis is between 4 and 10 ng/ml have disease outside the prostate, and that a PSA limit of 3 ng/ml is probably more effective for population screening since:

1. 12 per cent of tumours are found in men whose PSA is between 3 and 4 ng/ml;
2. almost half the patients diagnosed at screening have extraprostatic disease; and
3. 'PSA failure' (a gradually rising PSA following radical treatment) is found in up to 50 per cent of patients within 5 years of operation.

However, it should be noted that the death rate from prostatic cancer in the United States which rose during the 1990s and peaked in 1996 has since fallen for reasons which are not fully understood, but which may relate to early diagnosis and to radical therapy.

Carcinoma of the kidney

Aetiology and incidence

Though tumours may be produced in animals following irradiation, prolonged administration of oestrogens, exposure to nitrosamines, aromatic agents, and certain alkylating agents, the cause of renal tumours in humans is less well understood. Renal cell cancer is four times as common in males as in females, is linked with smoking, and associated with exposure to cadmium. It is more commonly found in areas with urban or industrial pollution than in rural areas. The incidence in males and females is 10.3 and 5.6 per 100 000 population, respectively.

Rarely, renal cancer appears to run in families, when a defect in the short arm of chromosome 3 is found in many cases (88 per cent in one series). Similar abnormalities are common in non-familial renal cancer and are found uniformly in von Hippel–Lindau disease—an inherited syndrome in which cysts or tumours in the kidney, pancreas, adrenal gland, epididymis, cerebellum, and spinal cord may form. Between one-third and one-half of patients with this condition develop renal cell tumours that are often bilateral and multifocal.

Investigation and diagnosis

Though some tumours are still diagnosed with the classic triad of haematuria, flank pain, and a palpable mass, many tumours are now discovered when completely asymptomatic and at a much earlier stage as a consequence of an incidental upper abdominal ultrasound (Fig. 2). It is also well recognized that renal cancer can present with a variety of apparently unrelated paraneoplastic syndromes. These are a consequence of the production of hormones or cytokines, or perhaps arise from an immune response to the tumour. Relatively common presentations include anaemia, hypertension, pyrexia of unknown origin, fatigue, and an increased plasma viscosity or raised erythrocyte sedimentation rate. Less common presentations include hypercalcaemia, polycythaemia, liver dysfunction, enteropathy, and neuromyopathy.

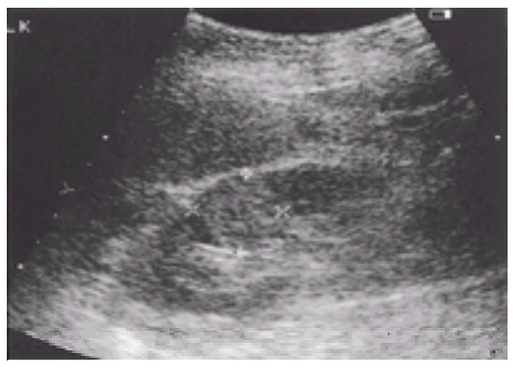

Fig. 2 Renal ultrasound scan showing an incidentally detected, small (2.5 cm diameter) renal cell carcinoma, proved to be stage T1 following nephrectomy. The edge of the tumour is marked by the four crosses.

Until 20 years ago it was necessary to rely upon an intravenous urogram to show evidence of a space-occupying lesion within the kidney and difficult to detect tumours less than 3 cm in diameter. Modern ultrasound and CT can detect and correctly characterize 95 per cent of renal masses greater than 1 cm in diameter. Detection rates for lesions less than 1 cm are 50 per cent.

Survival is crucially dependent upon tumour stage. The free use of upper abdominal ultrasound in the investigation of many patients with upper abdominal symptoms or with symptoms consistent with renal cancer has led to a rapid increase in the diagnosis of early stage tumours that are potentially curable. These small lesions do, however, present diagnostic difficulties to both the pathologist and radiologist whose task it is to separate the renal carcinoma from benign tumours such as oncocytomas, angiomyolipomas, and complex cysts.

The use of ultrasound, CT (Fig. 3), and MRI (Fig. 4), if necessary with image-guided biopsy, can nearly always determine the nature of the tumour and the extent, if any, of lymph node involvement and venous invasion, whilst a bone scan will complete the basic investigations required prior to surgical excision. Tumours diagnosed whilst still small (less than 3 cm) and without extension to lymph nodes or the venous system are likely to have a 10-year survival of 90 per cent if treated effectively.

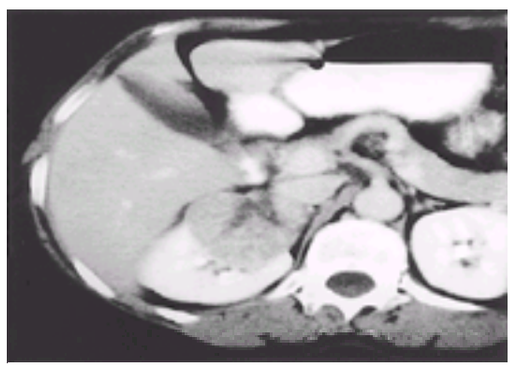

Fig. 3 CT scan showing a renal carcinoma extending into the retrocaval tissues.

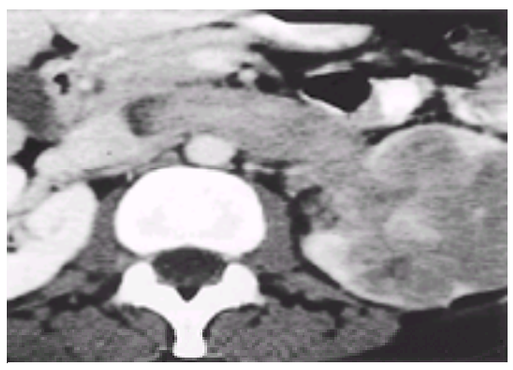

Fig. 4 MR scan showing a renal carcinoma distending and filling the left renal vein and the inferior vena cava.

Treatment

As yet renal tumours can only be cured by surgical excision. The standard treatment is still that of radical nephrectomy in which the affected kidney is removed with its perinephric fat and fascia. It has not yet been established that routine lymph node dissection is of value, but it is recognized that radiotherapy has little role in the management of the primary tumour or local recurrence, although it can be helpful in 'sterilizing' solitary bone metastases.

The use of nephron-sparing surgery is appropriate for smaller tumours, for the patient with a solitary kidney, for those with bilateral tumours, and in patients with von Hippel–Lindau disease. If the partial nephrectomy which such an excision involves leaves half of one functioning kidney, renal function will be adequate. For patients with very small lesions near the cortex of the kidney a simple wedge excision may be sufficient. If local recurrence occurs following partial nephrectomy, the remaining part of the kidney can be removed. It is often impossible for the surgeon to know exactly what sort of operation will be required until 'they get in there'. If there is any likelihood that the patient may be rendered anephric, this prospect should be fully discussed, and the patient introduced to the local renal unit for discussions regarding long-term dialysis before surgery is undertaken.

As yet neither chemo- nor immunotherapy have proved effective, but the use of interferon and interleukin 2 alone or in combination offers a 10 to 40 per cent chance of a partial or complete response in patients with advanced disease following preliminary nephrectomy and in good general condition. Metastases in the lungs are those which respond most frequently. Patients with a complete response have a two-thirds chance of surviving for longer than 1 year. Adoptive immunotherapy and trials of gene therapy remain at the investigational stage.

Advanced disease

For those in whom the diagnosis of renal carcinoma is not made until the local tumour is advanced, or with invasion of the vena cava, nodal involvement, or distant metastases, the outcome remains poor despite therapy. Nephrectomy may be considered for relief of symptoms but is unlikely to be able to offer the prospect of long-term survival. Spontaneous regression of metastases has been reported in fewer than 1 per cent of patients treated by nephrectomy, the responding lesions usually being in the lungs. The surgeon may also be of help to the patient with an apparently solitary skeletal metastasis, since it may be possible to excise it and provide a prosthetic replacement; also to relieve incipient spinal cord compression. In the management of such metastases adjunctive postoperative radiotherapy also plays a role.

Screening for carcinoma of the kidney

This tumour is relatively uncommon, is known to present with a wide variety of symptoms, and 30 per cent of people have metastases at diagnosis. Though no formal screening programme has been suggested, the increasing use of abdominal ultrasound for investigation of problems arising within the upper abdomen has brought to light many small and asymptomatic space-occupying lesions within the kidneys which present a diagnostic problem to the clinician and radiologist. CT scan or MRI with or without needle biopsy can confirm the diagnosis, but the decision as to the type of treatment to be offered is difficult, especially in the elderly patient in whom so many of these lesions are found.

Testicular tumours

Aetiology and incidence

Maldescent increases the risk of testicular cancer approximately fourfold and a range of other abnormalities in urogenital development, such as testicular atrophy or intersex states, have also been associated with an increased risk. This indicates that there are aetiological events associated with embryonic development, but the nature of these events is not known. Excessive oestrogenic exposure may play a role. The incidence has doubled in the last 20 years for reasons that are not understood, but germ cell tumours of the testis are rare, accounting for no more than 1 to 2 per cent of malignancies in males. The incidence (5.1 per 100 000 men) peaks between the ages of 25 and 34 years.

Clinical features, investigation, and diagnosis

From the clinical perspective it is important for the practising physician to remember that whilst most patients notice a lump, a few have symptoms consistent with epididymo-orchitis and a minority present with symptoms of metastases in nodes or other organs. Any disabling symptoms in a male under 35 years of age, such as malaise, loss of weight, backache, and pulmonary symptoms, including haemoptysis, may arise from a previously unrecognized testicular tumour that has metastasized. In a young adolescent or adult male in whom the diagnosis is in doubt or obscure, blood samples for a-fetoprotein and b-human chorionic gonadotrophin should be taken.

Examination of the abdomen in outpatients or on admission must include examination of the scrotal contents. Unless a completely normal testis can be identified, urgent ultrasound of the scrotum is indicated. This is very accurate in determining whether any mass is intratesticular (probably malignant) or extratesticular (probably benign). Samples of blood for a-fetoprotein and b-human chorionic gonadotrophin are mandatory investigations prior to surgery. Any tumour found must be removed without delay. The urologist should deal with such a patient on their next list by removing the testicle with spermatic cord as far as the internal inguinal ring.

Treatment

Following diagnosis by 'excision biopsy', as outlined above, all further management (staging, treatment, and subsequent follow-up) must be in the hands of a specialist cancer centre where expertise should be available to ensure that appropriate additional care is given without delay. Pathological assessment of the orchidectomy specimen is performed to confirm the germ cell origin of the tumour (other diagnoses to be considered include Sertoli or Leydig cell tumours and lymphoma). Germ cell tumours are divided into two main categories, seminoma and teratoma (non-seminomatous germ cell tumours in the American literature), which differ in terms of their relapse rates, patterns of spread, and treatment. Important clinical distinction is also made between patients who have disease clinically localized to the testis at the time of presentation and those who have evidence of metastatic disease.

Localized tumours

Relapse occurs in 16 per cent of patients with seminomas and twice as many with teratomas. Radiotherapy is the treatment of choice in seminoma because it is radiosensitive, and also because it tends to spread in a contiguous manner, with 80 per cent of relapses occurring in the retroperitoneum. Sites of relapse are less predictable in teratoma, and patients considered to be at high risk (generally because of the presence of vascular invasion in the orchidectomy specimen) are given chemotherapy in the United Kingdom. In North America, standard treatment involves a surgical retroperitoneal lymph node dissection and chemotherapy is reserved for those with evidence of established metastatic disease.

Metastatic disease

The dissemination of testicular cancer beyond the testis was a uniformly fatal illness until the 1960s. During the 1970s the introduction of a series of chemotherapy combinations, particularly those involving cisplatin, resulted in improving cure rates for patients with advanced disease. In modern practice, when treatment is delivered carefully by specialized multidisciplinary teams, 90 per cent of patients with testicular cancer, even if disseminated, can expect to be cured.

The International Germ Cell Consensus Classification, based on multivariate analyses of prognostic factors for progression and survival, determined that the most important factors for patients with a testicular primary were the level of serum markers (a-fetoprotein, b-human chorionic gonadotrophin, and lactate dehydrogenase) and the presence or absence of non-pulmonary metastases. The 5-year survival for patients with non-pulmonary visceral metastases was 18 per cent compared with 80 to 92 per cent for patients without such metastases. For the minority of patients for whom conventional therapy is not curative—identifiable by careful consideration of these prognostic factors—therapy including high-dose treatment, new drugs, and combined modality treatment with surgical resection of residual disease can still result in significant benefit.

Screening for tumours of the testis

Testicular self-examination is to be encouraged. Teenagers and men up to the age of 50 years should examine their testicles on a monthly basis, presenting themselves for consultation, diagnosis, and therapy if any abnormality is detected. Any abnormality not otherwise easily explicable should be investigated urgently by testicular ultrasound together with blood samples for a-fetoprotein and b-human chorionic gonadotrophin. Of the urological tumours, this is the only group for which therapy must rightly be given on an emergency basis.

20.16 Drugs and the kidney

D. J. S. Carmichael

Introduction

The kidney is the major route of elimination for many drugs and their metabolites. This excretion may be by glomerular filtration, tubular secretion, or in some cases both. In practice a minority of drugs need dose adjustment (dosage and/or interval). The major problems occur in those drugs with a narrow therapeutic range or whose adverse effects are related to the concentration of the drug or its metabolites.

Excretion is affected most by reduction in the glomerular filtration rate, but absorption, distribution (including protein binding), metabolism, and pharmacodynamics may be altered in patients with renal impairment. However, the major determinant of alteration in dosage is the change in drug clearance, which can be estimated by measurement of the glomerular filtration rate, and many handbooks provide guidelines for the adjustment of dosage in renal impairment. Many of these data are derived from measurement or estimation of changes in clearance, half-life ($t_{1/2}$), and volume of distribution (V_d). Renal impairment will often be defined as mild (glomerular filtration rate > 50 ml/min), moderate (glomerular filtration rate > 20 to < 50 ml/min) or severe (glomerular filtration rate < 20 ml/min).

Patients with established chronic renal impairment are often on many medications, either for treatment of the primary disease or its consequences (dialysis, transplantation) or concurrent medical problems. Conversely many patients who are prescribed drugs have impaired renal function (often unrecognized) coincidentally or as a result of other medical problems. Although alteration in pharmacokinetics in renal disease is important, problems are more likely to arise for the following reasons:

i. ignorance of renal impairment before a drug is prescribed;
ii. ignorance of how a drug is cleared from the body;
iii. failure to monitor therapeutic and adverse effects.

Pharmacokinetics

Renal excretion

Renal excretion of drugs depends upon:

i. filtration
ii. active tubular secretion and reabsorption
iii. passive diffusion.

Renal clearance of drugs is a function of the glomerular filtration rate, but tubular reabsorption, secretion, and passive diffusion are contributory factors. If renal clearance is less than the glomerular filtration rate, then tubular reabsorption must be taking place; if it is greater than the glomerular filtration rate, then there must be active tubular secretion.

Compounds with a molecular weight below 60 000 Da are filtered through the glomerulus to a variable extent depending on molecular size, unless they are protein bound when only the unbound portion is filtered. Non-polar (lipid soluble) drugs diffuse readily across tubular cells whereas polar (water soluble) compounds do not. Hence polar drugs generally remain in the tubular fluid and are excreted in the urine, whilst non-polar drugs are reabsorbed by passive diffusion down their concentration gradient into plasma. Some polar drugs are eliminated in the urine as a result of active or facilitated transport mechanisms that transport organic acids or bases (see Table 1). Many drugs are metabolized, primarily in the liver, to produce more polar compounds that cannot be passively reabsorbed and so are eliminated in the urine. In renal failure there may be reduced clearance of these metabolites, which could have therapeutic or adverse effects (see Table 2).

Elimination of organic acids (AH) or bases (B) is affected by the H^+ ion concentration of the tubular fluid, with any change of urinary pH that favours ionization leading to more drug excretion:

$$H^+ + B \; pK_B ?2; \; BH^+$$
$$AH \; ?2; pK_A \; H^+ + A^-$$

The amount of ionized drug at any particular pH is determined by its p K, this being the pH at which 50 per cent of the drug is ionized. If an organic acid has a p K_A of less than 7.5, making the urine alkaline (i.e. increasing its pH) increases the amount of ionized drug (A^-) and therefore its excretion. The converse is true for organic bases with a pK_B of more than 7.5, which are eliminated as the charged (BH^+) form favoured by acid pH. The excretion of salicylates (weak acids) and amphetamines (weak bases) exemplifies these principles.

Although it is an oversimplification to disregard the tubular handling of drugs in renal impairment, both filtration and secretion of drugs appear to fall in parallel and in proportion to the glomerular filtration rate. Hence by far the most important aspect of prescribing in renal disease is awareness of the existence of renal impairment and of changes in renal function: some measure of glomerular filtration rate is needed, serum creatinine measurement usually being sufficient, but more precise measurement is required in some circumstances, for example before the use of known nephrotoxins in chemotherapeutic regimes.

Drugs present in tubular fluid may affect the excretion of other compounds; for example, aspirin and paracetamol reduce methotrexate excretion and probenecid

reduces tubular secretion of penicillins and cephalosporins.

Drug kinetics

Most drugs that are eliminated by the kidney display first-order kinetics, meaning that the rate of removal is proportional to the concentration of the drug. The elimination rate constant k_e is the proportion of the total amount of drug removed per unit time, producing a simple exponential decline (and therefore a straight line on a semilogarithmic plot) in concentration (Fig. 1). The half-life ($t_{1/2}$) of a drug is the time for its plasma concentration to fall by half after absorption and distribution are complete. It is useful in determining dosage interval, drug accumulation (both extent of accumulation and the time taken to reach steady state), and persistence of drug after dosing is stopped. $t_{1/2}$is inversely related to k_e:

$$t_{1/2} = 0.693/k_e$$

(note: 0.693 = ln 2). The clearance of a drug depends upon $t_{1/2}$ (k_e) and the volume of distribution (V_d). The latter does not usually correspond to a real (physiological) volume, although for a drug confined exclusively to the plasma it would approximate to the plasma volume: it represents an apparent volume in which the amount of drug administered would have distributed to produce the measured plasma concentration. The volume of distribution itself may be affected by the protein and tissue binding of drugs, changes in intravascular and extravascular fluid volumes, and lean body mass. Digoxin is one of the few drugs in which a smaller loading dose is needed because of changes in V_d in renal impairment.

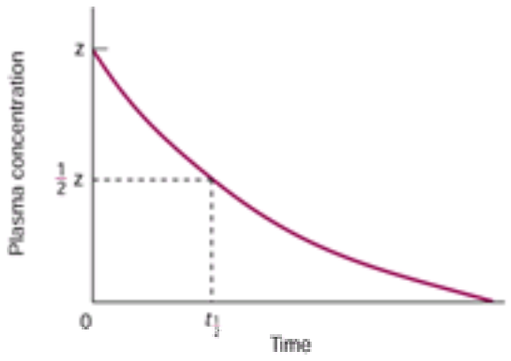

Fig. 1 Plot of log concentration of a drug against time to demonstrate the half-life of a drug.

Clearance can be used to calculate the steady state concentration of a drug (C_{ss}) that can be anticipated in response to any particular dosage regimen. This concentration is proportional to the dose and $t_{1/2}$ of the drug and inversely proportional to the V_d and dosage interval. From these relationships it can be seen that C_{ss} will increase with a longer $t_{1/2}$ and a smaller V_d; it can be reduced either by lowering the dose or by increasing the dose interval.

The relationship between the elimination of a drug in the presence of renal impairment and normal renal function can be estimated and used to gauge the appropriate reduction in dose or increase in dose interval compared with a standard regimen. If non-renal clearance accounts for 50 per cent or more of total drug clearance then no dose adjustment will be needed, provided that non-renal clearance is not affected by renal impairment. If dose reduction is required, then dose, dose interval, or both can be adjusted to reduce dose per unit time. However, in practice the decision whether to reduce dose or prolong dose interval is not always equivalent: for example in the use of aminoglycoside antibiotics, which must achieve a threshold peak concentration in order to kill bacteria effectively, when small but frequent doses may fail to achieve efficacy whereas the same total dose delivered less frequently may achieve the desired therapeutic effect without leading to accumulation and toxicity.

Other pharmacokinetic topics

Gastrointestinal absorption, distribution, metabolism, and renal haemodynamics are other factors that may be altered in the presence of renal impairment. They are less significant than the effects of changes in renal excretion and are dealt with in more specialized pharmacology texts.

Dialysis and haemofiltration

The clearance of drugs by haemodialysis and haemofiltration follows first-order kinetics. Estimates of clearance can be obtained by use of the sieving coefficient, which is the proportion of the drug (or solute) that will cross the membrane and should be constant for a particular drug and membrane (see Table 3). This depends on the drug's molecular weight (and size) and protein binding. Haemofilters have a pore size of 0.01 µm and artificial kidneys for haemodialysis have a pore size of 0.001 µm. In haemofiltration, drugs with a molecular weight below that of inulin (5200 Da) will pass through, whereas in haemodialysis most drugs with a molecular weight below 500 Da (which includes most antibiotics) will be cleared, but drugs such as vancomycin (1800 Da), amphotericin (960 Da), and erythromycin (734 Da) behave differentially with respect to haemofiltration/haemodialysis. Heavily protein bound drugs, even those of low molecular weight (propranolol 259 Da), will not be filtered, but drugs that are displaced from binding sites in the presence of renal impairment will become available for filtration. Water soluble drugs pass through filters more readily than those which are fat soluble. The other differences between the different techniques of haemodialysis, haemodiafiltration, and intermittent and continuous haemofiltration are dealt with in Chapter 20.6.1 and other specialized texts.

Digoxin and antidepressants are examples of drugs with a large volume of distribution that will have low plasma concentrations, hence little of the drug is available for filtration.

Peritoneal dialysis clears drugs very much less efficiently than haemodialysis/filtration, some needing careful adjustment of prescription, for example antibiotics in the treatment of continuous ambulatory peritoneal dialysis peritonitis.

Poisoning

Haemodialysis, peritoneal dialysis, haemofiltration, and haemoperfusion have all been used to eliminate poisons and drugs in overdose from the body. Peritoneal dialysis is very slow but can be used to clear alcohols, salicylate, and lithium if haemodialysis or filtration are unavailable. Similar principles apply to those for the handling of drugs in therapeutic dialysis and filtration. A substance that has a low V_d, low protein binding, and is unipolar will be cleared more efficiently. Note, however, that measurements of the amount of any drug in the body almost invariably report the plasma concentration, and simple estimates of the clearance of any substance will reflect the rate at which the plasma is cleared, ignoring the relationship between the plasma and other compartments. This is a gross oversimplification in some instances, when rebound of plasma concentration occurs as drug redistributes from intracellular compartments.

Haemodialysis

All toxins of size 100 to 2000 Da can be removed using conventional filters, preferably by dialysis with bicarbonate buffering as many toxins will cause acidosis. Should rebound of plasma levels of a substance occur after a period of treatment, as described above, then continuous haemofiltration or repeated haemodialysis may be required; for example thallium poisoning may need prolonged treatment over several days. High-flux membranes used in continuous haemofiltration and haemodiafiltration will remove larger sized molecules (up to 10 000 Da).

Haemoperfusion

Haemoperfusion relies on the affinity of an adsorbent for a toxin and can be used preceding filtration or dialysis in series. Activated charcoal or polystyrene exchange

resins are usually used in a column arranged like an artificial kidney. The technique is particularly useful for toxins with a low V_d: poisons and drugs that can be removed by these means are listed in (Table 4). Further information should be obtained from the National Poisons Centre (Toxbase http://www.spib.axl.co.uk/toxbaseindex.htm).

Prescribing drugs for patients with renal failure

Once the clinician has identified that renal impairment is present, and that a drug to be administered has clinically important renal excretion, the dose can be adjusted in two main ways. Either the size of each dose or the frequency of administration can be reduced. Plasma drug concentrations can be used to confirm that the initial adjustment of dosage is correct in that particular individual. Steady state concentrations of anticonvulsants, digoxin, and theophylline can be measured after the equivalent of five half-lives of the drug. For antibiotics such as gentamicin monitoring is required after the first day's administration and continued if renal function is impaired or changing.

The combination of reduction in dosage and less frequent administration is suitable for most drugs. Dosage reduction alone is more likely to lead to subtherapeutic plasma concentrations. Unfamiliar dosages and administration of drugs at odd times may result in errors, hence adjustments of dose and timing must be kept simple and clear. The physician should use a limited number of drugs and learn about their clearance in renal impairment and changes during renal replacement therapy.

Many of the most complex prescribing problems arise in patients with acute renal failure, particularly if this occurs as part of multisystem failure, perhaps in a patient requiring artificial ventilation and some form of renal replacement therapy.

Acute renal failure on the intensive care unit

Neuromuscular blocking agents

Succinylcholine is rapidly hydrolysed by plasma cholinesterase: no dose adjustment is needed. For more prolonged paralysis atracurium should be used; this is degraded by non-enzymatic Hofmann elimination independent of renal or hepatic function. It is removed by dialysis and haemofiltration: the dose must be titrated to produce a therapeutic effect. Avoid tubocurarine, gallamine, alcuronium, pancuronium, and vercuronium.

Anaesthetic and sedating agents

Propofol, fentanyl, and alfentanyl require no dose adjustment, but the latter two may have prolonged effects if there is concomitant hepatic dysfunction. Metabolites of diazepam accumulate and midazolam is preferable (with dosage reduction) if the glomerular filtration rate falls below 10 ml/min. Phenothiazines, butyrophenones, and chlormethiazole are given in the usual doses.

Treatment of pain or inflammation: analgesics and anti-inflammatories

Narcotic analgesics

Opiates are affected by renal failure, and retention of metabolites can produce adverse effects which may be reduced by intermittent dosing, epidural administration, or low-dose continuous infusions. Diamorphine is metabolized into morphine and then to morphine-3-glucuronide and morphine-6-glucuronide, both of which accumulate to prolong both analgesia and respiratory depression. Morphine and its metabolites are not cleared well by haemofiltration or dialsysis. Pethidine (meperidine) is converted to norpethidine (normeperidine), which accumulates and can cause seizures. Papaveretum is a mixture of alkaloids of opium including morphine, codeine, noscapine, and papaverene: its use is not recommended. Codeine and dihydrocodeine, although weaker analgesics, still have the potential to cause severe respiratory depression in some patients with renal failure, likewise dextropropoxyphene (combined with paracetamol as coproxamol). Its metabolite norproxyphene, which accumulates in renal failure, sometimes causes cardiac toxicity. Buprenorphine is metabolized in the liver and does not appear to have any important toxic metabolites.

If confronted with a patient with renal failure who is inexplicably drowsy or has depressed respiration and who has (or might have) received opiates in the last 72 h, then a trial of intravenous naloxone should be administered: this is sometimes dramatically effective.

Non-narcotic analgesics

Paracetamol (which in overdosage is an important cause of acute renal failure) is excreted in small amounts by glomerular filtration, with some passive tubular reabsorption. Most of the drug is metabolized and the glucuronide and sulphide metabolites, which are subject to active tubular secretion, accumulate in renal impairment, with some regeneration of the parent compound. Despite this, paracetamol is used in the usual doses. Aspirin has the disadvantage of causing gastric damage and increasing the bleeding diathesis of patients with renal failure. Renal elimination of its metabolite salicylate is enhanced in alkaline urine (see above).

Anti-inflammatory agents

Non-steroidal anti-inflammatory drugs including aspirin inhibit the synthesis of prostaglandin by inhibition of cyclo-oxygenase. The principal renal prostaglandins in humans are prostaglandin E_2 and prostaglandin I_2, each of which is vasodilator and natriuretic, having direct effects on both renal blood flow and tubular ion transport. In healthy individuals inhibition of cyclo-oxygenase has no detectable effect on renal function, but in patients with cardiac failure, nephrotic syndrome, liver disease, glomerulonephritis, and other renal disease cyclo-oxygenase inhibitors predictably cause a reversible fall in glomerular filtration rate that can be severe. They can also cause fluid retention and hyperkalaemia. There is evidence that sulindac causes less inhibition of renal cyclo-oxygenase than a dose of ibuprofen that is equieffective on extrarenal tissues and sulindac may cause less renal impairment than other non-steroidal anti-inflammatory drugs. Aspirin may also spare cyclo-oxygenase in the kidney to some extent. The clinical relevance of these observations remains uncertain and caution is needed in severe renal impairment when using any non-steroidal anti-inflammatory drugs.

Indomethacin, azapropazone, and diflunisal have important renal excretion, whereas most other non-steroidal anti-inflammatory drugs are eliminated by metabolism. The non-steroidal anti-inflammatory drugs are highly protein bound and are not removed by dialysis.

Treatment of circulatory disturbance, cardiac disease, or hypertension

Problems can be avoided or minimized by titration of a low starting dose of any drug to produce the required therapeutic effect.

Vasopressors and vasodilators

Adrenaline, dobutamine, dopexamine, dopamine, and noradrenaline should be used in the minimum doses possible to avoid renal vasoconstriction. They all have a short half-life and are not affected by haemo- or haemodiafiltration. Intravenous nitrates are given in the normal dosage. Sodium nitroprusside is metabolized in the liver to sodium thiocyanate, which is eliminated by the kidney and thus may accumulate in renal failure, causing toxicity. It is removed by haemofiltration or haemodiafiltration.

Antiarrhythmics

In patients with abnormal renal function it is advisable to keep treatment simple. Most antiarrhythmic drugs are used without dose modification, for example lidocaine (lignocaine) and verapamil. Digoxin is a notable exception, with a lower loading and maintenance dose than usual. Flecainide and disopyramide require dosage reduction. Amiodarone requires a lower maintenance dose (100 mg daily) when the glomerular filtration rate falls below 20 ml/min.

Diuretics

Spironolactone, triamterene, and amiloride, all potassium sparing diuretics, should be avoided or used with extreme caution in renal impairment because of the danger of hyperkalaemia. The same applies for combination diuretics such as 'Moduretic' (amiloride and hydrochlorothiazide) or 'Dyazide' (triamterene and hydrochlorothiazide). Thiazides, apart from metolazone (a quinolone), become less effective in treatment of both fluid retention and hypertension if the glomerular filtration rate is below 25 ml/min. Higher doses of loop diuretics are needed, but the synergistic effect with metolazone may overcome 'diuretic resistance' in refractory oedema.

Severe sodium and water depletion can occur in diuretic therapy. This may affect renal haemodynamics with secondary effects upon renal function and concomitant drug therapy.

Angiotensin converting enzyme inhibitors

Whether angiotensin converting enzyme inhibitors are being used to treat cardiac failure or hypertension the same precautions apply. Starting doses should be low and increased slowly with careful monitoring of serum creatinine and potassium. Particular caution is necessary if these drugs are used in combination with diuretics or in other high-renin states (for example volume depletion), when marked hypotension ('first-dose effect') may be anticipated. Caution is also necessary when there is (or may be) a possibility of renal artery stenosis, both because of the risk of hypotension and also because of the reduced glomerular filtration rate in the affected kidney(s). Angiotensin converting enzyme inhibitors should not generally be used with potassium sparing diuretics because of the added risk of hyperkalaemia. The kidney eliminates all angiotensin converting enzyme inhibitors, accounting for the reduced dose usually required in the elderly. Exactly the same advice pertains for angiotensin II receptor antagonists.

b-blockers

Atenolol, bisoprolol, pindolol, nadolol, and sotalol are all excreted by the kidney and reduced doses may be needed. The metabolites of acebutolol may accumulate. Other b-blockers are prescribed unchanged.

Vasodilators, calcium channel blockers, and a-blockers

No dose adjustment is needed for any of these drugs. Minoxidil therapy often requires concomitant use of a loop diuretic.

Centrally acting agents

a-Methyldopa, moxonidine, and clonidine are given in the usual doses and titrated for their effect.

Treatment of infection: antimicrobials

Many antimicrobial agents are excreted by the kidney. With the exception of aminoglycosides and vancomycin, most have a wide therapeutic index and little or no dose adjustment is typically made until the glomerular filtration rate is less than 20 ml/min. Antimicrobials that are removed by dialysis should be administered after dialysis, or a supplemental dose given at that time. Adjustments are shown in Table 5.

Penicillins

All penicillins need to be given in reduced dose. Carbenicillin and ticarcillin solutions contain approximately 5 mmol Na^+/g, and caution is needed in the presence of salt and water retention. Mezlocillin (unlike other penicillins) is not removed by dialysis.

Intravenous cephalosporins and other b-lactams

Cephalosporins are excreted in similar fashion to penicillins and need dose reduction in renal impairment (Table 5). The later generation drugs are relatively safe, but caution is still needed with cefuroxime. The carbapenems imipenem and meropenem have a broad spectrum of activity: the former is partially inactivated by a renal dipeptidase and hence administered in combined preparation with cilastatin, an inhibitor of this enzyme. Aztreonam (a monobactam) requires dose adjustment.

Aminoglycosides

Aminoglycosides need dose adjustment in mild renal impairment. Furthermore, they are inherently nephrotoxic and their use may worsen renal impairment as well as causing ototoxicity. Several factors predispose to nephrotoxicity: these include prior or prolonged treatment, hypovolaemia, dehydration, concomitant administration of diuretics, hypokalaemia, and hypomagnesaemia. Obstructive jaundice also increases the risk. The simplest way to prevent aminoglycoside toxicity is to avoid their use altogether in patients with any suspicion of renal impairment and prescribe alternatives.

Nomograms and other guidelines should be used for dose adjustment of aminoglycosides in patients with renal impairment, usually based on conventional multiple dosages. Since the volume of distribution of aminoglycosides is not materially affected by renal impairment, an adequate loading dose is required whatever the method of dose adjustment. Reduction of dose (without alteration in frequency of administration) may lead to an increased likelihood of subtherapeutic peak plasma levels. However, if only the frequency of administration is reduced, then subtherapeutic plasma concentrations are more likely to occur over longer periods. A combination of both methods with frequent peak measurements (taken 1 h after intravenous dosing) and trough measurements (immediately before the next dose) is optimal. An alternative method is to give a single daily dose, there being evidence that gentamicin is less nephrotoxic with an initial dose of 3 to 5 mg/kg body weight, with adjustment made on a daily trough level. Such measurements should be made daily when alterations in renal function are anticipated and two to three times a week under other circumstances. Doses and therapeutic concentrations are shown in (Table 6).

Vancomycin and teicoplanin

Vancomycin is excreted by the kidney and is not dialysed (except at extremely high flow rates in haemofiltration, by haemodiafiltration, or by haemodialysis with high-flux dialysers). In patients with endstage renal failure on dialysis, therapeutic concentrations can be maintained for 5 days or more after a single intravenous dose, the target steady state plasma concentration being approximately 15 mg/l. Following a loading dose of 15 mg/kg, further doses are given on the basis of plasma concentration.

Teicoplanin, a glycopeptide related to vancomycin, behaves rather differently. The half-life is prolonged by approximately threefold in renal failure, and after a loading dose of 400 mg the maintenance dose of 200 mg/day is reduced after 3 days, even in mild renal failure. It is not cleared by dialysis.

Ciprofloxacin

Renal excretion exceeds the glomerular filtration rate, and in patients with normal renal function approximately 60 per cent is cleared by passage through the kidneys. It is recommended that the dose should be reduced in renal impairment, but the proportion that is eliminated by the kidney is reduced in renal failure as a result of an increase in hepatic clearance and of secretion through the wall of the bowel. This becomes more problematic if there is combined renal and hepatic or intestinal failure. Ciprofloxacin is not significantly removed by haemodialysis, but is partially removed by haemofiltration.

Tetracyclines

All the tetracyclines, with the exception of minocycline and doxycycline, are renally excreted. Plasma half-lives are markedly prolonged (up to 100 h) in renal impairment. Tetracyclines are antianabolic and cause a concentration-related increase in blood urea, setting up a vicious cycle leading to deterioration in renal function. Doxycycline or minocycline can be used cautiously in patients with renal impairment, but the other tetracyclines are contraindicated. Demeclocycline, peculiar to itself, has an inhibitory effect on the tubular action of antidiuretic hormone.

Sulphonamides and cotrimoxazole and trimethoprim

Sulphonamides are eliminated by acetylation followed by renal excretion, and acetylated metabolites (which have no antibacterial activity) are a cause of crystalluria and tubular damage. High doses of cotrimoxazole are needed in the treatment of *Pneumocystis carinii*, the risk of adverse effects being balanced against the seriousness of the condition. Such patients often have impaired renal function. The dose is trimethoprim 20 mg and sulphamethoxazole 100 mg/kg body weight/day divided into two or more doses. The plasma concentration should be maintained at approximately 5 to 8 µg/l, measured after five doses. Full dosage should be given initially to those with renal impairment and then reduced if necessary.

Pentamidine

The usual dose is 4 mg/kg, given by slow intravenous infusion over 90 min. There is considerable tissue binding and the drug is excreted in the urine over long periods. The dose should be reduced in patients with renal impairment and, since the drug is nephrotoxic, the dose should be reduced by 30 to 50 per cent if the serum creatinine increases by 88 µmol/l (1 mg/dl).

Antituberculous chemotherapy

Rifampicin and isoniazid (given with pyridoxine) are given in the usual doses. Rifampicin is a potent inducer of the cytochrome P-450 system and will therefore affect cyclosporin metabolism. The dosage of ethambutol and pyrazinamide needs to be reduced. Capreomycin is nephrotoxic and, although streptomycin can be used, careful monitoring after each dose is required.

Antiviral agents

Aciclovir and ganciclovir are both eliminated by the kidney and both are dialysed. Similar dose reductions are needed for each (see Table 5). Antiretroviral drugs such as lamivudine, zalcitabine, and zidovudine all need reduced dosage.

Antifungal agents

Amphotericin is nephrotoxic: it should only be used with great caution in patients who already have renal impairment and discontinued if the plasma creatinine concentration exceeds 260 µmol/l. Liposomal amphotericin avoids this toxicity. Amphotericin is cleared by haemodialysis and should therefore be given after treatment. Both flucytosine and fluconazole are excreted in the urine. Fluconazole should be given at a dose of 200 mg/day after an initial dose of 400 mg. Ketoconazole is less well absorbed in renal failure and interferes with cyclosporin metabolism through action on the cytochrome P-450 system (see Table 7).

Antiprotozoal agents and malaria

Quinine is given in the usual doses unless acute renal failure develops, in which case the dose is reduced after two to three days. The dose of chloroquine is reduced by half if the glomerular filtration rate is less than 50 ml/min and to a quarter if the glomerular filtration rate is less than 10 ml/min; primaquine is given in the usual doses. For prophylaxis chloroquine (usual dose 300 mg/week) can be given to patients with renal impairment. Proguanil (usual dose 200 mg daily) should be given in half the usual dose if the glomerular filtration rate is less than 10 ml/min. Mefloquine has been used in haemodialysis patients in a dose of 250 mg weekly: it is not cleared by dialysis and no adverse effects were reported.

Drugs acting on the central nervous system

Drugs acting on the central nervous system may have a prolonged effect in renal failure, not only because of changes in pharmacokinetics, but also because of increased sensitivity as a consequence of uraemia.

Antidepressants

The data on antidepressant drugs are conflicting, but all should be used with caution. Tricyclics are given in the usual dosage. Fluoxetine, paroxetine, and other selective serotonin reuptake inhibitors have been used widely in patients on dialysis, although dosage reductions are advised. It is best to avoid citalopram and venaflaxine.

Lithium

Lithium is filtered and then reabsorbed, mainly in the proximal tubule. The dose should be reduced in renal impairment with careful monitoring of plasma concentration. In sodium depletion (for example with chronic use of thiazide diuretics) tubular reabsorption of lithium is increased, leading to higher plasma concentrations and toxicity. Lithium is a cause of chronic tubulointerstitial damage.

Major tranquillizers

No dose change is required when phenothiazines or butyrophenones are used in patients with renal impairment. Newer drugs such as clozapine, rispiridone, and sulpiride should be used with caution.

Minor tranquillizers

Benzodiazepines can be prescribed in the usual dosage. Diazepam and chlordiazepoxide have active metabolites that may accumulate in renal failure: drugs without active metabolites such as nitrazepam and temazepam may avoid hangover the morning after use as night sedation.

Anticonvulsants

Phenytoin, carbamazepine, and valproic acid are given in the usual dosage. Protein binding of phenytoin is reduced in renal impairment with a rise in the free (active) fraction such that plasma or serum levels may need to be adjusted downwards. Vigabatrin and gabapentin need dose reduction.

Antihistamines

Terfenadine should be avoided because of prolongation of the QT interval, perhaps made more likely in renal impairment. Prochlorperazine and chlorpheniramine are used in the usual dosage but may cause drowsiness.

Treatment of hyperlipidaemia and diabetes mellitus

Lipid lowering agents

There is now wide experience in the use of HMG-coenzyme A reductase inhibitors. Simvastatin and pravastatin are given in the usual doses, that of fluvastatin is reduced. All may cause myopathy and myositis, particularly in renal impairment or if used with cyclosporin or gemfibrizol. The fibrates (gemfibrizol, bezafibrate) can be used with dose reduction at a glomerular filtration rate of less than 20 ml/min.

Insulin

Insulin requirements fall with declining renal function, probably as a consequence of the reduced metabolism of insulin by the kidney in both acute and chronic renal

failure. In patients on haemodialysis it is often necessary to give supplemental insulin during treatment. The same situation applies in patients on haemofiltration for acute renal failure, particularly if they are being fed parenterally, and in continuous haemodiafiltration when the dialysate is a glucose-based solution. Non-diabetic patients may require insulin temporarily under these circumstances. Patients on continuous ambulatory peritoneal dialysis may need a change in insulin preparation and adjustment in the frequency and route of administration. The intraperitoneal requirement is approximately 50 per cent of that needed intravenously.

Oral hypoglycaemic agents

Glicazide, gliquidone, and glipizide are the safest drugs to use, although dose reduction may be needed if the glomerular filtration rate is below 10 ml/min. Other sulphonylureas, particularly chlopropamide, have a prolonged half-life. The biguanides should not be used if the glomerular filtration rate is below 20 ml/min.

Treatment of asthma

b-Agonists administered by inhalation, oral, or parenteral routes need no adjustment in patients with renal impairment, although tobuterol is an exception. Aminophylline and theophylline can be given in the usual doses but metabolites may accumulate. The leukotrione antagonist zafirlukast (but not montelukast) needs dosage reduction.

Treatment of gastrointestinal disorders

H_2-Antagonists and antiulcer drugs

Cimetidine is cleared by the liver but metabolites accumulate if the glomerular filtration rate is less than 20 ml/min. Ranitidine, which causes less cerebral confusion, is preferable in this situation, but may interfere with creatinine secretion and raises plasma creatinine. It is partly cleared by the kidneys (in common with famotidine) and the dose should be halved when the glomerular filtration rate less than 10 ml/min. It is dialysed, and a supplemental dose is needed after dialysis but not after haemofiltration. Omeprazole and misoprostol are given in the usual doses. Misoprostol may cause reductions in glomerular filtration rate through haemodynamic changes in the kidney.

Antacids

Alginates, magnesium trisilicate mixture (but not magnesium trisilicate powder), and sodium bicarbonate all have high sodium contents. The use of aluminium containing compounds, such as aluminium hydroxide or sulcralfate, in patients with severe renal impairment or those on dialysis is controversial because of the potential risks of aluminium retention with deleterious effects on bone, bone marrow, and the central nervous system. Calcium carbonate should not be used as an antacid but only as a phosphate binder.

Treatment of hyperuricaemia and gout

Allopurinol

Allopurinol is metabolized to oxypurinol, which is retained in renal impairment and may be responsible for some of the adverse effects including rashes, bone marrow depression, and gastrointestinal upset. The dose should be reduced to 100 mg/day when the glomerular filtration rate is less than 20 ml/min. The dose should be given after haemodialysis. Allopurinol interferes with the metabolism of 6-mercaptopurine (an active metabolite of azathioprine) causing accumulation and toxicity (for example leucopenia).

Probenecid

Probenecid inhibits secretion of acids in the proximal tubule and prevents reabsorption of urate from the tubular lumen. It prolongs the effect of penicillins, cephalosporins, naproxen, indomethacin, methotrexate, and sulphonylureas (all of which are weak acids), causing accumulation and the potential for toxicity. It also inhibits tubular secretion (and hence activity) of furosemide (frusemide) and bumetanide.

Colchicine

Colchicine has been largely replaced by non-steroidal anti-inflammatory drugs (see above) for the treatment of acute gout. However, it remains valuable in patients in whom non-steroidal anti-inflammatory drugs are undesirable (for example in those with peptic ulcer disease, cardiac failure, or renal impairment), and can be used without dose adjustment in renal failure.

Treatment or prevention of thrombosis and thromboembolism: anticoagulants and antiplatelet agents

Warfarin is used in the normal dosage and its effect is monitored by measuring prothrombin time in the usual way. It is highly protein bound and there may be slight displacement and consequent reduction in the volume of distribution in uraemia. In nephrotic patients hypoalbuminaemia leads to an increased sensitivity to warfarin, which is not removed by dialysis. Heparin is used in the normal dosage, but dosage reduction is required for tinzaparin. Prophylactic aspirin is given in the usual low dose (75–150 mg/day), but the dosages of clodiprogel and ticlopidine should be reduced.

Treatment of autoimmune rheumatic or vasculitic disorders: corticosteroids and immunosuppressive agents

Prednisone and prednisolone are not eliminated by the kidney. Methylprednisolone is cleared by haemodialysis, and should be given after dialysis. Azathioprine accumulates in renal impairment and the dose should be reduced from a maximum of 3 mg/kg/day to 1 mg/kg/day if the glomerular filtration rate falls below 10 ml/min. The dose of cyclophophamide, if given intravenously for systemic lupus erythematosus or systemic vasculitis, should be at the lower end of the therapeutic range with careful monitoring of the blood count before further doses are given.

Methotrexate is used frequently in rheumatological disorders (rheumatoid arthritis, psoriatic arthropathy), usually as a small (7.5 to 20 mg) weekly dose. It should be noted that the drug is a weak acid and is eliminated by proximal tubular secretion, which can be blocked by salicylates or non-steroidal drugs.

Cyclosporin is a highly lipid soluble drug that is extensively bound to plasma proteins and has a large volume of distribution. It is metabolized in the liver via the cytochrome P-450 system by mono- and dihydroxylation as well as *N*-demethylation. Only minor amounts are excreted as the parent drug or metabolites in the urine. Renal impairment does not affect its metabolism. However, since many other drugs may be prescribed to patients on cyclosporin therapy, several important interactions may occur. These may both increase plasma concentration and therefore increase the risk of nephrotoxicity, or reduce plasma concentrations to increase the risk of transplant organ rejection. Aminoglycosides may have an additive effect upon the nephrotoxicity itself. The common interactions are listed in Table 7.

Miscellaneous drugs

Acetazolamide

Acetazolamide may produce electrolyte disturbance, particularly in renal impairment and in the elderly. Its use should be avoided or carefully monitored.

Bisphosphonates

It is appropriate to use intravenous disodium pamidronate or etidronate in hypercalcaemia caused by malignancy, even if this is causing renal failure. The likely outcome is an improvement in renal function, particularly if other measures such as sodium and water depletion are addressed. Bisphosphonates (with the exception of alendronic acid) can be used to treat postmenopausal or corticosteroid induced osteoporosis and Paget's disease, with dosage reduced in moderate renal

impairment. Etidronate may cause hypercalcaemia if combined with calcium supplementation.

Anticancer drugs

The kidney excretes many anticancer drugs or their metabolites, and doses need to be calculated with accurate measurements of glomerular filtration rate (for example cisplatin). It is important to obtain appropriate information before prescribing.

Summary

- Always check the method of elimination of any drug before prescribing in the presence of known or suspected renal impairment.
- Monitor any changes in renal function.
- Look out for any adverse or side-effects.

21.1 Epidemiology

M. W. Adler and A. Meheus

Introduction

The sexually transmitted infections (**STIs**) are mainly spread by sexual intercourse (Table 1). However, some, such as genital candidosis, are only rarely spread in this way; others, like scabies and pediculosis pubis, are spread by close bodily contact without penetrative intercourse. The range of diseases spread by sexual activity continues to increase, with familiar bacterial and treponemal infections now being superseded in developed countries by herpes, warts, and human immunodeficiency virus infection (**HIV**). The detrimental effect of STIs on pregnancy and the newborn (for example, miscarriage, prematurity, congenital and neonatal infections, blindness) are more common and severe than had previously been realized. Furthermore, complications such as pelvic inflammatory disease, ectopic pregnancy, infertility, and cervical cancer are major health problems. The World Bank in 1993 estimated that for women aged 15 to 44 years, STIs, excluding HIV infection, were second only to maternal morbidity and mortality as causes of healthy lives lost.

Their incidence, distribution, and risk of complications is strongly influenced by a wide array of determining factors, including behavioural and sociocultural factors, population composition, susceptibility of individuals, changing characteristics of pathogens, and society's efforts at primary prevention and disease control.

Since the advent of HIV/AIDS, increased attention is being given to the other STIs, because they are important causes of morbidity and mortality in their own right and are important markers of behaviour associated with a high risk of HIV transmission. Some 80 per cent of HIV infection is spread sexually. STIs, especially genital ulcer disease, can enhance the acquisition and transmission of HIV by damaging the mucosa or skin, due to increases in HIV-susceptible macrophages and increased viral shedding.

The global burden of STIs is unknown because of the lack of effective control and notification systems in some countries. The World Health Organization (WHO) has estimated a total of 340 million new cases of curable STDs in adults per annum, mainly in South-East Asia (151 million new cases per year) and Sub-Saharan Africa (69 million). In Eastern Europe and Central Asia, the estimate is 22 million, and 17 million in Western Europe. The prevalence and incidence varies regionally: for instance, between Sub-Saharan Africa and Western Europe, 4.6- and 3.3-fold, respectively (Table 2).

The diseases

The accuracy of European data suffers from the reluctance of private doctors, who may see most of the patients, to notify the appropriate authorities. Notification systems include STD clinics (United Kingdom, France, Italy), laboratory/systems (Denmark, Sweden), and sentinel general practitioner (**GP**) systems (Belgium).

In the United Kingdom, a notification system was established in 1916, which also provided a free and confidential service for people with sexually transmitted infections. This service, mainly run outside hospitals, was integrated into the hospital structure following the creation of the National Health Service in 1948. At that time, syphilis and gonorrhoea made up the majority of the 132 000 cases diagnosed in clinics in England and Wales. Since then, the number of people attending clinics has increased exponentially and the disease profile has changed (Fig. 1). Gonorrhoea and syphilis now represent less than 2 per cent of all cases seen, while the new viral diseases, in particular genital warts and herpes, increased by 236 per cent and 160 per cent, respectively, between 1980 and 2000.

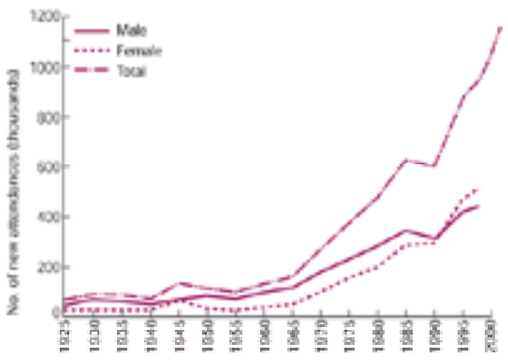

Fig. 1 New attendance at genitourinary medicine (**GUM**) clinics England and Wales 1925–2000.

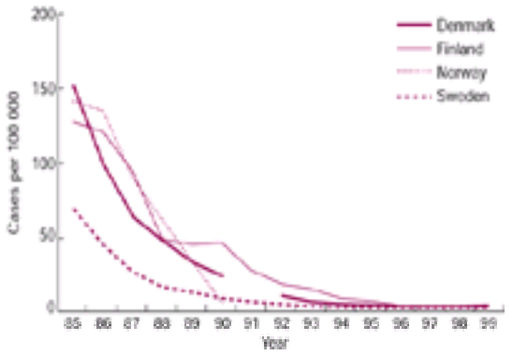
Gonorrhoea

Although rates of gonorrhoea vary between countries, there was a general upward trend over most of the last 40 or so years, with a flattening out in the mid-1970s and a subsequent decrease in the number of cases reported with recent increases in some countries. It is difficult to interpret differences between countries because of the variation in reporting practices and the provision of facilities.

Data tend to be more complete in developed countries. However, standards vary and countries like the United Kingdom, which has a network of genitourinary medicine/STD clinics and routine notification requirements, produce more accurate figures than some other European and North American countries where most patients are treated by private physicians who do not usually report cases. There was a peak in the number of cases of gonorrhoea during the early to mid-1970s in most European countries. The advent of AIDS/HIV infection in the 1980s led to safer sexual practices and a reduction in the number of cases of gonorrhoea, but this has not been sustained in all countries. Recently, there has been a substantial increase in both male and female cases of gonorrhoea in England and Wales. Between 1995 and 2000 there was a 105 per cent increase in the number of cases in men, from 6759 to 14 231, and in females an 85 per cent increase from 3394 to 6289. In males, this increase was seen in all age groups, particularly in those aged 16 to 19 and 35 to 44 years, but in females, it was mostly in teenagers. The incidence of gonorrhoea has increased since 1993 in homosexual men, particularly in those living in London and its immediate surrounding area.

In Nordic countries, the annual incidence of gonorrhoea declined (Fig. 2) from over 100 per 100 000 population in most countries in the early 1980s to less than 10 per 100 000 population by the late 1990s, but there have been recent slight increases. Although the incidence of gonorrhoea has declined in the United States, there

are considerable differences between ethnic groups (Fig. 3). In 2000 there was a total of 358 995 cases.



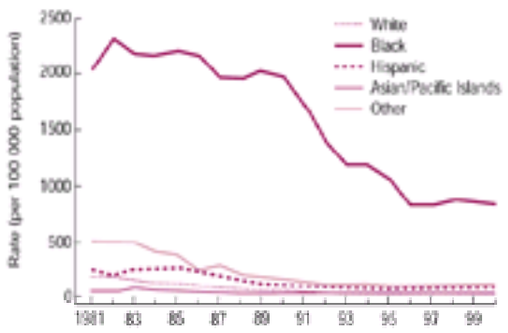


Fig. 2 Annual incidence of gonorrhoea per 100 000 population in Nordic countries.

Fig. 3 Gonorrhoea—rates by race and ethnicity: United States, 1981–2000, and the 'Healthy People year 2000 objective'. 'Other' includes Asian/Pacific Islander and Native American/Alaskan populations. Georgia did not report gonorrhoea statistics in 1994.

There is an epidemic of STIs in Eastern Europe, in the newly independent states of the former Soviet Union. The highest rates of gonorrhoea are in Estonia (166), Russia (139), and Belarus (125) per 100 000, compared to France 18.5, Germany 5, The Netherlands 8, and the United Kingdom 22 per 100 000.

Syphilis

The dramatic impact of penicillin on the incidence of early infectious syphilis throughout the world in the 1950s has not been maintained everywhere. The United States has experienced a continuous increase in the total number of cases of primary and secondary syphilis of seven- to ninefold in males and females, respectively, since 1956. These increases were particularly noticeable in the 1990s and are partly explained by the deployment of resources away from traditional STD control programmes to those for AIDS. However, the control of HIV and AIDS will only come through integrated STD/AIDS control programmes.

In most Western European countries, but particularly in Scandinavia, there has been a decline in incidence to below 5 per 100 000. However, in Eastern Europe there is an epidemic of syphilis in all Newly Independent States (**NIS**) of the former Soviet Union. The 1999 incidence of syphilis in these NIS ranged from 55 to 180 per 100 000 (Fig. 4); increases are particularly evident in older adolescents. Between 1986 and 1996, the incidence of syphilis increased in 18- to 19-year-old Russians, from 6 to 607 per 100 000 in men and from 20 to 1321 per 100 000 in women. The increase in Russia between 1992 and 1996 was 20-fold, Estonia 6-fold, Latvia 12-fold, and Lithuania 14-fold. An HIV/AIDS epidemic can be predicted in Eastern Europe, and already there have been outbreaks of HIV among intravenous drug users, particularly in Belarus, Russia, and Ukraine.

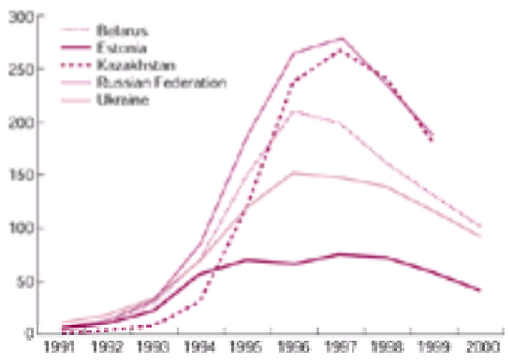

Fig. 4 Annual incidence of syphilis in Belarus, Estonia, Kazakhstan, the Republic of Moldova, the Russian Federation, and Ukraine, 1990–2000 (rate per 100 000 of the population).

There has been an encouraging fall in the incidence of congenital syphilis in developed countries, largely due to the control of early acquired infectious syphilis in women and the screening of all pregnant women for syphilis. However, congenital syphilis is still a major health problem in the countries of the former Soviet Union and in many developing countries.

Chlamydia

The introduction of antigen detection tests such as direct immunofluorescence techniques and enzyme immunoassays in the 1990s, and, more recently, sensitive nucleic acid detection-based tests such as polymerase or ligase chain reactions, has allowed a more widespread screening for chlamydia in most European countries. After the start of wide-scale screening in Sweden during the 1980s, the number of cases declined from 38 000 in 1987 to 14 000 by 1997, with an associated decrease in ectopic pregnancies.

In England and Wales there has been no such decline, and chlamydia remains a major public health problem; long-term sequelae associated with chlamydial infection include pelvic inflammatory disease, ectopic pregnancy, infertility, and abdominal pain. Genital *Chlamydia trachomatis* infection is now the commonest curable bacterial STI in England and Wales. There has been an increase in the number of cases since 1993, with females outnumbering males; in 2000, 63 037 people attended clinics—27 222 males, 35 815 females. It is commonest in young people: the peak age in men is between 20 and 24 years, and between 16 and 19 in women. Screening surveys carried out in antenatal and gynaecological clinics, general practice, family planning units prior to pregnancy termination, and those attending STD clinics have shown median prevalences ranging from 4.5 to 16.4 per cent. Similar prevalence rates have been seen in the United States. The increased availability of Chlamydia testing and more sensitive detection tests will, to some extent, account for the apparent increase in the number of cases seen.

Genital herpes and warts

The greatest increase in STIs in England and Wales during the 1980s was in the number of reported cases of genital herpes and warts. In 1978, 8406 cases of herpes and 24 136 of warts were seen in STD clinics, increasing to 30 199 and 100 124, respectively, by 2000 (Fig. 5). Compared to Chlamydia and gonorrhoea there has been a slowing down in the increase in the last few years.

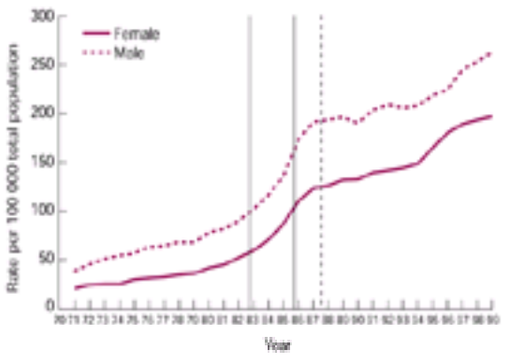

Fig. 5 New cases of genital warts infection seen in GUM clinics, 1970–1999 (England).

Genital herpes

There are between 200 000 and 500 000 new cases of herpes each year in the United States, with a prevalence of approximately 40 million cases. These extrapolations from STD clinic data may not be valid, for most of these patients attending such clinics are of lower socioeconomic status and unrepresentative of the whole population. In a Swedish STD clinic, herpes simplex virus (**HSV**) was isolated from the cervices of 8.4 per cent of all female attenders.

HSV-1 and -2 antibody tests allow prevalence studies to be carried out in different populations. In the United Kingdom, HSV-2 seroprevalence is low in blood donors (3 per cent in men, 12 per cent in women), intermediate in pregnant women (4 per cent in those under 20 years of age, 11 per cent in the 20 to 29 age group, and 16 per cent in those over 29 years), and high in STD clinic attenders (21 per cent in men, 25 per cent in women). In the United States, the pattern is similar but rates are approximately twice as high.

In the United Kingdom, STD clinic attenders showed an increasing proportion of HSV-1 genital infections during the 1980s and early 1990s. HSV-1 now accounts for most first episodes in women. The proportion of HSV-1 in genital specimens was 48 to 68 per cent in women, 25 to 35 per cent in men. In the United States most genital infections are caused by HSV-2.

Genital human papillomavirus (HPV)

Genital warts is now the commonest sexually transmitted disease seen in STD clinics in England and Wales (100 124 cases in 2000). They are difficult and time-consuming to treat. HPV infection is of particular concern because certain types are associated with cervical dysplasia and cervical cancer (see Chapter 7.10.17).

Pelvic inflammatory disease

Pelvic inflammatory disease (**PID**) is the most serious complication following gonococcal, chlamydial, and non-specific infections. Its incidence and prevalence is increasing in most countries. In Western industrialized countries its estimated annual incidence is 10 per 1000 women aged 15 to 39 years, with a peak incidence of 20 per 1000 in the age group 15 to 24 years. Risk factors include STIs, the use of intrauterine devices (**IUDs**), and postabortion and puerperal infections.

STIs cause most cases of PID. In developed countries, 75 per cent of cases in under 25-year-old women are attributable to STIs. In Uppsala, 50 per cent of patients with PID in 1965 had cervical gonorrhoea, but by 1975 this had dropped to approximately 10 to 15 per cent, at which time *Chlamydia trachomatis* was found to be responsible for 60 per cent of cases.

The most serious consequence of PID is infertility (see Chapter 21.4). It is difficult to obtain accurate data on the trends for PID since not all patients are hospitalized or correctly diagnosed.

STD epidemiology in developing countries

The frequency of STIs is much higher in developing countries. They are among the top five causes of consultation at general health services in many African countries. The incidence and prevalence of these infections are very high in specific population groups, such as female prostitutes and their clients. Prostitution is an important factor in the transmission of STIs in developing countries.

Genital ulcers are much more frequent. The so-called 'tropical STIs'—in particular chancroid and, to a lesser degree, lymphogranuloma venereum and granuloma inguinale—are major causes. More genital ulcers in developing countries are caused by syphilis than in industrialized countries; genital herpes accounts for a smaller proportion, but has become the leading cause of genital ulcers in areas of high HIV/AIDS incidence.

The incidence of STI complications and their sequelae is much higher in developing countries due to the lack of resources for adequate diagnosis and treatment. Important STI complications and sequelae include adverse pregnancy outcome for mother and newborn, neonatal and infant infections, infertility in both sexes, ectopic pregnancy, urethral stricture in males, blindness in infants due to gonococcal and chlamydial ophthalmia neonatorum and in adults due to gonococcal keratoconjunctivitis, as well as genital cancers, particularly cancer of the cervix uteri and penis.

The epidemiology of HIV infection and AIDS is very different from that in Western countries: level of sexual activity, not sexual orientation is, apparently, the major risk factor. HIV is predominantly transmitted heterosexually in developing countries. Genital ulceration, and other STIs, facilitate the sexual transmission of HIV. Many governments and international donor agencies have tended to ignore the real magnitude of the problem. It needed a fatal STI to alert decision-makers worldwide and the community to the STI problem and to generate resources for its prevention and control.

Control

Prevention is more effective and cheaper than treatment. The objectives of STI control are to interrupt the transmission of STIs, to prevent their development, complications, and sequelae and to reduce the risk of sexual transmission of HIV. These aims can be achieved by primary and secondary prevention and comprehensive patient care (Table 3).

Primary prevention

Primary prevention is achieved through health promotion (information, education, communication— **IEC**) and counselling activities (see Chapter 3.5). The aim is to educate people about the advantages of discriminative sex and prophylaxis ('safer sex'). Clearly, the best way to avoid STIs is to avoid sexual intercourse. This may not be acceptable to those who are already sexually active, but the dangers of frequent changes of sexual partners and the methods of reducing the risk must be emphasized. It is essential to use a condom to avoid contact with partners who have symptoms or lesions, and to have regular check-ups. This must be taught to

children before they become sexually active. The best place for this is at home or school in the context of growing up, understanding one's body, and being responsible for one's own health. Since the arrival of HIV infection and AIDS, sexuality has become less of a taboo in many countries. Health workers and health educators must, therefore, take advantage of this new openness. Through mass media campaigns targeted at the general public, IECs have become part of STD/AIDS control nearly everywhere.

A special target group for health promotion and individual counselling are patients with STIs; such infections prove them to be at risk of contracting STIs, including HIV infection. Their current infection and the awareness of their vulnerability might make STD patients more inclined to change risky sexual behaviour.

No effective vaccines are as yet available for STIs, apart from that for hepatitis-B virus (**HBV**).

Secondary prevention

P>Here the aim is to detect STIs early through screening ('check-up') and by education about what to do once disease is suspected (healthcare-seeking behaviour). Sexual intercourse should be stopped until medical care has been sought. Education should indicate how and where such advice can be found, and emphasize the importance of adhering to the treatment and advice.

Screening aims to detect asymptomatic or mildly symptomatic infections, and is carried out in specific populations if the prevalence of STIs is high. Good laboratory support is essential. Pregnant women may be screened for syphilis, HIV, or chlamydial infection. Where prostitution is legal or tolerated, prostitutes can be screened for various STIs. Blood donors are screened for HIV, HBV, and syphilis.

Adequate and comprehensive management of STI patients

The management of infected patients is a cornerstone of STI control. The aims of patient care are: to detect or rule out infection; to give treatment if necessary; to educate and counsel on treatment compliance and on STD/HIV prevention and condom use; to ensure that sexual partner(s) are evaluated and managed (contact tracing); and eventually to test for other STIs, including HIV infection. In a developed country, it is not appropriate to attempt the management of STIs without microbiological facilities, since doctors providing care in these countries usually have specialist knowledge of the diseases. However, in developing countries with limited resources, it is more realistic to use a syndromic approach based on STI signs, symptoms, and simple laboratory tests. To implement major intervention strategies, the following support components need to be developed:

- *Training* should be given to health workers and health educators, for instance in the use of flow-charts to simplify the management of STD patients, or to strengthen their health education and counselling skills.
- *Laboratory services* need to be expanded, depending on the level of healthcare provided. A reference laboratory should be developed in each country to allow the quality control and analysis of referred specimens.
- *Research* should be undertaken to include epidemiological and sociobehavioural baseline studies, assessment of antimicrobial sensitivity, as well as operational research to render the programme more cost-effective.
- *Information systems* or surveillance should be implemented to gather epidemiological data for magnitude and trend assessments, and to provide data for programme planning and monitoring. Various surveillance methods can be used—clinician notification, laboratory notification, sentinel site surveillance (either of syndromes or of aetiological diagnoses), prevalence studies in specific population groups, and aetiological surveys in patients.

Conclusion

A successful STI control programme, by reducing both the incidence and prevalence of STIs, will reduce the morbidity, suffering, and economic cost associated with these diseases. By eliminating STIs as a facilitating factor in HIV transmission, and by contributing to behavioural changes towards safer sex, it will play an important role in the prevention and control of HIV/AIDS.

21.2Sexual behaviour

Anne M. Johnson

Most men and women are sexually active for a large part of their adult lives and sexual fulfilment is an important part of the quality of life. Patterns of sexual behaviour in populations are a key determinant of fertility and transmission of sexually transmitted infections (**STIs**).

Discussion of sexual lifestyle and the ability to take a sexual history is relevant to a wide range of clinical consultations. A few common examples include management of genitourinary symptoms, contraceptive advice, sexual dysfunction, and resumption of sexual activity following childbirth, major illnesses, and surgery.

Sexual orientation

Sexual behaviour studies in representative population samples show that the majority of men and women are predominantly attracted to, and have experience with, members of the opposite sex throughout their lives. However, sexual orientation is not a simple dichotomy between 'homosexual' and 'heterosexual', but varies between individuals from exclusively heterosexual experience through various shades of attraction and experience with both genders, to exclusively homosexual experience.

In a large-scale British study of adults aged between 16 and 44, 8.5 per cent of men and 9.7 per cent of women reported having had any sexual experience with someone of the same gender. For some this may be a fleeting experience in adolescence, with subsequent exclusively heterosexual partnerships. A smaller proportion of the British population report homosexual partnerships involving genital contact (5.4 per cent of men and 4.9 per cent of women). Similar findings are reported from surveys in France and the United States. Most of those with same-gender partners have also experienced heterosexual intercourse at some time in their lives. Exclusively homosexual experience throughout life is thus a relatively unusual phenomenon.

Homosexual experience is more common among men in large metropolitan areas. For example, 10.5 per cent of men sampled in Greater London reported ever having a homosexual partner. Capital cities typically provide a more tolerant atmosphere and better social facilities for those with a homosexual lifestyle. This is reflected in the high proportion of homosexually acquired STIs which are reported from clinics in London, and the higher rates of homosexually acquired HIV and AIDS reported in many metropolitan areas in Europe and the United States.

Age of first heterosexual intercourse

The age of first heterosexual intercourse has been gradually declining over recent decades. The proportion of people having sexual intercourse before marriage has rapidly increased so that sex before marriage has become almost universal in Britain. For men born in between 1930 and 1935, the median age of first intercourse was 20 and for women 21. For men and women born between 1965 and 1975, the median age at first intercourse was 17. Similar trends have been observed in France and the United States.

English law gives the age of consent for heterosexual intercourse as 16 and it is illegal for a man to have sex with a women under 16 in England. The proportion of men and women reporting first intercourse before the age of 16 has risen rapidly over recent decades to 30 per cent of men and 26 per cent of women aged between 16 and 19 in 2000 in Britain. This has important implications for the provision of sex education. Those who are embarking on their sexual careers may be most susceptible to the unwanted consequences of unprotected sexual intercourse. The incidence of sexually transmitted diseases and termination of pregnancy is higher among 16- to 24-year-olds than in older men and women.

Heterosexual partners

There is great variability between individuals in the number of reported heterosexual partners. While many people have few partners, a small proportion have many. Among 16- to 44-year-old men in Britain, 51 per cent reported having none or one partner in the last 5 years; 8 per cent reported more than 10; and a small proportion reported hundreds or even thousands of partners in the course of their lives.

The risk of acquiring or transmitting an STI increases with the number of sexual partners. Those with high numbers of partners may account for a relatively high proportion of STI transmission in a society, and for sustaining endemic STI transmission. They are sometimes referred to as a 'core group for STI transmission'. The choice of partner also influences STI transmission in populations. Age, gender, and ethnic mixing are important, as well as the extent to which people choose partners with similar lifestyles to their own (assortative mixing) or different from their own (disassortative); and whether they have serially monogamous or concurrent partnerships.

Prostitutes and their clients remain at high risk of contracting HIV and STI in some parts of the developing world where condoms are rarely used. In some countries, such as Thailand, public health campaigns have recently led to considerable success in increasing the use of condoms during client and prostitute contacts. In many developed countries, although prostitutes are at increased risk of STIs, they use condoms frequently to protect both themselves and their clients.

The proportion of men who use prostitutes varies widely between countries. In the British survey, 4 per cent of men reported having paid money for sex with a woman in the last 5 years but considerably more frequent exposure is reported in other countries.

Multiple heterosexual partnerships are most common among the young, and among those who are neither married nor cohabiting. Close to one in seven men between the ages of 16 and 24 in Britain reported more than 10 partners in the last 5 years, even though in this group a high proportion are not yet sexually active. Age *per se* is not the only influence on sexual behaviour. Whatever their age, those who are separated, divorced, or widowed are more likely than married people of a similar age to have multiple partners, illustrating the effects of the lifecourse on patterns of partnership formation. Since the emergence of the HIV epidemic, public health campaigns have emphasized the need for a change in sexual behaviour. STI incidence fell in the 1980s but rose again in the late 1990s. In Britain since there has been an increase in number of partners as well as an increase in condom use. In some parts of the developing world, such as Uganda and Thailand, there is evidence of a reduction in the incidence of HIV infection attributable to a recent change in behaviour.

Heterosexual practices

There is variability in the repertoire and frequency of sexual practices between individuals. In heterosexual relationships, vaginal intercourse is the most common practice, but most couples include other practices in their repertoire, particularly mutual masturbation and orogenital contact.

The frequency of sexual contact varies with age, lifestage, and the availability of a sexual partner. For married couples, the median frequency of sexual intercourse is in the order of four times per month, but this is highly variable. The frequency of intercourse appears to decline with age in married and cohabiting couples, although this is partly a function of the increasing length of their relationship.

Among 16- to 44-year-old men and women in Britain, close to 80 per cent reported experience of orogenital contact in the last year, with the majority of couples who experience any orogenital contact practising both cunnilingus and fellatio. There is evidence of an increasing practice of orogenital stimulation in recent decades.

Mutual masturbation is also a common practice and has become more frequent in recent decades.

Anal intercourse is a relatively infrequent activity in heterosexual couples. In the British survey, 26 per cent of men and 24 per cent of women had experienced anal intercourse, but only around 12 per cent had experienced it in the last year. Anal intercourse can result in transmission of STIs. The practice of anal intercourse in addition to vaginal intercourse may increase the risk of heterosexual transmission of HIV. Since anal intercourse is a relatively infrequent practice in all parts of the world, most heterosexual HIV transmission worldwide is attributable to vaginal intercourse.

Homosexual behaviour

Male homosexual lifestyles have been rather more intensively studied than female homosexual lifestyles. Research in the 1970s of volunteer samples of homosexual men in the United States identified a particular lifestyle characterized by multiple casual sexual partners, often encountered at gay meeting places such as bars, clubs, and 'bath-houses'. These men were at high risk of contracting STIs and were among the first to suffer high rates of HIV infection. Research in Britain identified a group of homosexual men with similar lifestyles. However, studies of homosexual men recruited from sites other than STD clinics and gay meeting places show lower rates of sexual partner change and a lower prevalence of sexually acquired pathogens.

Men with multiple homosexual partnerships are at increased risk of HIV infection as well as other STIs, including hepatitis B and syphilis. Women with homosexual partnerships tend to be at low risk of STI and HIV as a result of their different sexual lifestyles and sexual practices, such as non-penetrative sex and orogenital contact.

Many male homosexual partnerships do not involve penetrative anal intercourse, but are restricted to mutual masturbation or orogenital contact. Anal intercourse, however, is the most important mode of transmission of sexually acquired organisms between homosexual men. Many men practise both anal receptive and insertive intercourse. Receptive anal intercourse is the highest risk behaviour for HIV transmission. Since the emergence of the HIV epidemic, there is evidence of a reduction in high-risk behaviour among gay men, characterized by increased condom use and reduced exposure to unprotected anal intercourse. However, there have been recent concerns of a resurgence in high-risk behaviour.

Risk-reduction strategies and sexual health

Increasing attention is being paid to promoting sexual health and reducing the adverse consequences of sexual behaviour. Extensive discussion of population strategies is outside the scope of this chapter. However, people can reduce their risk of STI and unwanted pregnancy by reducing the numbers of partners with whom they have unprotected intercourse, by using condoms, by using effective contraception, and by enjoying sexual practices that may reduce transmission risks. Negotiating sexual fulfilment is a more difficult matter, but greater focus on communication between partners, and sexual technique, is also important. Health professionals have an important role to play, not only by being well informed but by including tactful sexual history-taking among their clinical skills and by being concerned about sexual health and health promotion.

21.3Vaginal discharge

J. Schwebke and S. L. Hillier

Vaginal discharge is an extremely common reason for women to seek medical care, but its causes, treatment, and potential complications are poorly understood by patients and medical personnel. In the past, it has often been regarded as simply a nuisance. Only recently have accurate diagnosis and treatment of vaginal discharge been recognized as means of preventing future costly morbidity.

The healthy vagina

It is important to understand the normal vaginal ecosystem. At puberty the vagina becomes colonized predominantly with lactobacilli (Fig. 1). These Gram-positive facultative bacilli convert glucose to lactic acid, which helps maintain the normal vaginal pH at less than 4.5. This acidic environment helps to stabilize the ecosystem, as many pathogens, with the exception of *Candida* spp., are inhibited at this pH. Vaginal lactobacilli produce other antibacterial compounds, most notably hydrogen peroxide, which can inhibit the growth of bacterial vaginosis-associated pathogens *in vitro*. Women with peroxide-producing lactobacilli in the vagina are less likely to have gonorrhoea, chlamydial infection, trichomoniasis, or bacterial vaginosis.

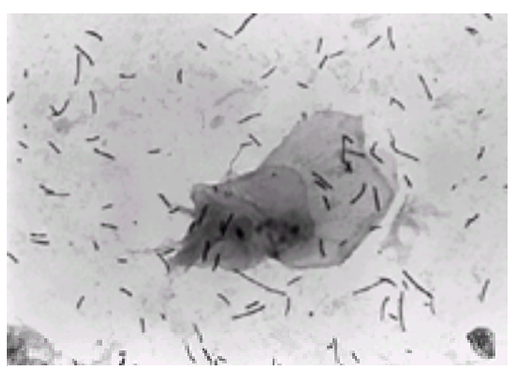

Fig. 1 Gram stain of normal vaginal fluid (copyright Dr Sharon Hillier).

Factors that alter the normal vaginal milieu and predispose the vagina to infection are poorly understood. They probably include hormonal and immunological factors as well as exogenous influences such as antimicrobial therapy, multiple sexual partners, and the use of vaginal douches.

Vaginitis and vaginosis

There are three main types of vaginal infections: trichomoniasis, bacterial vaginosis, and vulvovaginal candidiasis. Trichomoniasis is the only one known to be sexually transmitted, although bacterial vaginosis is most commonly seen in sexually active women and frequently coexists with sexually transmitted infections.

Trichomoniasis (see also Chapter 7.13.13)

Trichomoniasis is one of the few sexually transmitted infections that is more easily diagnosed in the female than in the male. In males, infection is usually asymptomatic and so they may be an important reservoir of infection. Annual worldwide incidence is estimated at 180 million cases. Prevalence varies with the population being studied. It is high among women attending sexually transmitted disease clinics. *Trichomonas* spp. and *Neisseria gonorrhoeae* are frequent coinfections. Symptomatic patients with trichomoniasis most frequently complain of discharge and vaginal pruritus. Intermenstrual or postcoital spotting may occur because the ectocervix is involved. Occasionally the urethra and Skene's glands may be infected, resulting in dysuria. Some 50 per cent of all infected women are probably asymptomatic.

Signs of trichomoniasis are vaginal discharge (42 per cent), odour (50 per cent), oedema or erythema (22–37 per cent). The often copious discharge is described as frothy and yellowish-green, but varies in consistency and colour and is actually frothy in only 8 to 12 per cent of women. Colpitis macularis ('strawberry cervix'), detected by colposcopy, is reported in almost half the patients and is the most specific clinical sign for trichomoniasis, but is rarely seen during routine examination.

Because the clinical signs and symptoms are not diagnostic, the organism should be sought either by direct wet-mount preparation or culture. Trichomonads are motile by means of flagella that can be seen beating even when the organism is at rest; the organism is about the size of a white blood cell (10–20 μm wide). The vaginal fluid contains numerous polymorphonuclear neutrophils because this disease is a true vaginitis, causing a local inflammatory response. The vaginal pH is usually elevated to above 4.5 and can be as high as 6.5 to 7.5. The background bacterial flora is often abnormal as bacterial vaginosis may also be present. The sensitivity of microscopical examination of the vaginal fluid for the diagnosis of trichomoniasis ranges from 40 to 80 per cent. Culture is the current diagnostic 'gold standard' but requires 2 to 5 days before a result can be obtained. As trichomoniasis can occur with other sexually transmitted diseases, screening should be carried out for gonococcal and chlamydial infections.

Treatment is with nitroimidazoles; metronidazole is most frequently used. A single oral dose of 2.0 g is preferred to 250 mg orally three times daily for 7 days because of better compliance and reduced total dosage. The use of nitroimidazoles is often complicated by gastrointestinal side-effects. Some strains of *T. vaginalis* are resistant to metronidazole, but treatment fails most often because the sexual partner has not been treated. For strains of *T. vaginalis* with decreased susceptibility to metronidazole, higher doses are given orally (up to 1 g three times daily), often in combination with intravaginal metronidazole.

New data link trichomoniasis with preterm labour, and no adverse outcomes of pregnancy have been associated with the use of metronidazole, therefore treatment during pregnancy is recommended.

Women in whom *T. vaginalis* is detected, but who are asymptomatic, should be treated as above. If left untreated they may later become symptomatic and, without treatment, they serve as an important reservoir for continued ransmission of the disease. Furthermore, there is data which suggests that trichomoniasis may facilitate the transmission of the human immunodeficiency virus (**HIV**). Because *T. vaginalis* is sexually transmitted it is imperative that the male partners of women with trichomoniasis be treated empirically for *T. vaginalis* and screened for other sexually transmitted diseases.

Bacterial vaginosis

Bacterial vaginosis is the most common diagnosis made in women complaining of abnormal vaginal discharge. The microbiology of bacterial vaginosis is now much better understood, but not its pathogenesis. Recently, complications associated with bacterial vaginosis have been recognized, such as preterm birth, low birth weight,

and infectious complications of pregnancy including postabortive endometritis, intra-amniotic infection, and postpartum endometritis. Among non-pregnant women, bacterial vaginosis has been linked to infection of the vaginal cuff following hysterectomy, and possibly pelvic inflammatory disease.

Despite the fact that bacterial vaginosis is most often diagnosed in sexually active women and is frequently seen together with other sexually transmitted infections, there remains no direct proof that it is exclusively sexually transmitted.

Unlike trichomoniasis and candidiasis, bacterial vaginosis does not appear to be caused by a single organism. Instead there is a change in the entire vaginal flora, resulting in the loss of normal hydrogen peroxide-producing lactobacilli and the appearance of increased numbers of mycoplasmas, *Gardnerella* spp., and anaerobic bacteria. Included among the anaerobes are the black-pigmented *Bacteroides (Prevotella)* spp., *B. (Prevotella) biviens*, *Peptostreptococcus* spp., and *Mobiluncus* spp. There is no inflammation of the vaginal epithelium, unlike in trichomoniasis and candidiasis, hence use of the term 'vaginosis' instead of 'vaginitis'. However, one-third of women with bacterial vaginosis and without other infections have more than 30 white blood cells per high-power field in the vaginal fluid. The predominant cell type is the squamous epithelial cell, many of which are covered by adherent bacteria ('clue cells') (Fig. 2).

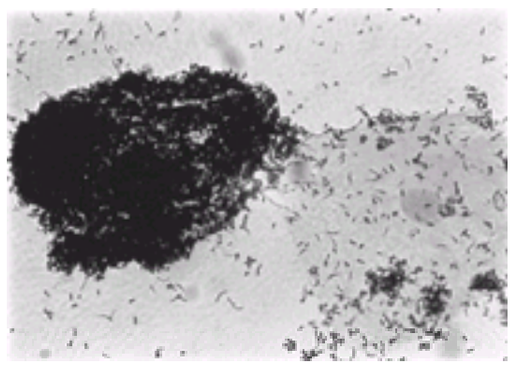

Fig. 2 Gram stain from a patient with bacterial vaginosis (copyright Dr Sharon Hillier).

The symptoms of bacterial vaginosis are vaginal discharge (90 per cent) and an unpleasant odour (90 per cent). The odour is often first noticed after intercourse as the alkaline semen mixes with the vaginal fluid releasing volatile amines. Many women complain of increased odour during menses, at which time vaginal pH increases due to the presence of menstrual blood. As with sexually transmitted infections there is a wide range of symptoms, and many women with bacterial vaginosis are asymptomatic or unaware of their symptoms. Thus, it is of great importance to make a careful evaluation of the following clinical signs:

1. homogeneous-looking, white to grey vaginal discharge;
2. vaginal pH greater than 4.5;
3. positive amine odour when vaginal secretions are mixed with 10 per cent potassium hydroxide ('whiff' test);
4. the presence of 'clue cells'.

It is important to note the type of bacteria present in the vaginal fluid. Careful observation will alert the microscopist to the absence of characteristic lactobacilli and the presence of large numbers of coccobacilli and curved, motile rods (*Mobiluncus* spp.). Culture techniques are not helpful in the diagnosis of this infection, as many of the offending organisms are present in the normal vagina but in low numbers.

Antimicrobial therapy directed at anaerobic organisms is the mainstay of treatment. The most commonly used antibiotic is metronidazole (500 mg orally twice a day for 1 week). Clindamycin is also effective. Intravaginal therapy in the form of clindamycin 2 per cent cream or ovules and metronidazole 0.75 per cent gel is associated with fewer side-effects than oral metronidazole and are of equivalent efficacy.

Although antimicrobial therapy alleviates symptoms in up to 80 per cent of women, recurrences are common. There is no proven regimen for the management of recurrences; however, retreatment with an identical regimen is generally successful in four out of five women. Recurrences may occur because therapy is directed towards eliminating organisms rather than re-establishing the normal vaginal flora. Microbiological studies have shown that the return to normal is slow, often taking several weeks. During this time the vagina is vulnerable to regrowth of the organisms associated with bacterial vaginosis and to clinical relapse. Future directions in treatment may involve some means of reintroducing healthy lactobacilli into the vaginal ecosystem.

Treatment of women with asymptomatic bacterial vaginosis remains controversial. Further studies are needed to define the natural history of bacterial vaginosis in these women. However, because of the association of bacterial vaginosis with infectious complications of gynaecological surgery, treatment is justified in this setting. Although bacterial vaginosis has been associated with complications of pregnancy, routine screening and treatment of pregnant women with asymptomatic bacterial vaginosis is not yet recommended. There is some data to support screening and treatment of women at high risk for preterm delivery, namely those who have had a prior preterm delivery. However, published studies have yielded different results, suggesting that simple treatment of bacterial vaginosis is inadequate to prevent preterm birth. A clearer understanding of the mechanisms by which bacterial vaginosis could cause preterm birth are needed before devising appropriate intervention trials. Because bacterial vaginosis has now been associated with an increased risk for acquisition of HIV, there is interest in promoting widespread screening and treatment in areas with high incidences of HIV. However, the current suboptimal cure rates and high recurrence rates associated with current therapies may make these initiatives untenable.

Candidiasis (see also Chapter 7.12.1)

Vaginal candidiasis or 'yeast' infections are perhaps the best known of vaginal infections to patients and physicians alike. Any type of vaginal discharge is likely to be self-diagnosed as a yeast infection by the patient, yet these represent only 20 to 30 per cent of all vaginal infections. Therefore, many women who have identified themselves as having yeast infections actually have other types of infections, or sometimes no infection at all.

Risk factors for candidiasis include the use of oral contraceptives, containing a high dose of oestrogen, recent use of broad-spectrum antimicrobials, pregnancy, diabetes mellitus, and immunosuppression.

Vaginal candidiasis is not thought to be a sexually transmitted infection but an overgrowth of vaginal yeasts with the development of local symptoms. The most common species causing vaginitis is *Candida albicans*, although other candidal species account for 10 per cent of genital yeast infections.

The symptoms of vaginal candidiasis are a thick, white discharge and pruritis. Frequently, there is extensive inflammation, which may involve the vulva. Examination may reveal a discharge, erythema, and often excoriations. The discharge is classically described as resembling cottage cheese but it can be variable.

Diagnosis is confirmed microscopically by the presence of pseudohyphae and budding yeasts in the vaginal fluid. Addition of 10 per cent potassium hydroxide may help to clarify these appearances by dissolving epithelial cells and bacteria. Typically the pH is below 4.5 and there are many neutrophils present, although candidiasis can occur simultaneously with trichomoniasis or bacterial vaginosis. Culture is not useful because low numbers of yeasts may be present in the vagina without causing disease. Culture may be of use when characteristic signs and symptoms are present, but pseudohyphae are not identified in the wet-mount examination.

Treatment of vaginal candidiasis relies heavily upon intravaginal imidazole preparations such as clotrimazole, terconazole, miconazole, and butoconazole for 3 to 7 days. Fluconazole is an attractive, single-dose, oral alternative to the topical preparations in women with uncomplicated vaginal candidiasis.

Diagnostic approach to the patient with vaginal discharge

As with any problem in medicine, the history is of great importance. This should include a detailed sexual history to help assess the patient's level of risk for sexually transmitted infections. During the examination the pH of the vaginal fluid should be determined and a sample of the fluid placed in small amounts of both saline and 10 per cent potassium hydroxide for microscopy. The presence or absence of an amine odour when the potassium hydroxide preparation is made should be noted ('whiff test'). The presence of blood, semen, or exogenous vaginal preparations (douches, creams) will interfere with the determination of pH and with the 'whiff test'. Microscopical examination of the saline preparation should be done at 400 × to look for pseudohyphae, 'clue cells', motile trichomonads, and polymorphonuclear leucocytes. The predominant type of bacteria should also be noted.

Vaginal Gram stains may also be useful to determine if 'clue cells' and bacterial morphotypes suggestive of bacterial vaginosis are present. Table 1 reviews the bedside diagnosis and treatment of vaginal infections.

Conclusion

The aetiology of vaginal discharge can be easily determined by taking a careful history, by physical examination, and simple laboratory techniques. Timely and appropriate treatment will prevent recurrent illness and costly complications to the patient and, perhaps, to neonates.

21.4 Pelvic inflammatory disease

David Eschenbach

Pelvic inflammatory disease (**PID**) comprises a spectrum of female upper genital tract infections that includes any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Salpingitis, or infection of the fallopian tubes, is the most important feature of PID. This is one of the most common and serious infections of the female genital tract because of the long-term effects after PID including infertility, ectopic pregnancy, and pelvic pain.

PID is caused by the canalicular spread of micro-organisms along the mucosal surfaces from the cervix, and to a lesser extent from the vagina, into the upper genital tract. Cervical mucus provides a relative barrier to this spread, but virulent microbes can traverse cervical mucus, which, in any case, is lost during menses. Little is known of local defence mechanisms to prevent this spread of micro-organisms. Certain HLA types appear to be important in chlamydial PID. Factors that appear to influence the ascent of microbes from the cervix into the upper genital tract include surgical procedures such as dilatation and curettage, induced abortion, intrauterine device (**IUD**)-insertion, and hysterosalpingograms. Vaginal douching with medicated products disrupts the vaginal flora and appears to increase the incidence of PID. Furthermore, contraceptive use influences PID rates. Barrier contraception reduces the risk of PID by preventing the acquisition of *Gonorrhoea* and *Chlamydia* spp. Oral contraceptives also appear to decrease the incidence of PID, perhaps by reducing the inflammatory response to chlamydia infection. The IUD appears to increase the risk of PID by allowing the attachment of bacteria.

Most initial episodes of PID are attributable to *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. While one or both bacteria can be isolated from the cervix in up to 75 per cent of patients with PID, there is a wide variation in the prevalence of these bacteria. In populations where gonorrhoea is highly endemic, there is a 50 to 80 per cent prevalence of *N. gonorrhoeae* in women with PID. A study conducted across eight countries of 1900 patients with PID found that the prevalence of *N. gonorrhoeae* varied from 5 to 80 per cent, with a mean of 26 per cent. In the same 1900 patients, *C. trachomatis* was isolated from 5 to 50 per cent of these women (mean prevalence of 29 per cent). In Europe, there was a 30 to 50 per cent prevalence of *C. trachomatis* in women with PID, and a 5 to 15 per cent prevalence of *N. gonorrhoeae*. Between 10 and 20 per cent of patients with PID harbour both bacteria. However, the use of DNA amplification techniques may reveal even higher numbers of infections with these bacteria.

Mycoplasma hominis and *M. genitalium* cause tubal infection in primates, but their role in human PID is unclear. *Ureaplasma urealyticum* has been isolated from the fallopian tubes but appears to play little role in the development of PID.

Facultative and anaerobic bacteria common to the vagina are also isolated from the fallopian tubes of women with PID. In the initial episode of PID, these bacteria appear less frequent than *N. gonorrhoeae* and *C. trachomatis*, but they can become secondary invaders and are important among women with prolonged symptoms. Anaerobic bacteria are virtually always present in pelvic abscesses associated with initial or recurrent episodes of PID. These bacteria are important in recurrent PID, where *N. gonorrhoeae* and *C. trachomatis* are infrequent.

Women with PID have a vast array of clinical symptoms, ranging from virtually no symptoms to ones that are severe. No symptom, clinical sign, or laboratory result is pathognomonic of PID. In women with mild or uncharacteristic manifestations, the diagnosis of PID is usually missed. Perhaps two-thirds of cases of PID go unrecognized. Some patients' symptoms are too mild or are suggestive of common, less serious conditions. The diagnostic threshold of PID must be sufficiently low to include women with mild PID, but as the threshold is lowered, specificity decreases. However, it is better to overdiagnose than to fail to treat mild PID. Most recognized cases of PID present with moderate symptoms and signs such as lower abdominal pain. Symptoms such as abnormal vaginal discharge or bleeding, dysuria, or vomiting do not distinguish women with PID from those with apparently normal fallopian tubes at laparoscopy. Among women with PID diagnosed by laparoscopy, a temperature over 38 °C is present in only 40 per cent of cases, 60 per cent have a leucocytosis, and 75 per cent an elevated erythrocyte sedimentation rate. Women with severe symptoms and signs usually have peritonitis, often from *N. gonorrhoeae* infection, or they have an abscess. These patients can be very ill. Laparoscopy should be considered both for those with florid peritonitis, to exclude other causes such as appendicitis, and for those with abscesses greater than 6 cm in diameter to allow percutaneous drainage.

Perihepatitis occurs in about 10 per cent of women with PID. Often there is moderate to severe pleuritic pain and tenderness, usually in the right upper quadrant. These symptoms are often so severe that lower abdominal pain, suggesting PID, may not be noticed. Perihepatitis must therefore be distinguished from other causes of upper quadrant pain and tenderness by careful pelvic examination. Perihepatitis is associated with *N. gonorrhoeae*, *C. trachomatis*, and other aetiologies.

Cervical samples should be obtained to identify *N. gonorrhoeae* by culture or DNA technology and to identify *C. trachomatis* by DNA technology. Patients with severe manifestations should have peripheral white blood cell counts. Other laboratory tests are usually of little benefit. Ultrasound is helpful for identifying the presence, and particularly the size, of an abscess. Dilated or thickened tubes or fluid within tubes are found in 80 to 90 per cent of women with severe to moderate PID, but in only two-thirds of those with mild PID. Most sonographers have little experience with these findings. Laparoscopy provides an accurate diagnosis and is particularly useful for excluding serious surgical conditions such as ectopic pregnancy, appendicitis, bleeding ruptured ovarian cyst, or a ruptured abscess. Laparoscopy is also useful for difficult cases, such as those unresponsive to antibiotics in which the only objective finding is pelvic tenderness.

Differential diagnosis of PID

Among 814 women who underwent laparoscopy because of a clinical diagnosis of PID, 12 per cent had intra-abdominal conditions other than PID: ectopic pregnancy, appendicitis, ruptured ovarian cysts, and endometriosis. In older women, pyelonephritis, gastroenteritis, and diverticulitis can masquerade as PID. A patient with severe signs of peritonitis should be admitted to hospital for ultrasound examination and/or exploratory laparoscopy. A pregnancy test is needed. If positive, an ectopic pregnancy or other pregnancy complications must be considered. If the pregnancy test is negative and a wet mount of vaginal/cervical secretions reveals no neutrophils or bacterial vaginosis, an ultrasound is needed to diagnose gynaecological diseases other than PID or a gastrointestinal or urinary disorder. If the wet mount shows more neutrophils than vaginal epithelial cells, PID is probable, but other pelvic conditions are not completely excluded. Ultrasound or an endometrial biopsy examined for plasma cells is useful to increase the accuracy of diagnosis.

Treatment is aimed at eradicating *N. gonorrhoeae* and *C. trachomatis*, and, especially for those with moderate to severe disease, anaerobic bacteria (Table 1). Women with PID who are HIV-seropositive appear less likely to be infected with *N. gonorrhoeae* and *C. trachomatis*, but they are more likely to develop abscesses. These patients respond to treatment as promptly as those who are HIV-seronegative, unless they are severely immunosuppressed.

Despite prompt treatment, sequelae are common. Tubal infertility is the most common and disturbing complication. About 10 per cent of women develop tubal infertility after a single episode of PID. Tubal infertility is increased by delaying the treatment of abdominal pain by more than 3 days in chlamydial PID, in women aged over 25 years at the time of PID, and particularly by the number of episodes of PID. Tubal infertility occurs in about 20 per cent of women after two episodes and 40 per cent after three episodes of PID. Tubal infertility occurs in about two-thirds of those with a pelvic abscess or severely damaged tubes observed laparoscopically. There is no correlation between clinical manifestations and the degree of tubal damage observed laparoscopically. Thus, women with mild symptoms but severe tubal damage may become infertile from a single episode of PID. About 7 to 10 per cent of women who become pregnant following PID develop an ectopic pregnancy. Chronic pelvic pain of over 6 months' duration occurs in about 15 per cent of patients following PID.

Attempts should be made to prevent PID. Ideally *N. gonorrhoeae* and *C. trachomatis* infection should be diagnosed and treated before PID can develop. Reduction of *C. trachomatis* infection has lowered the incidence of PID. This should be the aim of primary care providers, especially since *C. trachomatis* can now be diagnosed more readily using new sensitive DNA detection methods.

21.5 Infections and other medical problems in homosexual men

A. McMillan

Many homosexual men have adopted safer sexual practices to prevent the acquisition or transmission of the human immunodeficiency virus (**HIV**). However, condom use is often inconsistent and these men may be at risk of contracting sexually transmissible infections (**STIs**), spread by unprotected receptive/insertive genitoanal and orogenital sex, and faecal–oral infections.

An approach to patients with a suspected sexually transmitted infection that has been acquired homosexually

History

Symptomless, sexually transmissible infections in homosexual men are common, particularly when the pharynx or rectum is affected. A history of a sore throat developing within a few days of receptive orogenital contact is common, and often is not associated with a detectable infection. However, pharyngeal gonorrhoea sometimes produces a sore throat. In HIV-infected men, oral discomfort may be a feature of candidiasis or of oral hairy leucoplakia. A rash may be a feature of several STIs, including primary HIV infection. The patient with various viral STIs, including HIV infection, may notice the presence of enlarged lymph nodes. There may be symptoms of viral hepatitis. Constipation, a mucopurulent anal discharge, anal bleeding, perianal discomfort or pruritus ani, and, in severe cases, pain and tenesmus are symptoms of proctitis caused, for example, by *Neisseria gonorrhoeae*. Many men with proctocolitis, such as results from campylobacter infection, have similar symptoms, but diarrhoea with abdominal cramping, bloating, and fever are the principal features in some people. Diarrhoea, epigastric fullness, abdominal cramps, increased flatulence, and nausea may be features of enteritis caused by *Giardia intestinalis*. All patients, but particularly those with a diarrhoeal disease, should be asked about recent travel to tropical or subtropical areas and sexual contacts there. Perianal pain may be a feature of proctitis, but it is also a symptom of localized disease such as traumatic anal fissure and perianal haematoma. A common cause of pruritus ani is threadworm infestation.

Urethral discharge and dysuria are symptoms of urethritis, caused, for example, by *N. gonorrhoeae*.

The proper interpretation of serological tests for syphilis requires information about previous infection. Similarly, a history of vaccination against hepatitis B should be noted.

Since many homosexual men have psychological problems, careful enquiry should be made about, for example, problems with sexual identity.

Physical examination and investigations

The following should be examined:

- *The skin*: for example, a macular rash may indicate early secondary syphilis, acute HIV, or primary Epstein–Barr virus infections. There may be other dermatological features of HIV (see Chapter 7.11.23). Patients with acute hepatitis may be jaundiced.
- *The mouth and pharynx:* tender superficial ulceration may be caused by herpes simplex virus infection but can also occur during acute HIV infection. Other oral manifestations of HIV infection may be seen (Chapter 7.10.21). Painless superficial ulceration may be a manifestation of secondary syphilis.
- *The superficial lymph nodes*: generalized lymphadenopathy (each node being at least 1 cm in diameter) may be associated with some STIs, including HIV infection. Tender enlargement of the inguinal or femoral nodes may be found in, for example, herpes simplex virus infection of the external genitalia or of the perianal region, respectively.
- *The abdomen*: tender hepatic enlargement is a feature of viral hepatitis and splenomegaly may be found in acute viral infections.
- *The external genitalia:* see Chapter 7.10.21.
- *The anal region*: erythema without specific features may be found in patients who have pruritus ani secondary to an anal discharge. Threadworms may be seen. Multiple tender ulcers are most commonly caused by herpes simplex virus (**HSV**) infection. A solitary ulcer at the anal margin may be traumatic in origin, but primary syphilis must always be excluded. Papillomatous lesions of the perianal region are usually caused by human papillomavirus infection, although the condylomata lata of secondary syphilis should always be considered in the differential diagnosis.
- *The rectum*: the distal rectal mucosa should be inspected in those who give a history of receptive anal intercourse or who have anorectal symptoms. In primary perianal and anal HSV infection, however, proctoscopy should be postponed until the lesions have healed. Signs of proctitis are: loss of the normal vascular pattern of the mucosa (although sometimes this may be a normal finding in the distal rectum), mucosal oedema, friability with contact bleeding, and the presence of mucopus in the lumen (Plate 1). Table 1 lists the sexually transmissible causes of proctitis. Ulceration may be noted in HSV infection, and rarely in primary syphilis or lymphogranuloma venereum. As the proctoscope is withdrawn, the anal canal should be examined for ulceration and condylomata (Plate 2).

In patients with anorectal symptoms and in whom microbiological tests yield negative results for the more common pathogens, sigmoidoscopy may define the extent of proctitis and may identify any lesions beyond the reach of the proctoscope. Rectal biopsy is only occasionally helpful in the diagnosis of rectal sexually transmitted diseases (for example, in lymphogranuloma venereum), but may help to exclude other causes of proctocolitis such as Crohn's disease.

Table 2 indicates the routine microbiological investigations that should be undertaken in the management of a symptomless homosexual man who requests a sexual health screen.

Homosexually transmissible infections

The clinical features, diagnosis, and treatment of these conditions are detailed elsewhere and only those aspects that particularly concern homosexual men are discussed here.

Bacterial infections

Gonorrhoea

In homosexual men the urethra is the most frequently infected site, but infection at multiple sites occurs in about 10 per cent of men.

Although pharyngeal gonorrhoea is usually symptomless, occasionally the patient complains of a sore throat, the pain sometimes radiating to the ear. The physical signs are non-specific but include pharyngeal erythema and sometimes tender enlargement of the anterior cervical lymph nodes. Systemic spread of the gonococcus from the site is extremely rare.

At least 40 per cent of homosexual men with rectal gonorrhoea are symptomless and the rectal mucosa appears normal. When present, symptoms and signs are those of a distal proctitis; the histological findings are non-specific. Perianal abscess is an uncommon complication and disseminated infection is rare.

Neisseria meningitidis infection

N. meningitidis is the most common *Neisseria* species to colonize the oropharynx, and is isolated more frequently from this site in homosexual than in heterosexual men. Urethral carriage of the organism occurs in fewer than 1 per cent of homosexuals and rarely causes urethritis. The rectum is colonized in about 2 per cent of homosexually active men, but this organism is a rare cause of proctitis.

Syphilis

The primary lesion may occur on the penis and have the classical features. A chancre may be found at the anal margin or, rarely, in the distal rectum or in the oropharynx. The clinical presentation of extragenital lesions is often atypical. For example, an anal chancre often resembles a traumatic anal fissure—it is often painful, tender, bleeds easily, and often lacks induration; there is usually femoral lymph-node enlargement. The most common symptoms of primary syphilis of the rectum are rectal pain, an alteration of bowel habit, a mucoid anal discharge, and bleeding; the lesion is usually ulcerative but can be polypoidal, resembling a carcinoma. Biopsy can cause profuse haemorrhage.

Chlamydia infection

Although non-gonococcal urethritis is common in homosexual men attending sexually transmitted disease (**STD**) clinics, *C. trachomatis* is isolated much less frequently from homosexual than heterosexual men with non-gonococcal urethritis. The aetiology of non-chlamydial, non-gonococcal urethritis is uncertain. Rectal chlamydial infection is found in about 6 per cent of STD clinic attenders who have had unprotected, receptive anal intercourse. Pharyngeal chlamydial infection, diagnosed either by culture or by the detection of chlamydial DNA, is uncommon. In temperate climates, infection with the lymphogranuloma venereum serovars of *C. trachomatis* is rare.

The clinical features of non-gonococcal urethritis associated with infection by the oculogenital serovars (D–K) of *C. trachomatis* are described in Chapter 7.11.40. Pharyngeal infections are often symptomless but can be associated with pharyngitis lacking specific features. Most men with rectal infection are symptomless with normal proctoscopic findings, but there may be features of a distal proctitis. Histologically, there is a non-specific proctitis consisting of a mild increase in the number of chronic inflammatory cells and polymorphonuclear leucocytes within the lamina propria.

Infection with lymphogranuloma venereum serovars is associated with a more severe proctitis with systemic features. Although the sigmoidoscopic findings are those of a severe proctitis, the inflammatory changes seldom extend more proximally than 12 cm from the dentate line. Occasionally, the inflammation is more localized, with an irregular ulcerated mass that may be polypoidal and extend circumferentially to produce stenosis. Inguinal lymph-node involvement may be a feature of lesions of the anal canal and distal rectum. Untreated, lymphogranuloma venereum can be complicated by perianal abscess formation, strictures, and fistulas in the anus. Histologically, there is a dense infiltration of the lamina propria and submucosa by lymphocytes, plasma cells, histiocytes, and sometimes eosinophils. Occasionally, granulomas with giant cells are found with focal areas of acute inflammation with crypt abscesses.

Chancroid

Chancroid, caused by *Haemophilus ducreyi*, is common in tropical countries. Although there are few reports on the features of perianal chancroid, it is likely that the ulceration is similar to that occurring on the genitalia (Chapter 7.11.13).

Donovanosis (granuloma inguinale)

Klebsiella granulomatis infection is regarded as a sexually transmitted disease. Perianal donovanosis usually occurs in homosexual men, presenting as ulceration. Extensive fibrosis with anal stenosis may occur and, rarely, extensive areas of skin and subcutaneous tissue undergo necrosis. Basal-cell or squamous-cell carcinomas may complicate the infection.

Shigellosis

The sexual transmission of *Shigella* spp. among homosexual men was first recognized in 1974 in San Francisco. Subsequent reports have confirmed the spread of this organism through oroanal sexual contact.

Salmonellosis

Cases of typhoid fever acquired from anilingus with symptomless carriers of *Salmonella typhi* have been described.

Campylobacter infection

In some areas of the United States, *Campylobacter* spp. (particularly *C. jejuni* and, to a lesser extent, *C. fetus*, *C. fennelliae*, and *C. cinaedi*) can be isolated from over 20 per cent of homosexual men with diarrhoea. The source of infection is often uncertain but symptomless carriers are known to exist.

Corynebacterium diphtheriae infection

An increased pharyngeal carriage rate of non-toxigenic *C. diphtheriae* has been reported, but, although these organisms may be associated with pharyngitis, the significance of the finding is uncertain.

Viral infections

Human papillomavirus (HPV)

Condyloma is the most common clinical presentation of HPV infection, a lesion that is almost always associated with HPV type 6/11. In homosexual men, condylomas are found on the genitalia and in the perianal region and within the anal canal, where they may cause pruritus ani and bleeding during defaecation. Rarely, condyloma acuminata may develop in the oropharynx. Although condylomas may be very extensive and persistent in immunocompetent individuals, this is particularly so in immunocompromised patients, including those with HIV infection.

Non-condylomatous HPV lesions of the anal canal may be associated with squamous intraepithelial lesions (SIL). The lesions can be identified through an operating microscope after the application of acetic acid (5 per cent v/v), they are white, well-demarcated from the surrounding mucosa, and have a punctate appearance similar to that seen in HPV infection of the uterine cervix. Definitive diagnosis is by biopsy.

Herpes simplex virus (HSV)

Both HSV-1 and -2 can affect the anogenital region. In Edinburgh, between 1989 and mid-1999, 65 per cent of 65 primary or initial episodes of anogenital disease in homosexual men were associated with HSV-1. These had probably been acquired during orogenital or oroanal sexual contact. Inapparent infection with either type is common.

Primary perianal herpes causes anal pain, constipation, tenesmus, anal discharge, and bleeding on defaecation; systemic symptoms are often prominent. Sacral nerve-root involvement may result in paraesthesia in the affected nerves, urinary hesitancy or acute retention, and impotence. There are often multiple tender ulcers in the perianal region and within the anal canal. Distal proctitis associated with HSV may have no specific features but discrete vesicular or pustular lesions or ulcers may be seen. HSV is an uncommon cause of proctitis. It can occur in the absence of perianal or anal ulceration. Rectal biopsies show a marked infiltration of the lamina propria with neutrophils (sometimes with the formation of crypt abscesses), perivascular infiltration of the submucosal vessels with lymphocytes, and multinucleated cells occasionally with intranuclear inclusions.

HSV-2 is more likely to recur than in HSV-1, but the symptoms and signs are generally much less severe and there are no systemic features.

Cytomegalovirus (CMV)

CMV infection is more prevalent among homosexual than heterosexual men and women. A study in San Francisco during 1981 reported that 94 per cent of sexually active, homosexual men were seropositive for CMV compared with only 54 per cent of heterosexuals. Receptive anal intercourse is the most likely means of acquisition. The virus is present in semen. Restriction enzyme analysis of serial isolates from homosexuals has shown that infection with multiple strains of CMV is common and that multiple strains can be shed simultaneously. CMV is a rare cause of anorectal ulceration.

Hepatitis A virus (HAV)

HAV is transmitted by the faecal–oral route and, although there are conflicting data, homosexual men may be at increased risk of infection. Epidemic outbreaks of homosexually acquired, acute hepatitis A are reported occasionally. Inactivated HAV vaccine may be indicated in sexually active homosexual men to prevent the spread of this infection.

Hepatitis B virus (HBV)

The homosexual transmission of HBV was first recognized more than 20 years ago when it was shown that the prevalence of hepatitis B surface antigen (**HBsAg**) was significantly higher in sera of Caucasian homosexuals than in the sera of Caucasian heterosexual men attending an STD clinic in London. HBV-seropositivity has been related to the duration of regular homosexual activity and to the numbers of different sexual partners. As hepatitis B e antigenaemia is closely associated with infectivity, and as the sera of some 70 per cent of homosexual men who are persistent carriers of HBsAg contain e antigen, their sexual contacts are at particular risk of infection. The means of transmission of HBV between homosexual men is uncertain. In some areas there has been a recent decline in HB prevalence, presumably as a result of the adoption of safer sexual practices to avoid HIV infection and to the more widespread use of hepatitis B vaccine. Vaccination of sexually active homosexual and bisexual men who are antiHBs-negative, is a cost-effective method of preventing spread. However, in HIV-infected homosexual men, the humoral response to vaccination is frequently impaired.

Hepatitis C virus (HCV)

HCV can be transmitted sexually, but the risk of infection to homosexual men who do not inject drugs is low.

Hepatitis D virus (HDV)

In the United States, sera from 7.7 per cent of 298 homosexual men who were HBsAg-positive contained anti-HDV antibodies. There was an association with the number of sexual partners and the occurrence of anorectal trauma in the 2 years before testing. These data, and the finding of HDV markers in the serum and viral RNA in liver tissue from HBV-infected homosexuals who had never injected intravenous drugs, suggests that sexual transmission of this virus occurs within this population.

Hepatitis G virus/GB virus C

The prevalence of serum antibodies against this virus is significantly higher among homosexual than heterosexual men, suggesting that it is sexually transmissible. The pathogenic significance of the virus, however, remains uncertain.

Human immunodeficiency virus (HIV)

The epidemiology, pathogenesis, and manifestations of this viral infection are discussed in Chapter 7.10.21.

Human T-cell leukaemia viruses (HTLV) types 1 and 2

Although HTLV-1 and HTLV-2 can be transmitted sexually, the prevalence of infection among homosexual men is low.

Human herpesvirus 8 (HHV-8)

Kaposi's sarcoma is more common among homosexual men than other groups affected by the HIV. The association with HHV-8 is now well established, but its epidemiology is not fully understood. The prevalence of antibodies against HHV-8 in the sera of homosexual men is significantly higher than that of the general population and correlates with the number of male sexual partners. Orogenital insertive and orogenital receptive sex have been implicated in the transmission of HHV-8 amongst homosexual men.

Protozoal infections

Amoebiasis

Entamoeba histolytica can be transmitted sexually, but the incidence of infection among homosexual men in industrialized countries is low. Previous reports on the apparent high prevalence of infection were erroneous because the organism that was reported as *E. histolytica* was almost invariably *E. dispar*, a non-pathogenic protozoan that is morphologically indistinguishable from *E. histolytica*.

Giardiasis

The prevalence of *Giardia intestinalis* in homosexual men attending STD clinics in temperate climates varies between 2 and 12 per cent. Most infections are symptomless, but a diarrhoeal illness may result.

Cryptosporidiosis

Cryptosporidium parvum can cause diarrhoeal illness. Person-to-person spread has probably been responsible for infection in household contacts. It is a cause of diarrhoea in some homosexual men, but the importance of sexual transmission in the epidemiology of cryptosporidium is uncertain.

Nematode infection

Enterobius vermicularis

Sexual spread by oroanal contact is the most likely route of infection in homosexual men.

Strongyloides stercoralis

Non-infective rhabditaform larvae may develop into infective filariform larvae before leaving the colon. During oroanal contact, these larvae may be transmitted by ingestion of faeces. Penetration of the skin or mucous membrane of the penis by these larvae cause infection during or after anal intercourse.

Other medical conditions in homosexual men

Urinary-tract infection and epididymitis

Bacteriuria may be more prevalent among homosexual men. Acute epididymitis in homosexuals under 35 years of age is more likely to be caused by enterobacteria than *N. gonorrhoeae* or *C. trachomatis*, the most common aetiological agents in heterosexual men under the age of 35 years.

Anorectal trauma

Violent anal intercourse can cause anal fissure or a perianal haematoma. Profuse rectal haemorrhage from mucosal laceration or rupture of the colon at the rectosigmoid junction may result from the insertion of a closed fist into the rectum. Extraperitoneal microperforation of the rectum during 'fisting' may result in pelvic cellulitis: within a few days, lower abdominal and rectal pain develops and the temperature rises. Abdominal examination is usually normal but there may be tenderness in the left iliac fossa. There is marked proctitis and induration of the pararectal tissues. Treatment is with broad-spectrum antimicrobial agents.

Rectal spirochaetosis

In this condition, spirochaetes lie parallel to the microvilli of the epithelial cells of the rectum and superficial portions of the crypts. The condition is indicated by the presence in a haematoxylin and eosin-stained section as a haematoxyphil zone, 3 µm wide, on the luminal surface of the cells. At least one species of spirochaete, *Brachyspira aalborgi*, has been associated with this condition.

Rectal spirochaetosis is found in at least one-third of homosexual men who attend STD clinics but in only 2 to 7 per cent of patients attending general outpatient departments, suggesting sexual transmission. The pathogenicity of the spirochaetes is uncertain.

Carcinoma of the anal canal

In men, receptive anal intercourse may be a risk factor for squamous- and transitional-cell carcinomas of the anal canal. HPV types, particularly HPV-16, have been detected in anal squamous-cell carcinomas. The development of squamous-cell carcinomas in HIV-infected individuals is now well recognized. The immune deficiency associated with HIV infection may permit reactivation of latent HPV resulting in epithelial abnormalities. The situation may be analogous to the development of cancers at other sites in iatrogenically immunosuppressed patients.

Anal squamous intraepithelial lesions (**SIL**) were first described in 1986 and are most commonly found at the junction of the squamous epithelium of the anal canal and the columnar epithelium of the rectum. SILs have been found in tissue removed from the anal canal of homosexual men, and with the operating microscope, after the application of acetic acid, high-grade SILs may be seen as irregular white areas with cobblestoning and mosaicism, and corkscrew vessels.

Low-grade SILs tend to be associated with HPV types 6 and 11 and high-grade SILs with types 16 and 18. Abnormal anal cytology is common in homosexual men with late-stage HIV disease (Centers for Disease Control group IV) and is significantly associated with infection with multiple types of HPV, including those with oncogenic potential. The natural history of SILs, particularly progression to invasive cancer and whether treatment is necessary, is as yet unknown.

21.6 Cervical cancer and other cancers caused by sexually transmitted infections

V. Beral

Occurrence

Worldwide, cervical cancer is the second most common cancer in women. It is far more frequent in Third World countries than in the West (Fig. 1). About 1 per cent of women in Britain have invasive cervical cancer diagnosed during their lifetime, and 0.4 per cent die from it. Mortality rates have been falling throughout the twentieth century, except among recent generations of women who became sexually active during the 1960s, a time when exposure to sexually transmitted diseases increased rapidly: 0.2 per cent develop vulval cancer and 0.2 per cent anal cancer.

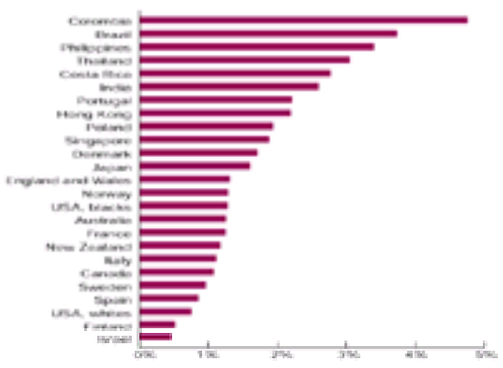

Fig. 1 Percentage of women who develop cervical cancer before the age of 75 years, by country.

The role of human papillomaviruses and other factors

There is now overwhelming evidence that the vast majority of cervical, vulval, anal, and penile cancers are caused by specific types of the human papillomavirus (see Chapter 7.10.2). DNA from human papillomavirus types 16, 18, 31, 33, and 35 (mostly type 16) has been found in as many as 99 per cent of cervical and other anogenital cancers. Fewer than 10 per cent of people without such cancers have detectable evidence of these types of papillomaviruses in their anogenital cells.

The risk of cervical cancer is increased in women who are poor, have little education, were young when they first had sexual intercourse, had many sexual partners and multiple sexually transmitted infections, had many children, especially when they were young, and who smoked cigarettes and used oral contraceptives. Recent evidence suggests that hormonal and reproductive factors and cigarette smoking may independently influence the development of cervical cancer in papillomavirus-infected women, whereas other sexually transmitted infections may be of no direct aetiological significance.

The natural history of infection with the human papillomavirus and associated changes in the cervical epithelium

Some cervical papillomavirus infections cause no obvious epithelial changes—cervical colposcopy, cytology, and biopsy are normal—and the only way infection can be identified is by virological study. Other papillomavirus infections cause 'cervical warts', which are asymptomatic but can be seen as white patches at colposcopy after acetic acid has been applied to the cervix. Cervical smears from women with cervical warts may show various degrees of dysplasia or dyskaryosis, and cervical biopsy may show various grades of cervical intraepithelial neoplasia (**CIN**) (or squamous intraepithelial lesions (**SIL**) according to a new classification known as the 'Bethesda system'). The most extreme change in the epithelium is the development of invasive cervical cancer, which seems to be associated with persistent viral infection and long-standing epithelial abnormalities.

Very little is known about why some lesions progress or regress. Most changes (up to the development of invasive cancer) seem to be reversible. Moreover, lesions of different severity often coexist in the same woman. The more severe lesions tend to be rarer and found in older women: estimates of the proportion of women in Britain likely to develop various types of lesions are given in Table 1, and the age-specific prevalences of some of these lesions are shown in Fig. 2. At least 1 woman in 10 is likely to be infected with human papillomavirus types 16 or 18; 1 in 20 is likely to develop persistent infection or some abnormality of her cervical epithelium; 1 in 50 is diagnosed with *in situ* cervical cancer; and 1 in 100 develops invasive cervical cancer. Papillomavirus infection is most prevalent in women in their twenties, corresponding to the age when they acquire other sexually transmitted infections; the peak prevalence of *in situ* cancer tends to be about 10 years later (in women in their thirties), whereas invasive cancer is rare before 30 years of age.

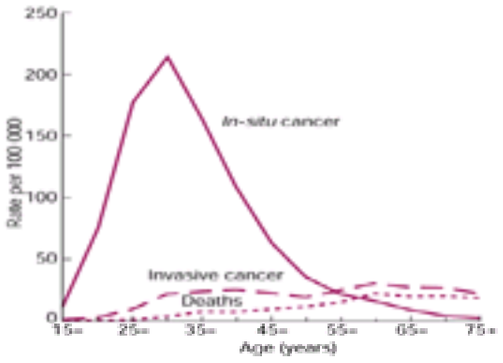

Fig. 2 Age-specific incidence of *in situ* and invasive cervical cancer and of death from cervical cancer in England and Wales.

Clinical implications

Most premalignant cervical changes are caused by papillomaviruses, although most infections resolve spontaneously. Cervical infection with papillomaviruses is especially common in young women, but invasive cervical cancer is rare before the age of 30 years and seems to be associated with persistent infection and long-standing epithelial abnormalities.

We do not know why infection persists in some women and what determines who goes on to develop cervical cancer. Although intensity of infection, age at exposure,

immune response, genital hygiene, reproductive history, and the use of oral contraceptives could be relevant, further research is needed to clarify the role of these possible risk factors. In the meantime, it seems sensible not to resort to active treatment for women in their twenties with papillomavirus infection and related mild cervical lesions, but to reassure them that most lesions will resolve spontaneously and encourage them to have regular cervical smears. Only in young women with severe lesions and older women with persistent epithelial abnormalities is there an appreciable risk of progression to invasive cervical cancer, and active treatment is required.

Prevention

Well-organized screening programmes, based on exfoliative cervical cytology, are known to be effective in reducing the incidence and mortality of cervical cancer. Testing for papillomaviruses should not replace cervical cytology as a first-line approach in screening, since this would result in unnecessary treatment in many young women and because not all cervical cancers are associated with papillomavirus infection. Testing for papillomaviruses may be useful, however, in deciding how to manage the large number of women who have equivocal cervical cytology. Its efficacy must be evaluated before it is adopted on a large scale.

Effective vaccines have already been produced for bovine tumours caused by papillomavirus. Vaccines against the human papillomaviruses have been developed in the last few years and are now being tested in clinical trials.

22.1 Introduction

D. J. Weatherall

The study of blood is one of the most fascinating branches of clinical medicine. Almost all diseases produce changes in the blood at some time during the course of the illness. Furthermore, the primary disorders of the blood and blood-forming tissues can give rise to extremely diverse clinical manifestations, which may involve any of the organ systems. Textbooks often give their readers an unbalanced picture of haematology in the real world. Primary disorders of the blood and blood-forming organs account for only a small percentage of a haematologist's practice. Most patients who are referred with haematological abnormalities have diseases in other systems. Anaemia is a good example. Most anaemias are due to blood loss, infection, renal failure, malignant disease, and malnutrition or parasitic infestation. Anaemia may be the first indication of a chronic urinary tract infection, hypothyroidism, pituitary failure, bacterial endocarditis, polymyalgia rheumatica, or even that endemic disease of 'medical grand rounds', atrial myxoma.

This section emphasizes primary diseases of the blood and blood-forming organs, but the reader should be aware that many of these conditions are relatively uncommon. The summary of the haematological manifestations of non-haematological diseases that appears later in this section should leave the reader with a more balanced view of the scope of this absorbing subject.

An approach to patients with haematological disorders

The diagnosis of blood diseases follows the same process as any other condition; expertise in the laboratory will never make up for an inadequate history and clinical examination. It should be remembered that many patients who are referred to hospital for a specialist opinion on their blood are worried about the possibility of leukaemia, although they will rarely say so. It is important to reassure them as soon as possible if this is not the diagnosis. Where leukaemia is suspected, no time should be lost in determining an accurate diagnosis and a well-worked out plan of management. The situation can then be discussed frankly with the patient and his or her family; knowledge of what they face and precisely what form of treatment is to be instituted often engenders a great sense of relief after weeks or months of fearing the worst.

History

In taking a history from a patient who is suspected of having a haematological disorder, certain factors are of particular importance. The symptoms of anaemia are described in detail later in this section. However, a slowly developing anaemia may be completely asymptomatic, even when the haemoglobin level is extremely low. Individuals who are otherwise healthy should be able to compensate for a relatively mild anaemia; a young individual with a haemoglobin level of 10.5 g/dl who complains of tiredness and an inability to cope with life is more likely to have these symptoms because of chronic anxiety rather than the anaemia. Other general symptoms are of great importance, particularly weight loss, night sweats, bone pain, and pruritis. Moderate nocturnal sweating is common in anxiety states; drenching sweats requiring several changes of nightclothes and sheets are a more ominous symptom, often associated with infection or lymphoproliferative disease. Pruritus occurs in conjunction with many disorders of the blood. When associated with lymphoma it is non-specific, but when it accompanies the myeloproliferative disorders it is often precipitated by warmth such as getting into bed or a hot bath. A detailed drug history is essential; many drugs produce haematological side-effects.

Although a complete systematic history must be taken, gastrointestinal and haemostatic functions are particularly relevant to diseases of the blood. A detailed dietetic history is essential when investigating anaemia, and it is important to ask specifically about symptoms such as a sore tongue, bleeding gums, dysphagia, dyspepsia, disturbance of bowel habit suggestive of malabsorption, and rectal bleeding. Patients are often referred to haematological departments for investigation of easy bruising. Many people, particularly women, bruise easily and the key question is whether the bruising is unusual for them. Is it spontaneous or related to only mild trauma? It is also extremely helpful to enquire into certain key episodes in a patient's life that may provide a clue as to whether there is an inborn bleeding tendency. These include circumcision, dental extraction (was a return to the dentist for stitching or packing ever required?), menstruation, surgical procedures, and so on.

Assessment of menstrual blood loss is an important part of the history in women with iron deficiency, as well as for assessing haemostatic function. It is not enough to ask a woman whether she considers that her periods are normal. If she only uses internal tampons, she probably does not have menorrhagia. However, the use of one or more packets of the more absorbent brands of external pads, or the need to get up at night to change pads or to stay at home during the menstrual period, suggests a heavy loss.

Family histories are particularly important for the diagnosis of blood diseases. It is not only essential to ask for a family history of anaemia or bleeding disorders, the racial origin of the patient's ancestors may also give valuable clues to the cause of anaemia. The long-forgotten, Italian great-grandparent may have been the source of the thalassaemia gene that is responsible for a refractory hypochromic anaemia or the red-cell enzyme deficiency that leads to a haemolytic drug reaction. A detailed personal history is also essential. Cigarette- or cigar-smoking is probably the most common cause of mild polycythaemia. Alcohol can produce remarkably diverse haematological changes. A detailed occupational history may reveal exposure to industrial solvents or other agents responsible for bone marrow depression; unusual hobbies may also result in contact with toxic agents.

Physical examination

The examination of a patient with a haematological disorder follows the same pattern as any physical examination, but there are certain aspects of particular importance. On general inspection it is essential to examine the skin carefully for evidence of bruising, purpura, infiltration, or ulceration. The distribution and pattern of bruising or petechiae may be diagnostic, particularly in disorders such as Henoch–Schönlein purpura, senile purpura, scurvy, purpura due to venous obstruction, and the painful bruising syndrome. Thrombocytopenic purpura is often seen most easily over pressure areas; a few lesions in these regions are easily overlooked. Cutaneous lymphoma may mimic a variety of skin diseases. Chronic leg ulceration is a common finding in sickle-cell anaemia; it occurs occasionally with other genetic haemolytic anaemias. The perianal region and perineum should be carefully inspected. There may be perianal infiltration, particularly in the monocytic leukaemias, and it is very important to recognize perianal infection early in neutropenic patients. Digital examination of the rectum should be avoided in neutropenia for fear of disseminating an infection. Potential sites of infection in compromised patients must be examined daily. They include the skin, intravenous infusion sites, the mouth and throat, and the perineum. The mucous membranes, nailbeds, and palmar creases should be examined carefully for pallor, always remembering that the clinical assessment of anaemia is very inaccurate. Pigmentation of the face is sometimes a feature of folic acid deficiency. Mild jaundice may be a useful indicator of haemolysis, while a greyish pigmentation of the skin is common in patients with iron overload, both primary and secondary to repeated transfusion. There is an association between vitiligo and pernicious anaemia. In patients with polycythaemia there may be suffusion of the conjunctivae, a high colour, and prominence of the vessels over the face, neck, and upper part of the chest. The nails should be examined for unusual fragility; flattened, spoon-shaped nails, koilonychia, which are supposed to be diagnostic of chronic iron deficiency, are now rarely seen.

An assessment of the size of the lymph nodes and an inspection of other lymphatic tissue are a major part of the examination of patients with haematological

disorders. It is most important to develop a systematic approach to lymph-node examination. Each group of nodes in the head and neck, axillae and groins, together with the epitrochlear nodes, must be examined in detail. In the head and neck it is useful to start with the occipital nodes, then move to the preauricular and postauricular nodes, and, finally, to examine systematically the anterior and posterior triangles and supraclavicular regions. In patients with enlarged occipital or posterior cervical nodes, the scalp should be inspected for signs of infestation and secondary infection due to scratching. A simple way of describing enlarged lymph nodes should be used, without the use of too many adjectives. Nodes should be labelled as hard, firm, or soft, and tender or non-tender. Ambiguous terms such as 'rubbery' should be avoided. Soft, tender nodes usually indicate infection. Large, firm nodes are characteristic of lymphoma. Hard nodes occur in secondary carcinoma, although calcified nodes, matted together and attached to skin, are still encountered in patients with tuberculous adenitis. The approximate size of the nodes should be recorded, together with whether they are mobile, attached deep or superficially, and discrete or matted together. It is also very important to examine the tonsils and adenoids, particularly in a patient suspected of having a lymphoproliferative disease.

A detailed examination of the mouth should include the state of the tongue, mucous membranes, gums, teeth, and fauces. Glossitis, as evidenced by a smooth, depapillated tongue, occurs in iron-deficiency and megaloblastic anaemia. Small, black bullae (blood blisters) on the tongue or mucous membranes, which burst and leave superficial ulcers, are characteristic of thrombocytopenic purpura. Gingival hypertrophy is sometimes found in patients with acute leukaemia, particularly the monocytic type, and in some individuals with megaloblastic anaemia due to phenytoin therapy. Ulcers of the mouth and fauces occur in all forms of acute leukaemia. Oral infection, often associated with ulceration, is very common in neutropenic patients. Candidosis may be seen on the fauces, tongue, or mucous membranes. Candidal infection of the throat, associated with dysphagia, should raise the suspicion of oesophageal candidosis (-iasis). The teeth may be badly formed and the bite may be abnormal in patients with severe forms of thalassaemia. Dental abscesses are common in patients with neutropenia; suspect teeth should be gently percussed for evidence of apical infection. Telangiectases may be found on the lips and oral mucous membranes of patients with hereditary telangiectasia.

On abdominal examination the most important questions are the size of the liver, whether there is splenomegaly, and if there are any palpable para-aortic lymph nodes. It is not possible to learn how to examine the spleen from a textbook, but a few hints may be helpful. Large spleens can often be seen to move up and down on respiration if the abdomen is well illuminated and the observer stands at the end of the bed. Very large spleens tend to move downwards and medially towards the right iliac fossa and can be missed if the examiner does not start palpating from this region, moving upwards and medially towards the left subcostal region. A sure way to miss a moderately enlarged spleen is to go digging in with the fingers without eliciting the patient's help. With the left-hand hooked round the region above the left costal margin, and the right hand resting lightly on the abdomen, the patient should be asked to gently breathe in and out through the mouth. The secret of success is to persuade the patient to breathe just deeply enough to move the spleen down without contracting the abdominal muscles. The examiner should wait for the spleen tip to meet their fingers rather than to try to find it by deep palpation. Once defined, the position of the lower border of the spleen should be recorded in centimetres, vertically below the costal margin. Manoeuvres designed to facilitate the palpation of a slightly enlarged spleen, such as turning the patient on their right side, while useful for impressing clinical examiners, are rarely of much help in practice. Be gentle! The author has seen enlarged spleens ruptured by overenthusiastic medical students. If there is pain over the spleen or referred to the left shoulder, don't forget to listen for a rub. Finally, remember that spleens come in all sizes and shapes, and often lie more laterally than expected. Do not be disappointed not to feel the much publicized notch; it happens once or twice in a clinical lifetime! The differential diagnosis of palpable masses in the region of the spleen is considered later in this section.

The eyes are a mine of information in patients with haematological disorders. Periorbital oedema is sometimes seen in infectious mononucleosis. The conjunctivae may show mild icterus not obvious in the skin, and there may be haemorrhages in bleeding disorders. Pingueculae of the conjunctivae are seen in Gaucher's disease. Retinal haemorrhages are common in patients who have had a sudden fall in haemoglobin level. They are less frequent in severely thrombocytopenic patients with normal haemoglobin levels; the combination of anaemia and thrombocytopenia is particularly likely to lead to severe retinal bleeding. Papilloedema occurs commonly in patients with leukaemia involving the central nervous system. Proliferative abnormalities of the retinal vessels are often seen in patients with sickling disorders, particularly haemoglobin SC disease. The hyperviscosity syndrome associated with macroglobulinaemia and some forms of myeloma is characterized by fullness of the retinal veins, which are sometimes broken up into segments like a string of sausages. These changes are often associated with widespread retinal haemorrhages. Optic atrophy may occur in patients with severe vitamin B_{12} deficiency. Unilateral exophthalmos occurs occasionally in patients with myeloma deposits or lymphoma involving the orbit.

Examination of the musculoskeletal system may be particularly rewarding in patients suspected of having genetic blood disorders. In patients with coagulation defects such as haemophilia or Christmas disease, recurrent bleeding into joints may produce a chronic deforming arthritis. Muscle haematomas are also common and are easily missed. For example, bleeding into the psoas sheath may produce a discrete swelling above the inguinal ligament, which may later be associated with nerve compression leading to weakness of the quadriceps and anaesthesia over the anterior aspect of the thigh. If muscle pain is the presenting symptom, it is very important to palpate the muscle groups carefully for the cystic swellings that may occur in haemophiliacs after bleeding into muscles. The joints have other important associations with blood disorders. A mild refractory anaemia is a very common accompaniment of rheumatoid arthritis. Painful arthritis of the large joints may be the presenting symptom of primary haemochromatosis. Gout is a common complication of all the myeloproliferative diseases; the ears should be examined carefully for tophi, in addition to a full assessment of the joints. The value of bone tenderness in the diagnosis of acute leukaemia has been overemphasized. When present it is best elicited by carefully palpating the sternum or tibias, or by rib compression. Be gentle, because sometimes the tenderness is quite exquisite. Bone tenderness or local swelling are also found in patients with myeloma or sickle-cell anaemia. In children with thalassaemia or other hereditary haemolytic anaemias there may be reduced growth, bossing of the skull, and facial deformities. A wide variety of skeletal changes may occur with congenital hypoplastic anaemia.

The use of the laboratory

The diagnosis and management of blood disease requires an examination of the blood and, if appropriate, the bone marrow. Clinicians will obtain the maximum information from their colleagues in the laboratory if they ask the right questions. Scribbling down 'full blood count' on a laboratory request form is useless. It is essential to ask for an examination of the blood film in any patient who is suspected of having a haematological disorder. More can be learned from the help of an experienced morphologist than any other investigation in clinical haematology. Some haematological investigations are underused; others are requested far too often. For example, the often forgotten reticulocyte count is an invaluable guide to the response of the bone marrow to anaemia and for the recognition of bleeding or mild haemolysis. On the other hand, bone marrow examination is an unpleasant investigation and should only be requested with very clear indications. For example, clinicians should stop and think why they are ordering a bone marrow examination in an elderly patient with a peripheral blood lymphocyte count of 80×10^{9}/l. This can only be chronic lymphatic leukaemia; the bone marrow will be infiltrated with lymphocytes. Why put the patient through this traumatic investigation? The result is predictable and will not help in their management.

It cannot be emphasized too strongly that the most useful information is obtained by very close liaison between the laboratory and the ward. Clinicians should visit the haematology laboratory regularly, review films and haematological data with their laboratory colleagues, and be very precise in setting out the reasons for the investigations they order. Much valuable information is lost because of the lack of good liaison between the bedside and laboratory.

Examination of the blood

Constituents of normal blood

Blood consists of several different types of cells suspended in plasma. The classification and morphological analysis of blood cells was made possible by the studies of Ehrlich, who, in 1877, described the use of aniline dyes for staining dried blood films. This approach has been refined over the years. The fine structure of the blood cells has been analysed in greater detail with the electron microscope and, more recently, with the scanning electron microscope (Fig. 1).

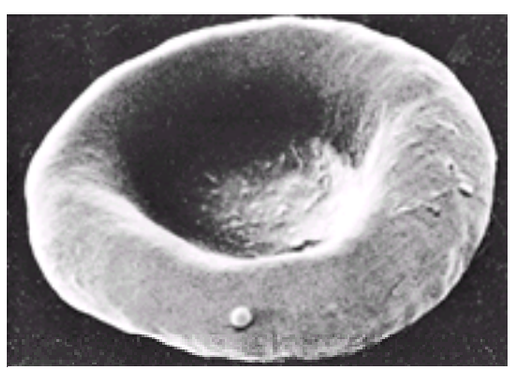

Fig. 1 A human erythrocyte as viewed through the scanning electron microscope. (By kind permission of Dr S. M. Lewis.)

The formed elements of the blood, or blood cells, consist of the red cells, white cells, and platelets. The red cells are biconcave discs approximately 7 to 8 µm in diameter (Fig. 1). They consist of a membrane that contains a concentrated solution of haemoglobin and a variety of other proteins, salts, and vitamins. Normally they are of a uniform shape and size, and contain similar amounts of haemoglobin. On supravital staining, approximately 1 per cent of the red cells show a reticular appearance. These are newly released cells and because of their staining characteristics are called reticulocytes.

The white cells are classified according to their morphological appearances into granulocytes (polymorphonuclear leucocytes (PMNs)), monocytes, and lymphocytes. The granulocytes and monocytes are phagocytic cells, while the lymphocytes are involved in a variety of immune mechanisms. The granulocytes can be further classified according to their maturity. In the newly produced forms, band cells or juvenile polymorphonuclear leucocytes, the nucleus is horseshoe-shaped but single. In a normal blood film the majority of the granulocytes have matured beyond this stage and their nuclei consist of two or more lobes separated by thin, filamentous chromatin strands. These cells are about 12 to 15 µm in diameter. The granulocyte series is further classified according to the staining characteristics of the granules into neutrophils, eosinophils, and basophils. The monocytes are of similar size to the granulocytes but have oval nuclei with a slate-coloured cytoplasm, which may contain some fine granules.

There are two morphologically distinct forms of lymphocyte: a large cell with a diameter of 8 to 16 µm and a smaller one measuring 7 to 9 µm. Both forms are round and have a light blue cytoplasm. In the large lymphocytes the nucleus fills about half of the cell whereas in the small lymphocytes it almost completely fills the cell.

The platelets are disc-shaped cells measuring approximately 2 to 3 µm in diameter. In normal blood they are relatively homogeneous in structure; their fine structure cannot be distinguished by conventional light microscopy.

A more detailed description of the structure and function of these different blood cells and their precursors appears later in this chapter.

Investigation of the blood—the normal blood count

A full blood count can be carried out on a 5-ml anticoagulated blood sample. A stained blood film is prepared for examination of the morphology of the different cells. Using either chemical and physical methods, or the more accurate electronic cell counters, the relative volume of packed red cells and white cells, the haemoglobin level, and the red-cell, white-cell, and platelet counts can be determined. From a series of calculations relating the volume of packed cells, haemoglobin level, and red-cell count, it is possible to derive a series of absolute indices that provide useful information about the size and degree of haemoglobinization of the red cells. Finally, the relative numbers of reticulocytes and the erythrocyte sedimentation rate can be determined.

The stained blood film

An examination of the stained blood film is the most important investigation in haematology. Each of the cell types is studied separately.

The red cells are examined to assess their degree of haemoglobinization and their shape; if both are normal, they are described as normochromic and normocytic. Disorders of the red cell are frequently associated with changes in their morphology or staining properties. These include variation in size or anisocytosis; an increase in size or macrocytosis; a reduction in size or microcytosis; variability in shape or poikilocytosis; pale staining or hypochromia, which suggests underhaemoglobinization; and variation in the degree of staining from cell to cell, which is called anisochromia. In addition to these changes there may be more specific alterations in the morphology of the red cells. Some of these, together with the different clinical disorders with which they are associated, are summarized in Table 1 and illustrated in Fig. 2.

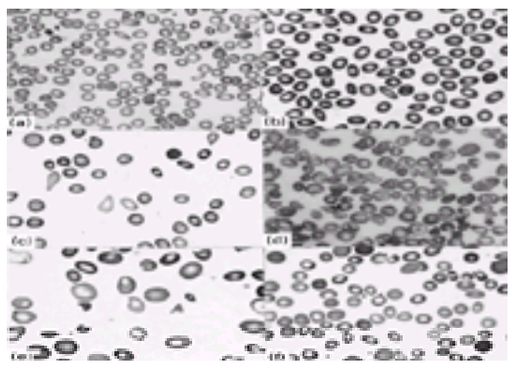

Fig. 2 Morphological changes of the red cells (600–800 ×). (a) Hypochromia and microcytosis. (b) Elliptocytosis. (c) Poikilocytosis (myelosclerosis). (d) Target cells and intracellular crystals (haemoglobin C disease). (e) Macrocytosis and anisocytosis (pernicious anaemia). (f) Dimorphic picture—normochromic and hypochromic (sideroblastic anaemia).

The white cells may be abnormal in number or morphology. An increased white-cell count is called a leucocytosis. If this involves the polymorphonuclear series, it is called a polymorphonuclear leucocytosis or granulocytosis. An elevated eosinophil, basophil, monocyte, or lymphocyte count is called an eosinophilia, basophilia, monocytosis, or lymphocytosis, respectively. A reduced white count is called a neutropenia or lymphopenia, depending on the cell type involved. An absence of granulocytes in the blood is called agranulocytosis. Much can be learned by morphological examination of the white cells. A blood film is said to show a 'shift to the left' if there are relatively more 'young' polymorphonuclear leucocytes present than normal. This is reflected by an increased proportion of band forms and, in more extreme cases, by a variable number of myelocytes or metamyelocytes. In acute bacterial infections, vacuoles may appear in the cytoplasm of polymorphonuclear leucocytes. In addition, the granules may become morphologically abnormal; heavy granulation of this type is called toxic granulation. This change is sometimes associated with the presence of small (1–2 µm) oval bodies called Döhle bodies. A variety of genetic changes of nuclear configuration or of the granules of the polymorphonuclear leucocytes has been described; these are discussed later in this section.

The packed-cell volume, haemoglobin level, and red-cell indices

A great deal can be learned about the character of an anaemia from a few simple haematological tests. The volume of packed red cells (**PCV** or haematocrit) can be estimated either by centrifugation of a blood sample, or by a conductivity method in which it is derived from measurement of the red-cell volume and the number of red cells using an electronic counting system. The haemoglobin concentration is usually determined spectrophotometrically by comparing a test sample with a stable standard, usually of the cyanmethaemoglobin derivative. Red-cell counting has become part of a standard blood count because of the accuracy of electronic cell counters.

Normal values for the PCV, haemoglobin level, and red-cell count are shown in Table 2. It is important to become familiar with the variability of these figures between the sexes and at different stages of development (Table 3). Furthermore, it should be emphasized that the accuracy of these measurements relies very much on the method used for their determination. An electronic cell counter gives extremely reproducible results for all three measurements, whereas a red-cell count made with a counting chamber is of little value. The red-cell indices can be estimated by combining information obtained from these measurements. The mean cell haemoglobin (**MCH**), which is derived from the haemoglobin value and the red-cell count and is expressed in picograms (pg), gives a reliable indication of the amount of haemoglobin per cell. The mean cell haemoglobin concentration (**MCHC**) represents the concentration of haemoglobin in g/dl (g/100 ml) of erythrocytes. The mean cell volume (**MCV**), calculated in femtolitres (fl), gives an indication of the size of the erythrocytes. Hence it is elevated in patients with macrocytic disorders and

reduced in the presence of microcytic red cells. The normal values at different stages of development are summarized in Table 3.

It should be emphasized that the red-cell indices give an indication of the average size and degree of haemoglobinization of the red cells. They are only of value if combined with an examination of a blood film to provide information about the relative uniformity of any changes in size or haemoglobin concentration.

The total and differential leucocyte count

The leucocyte count can be determined either by using a counting chamber or electronically. The differential count is obtained from analysing the different types of white cells in a total of 200 to 300 cells, or more if the total white-cell count is unusually low. It should be remembered that the total white-cell count shows remarkable variability even in the same individual at different times. There are variations during the menstrual cycle and a marked diurnal rhythm with minimum counts in the morning with subjects at rest. Activity may increase the white-cell count slightly, as may emotional stress and eating. Furthermore, the differential white-cell count varies considerably during normal human development. There is a preponderance of lymphocytes during the first few years of life and of polymorphonuclear leucocytes during later development and in adult life. These normal variations are shown in Table 3.

The platelet count

This is most accurately determined with an electronic cell counter, although a rough approximation can be obtained by using a counting chamber. There is marked variation in the normal platelet count and the range in health is approximately 150 to 400×10^{9}/l. A slight drop in the count occurs before menstruation but on the whole it varies less within an individual than the white-cell count.

Blood volume, red-cell mass, and plasma volume

Because the haemoglobin level or PCV may vary due to expansion or contraction of the plasma volume, it is sometimes necessary to measure the red-cell mass and plasma volume directly. This is usually done by radioisotope dilution. The red-cell volume (**RCV**) is measured by labelling the red cells with ^{51}Cr and the plasma volume (**PV**) by the use of isotope-labelled albumin. These measurements are fraught with difficulties because of the variation of vascularity and PCV between different organs, and because fat is a relatively avascular tissue. There is still considerable controversy about how best to express the results. A variety of correction factors has been derived, which attempt to relate the measured RCV or PV to an ideal body weight. In practice it is usual to simply calculate the RCV or PV in ml/kg. The wide range of normal values is summarized in Table 2.

The erythrocyte sedimentation rate (ESR)

The ESR is a measure of the suspension stability of red cells in blood. It is usually expressed in millimetres (mm) and is obtained by measuring the distance from the surface meniscus to the upper limit of the red-cell layer in a column of blood after 60 min. The ESR depends on the difference in specific gravity between the red cells and plasma but is influenced by many other factors, particularly the rate at which the red cells clump or form rouleaux. The increased sedimentation rate of clusters of cells reflects reduced fluid friction resulting from a decreased surface:volume ratio. Rouleaux formation is related to the concentration of fibrinogen and, to a lesser extent, of a_2- and g-globulins in the plasma. Unfortunately, the ESR is also subject to many technical difficulties including the dimensions of the tube, the nature of the anticoagulant used, and any degree of tilt of the tube from the horizontal.

The ESR is still widely used as a non-specific index of organic disease. It is elevated in many acute or chronic infections, neoplastic diseases, collagen diseases, renal insufficiency, and any disorder associated with a significant change in the plasma proteins. Anaemia may cause an increased rate of sedimentation. Although many attempts have been made to develop correction factors to allow for this variable, none is satisfactory. Like all haematological measurements, the ESR changes in certain physiological states, particularly in pregnancy and with increasing age. In men and women over the age of 60 a slightly elevated ESR is often found without an obvious cause (Table 2).

Other haematological investigations

The simple tests that have been outlined in this section form the general screening investigations for all haematological disorders. In later sections we will describe the more specialized investigations that are often required to diagnose specific disorders of the red cells, white cells, and platelets, or of haemostasis and coagulation. Normal values for some of these investigations are given in Table 2.

Examination of the marrow

Bone marrow can be examined by needle aspiration, closed needle biopsy, or open surgical biopsy. In adults the sites most easily available are the sternum and the anterior or posterior iliac crests, although the marrow at the iliac crests tends to become rather fatty in elderly subjects. In under 1-year-old children the anterior surface of the tibia is the site of choice, but in older children the iliac crest or the lumbar vertebral spines are suitable. After aspiration of the marrow, films are made and stained with a Romanowsky stain. Needle or surgical biopsy samples are fixed and sectioned by standard methods.

The marrow films are initially examined under low power to assess the overall cellularity and for the presence of abnormal cells. It is sometimes useful to obtain a differential count and from this to determine the myeloid/erythroid (**M/E**) ratio. This is approximately 3:1 in health, although, if there is increased erythroid activity, it may fall to unity or less. It should be remembered that differential counts may be quite inaccurate because the precursors may not be distributed homogeneously. This is a particular problem in disorders in which there are abnormal cells in the marrow. Having determined the overall cellularity, the morphology of the individual cells is examined. The degree of maturation of the red cells, white cells, and megakaryocyte series is assessed and the marrow examined carefully for the presence of any abnormal cells.

A biopsy specimen is particularly useful for looking at overall cellularity and relating the amount of haemopoiesis to the amount of fatty tissue. It is of particular value if an aspiration yields a 'dry tap' when it may show replacement by fibrous or tumour tissue, which may not aspirate readily. Using appropriate stains it is possible to estimate the amount of iron and reticulin in the marrow.

Assessment of bone marrow activity and distribution

Some indication of marrow function is obtained from its morphological appearances and from the M/E ratio. It is also possible to measure the rates of production and turnover of the red-cell series using radioactive iron. It is sometimes necessary to attempt to estimate the distribution of the haemopoietic marrow, and this is usually done by using isotopes to produce scintograms that show the distribution of erythropoietic or reticuloendothelial marrow throughout the body. Erythropoietic marrow can be visualized using the short-lived, positron-emitting isotope ^{52}Fe with a scintillation camera. In health this shows erythropoietic marrow in the ribs, spine, pelvis, scapula, and clavicle, with a variable amount in the skull. The reticuloendothelial portion of the marrow can be labelled with a radiocolloid with an appropriate particle size; the most effective and commonly used is ^{99}Tc^{m}-sulphur colloid.

22.2.1 Stem cells and haemopoiesis

C. A. Sieff and D. G. Nathan

Introduction

Normal haemopoiesis in the adult depends on the production of blood cells from their recognizable precursors in the bone marrow, their survival in the vasculature, and their demise in the reticuloendothelial system, predominantly in the spleen, liver, lung, and the marrow itself. Though the concentration of cells in the blood varies widely, the values observed in normal individuals are remarkably consistent, particularly considering the vast differences in the lifespans of these cells. For example, the mean lifespan of granulocytes in the peripheral blood may be measured in hours. In contrast, platelets survive for 7 to 10 days. Though platelets are removed from the blood in part by random forces, most of their lifespan is dictated by metabolic changes within them that lead to predetermined death. Normally, red cells are lost by a process of metabolic decay that begins after the erythrocyte has attained an age of approximately 100 days. Lymphocytes have very dramatic differences in lifespan. Some are removed from the circulation in 2 or 3 weeks by a process that is not understood. Others, particularly certain T lymphocytes, appear to survive for the entire lifespan of the individual, carrying within them the programmes embossed upon them by the thymus.

The steady-state concentrations of blood cells vary from one another by three logs or more, but the marrow production rates that maintain them are very similar. Approximately 5×10^4 red cells, 2×10^4 platelets, and 2×10^4 granulocytes are produced per microlitre of blood per day to maintain a normal blood count. Lymphocyte production must be considerably lower because the bulk of lymphocytes in the peripheral blood are long-lived T lymphocytes.

The relatively constant production rates of blood cells are regulated by a highly complex marrow tissue characterized morphologically by recognizable, differentiating precursor cells. These are partially renewed by a variable population of invisible progenitor cells, some of which have the characteristics of stem cells. Precursor cells and their progenitors are packed together into fronds surrounded by endothelial cells that separate marrow cells from the venous sinuses. The completed blood cells find apertures through the endothelial cells and migrate between them to fall into the sinuses, the currents of which carry them into the peripheral blood.

In this chapter, we shall describe critical aspects of the physiology of haemopoiesis in the marrow. To understand this process, we must first review its ontogeny and comparative development.

Phylogeny and ontogeny

In the developing human being, haemopoiesis moves through several overlapping anatomical and functional stages, beginning in the yolk sac, entering the hepatic phase at 6 weeks', and the marrow phase at 20 weeks' gestation. Transfer to the bone marrow phase is generally complete at birth. These anatomical shifts are associated with marked alterations in functional properties, particularly with respect to the pattern of globin synthesis in the red cell. These changes are referred to as the 'fetal switch'. This transition is not a single event involving only the g-chains of fetal haemoglobin, it is instead polygenic involving a series of changes regulated in a programmed fashion. The mechanism of this co-ordinated series of changes is as yet undetermined. It appears to be mediated at the level of the progenitors of haemopoietic cells and is strongly influenced by site-specific regulatory factors.

Marrow anatomy

The relative red (active) marrow space of a child is much greater than that of an adult, presumably because the high requirements for red-cell production during neonatal life demand the resources of the entire production potential of the marrow. During postnatal life the demands for red-cell production ebb. Much of the marrow space is progressively filled with fat (Fig. 1). In certain diseases that are usually associated with anaemia, such as myeloid metaplasia, haemopoiesis may return to its former sites in the liver, spleen, and lymph nodes and may also be found in the adrenals, cartilage, adipose tissue, thoracic paravertebral gutters, and even in the kidneys.

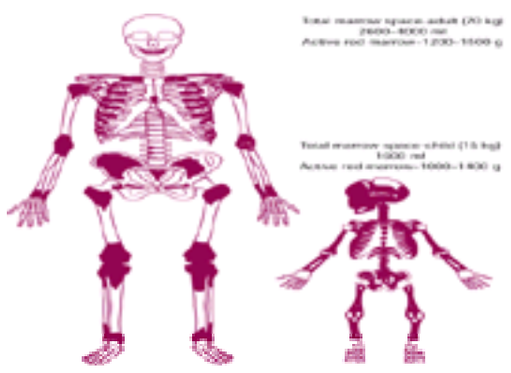

Fig. 1 A comparison of active red marrow-bearing areas in a child and adult. Note the almost identical amount of active red marrow in the child and adult despite a fivefold discrepancy in body weight. (Reproduced from MacFarlane RG and Robb-Smith AHT, eds, 1961. *Functions of the blood*, p 357. Blackwell Scientific, Oxford, with permission.)

The microenvironment of the marrow cavity is a vast network of endothelial cell-lined vascular channels or sinusoids that separate clumps of haemopoietic cells, including fat cells, that reside in the intrasinusoidal spaces. These two compartments are separated by reticular cells (derived from fibroblasts) that form the adventitial surfaces of the sinuses and extend cytoplasmic processes to create a lattice on which blood cells are found. The lattice is demonstrated by reticulin stains of marrow sections (Fig. 2). The conformation of the meshwork of cytoplasmic extensions and the placement of haemopoietic cells in the network of sinuses are best illustrated by scanning electron microscopy. The fibroblast–endothelial cell network provides two major functions: (i) an adhesive framework on to which the developing cells are bound by fibronectin and other integrins, and (ii) the production of haemopoietic growth factors by these cells. Cell–cell adhesion may be mediated by binding of the haemopoietic VLA-4 integrin to stromal fibronectin or VCAM-1.

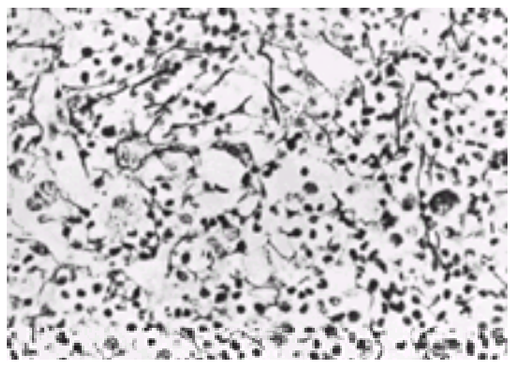

Fig. 2 Bone marrow biopsy of a patient with mild myelofibrosis. A slight increase in the number of reticulin fibres in a delicate discontinuous fibre network is present. Gomori stain, ×350. (Reproduced from Lennert K *et al.*, 1975, *Clinical Haematology* **4**, 335, with permission.)

The central and radial arteries ramify in the cortical capillaries, which in turn join the marrow sinusoids and drain into the central sinus. Cells that egress from the marrow sinusoids then join the venous circulation through concomitant veins. The inner, or luminal, surface of the vascular sinusoids is lined with endothelial cells, the cytoplasmic extensions of which overlap, or interdigitate, with one another. The escape of developing haemopoietic cells into the sinus for transport to the circulation occurs through gaps that develop in this endothelial lining and even through endothelial-cell cytoplasmic pores.

The haemopoietic growth factors comprise a family of small glycoproteins that not only affect immature cells but also influence the survival and function of mature cells. They do so by binding to specific cell-surface receptors. The genes for many of the growth factors and their receptors have been isolated. The cellular origin and the major sites of action of important members of the haemopoietic growth-factor family are shown in Fig. 3. Three of the receptors, c-*kit*, the receptor for Steel factor, Flt-3, the receptor for Flt-3 ligand, and c- *fms*, the monocyte colony-stimulating factor (**M-CSF**) receptor, are members of the transmembrane tyrosine kinase family. In contrast, the receptors for the other haemopoietic growth factors such as interleukin 3(**IL-3**), granulocyte–macrophage colony-stimulating factor (**GM-CSF**), granulocyte-CSF (**G-CSF**), IL-5, IL-6, erythropoietin, and thrombopoietin are members of the haemopoietic growth-factor receptor family. They share several structural features; lacking cytoplasmic tyrosine kinase domains, they activate cells by dimerizing after binding their cognate ligands. This promotes the recruitment and activation of cytoplasmic tyrosine kinases such as members of the Janus kinase (**JAK**) family. The JAK proteins in turn activate members of the signal transducer and activator of transcription (STAT) family and phosphorylate tyrosines of the cytoplasmic domains of the receptor itself. This stimulates recruitment of other signalling or adaptor proteins that activate pathways, such as that involving the RAS protein.

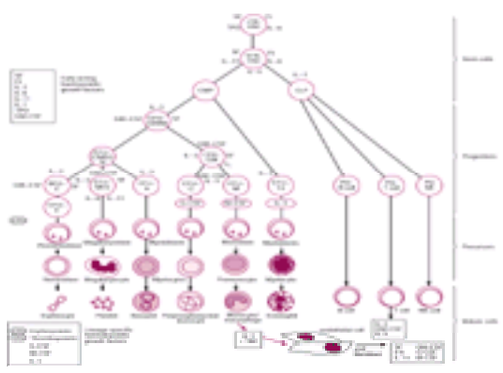

Fig. 3 Maturation of haemopoietic cells and sources and actions of haemopoietic growth factors (HGFs). The predominant actions of several major HGFs are indicated diagrammatically. Steel factor (SF), Flt-3 ligand (FL), IL-11, IL-3, IL-6, and thrombopoietin (TPO) act early during haemopoiesis on haemopoietic stem cells (HSC), while GM-CSF probably act slightly later. The lineage-specific factors erythropoietic (EPO), granulocyte colony-stimulating factor (G-CSF), monocyte-CSF (M-CSF), IL-5, and thrombopoietin act on single lineage-committed progenitors and precursors. Monocytes and macrophages also produce IL-1 and tumour necrosis factor (TNF), potent inducers of HGF production by microenvironmental endothelial and reticular fibroblastoid cells. In addition, macrophages can produce these factors after induction with endotoxin (not shown) and T cells produce IL-3, GM-CSF, and IL-5 in response to IL-1 plus antigenic stimulation.

The location of the different haemopoietic cells is not random. Clumps of megakaryocytes are found adjacent to marrow sinuses. They shed platelets, the fragments of their cytoplasm, directly into the lumen. This reduces the requirement for movement of bulky mature megakaryocytes, a mobility characteristic of the granuloid- and erythroid-differentiated precursors as they approach the point at which they egress from the marrow.

The formed elements of blood in vertebrates, including humans, continuously undergo replacement to maintain a constant number of red cells, white cells, and platelets. The number of cells of each type is maintained in a very narrow range in normal adults—approximately 5000 granulocytes, 5×10^6 red blood cells, and 150 000 to 300 000 platelets per microlitre of whole blood. In the following section we shall review the nature of the signals that affect the proliferation of the stem and progenitor cells, and the normal regulatory mechanisms that maintain balanced production of new blood cells.

Function of stem cells and progenitors

The progenitors of recognizable precursor cells are mononuclear 'blast' cells with large nuclei, prominent nucleoli, and basophilic cytoplasm devoid of granules. These primitive progenitors are present at extremely low frequencies, approximately 1 in 10^4 to 10^5 marrow cells for the stem cell population and 1 in 10^3 for their committed progenitor progeny. A single pluripotent stem cell is capable of giving rise, in a stochastic fashion, to increasingly committed progenitor cells according to the schema outlined in Fig. 3. These committed progenitors are destined to form differentiated recognizable precursors of the specific types of blood cells.

Pluripotent stem cells are defined as cells capable of both self-renewal and multilineage differentiation under the influence of certain non-lineage-specific growth factors such as Flt-3 ligand, Steel factor, IL-6, and thrombopoietin. Their differentiation programme is random and leads to a broad array of more mature lineage-committed progenitors that are themselves responsive to broadly active factors such as IL-3, GM-CSF, IL-11, and subsequently to the more lineage-restricted growth factors, including erythropoietin, thrombopoietin, G-CSF, IL-5, and M-CSF. Some of the lineage-restricted growth factors, particularly erythropoietin, are produced in response to the circulating levels of differentiated blood cells.

Lineage-committed progenitors are characterized by limited proliferative potential that depends upon the presence of specific growth factors that interact with specific receptors on progenitor surfaces. Progenitors are not capable of indefinite self-renewal. In fact, they 'die by differentiation' to mature precursors of the blood cells. The maintenance of their numbers ultimately depends upon the presence of lineage-specific growth factors and on random influx into their pool from the pluripotent stem-cell pool. Therefore, amplification of blood-cell production occurs at the level of the committed progenitor pool, while maintenance of the progenitors depends upon the capacity of members of the pluripotent stem-cell pool to differentiate into the committed progenitor pool.

Haemopoietic differentiation requires an appropriate microenvironment. In normal adults, this is confined to the bone marrow, whereas in the mouse it includes both the spleen and bone marrow. The existence of certain strains of mice that exhibit a deficiency in the haemopoietic microenvironment suggests that the interactions between haemopoietic cells and the bone marrow microenvironment involve very specific molecular mechanisms. Insight into the nature of one of these interactions has come from isolation of the genes that determine the *White Spotting (W)* and *Steel (Sl)* mutations in mice. Animals affected by mutations at both of these loci have a severe macrocytic anaemia associated with defects in skin pigmentation and fertility. The mutations, however, map to different chromosome loci (*W* to chromosome 5, *Sl* to chromosome 10). This is consistent with the results of transplant experiments, which demonstrate that the *W* mutation is one of stem cells whereas the *Sl* defect is one of the bone marrow microenvironment. The *W* gene has now been shown to be allelic with the c-*kit* proto-oncogene, a member of the tyrosine kinase cell-surface receptor family; in contrast, the *Sl* mutation results in defective production of the ligand for this receptor (Steel factor, also known as kit ligand, stem-cell

factor, or mast-cell growth factor). Interestingly, Steel factor is produced in both a secreted and membrane-bound form by fibroblasts and other cells. The latter form may thus provide one molecular explanation for interactions between the stem cells and their microenvironment.

Progenitors can exist outside the marrow. Early haemopoietic cells, including the pluripotent stem cells and certain committed progenitor cells, have been demonstrated in the circulation of normal individuals and experimental animals. The capacity of haemopoietic stem cells to negotiate the circulation is especially significant in relation to stem cell transplantation. While this procedure is still often carried out by infusion of bone marrow from the donor into the circulation of the recipient, mobilized blood stem and progenitors cells are now frequently being used.

The relatively limited production of lymphocyte progenitors has made it difficult to demonstrate that the lymphocyte is derived from the same population of stem cells as the other cellular elements of blood. Recent evidence indicates, however, that both T and B lymphocytes and natural killer cells are derived from a common lymphoid progenitor, while a common myeloid progenitor cell matures to form the committed progenitors of red blood cells, phagocytes, and megakaryocytes (Fig. 3).

The pluripotent stem cell

The concept that sustained haemopoiesis comes from pluripotent stem cells derives from the observation that mice can be protected from the lethal effects of whole-body irradiation by exteriorization and shielding of the spleen. This protective effect was shown to be cell mediated as the injection of spleen cells could initiate recovery and re-establish haemopoiesis in irradiated animals. Till and McCulloch demonstrated that colonies of haemopoietic cells could be observed in the spleen in bone-marrow transplanted, irradiated recipient mice within 10 days after the transplant. These spleen colony-forming units (**CFU-S**) produce colonies that contain precursors of erythrocytes, granulocytes, macrophages, and megakaryocytes. Subsequent experiments using karyotypically marked donor cells confirmed the clonal origin of the differentiated cells. Recent experiments in which foreign genes have been inserted into spleen colony-forming cells have further substantiated this finding. Each colony contains a variable number of stem cells that could again form spleen colonies of differentiated progeny in a second irradiated recipient, indicating the self-renewal property of stem cells. The demonstration of a stem cell that can differentiate to form progenitor cells for erythropoiesis, granulopoiesis, and megakaryopoiesis is completely consistent with subsequent observations in diseases such as chronic myeloid leukaemia and polycythaemia vera in which a clonal origin of abnormal erythroid, granulocytic, and megakaryocytic precursor cells can be demonstrated (see Chapter 22.3.5). In addition, these studies of chronic myeloid leukaemia have demonstrated a pluripotent stem cell that gives rise to B cells as well as to the aforementioned blood cells.

Recent studies provide a model in which the CFU-S is viewed as part of a continuum of cells with a decreasing capacity for self-renewal, increasing likelihood for differentiation, and increasing proliferative activity. The cells progress in a unidirectional fashion in this continuum. CFU-S can be distinguished from a more primitive precursor that has the capacity for long-term haemopoietic reconstitution after bone marrow transplantation (**LTR-HSC**, Fig. 3). In the mouse, as few as 30 cells of a highly purified marrow population that lacks lineage-specific antigens but expresses Ly-6 (Sca-1) and low levels of Thy-1 (that is, lin $^{-}$ Sca-1^{+} Thy-l^{10}) can reconstitute haemopoiesis in 50 per cent of lethally irradiated mice. This fraction appears to comprise virtually 100 per cent CFU-S, but single-cell transfer experiments have shown that it is still heterogeneous. Indeed, cell elutriation studies have shown that most of the CFU-S population is contained within a cell fraction that confers short-term radioprotective capacity (STR-HSC, Fig. 3). It can be separated from a cell fraction with the capacity for long-term haemopoietic reconstitution.

Differences in physical properties and expression of the antigens CD34 and CD33/CD38 have been used to enrich for human stem cells. Most colony-forming cells express all three cell-surface molecules. Cells that give rise to colony-forming cells in long-term bone marrow cultures (that is, long-term culture-initiating cells; LTC-IC) can be separated by their expression of CD34, lack of expression of CD33, CD38, and other lineage-specific markers, and intermediate forward light scattering properties. The importance of CD34^{+} marrow cells is emphasized by *in vivo* simian studies. Like human bone marrow, the CD34 antigen is expressed by a minority of baboon cells. Infusion of these purified cells can reconstitute lymphohaemopoiesis in lethally irradiated baboons. The recent cloning of the murine CD34 cDNA has cast some doubt on expression of CD34 by LTR-HSC. A monoclonal antibody raised to a murine CD34–GST fusion protein was use to separate marrow cells into CD34$^{lo/-}$, CD34^{lo}, and CD34^{+} fractions. Interestingly, long-term multilineage reconstitution was observed after transplantation of the CD34 $^{lo/-}$ cells, whereas the CD34^{+} fraction gave early but unsustained multilineage reconstitution. These data are supported by experiments demonstrating that a tiny subset of murine bone marrow cells that exclude the Hoechst 33342 dye at blue and red wavelengths (called the side population) contains all the LTR-HSC activity, but is CD34 $^{-}$. Recent human studies have also raised the possibility that LTR-HSC do not express CD34. When primitive human lin $^{-}$ cells are separated into CD34^{+} and CD34^{-} fractions, the capacity to reconstitute haemopoiesis in immunodeficient mice (called SCID repopulating cells or SRC) is found in both cell fractions. A resolution to this controversy may come from the recent demonstration that resting murine haemopoietic stem cells are CD34^{-}, while activated haemopoietic stem cells express the CD34 antigen.

Studies with purified populations of stem cells have shown that combinations of specific haemopoietic growth factors such as Steel factor, Flt-3 ligand, IL-6, and surprisingly, thrombopoietin can act at the stem cell level to induce cell cycling and proliferation. IL-3, produced by T cells and natural killer cells, and GM-CSF, a product of both stromal cells and T cells, appear to be factors essential for the survival *in vitro* of a class of stem cells that forms blast colonies in methylcellulose culture. These 'blast' colonies contain multilineage and unilineage progenitors. They are probably at the myeloid stem-cell stage of differentiation (Fig. 3). When isolated from bone marrow, these stem cells are mostly in a non-cycling, quiescent state. The addition of IL-3, GM-CSF, or Steel factor or other stromally produced haemopoietic growth factors such as IL-6, IL-11, or G-CSF shortens the G_0 phase in these cultures, thus hastening the onset of blast colony formation.

The factors that control the fate of stem cells to undergo either self-renewal or commitment to differentiate down a lineage pathway are poorly understood. However, nuclear transcription factors have been shown to play a role in haemopoietic cell proliferation and lineage commitment. The tal-1/SCL, Rbtn2/LMO2, and GATA family of transcription factors are important in this regard. In particular, tal-1/SCL, a basic helix–loop–helix (bHLH) transcription factor, is expressed in biphenotypic (lymphoid/myeloid) and T-cell leukaemias, and in both early haemopoietic progenitors and more mature erythroid, mast, megakaryocyte, and endothelial cells. Targeted disruption of the *tal-1/SCL* gene in murine embryonic stem cells leads to death *in utero* from absence of blood formation; a lack of *in vitro* myeloid colony formation suggests a role for this factor very early during haemopoiesis.

Another transcription factor implicated in T-cell ALL is the LIM domain nuclear protein rhombotin 2 (rbtn2/LMO2). Mice that lack this factor die *in utero* and have the same bloodless phenotype as the tal-1/SCL$^{-/-}$ animals. GATA-2 is expressed in the regions of the *Xenopus* and zebrafish embryos that are fated to become haemopoietic, and is highly expressed in progenitor cells. Overexpression of GATA-2 in chicken erythroid progenitors leads to proliferation at the expense of differentiation. Targeted disruption of the *GATA-2* gene by homologous recombination in embryonic stem cells leads to reduced primitive haemopoiesis in the yolk sac and embryonic death by day 10 to 11. Definitive haemopoiesis in liver and bone marrow is profoundly reduced with loss of virtually all lineages. *In vitro* differentiation data show a marked deficiency of Steel factor-responsive definitive erythroid and mast cell colonies and reduced macrophage colonies, suggesting that GATA-2 serves as a regulator of genes that control haemopoietic growth factor responsiveness or proliferation of stem and/or early progenitor cells. These data contrast with the later time of embryonic death from anaemia (day 15) in mice with targeted disruption of the c-*myb* or retinoblastoma (*Rb*) genes, or with severe forms of *W* and *Sl* mutations. Similarly, loss of function of the AML-1 gene, which encodes one of the a subunits of the heterodimeric core-binding factor (**CBF**), results in fetal death by day 12.5 due to failure of production of all definitive haemopoietic lineages. CBF recognition sequences are present in the IL-3, GM-CSF, M-CSFR, and T-cell antigen receptor promoters. The *AML-1* gene is frequently rearranged in acute myeloid leukaemia (AML) and childhood acute lymphoblastic leukaemia (ALL), and is expressed in myeloid and lymphoid cells.

The survival of a particular stem cell in the marrow requires a 'niche'; thus isogeneic marrow infusions are not successful unless the recipient is irradiated or treated with sufficient doses of cytotoxic drugs to create an adequate number of niches. Therefore, reports of failure of engraftment in aplastic anaemia using identical twin donors do not necessarily implicate an immunological basis for the disease. Equally likely is persistence of non-functional pluripotent progenitors in the aplastic marrow niches. These abnormal cells must be destroyed in order to allow implantation of transfused normal progenitors.

The stem cell model of haemopoiesis has parallels in other organ systems. That rapidly self-renewing epithelial tissues like skin and intestine have stem cells that continually replenish the cells lost by differentiation is well described. It is likely that most epithelial tissues, for example liver and pancreas, also contain stem cells that are brought to bear after organ damage. The demonstration of the existence of neural stem cells in the adult brain has raised the possibility that many organ systems might retain a population of self-renewing stem cells. Muscle satellite cells also appear to fulfil this role.

Much more surprising are recent demonstrations of stem cell plasticity. Transplantation of genetically marked bone marrow showed that the donor cells can migrate into areas of damaged muscle, differentiate into myogenic cells, and participate in tissue regeneration. Similarly, transplanted haemopoietic cells can differentiate into glial cells in adult mouse brain, into endothelial cells, and into hepatocytes in damaged liver. Mesenchymal stem cells, derived from an adherent bone marrow cell population, express neither CD34 nor CD45, markers of primitive haemopoietic cells. Mesenchymal stem cells are capable of marked expansion in culture, and can then be induced to differentiate into osteoblasts and osteocytes, chondrocytes, adipocytes, and myotubules.

That stem cell plasticity may be therapeutically useful is suggested by bone marrow transplant studies in three patients with ostegenesis imperfecta, in which low-level osteoblast engraftment was demonstrated 3 months post-transplantation, with histological changes indicating new dense bone formation. These studies do not address the question of the identity of the engrafting cell, since whole unfractionated marrow was used. Further studies with purified cell populations and longer follow-up will be required. The relationship of the mesenchymal stem cells to the haemopoietic stem cells is not clearly defined, especially in view of the recent demonstration that the highly purified CD34– side population of murine marrow can reconstitute not only haemopoietic activity, but also contribute nuclei to muscle fibres, partially restoring expression of dystrophin in the *mdx* mouse, a model of Duchenne muscular dystrophy. Finally, it is now apparent that the plasticity of primitive cells is not confined to the haemopoietic system, with the demonstration that blood cells can be derived from both neural and myogenic satellite cells.

Erythropoiesis

The rate of erythropoiesis is driven by anaemia or hypoxia. Both stimulate a class of peritubular kidney cells, through a haem-containing oxygen sensor, to transcribe the erythropoietin gene and release the hormone into the blood. The hormone binds to the erythropoietin receptor in erythroblasts and erythroid progenitors to stimulate their division and differentiation. The least mature committed erythroid progenitor is known as an erythroid burst-forming unit (**BFU-E**), because when it differentiates *in vitro* it forms large colonies of erythroblasts and reticulocytes that may contain as many as 50 000 cells. The colonies, derived from single cells, have a burst-like appearance because they may be composed of multiple subcolonies. Thus one BFU-E may first divide in culture to form subcolony-forming cells, which then differentiate into colonies of erythroblasts and reticulocytes. BFU-E progressively mature during their sojourn in the marrow. In doing so they lose their capacity to divide and migrate *in vitro,* but gain in sensitivity to erythropoietin until they reach the stage at which they are known as erythroid colony-forming units (**CFU-E**).

The regulated proliferation and maturation of erythroid progenitors depends on interaction with a number of growth factors. Erythropoietin is essential for the terminal maturation of erythroid cells. Its major effect appears to be at the level of the CFU-E during adult erythropoiesis. Recombinant preparations are as effective as the natural hormone. These very mature progenitors and proerythroblasts do not require 'burst-promoting activity' in the form of IL-3, GM-CSF, or Steel factor. Their dependence on erythropoietin is emphasized by the observation that they will not survive *in vitro* in its absence.

Steel factor has also been shown to have marked synergistic effects on BFU-E cultured in the presence of erythropoietin. Alone, it has no colony-forming ability. The majority of CFU-E are in cycle; their survival in the presence of erythropoietin is probably tightly linked to their proliferation and differentiation to proerythroblasts and mature erythrocytes. Erythropoietin also acts on a subset of presumptive mature BFU-E that require it for survival and terminal differentiation. A second subset of BFU-E, presumably less mature, survive deprivation of erythropoietin if 'burst-promoting activity' is present, either as Steel factor, IL-3, or GM-CSF. Under serum-deprived culture conditions, the combination of erythropoietin and IL-3 or GM-CSF results in more BFU-E-derived colonies than when erythropoietin is added alone.

Factors distinct from the classic colony-stimulating factors may positively regulate erythropoiesis, either directly or indirectly. Limiting dilution studies of highly purified CFU-E in serum-free culture show that insulin and insulin-like growth factor I act directly on these cells. The presence of erythropoietin is also essential. CFU-E and mature BFU-E are highly responsive to the mitogenic effect of erythropoietin as well as to its differentiating role. Therefore, in haemorrhagic or haemolytic anaemias with elevated levels of erythropoietin, the numbers of CFU-E and mature BFU-E may rise remarkably in the marrow. Immature BFU-E are less responsive to the mitogenic effect of erythropoietin, and therefore, the frequency of this subset of BFU-E changes little in anaemia.

Negative regulation of erythropoiesis

Subsets of lymphocytes with an immunological suppressor phenotype isolated from normal subjects can inhibit erythroid activity *in vitro.* Similarly, some patients with anaemia or granulocytopenia have an associated expansion of certain T-lymphocyte populations. In the rare disorder 'T lymphocytosis with cytopenia', *in vitro* suppression of erythropoiesis (or granulo-cytopoiesis) has been correlated with the expansion of a T-lymphocyte population that may be the counterpart of the haemopoietic suppressor cells isolated from normal peripheral blood. The phenotype of these cells has been described in detail. The cell is a large, granular lymphocyte that is both CD2 and CD8 (classic suppressor phenotype) positive. Suppressor T cells may also be involved in some cases of aplastic anaemia or neutropenia without any underlying immunological disorder or an overt T-cell proliferation.

Exactly how suppressor T cells interact with haemopoietic progenitors, and what surface antigens are 'seen' by the suppressors is not known. There is evidence to support the concept that suppression of erythroid colony expression *in vitro* can be regulated by T cells and may be genetically restricted. Certain phenotypes of T cells 'recognize' distinct classes of histocompatibility antigens on immunological cell surfaces. Thus, the observation that haemopoietic progenitors have a unique distribution of class II histocompatibility antigens on their cell surface suggests a role for these antigens in the cell–cell interactions that regulate haemopoietic differentiation.

T cells may also inhibit erythropoiesis in a non-HLA restricted fashion by the production of inhibitory cytokines. Some lymphokines may inhibit erythropoiesis *in vitro* by a complex lymphokine cascade. Activation of T cells by the T-cell antigen receptor CD3 results in cell-surface expression of the IL-2 a-chain (p55) and the acquisition of IL-2 responsiveness. IL-2 inhibits BFU-E in the presence of these IL-2R positive cells, possibly by inducing their release of interferon-g. CD2 can serve as an alternative pathway of T-cell activation, and may do so through binding to its ligand LFA-3 on antigen-presenting cells. Blockade of CD2 with monoclonal antibody leads to abrogation of IL-2/ interferon-g-mediated BFU-E suppression. These data are difficult to reconcile with the observation that IL-2 incubation of activated CD4+ T cells leads to marked expansion of IL-3 and GM-CSF mRNA-positive cells by *in situ* hybridization. Most, but not all, CD4+ T cells express CD28 as well, and there is evidence to suggest that IL-3 production is restricted to CD28+ T cells. It thus appears paradoxical that potent stimulating and inhibitory lymphokines can be produced by activation of T cells through the same pathway.

Tumour necrosis factor also suppresses erythropoiesis *in vitro*. The injection of peritoneal macrophages into animals infected with Friend murine leukaemia virus results in rapid but transient resolution of the massive erythroid hyperplasia associated with this disease. This may be due to elaboration by macrophages of IL-1a, which does not suppress erythropoiesis itself, but acts by the induction of tumour necrosis factor. This effect is reversed by erythropoietin.

Proerythroblasts represent the ultimate stage of differentiation of committed erythroid progenitors. In contrast to the progenitors, which comprise less than 0.1 per cent of the marrow cell population, proerythroblasts are present at 3 to 5 per cent, and their daughters, the recognizable erythroid precursors, comprise 30 per cent of the population.

Estimates of reticulocyte production and erythroblast content of marrows, together with measurements of the rate at which the proerythroblast compartment is renewed from the progenitor pool, suggest that approximately 10 per cent of the daily reticulocyte production is derived from the terminal differentiation of proerythroblasts newly developed from the progenitor department. During anaemic stress the rate at which progenitors differentiate to proerythroblasts may increase 10-fold or more. This increase in the rate of proerythroblast formation from progenitors is associated with an increase in the production of fetal haemoglobin in a large fraction of the erythroid cells derived from them. The basis of this reactivation of fetal haemoglobin synthesis is not understood. The extent to which fetal haemoglobin may be increased in such settings could be genetically controlled. It is an important phenomenon because those with the capacity to develop large increases in fetal haemoglobin who are also homozygous for major b-chain haemoglobinopathies may have a remarkably mild course. Fetal haemoglobin elevation occurs in many forms of accelerated erythropoiesis and is a marker of such a condition.

Phagocytopoiesis

The development of a clonal assay for granulocyte and macrophage progenitors preceded the development of erythroid progenitor assays by nearly a decade, yet a clear understanding of the regulation of myeloid differentiation remains elusive. Figure 3 describes the development and regulation of granulocyte, monocyte, and macrophage production from the pluripotent stem cell. The colony-forming unit-granulocyte-macrophage (**CFU-GM**) is derived from the pluripotent progenitor. It gives rise to separate granulocyte and monocyte progenitors (CFU-G and CFU-M), which, under the influence of unique colony-stimulating factors, differentiate to mature granulocytes and/or monocytes, respectively. Both IL-3 and GM-CSF affect a similar broad spectrum of human myeloid progenitor cells. This includes colonies that contain granulocytes, erythrocytes, monocytes, and megakaryocytes (**CFU-GEMM**), eosinophils (**CFU-Eo**), CFU-GM, CFU-G, and CFU-M. Data from serum-free cultures suggest that in the presence of IL-3 or GM-CSF alone, myeloid colony formation is much reduced. Optimal CFU-G or CFU-M proliferation requires the addition of G-CSF or M-CSF, respectively, to the cultures. Even in serum-replete conditions, IL-3 acts additively or synergistically with G-CSF to induce more granulocyte colony formation than is observed with either factor alone.

Serum-free studies may have important implications for the use of combinations of colony-stimulating factors *in vivo.* The use of such culture conditions should

provide further insight into the *in vitro* activities of the different factors.

Colony-stimulating factors also induce a variety of functional changes in mature cells. GM-CSF inhibits polymorphonuclear neutrophil migration, induces antibody-dependent cellular cytotoxicity (**ADCC**) for human target cells, and increases neutrophil phagocytic activity. Some of these changes may be related to GM-CSF-induced increase in the cell-surface expression of a family of antigens that function as cell adhesion molecules. The increase in antigen expression is rapid and is associated with increased aggregation of neutrophils. Granulocyte–granulocyte adhesion can be inhibited by an antigen-specific monoclonal antibody. GM-CSF also acts as a potent stimulus of eosinophil ADCC, superoxide production, and phagocytosis. G-CSF acts as a potent stimulus of neutrophil superoxide production, ADCC, and phagocytosis, while M-CSF activates mature macrophages and enhances macrophage cytotoxicity.

Monocytes leave the circulation and differentiate further to become fixed tissue macrophages. These tissue macrophages include alveolar macrophages and hepatic Kupffer cells, dermal Langerhans cells, osteoclasts, peritoneal macrophages, pleural macrophages, and possibly brain microglial cells, though the origin of these is still uncertain. The wide variety of cells with diverse functions that must be supplied from the granulocyte–macrophage progenitor requires that this system be highly regulated at many levels of differentiation.

The granulocyte compartment itself is more complex than either the erythroid or megakaryocyte compartments. The circulating half-life of the newly rapidly deployed granulocyte is only 6.5 h. In order to meet sudden demands, an additional non-circulating granulocyte pool exists in the spleen, marginated around blood vessels, and in a readily releasable bone-marrow pool. The rate at which new myeloblasts or monoblasts are produced by progenitors *in vivo* is not known, but exhaustion of progenitors in infection, particularly in the neonatal period, is associated with a fatal outcome due to a failure of granulocyte production.

Suppression of phagocyte production

An elaborate system exists for suppression of granulocyte and macrophage production. It involves T lymphocytes and their products, particularly interferon-g, monocytes, and perhaps acidic isoferritins. In some circumstances, clones of T cells that suppress granulocyte production *in vitro* and *in vivo* have caused profound granulocytopenia. Clearly, a twin regulatory system exists that contributes to the fine control of phagocyte production by close control between progenitors and adventitial cells that secrete inducer and suppressor molecules. It is well established that T lymphocytes capable of the suppression of phagocyte colony formation may be present in human marrow and induce neutropenia.

Megakaryocytopoiesis

The cloning of thrombopoietin has greatly clarified our understanding of the regulation of megakaryocytopoiesis. Prior to the discovery of thrombopoietin, several factors including IL-3, IL-6, IL-11, Steel factor, and even erythropoietin were shown to stimulate megakaryocytopoiesis and thrombopoiesis *in vitro* and *in vivo*. IL-11 has even entered clinical trials. Hence, all of the above mentioned haemopoietic growth factors, except erythropoietin, can contribute collectively to 'megakaryocyte colony-stimulating activity' (**Meg-CSA**). Meg-CSA is therefore a 'soup' of growth factors that transduce three of the four classes of receptors that drive haemopoietic differentiation; these comprise the b common, tyrosine kinase, and gp130 families. All of these receptors, when engaged, drive early progenitor proliferation and partial differentiation to more mature progenitors. The final steps of lineage-committed mature progenitor development into recognizable marrow precursors require a lineage-specific growth factor—G-CSF for the granulocyte, M-CSF for the macrophage, IL-5 for the eosinophil, and erythropoietin for the erythrocyte.

The discovery of thrombopoietin provides the final step of understanding of megakaryocytopoiesis because this factor, and probably none other, actually induces lineage-restricted megakaryocyte progenitor proliferation, differentiation of those committed progenitors to megakaryoblasts, and finally, differentiation of megakaryoblasts to the megakaryocytes that in turn produce platelets. However, this in no way implies that other Meg-CSA components may not be useful in the therapy of hypoplastic thrombocytopenias. Circulating thrombopoietin levels are high in those conditions, just as erythropoietin levels are elevated in the erythroid hypoplasias. Administration of high doses of erythropoietin is usually of little benefit in the latter conditions. Thrombopoietin may be just as unsuccessful in certain megakaryocyte hypoplasias because those conditions are often associated with severe depletion of lineage-specific or multipotent progenitors. One or more of the growth factors that comprise Meg-CSA, such as IL-11, may be more useful in such circumstances. Clinical trials now in progress will decide this issue.

Thrombopoietin

Identification of the proto-oncogene c-*mpl* revealed an orphan haemopoietic growth factor receptor that proved to be crucial for megakaryocytopoiesis. In 1993, Methia and coworkers performed a critically important experiment, when they demonstrated that exposure of CD34+ progenitor cells in culture to oligonucleotides that were antisense to c-mpl inhibited the ability of these cells to form megakaryocyte, but not other haemopoietic colonies. In 1994 several laboratories cloned the all-important ligand for this receptor, the growth factor thrombopoietin, and important physiological studies of thrombopoietin were launched.

The thrombopoietin gene is localized on the long arm of chromosome 3. It contains five exons, the boundaries of which line up precisely with those of the erythropoietin gene. The gene is widely expressed in liver, kidney, smooth muscle, endothelial cells, and fibroblasts. Thus thrombopoietin is produced at the site of stoma supporting haemopoiesis. Though its activity is increased in the blood during episodes of thrombocytopenia, it does not necessarily function as a hormone because it is produced directly at the site of thrombopoiesis. In this sense, it differs from erythropoietin, which is not produced at all in marrow stroma. It is likely that the level of production of thrombopoietin is quite constant in all tissues. The blood levels may increase in thrombocytopenic states merely because circulating platelets and tissue megakaryocytes sop up the growth factor and carry it out of the circulation. This theory has received support from observations in mice with disruption of the murine transcription factor gene called *NF-E2*; although these animals are thrombocytopenic they have an increase in megakaryocyte mass and no increase in serum thrombopoietin levels.

The thrombopoietin molecule is considerably longer than the other haemopoietic growth factor polypeptides. Its 5' half bears 23 per cent sequence homology to erythropoietin, while the 3' half bears no structural homology to any cytokine and may be removed by a proteolytic mechanism. Indeed, removal of this half does not ablate physiological function. The resemblance of the 5' domain of the molecule to erythropoietin may explain the synergy of thrombopoietin and erythropoietin in megakaryocyte colony formation and platelet production. It is well recognized that splenectomized individuals with persistent anaemia usually have significant thrombocytosis and many individuals with red cell aplasia and high erythropoietin levels also have thrombocytosis and megakaryocytosis.

Circulating platelets

The differential diagnosis of thrombocytopenia rests first on evaluation of platelet morphology. In conditions in which megakaryocytopoiesis is accelerated, circulating platelet volume (and usually diameter) is increased. The reasons for this shift in volume are disputed. Some claim that young platelets are larger than old platelets, while others suggest that large megakaryocytes give rise to large platelets. Neither explanation satisfies all experimental and clinical conditions, but in general, thrombocytopenia secondary to increased destruction of platelets is associated with platelets of large volume. Thrombocytopenia related to decreased production of platelets is associated with platelets of normal size.

There are major exceptions to this rule. Patients with hyposplenism tend to have large platelets in their blood, whether thrombopoiesis is increased or not, and patients with primary abnormalities of platelet function, such as Wiskott–Aldrich syndrome or Bernard–Soulier syndrome, have small and large platelets, respectively, that bear no relationship to platelet production. Thrombopoietin increases platelet production by increasing both the number and size of individual megakaryocytes. Though thrombopoietin is probably solely responsible for the later stages of recognizable megakaryocyte differentiation and proliferation of megakaryocyte progenitors, its function depends, at least in part, on the additional stimulation of earlier megakaryocyte progenitors with other growth factors, including IL-3, IL-11, and Steel factor.

Down-regulation of megakaryocytes

There is great uncertainty about possible down-regulation of megakaryocytes. Platelet factor 4 seems to down-regulate colony formation *in vitro*. If active *in vivo*, this would provide an interesting feedback loop. Transforming growth factor-b is also a potent inhibitor *in vitro*. Natural killer cells, which are thought by some to be general suppressors of haemopoiesis *in vitro*, actually enhance megakaryocyte colony formation *in vitro*. In addition, an antibody to natural killer cells, when it is given intraperitoneally in massive doses to mice, abolishes the formation of colonies of mega-karyocytes that can be grown in culture from murine marrow. Natural killer cells may thus actually play a stimulating role *in vivo*.

Megakaryocyte progenitors in disease

A number of attempts have been made to relate diseases associated with elevated or depressed platelet counts to the number or the growth characteristics of megakaryocyte progenitors. Megakaryocyte progenitors in essential thrombocythaemia are similar in their growth characteristics to the expanded numbers of erythroid progenitors in polycythaemia vera. The latter develop into erythroid colonies without additions of erythropoietin to the culture medium. The trace of erythropoietin in the serum is sufficient to drive the sensitive receptor system in these progenitors. In a similar fashion, the numerous CFU-Meg in essential thrombocythaemia develop into megakaryocyte colonies in the absence of stimulation by aplastic anaemia serum. They are 'thrombopoietin independent' and many produce endogenous thrombopoietin.

Clinical studies with haemopoietic growth factors

Several recombinant haemopoietic growth factors are currently in use and under evaluation in a variety of clinical settings. Initial studies focused on erythropoietin in the anaemia of chronic renal failure, and GM-CSF and G-CSF in both transient and long-standing bone marrow-failure syndromes. These three factors are now commercially available for clinical use. More recently, other haemopoietic growth factors such as M-CSF, IL-3, and Steel factor are coming under scrutiny.

Anaemia is a major complication of endstage renal failure, and is due primarily to a reduction in erythropoietin production. Several phase I, II, and III studies have documented that recombinant human erythropoietin can induce a dose-dependent increase in effective erythropoiesis. The extension of this treatment to patients who do not yet require dialysis has met with similar success. Erythropoietin may also be useful in the anaemia of chronic disease and in the anaemia that complicates azidothymidine treatment of patients with acquired immune deficiency disease (**AIDS**).

G-CSF has proven to be useful for shortening the period of neutropenia following myelosuppressive anticancer chemotherapy, and has been approved in the United States and Europe for reduction of infection in patients with non-myeloid malignancies. GM-CSF and G-CSF can accelerate haemopoietic reconstitution after bone marrow transplantation, and GM-CSF has been approved for use in the United States in autologous transplantation. In the context of bone marrow failure, GM-CSF is a useful palliative treatment as it can increase the neutrophil count, particularly in the majority of children with acquired aplastic anaemia. GM-CSF can also increase neutrophils, eosinophils, and monocytes in AIDS. Most patients with Kostmann syndrome, a rare inherited severe failure of neutrophil production, respond dramatically to G-CSF treatment. Patients with other defects of neutrophil production such as cyclic neutropenia and chronic idiopathic neutropenia have also responded to this factor.

Recombinant human thrombopoietin or its polyethylene glycol (**PEG**)-derivatized 163 residue aminoterminus (PEG-MGDF) stimulates megakaryocyte proliferation and endoreduplication *in vitro* and is a potent inducer of megakaryocytopoiesis and platelet production *in vivo* in mice and non-human primates. Both recombinant human thrombopoietin and PEG-MGDF are safe and show no organ toxicity. In normal volunteers a single bolus of 3 µg/kg per day of PEG-MGDF doubles the blood platelet concentration by day 12, with a return to baseline by day 28. A stimulatory effect on platelet production was observed when thrombopoietin or PEG-MGDF was administered after chemotherapy to more than 100 patients with cancer, with a decrease in the time for platelet counts to return to normal and elevated platelet nadirs. Antibodies to thrombopoietin have been reported in one patient with cancer and in volunteers given subcutaneous PEG-MGDF. Further clinical development of this thrombopoietin formulation has been stopped, since transient decreases in platelet count were noted. It is possible that the factor is more antigenic when given by the subcutaneous route.

Summary

Haemopoiesis is the process of terminal differentiation of recognizable immature precursors of the formed elements of the blood. Renewal of the precursor pool is accompanied by the differentiation of committed progenitor cells that are themselves renewed by a process of stochastic maturation of stem cells. A group of haemopoietins derived from T cells, monocytes, and fibroblasts governs the differentiation of committed progenitor cells by mechanisms yet to be defined.

The *mélange* of marrow cells described above exists in delicate fronds thrust into the venous sinuses. Cells are packed in close proximity within the fronds, held together by extensions of fibroblast cytoplasm and fibronectin. Such a delicate anatomy is subject to a myriad of abnormalities that can disturb the orderly progress of cell–cell interactions that govern the system. The multiple symptoms of bone marrow failure are the results of these disturbances.

22.2.2Stem-cell disorders

D. C. Linch

Concept of the haemopoietic stem cell and its disorders

The haemopoietic stem cell is a poorly defined entity with an undifferentiated phenotype, which resides within the haemopoietic tissue. It has the ability to self-renew, and the capacity to generate large numbers of mature progeny of multiple haemopoietic lineages. It was considered that such cells were irreversibly committed to haemopoiesis. More recent data suggest that stem cells have far greater plasticity than previously appreciated. Within the adult marrow, stem cells have been found that can give rise not only to blood cells, but also to other mesodermally derived tissues such as endothelium and muscle and to hepatic and neuronal cells traditionally thought to be derived from the endoderm and ectoderm, respectively. In some instances the extensive repertoire is due to the presence of non-haemopoietic mesenchymal stem cells within the bone marrow, but there is also evidence that stem cells with haemopoietic potential can give rise to other tissue-types. In addition, stem cells within the brain have been shown to be capable of generating cells that are embryologically derived from all three germ layers, and this includes the generation of haemopoietic cells. Either very undifferentiated multipotent stem cells persist in many adult tissues or, under appropriate conditions, some stem cells can undergo dedifferentiation and reprogramming. The most dramatic evidence for the possibility of dedifferentiation comes from 'Dolly the sheep', generated by the transfer of a mature cell nucleus into an enucleated egg. Clearly, the environment within the egg cytoplasm can reprogramme the genetic material within the nucleus. It is conceivable that similar processes could be induced by an appropriate extracellular milieu. It is not yet clear whether these new insights into the potential of the stem cell will alter the way in which we consider the haemopoietic stem cell disorders, but some of the fundamental assumptions of recent decades may be challenged.

Quantitative and qualitative abnormalities of haemopoietic stem cells can be envisaged. The stem-cell population might become depleted and fail to produce adequate mature progeny. Similarly, a normal number of abnormal stem cells could fail to proliferate normally and thus generate the same deficiency of end-cells. Abnormal stem cells could also produce normal numbers of defective end-cells, or he stem cells could undergo malignant transformation. These possibilities are not mutually exclusive and transitional forms can be envisaged.

In practice, the definition of a stem-cell disorder is often extremely difficult. Self-renewal, one of the hallmarks of a stem cell, cannot be considered in the context of malignant disorders, as any malignant clone, arising in any tissue, at any stage of differentiation, must have undergone immortalization and be capable of self-renewal. The term 'stem-cell disorder' is usually used, therefore, to imply that the target cell for the disease process has occurred in a cell with the potential to develop into cells of different lineages. Such a cell could be a relatively 'late' or 'lineage-restricted, stem-cell' capable, for example, of giving rise to phagocytes and erythrocytes, or it could be a very primitive stem cell capable of giving rise to all myeloid and lymphoid lineages. There are, however, a number of difficulties with such a definition. First, malignant change in a very primitive cell does not necessarily lead to the production of mature cells of multiple lineages. It is a feature of the acute leukaemias that there is a block in differentiation; in some cases of acute myeloid leukaemia (**AML**), no mature progeny are produced by the malignant clone. In other cases of AML, neutrophils alone are produced. However, it cannot be assumed that the target cell of the original oncogenic event was not a cell with the potential to form all the myeloid elements, including the red cell series. Second, whereas an immature phenotype of a malignant cells was always considered to be indicative of the transformation of a very early cell, we must now consider the possibility that transformation could arise in a later cell with subsequent dedifferentiation.

The concept of a haemopoietic stem-cell disorder is, therefore, imprecise. Pragmatically a stem-cell disorder is most easily considered as a disease with multilineage involvement.

Detection of multilineage involvement

In the bone marrow hypoplastic states, stem-cell involvement is obvious because of the pancytopenia that occurs. In the myeloproliferative disorders examination of the blood count and blood film also reveals the involvement of multiple lineages; neutrophil leucocytosis may coexist with eosinophilia, basophilia, and thrombocytosis. A number of more sophisticated techniques have also been used to demonstrate that a particular cell lineage is involved in a clonal process (Table 1).

Analysis of non-random cytogenetic abnormalities represents one of the most longstanding techniques for examining cell-lineage involvement in the haematological malignancies. This approach was used in the investigation of acute myeloid leukaemia to show that the large majority of T cells in the peripheral blood were not part of the malignant clone. The combination of this technique with immunophenotyping for lineage-specific markers provides a powerful addition to this approach. Conventional cytogenetic studies suffer the disadvantage that only cells in metaphase can be analysed, but techniques such as fluorescent *in situ* hybridization (**FISH**) (with or without immunophenotyping) allow cells in interphase to be examined.

Somatic mutations, from major chromosomal alterations to point mutations, can also be detected using non-microscopic methods employing recombinant DNA technology. Polymerase chain reaction (**PCR**) methods are particularly sensitive and make it possible to study small samples of cells, but it is difficult to make the techniques fully quantitative. Errors in interpretation can readily arise from minor contaminating cells in supposedly purified cell populations. Analysis of somatic mutations is subject to a further potential problem if the mutation is a secondary event in the disease process. Under these circumstances the mutation observed could have arisen in a subclone and not be present in all the malignant cells. In acute myeloid leukaemia mutations in *N-ras* may be present in all or just a few cells; sometimes a mutation detected at presentation cannot be found in relapse, indicative of the process of clonal evolution and the fact that the *ras* mutation was not an early event in the leukaemogenic process.

The use of polymorphic X-linked markers has been a very useful tool for examining clonality in informative females, and is not subject to the problems of clonal evolution. The original studies used the enzyme glucose-6-phosphate dehydrogenase (**G6PD**). However, there are many structural variants of this enzyme, the most common normally active variant being designated as B type. In populations of African descent a common normal variant exists which is designated as A type. Although this variant only differs by one amino acid it can be readily separated from the B type on starch-gel electrophoresis. Because the gene which codes for G6PD is on the X-chromosome, individual cells of a heterozygous female (AB) express only one enzyme type, with approximately half the cells expressing type A and half type B (in other words, the individual is a mosaic). This restricted pattern of gene expression arises because of the process of random X-inactivation, known as lyonization, which occurs in early embryonic life and is passed on to the progeny of those cells in a stable manner. (Fig. 1). Malignant disorders nearly always arise in a single cell, and thus all the malignant cells in a particular patient will have the same X-chromosome inactivated. In an informative G6PD female all the tumour cells will express either type A or type B enzyme. Analysis of the G6PD levels in blood cells of different lineages will help to determine whether they are involved in a haematological malignancy. This technique is limited by the low frequency of informative polymorphisms in populations other than those of African descent.

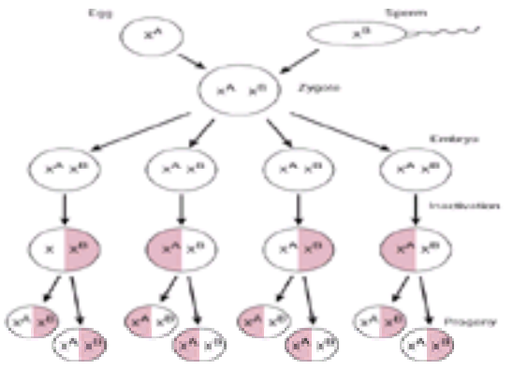

Fig. 1 X-chromosome inactivation.

Clonality can also be investigated using X-linked DNA polymorphisms which do not result in different protein products. This is based on the fact that the active and inactive genes are differentially methylated at specific cytosine residues. DNA samples are first digested with an appropriate restriction endonuclease to distinguish maternal and paternal copies of the gene, and subsequently with a restriction endonuclease sensitive to cytosine methylation in its recognition sequence to distinguish active from inactive copies of the gene. Useful genes to study include the hypoxanthine phosphoribosyl transferase (*HPRT*) gene and the phosphoglycerate kinase (*PGK*) gene (Fig. 2). The X-linked, multiple tandem repeat recognized by the probe M27B is highly informative (approximately 80 per cent of females are heterozygous), but as this is not a gene it is not really correct to talk about active and inactive copies. None the less, it acts as a useful marker of the inactivated X-chromosome, and results with this probe are concordant with those obtained with HPRT or PGK. PCR-based assays have also been developed to examine the methylation status of a number of genes, including the monoamine oxidase A gene (*MOA*), the human androgen-receptor gene (*HUMARA*), and the Fragile X gene. These assays require far fewer cells than are required for techniques based on Southern blotting and hence are now more frequently used. The *HUMARA* gene is the most informative, with heterozygosity rates in Caucasian populations of about 90 per cent. More recently a number of reverse transcriptase, polymerase chain reaction (**RT-PCR**) assays have been introduced that enable direct analysis of the relative expression of the two alleles at the transcript level, which may circumvent the problem of complex DNA methylation patterns. Informative genes must contain polymorphisms in the coding sequence, although these do not necessarily have to lead to changes in the amino acid sequence. It is also essential that the gene to be analysed is expressed by the cell type being investigated.

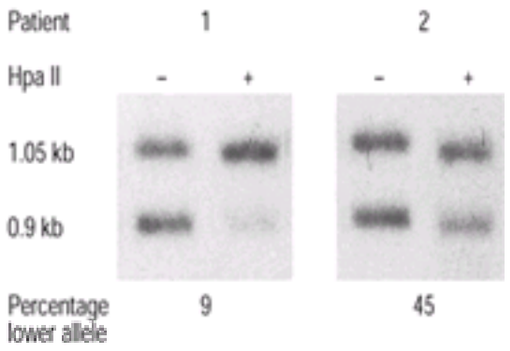

Fig. 2 Clonal analysis of PCK heterozygotes.

The *HUMARA* gene is again the most informative gene as the polymorphic variable number tandem repeat (**VNTR**) is contained within the coding sequence. The two alleles can be readily distinguished on electrophoresis of the RT-PCR product, but unfortunately this gene is not expressed in all haemopoietic tissues. The transcripts most commonly studied in haematological samples include G6PD, iduronate-2-sulfatase (**IDS**), and the palmitoylated membrane protein p55 (p55). Together these three RNA transcripts are informative in about 70 per cent of females. Once the mRNA has been reverse-transcribed into cDNA the different alleles, which differ only by single base changes, are then be detected by allele-specific PCR or allele-specific restriction analysis. Even with these genes expression is not constant between different haemopoietic cell-types. In one study IDS expression was shown to be sixfold higher in T cells than in neutrophils. High sample purity is thus essential when using this methodology.

Clonality studies based on X-chromosome inactivation patterns have three main drawbacks. First, it must be appreciated that lyonization occurs early in embryogenesis when there are few stem cells destined to give rise to the different tissues. As a consequence of this and the random nature of X-inactivation, considerable constitutive skewing away from the expected 50:50 expression of maternal and paternal alleles occurs in some individuals. An ill-defined inherited component may also contribute to this random process. In approximately one-quarter of females more than 75 per cent of the expressed genes derive from the same allele, and in 3 per cent of normal individuals more than 90 per cent. It is therefore essential that X-chromosome inactivation patterns are interpreted with reference to normal tissue. This has frequently been omitted and many of the reports in the literature are thus suspect. Furthermore, in the case of the haematological malignancies it is not always easy to obtain appropriate control samples. Non-haemopoietic tissues can be misleading controls, as X-inactivation patterns can vary between tissues. T cells are probably a good control in most myeloid malignancies as they derive from the same stem-cell pool as the myeloid cells, and it is unlikely that the majority of T lymphocytes will be involved in the malignant clone. Second, it has been clearly demonstrated that skewing of the myeloid lineages is acquired in a significant proportion of elderly females, so clonal analysis of haemopoietic lineages must be limited to females under the 65 years of age. Third, it must be remembered that the study of X-inactivation patterns is an insensitive technique which can not be used to detect a minor clone within a polyclonal population.

Myeloproliferative disorders

The term 'myeloproliferative disorders' was invented by Dameshek and others in the 1950s in an attempt to explain the variability of the haematological findings in polycythaemia rubra vera, chronic myeloid leukaemia, and myelofibrosis, and the existence of intermediate and transitional forms. The myeloproliferative disorders are characterized by the predominant cell type produced by the malignant clone, but they all involve a primitive stem cell (Fig. 3). Acute myeloid leukaemia frequently arises at the stem-cell level and diseases such as chronic myeloid leukaemia and polycythaemia rubra vera not infrequently terminate in 'blastic transformation'. By convention, however, the term 'myeloproliferative disorders' is usually reserved for the chronic malignancies where mature myeloid cells predominate.

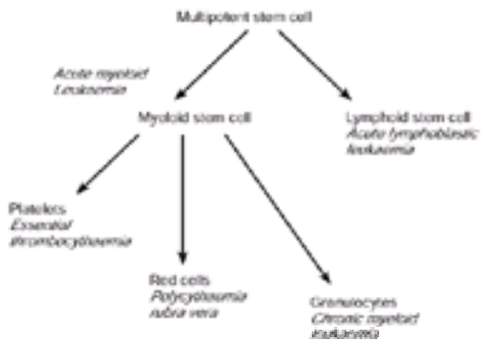

Fig. 3 The myeloproliferative disorders.

Lineage involvement was first studied in chronic myeloid leukaemia because of the presence of the characteristic Philadelphia chromosome [t(9;22)(q34;q11)]. Not only were all cells of the phagocytic- and red-cell series found to be involved, but Epstein–Barr virus (**EBV**)-transformed B lymphocytes were also shown to contain the Ph1 chromosome, thus indicating that the target cell for malignant transformation was a primitive stem cell with both myeloid and lymphoid potential. This is confirmed by the fact that about one-third of blastic transformations are due to the accumulation of primitive B cells.

A similarly primitive stem cell is thought to be the cell of origin of polycythaemia rubra vera (**PRV**), and at least some cases of essential thrombocythaemia (**ET**). Clonality studies have revealed, however, that a significant proportion of cases of ET are polyclonal and not malignant disorders, despite fulfilling the usual diagnostic criteria. The cause of the dysregulated blood cell production in such cases is unknown. An important observation made by several groups is that people with the

polyclonal forms of ET have a lower incidence of thrombosis.

Dameshek had considered that idiopathic myelofibrosis was part of the myeloproliferative disease spectrum, and indeed this is the case. The fibroblasts are not part of the malignant clone, however, but are a reaction to an underlying myeloid malignancy. Where studied, the myeloid cells have been shown to be clonal. Fibrosis is particularly common when cells of the megakaryocytic series predominate, and may be due to the excessive local production of platelet growth factors such as platelet-derived growth factor (**PDGF**) and transforming growth factor-b (**TGF-b**).

Acute leukaemias

In children with acute myeloid leukaemia (**AML**) the red cells and platelets do not appear to be part of the malignant clone, whereas such tri-lineage involvement is frequent in adults. There is no convincing evidence of lymphoid involvement. Considerable attention has been focused on the notion that remission in AML may represent persistence of the malignant clone with full differentiation to give a normal blood count. This view is based on studies that did not pay adequate attention to the skewing of X-inactivation patterns that can occur in normal individuals; true 'clonal remission' is rare.

Myelodysplasia, which frequently precedes AML, often involves all myeloid lineages, as is evident from examination of the blood and bone marrow films. There is considerable controversy within the literature, but the majority of studies do not demonstrate involvement of the lymphoid series.

Acute lymphoid leukaemia (**ALL**) is usually restricted to the B-cell or T-cell lineage. An exception occurs in cases of Ph1-positive ALL where the myeloid lineages are often involved. This entity is akin to chronic myeloid leukaemia (**CML**) presenting in lymphoid blast crisis.

Aplastic anaemia

Aplastic anaemia by definition refers to involvement of multiple myeloid lineages (pancytopenia). In severe cases the lymphocyte count is also reduced, suggesting that the defect is at the level of stem cells with the potential to give rise to both myeloid and lymphoid elements. Although T-cell numbers tend to be relatively well preserved, it must be appreciated that many T cells are long-lived cells and their numbers would not be expected to fall rapidly if their production from stem cells ceased. Furthermore, the basis of immunological memory, and a characteristic difference between myeloid and lymphoid cells, is that the mature progeny of the lymphoid stem cells can undergo amplification-division and self-renewal.

In those patients who respond (at least partially) to immunosuppression, with long-term follow-up there is a very high incidence of the development of clonal disorders such as paroxysmal nocturnal haemoglobinuria (**PNH**), myelodysplasia, and AML. In some patients at presentation, the few remaining granulocytes are clonal, although it is not clear how a clonal disorder can give rise to a hypoplastic bone marrow.

Paroxysmal nocturnal haemoglobinuria

PNH is a clonal disorder, due to a somatic mutation in the haemopoietic stem cell in the X-linked phosphatidylinositol glycan-A (**PIG-A**) responsible for the assembly of glycosyl phosphatidylinositol (**GPI**)-linked proteins on the cell surface of that cell and its progeny. This results in complement hypersensitivity and low-level expression of a number of antigens which are useful for defining lineage involvement. These include CD59 for red cells, platelets and T cells, CD67 for granulocytes, CD14 for monocytes, and CD24 for B cells. Flow cytometric studies have revealed variable lineage involvement: red cells, granulocytes, and monocytes and natural killer (**NK**) cells are involved in most cases; B cells are involved in a proportion of cases, and there is one report of a subpopulation of T cells involved in the PNH clone. It is possible that the variable lineage involvement represents differences in the target cell for the initiating mutation. The immunophenotypic studies have also confirmed that there is variable persistence of normal haemopoiesis, and some patients have more than one PNH clone with different levels of expression of GPI-linked molecules. One of the major unresolved questions in PNH is how does the PNH clone, which is not usually considered to be a malignancy, acquire a growth advantage over the normal haemopoietic tissue.

22.3.1 Cell and molecular biology of human leukaemias

*Thomas Look**

Introduction

The human leukaemias arise from haemopoietic stem and progenitor cells, and exhibit differentiation arrest in any lineage and in any stage of maturation. Attempts to understand the pathobiology of these diseases have focused on clinical presentation, cell morphology, histochemistry, cell immunophenotype, cytogenetics, and, in recent years, molecular genetics. Although useful in diagnosis and risk assessment, clinical and cell-biological findings ultimately fail to reveal underlying mechanisms of leukaemic transformation and, therefore, cannot account for treatment failures among groups of patients with ostensibly similar features. The emerging picture of leucocyte transformation indicates that most cases of leukaemia involve chromosomal translocations that result in aberrantly expressed transcription factors or activated tyrosine kinases, which drive malignant conversion and maintain the leukaemic phenotype. Some of these genetic changes affect cell proliferation or survival, while others exert their primary effects on cell differentiation. Almost always, the critical lesion involves a 'master' transcriptional regulatory gene or tyrosine kinase signalling molecule that stands near the top of a hierarchy of gene control, so that leukaemia is efficiently instigated by a limited number of alterations rather than by multiple changes affecting tens of responder genes in the biochemical cascade.

This chapter describes the human leukaemias in terms of their characteristic molecular genetic and developmental features. A recurring theme is that the genes most frequently altered in these diseases are those with evolutionarily conserved roles in the embryological development of various cell lineages and organ systems, including, but not limited to, genes that control normal blood cell production (haemopoiesis). Whenever possible, I have attempted to link advances in the molecular biology of a particular leukaemia to any unique implications for treatment and prognosis.

Oncogenic transcription factors and activated tyrosine kinases

Transcriptional control genes are common mutational targets in the human leukaemias because their protein products (transcription factors) bind to regulatory elements in DNA, such as promoters and enhancers, and stimulate or inhibit gene expression. These proto-oncogenes are frequently activated by chromosomal translocations, either by fusion of disparate gene fragments or by mobilization of the gene into the vicinity of transcriptionally active T-cell receptor (*TCR*) or immunoglobulin (*IG*) genes. More than 80 per cent of the oncogenic transcription factors identified to date can be classified according to the structural motifs within their DNA- and protein-binding domains: **bHLH** (basic region/helix–loop–helix), **bZIP** (basic region/leucine zipper), **HTH** or homeodomain (helix–turn–helix), A–T hook, Ets-like, Runt homology, zinc finger, and LIM (cysteine-rich). Each of these motifs has functional significance, in that it defines the downstream responder genes that determine the altered patterns of gene expression during normal development and malignant transformation.

Current observations indicate that oncogenic transcription factors act positively to aberrantly upregulate critical target genes that coordinate the production of proteins needed for normal cell proliferation, differentiation, or survival (gain of function), or negatively to interfere with normal regulatory cascades controlling apoptosis and the growth that normally accompanies differentiation (loss of function). Similarly, activated tyrosine kinases act through signal-transduction cascades that ultimately dysregulate the transcriptional control of gene expression. The oncogenic transcription factors or activated tyrosine kinases involved in the human leukaemias have unique transforming properties, which tend to be specific for different types of progenitor cells developing in the lymphoid or myeloid pathways. In most cases of acute lymphoblastic leukaemia and acute promyelocytic leukaemia, the initial lesion appears to affect progenitors at the same stage of differentiation as the predominate phenotype in the malignant clone. However, most types of acute myeloid leukaemia appear to arise in a primitive haemopoietic stem cell rather than a committed myeloid progenitor, with subsequent blockade of differentiation that determines the morphological (FAB) subtypes of myeloid leukaemia apparent at diagnosis. Primitive normal stem cells are also thought to be the targets of leukaemic transformation in chronic myeloid leukaemia and in some cases of acute lymphoblastic leukaemia, at least those expressing the *BCR–ABL* and *MLL* fusion oncogenes.

Acute lymphoblastic leukaemia

Approximately 3000 to 4000 people in the United States, two-thirds of them children, develop acute lymphoblastic leukaemia (**ALL**) each year. Only 20 to 25 per cent of the childhood cases are resistant to modern multiagent therapy, attesting to the remarkable treatment advances that have been made over the past three decades. Unfortunately, the prognosis for adults with ALL remains poor. Fewer than 50 per cent of the patients treated solely with chemotherapy become long-term survivors, and many patients are ineligible for or fail in spite of bone marrow transplantation. The difference in curability between acute leukaemias in children and adults can be attributed partly to the much larger proportion of adult cases with the *BCR–ABL* chimeric tyrosine kinase oncogene, resulting from the Philadelphia chromosome, and to the poor tolerance of intensive chemotherapy by patients over 50 years of age. There is also the possibility that ostensibly similar cases of ALL in children and adults differ in, as yet undefined, genetic ways that influence the outcome of therapy.

B-Lineage ALL

Normal B-lymphoid cell populations undergo diverse, clonal rearrangements of their *IG* genes, followed by highly regulated proliferation of cells that successfully complete the process and produce immunoglobulin. When this developmental process is altered, the developing B lymphocytes may undergo transforming events that eventually lead to overt ALL. In most instances, the pathobiology of transformed lymphoid cells mirrors the altered expression of genes that contribute to the normal functioning of pro-B (immunoglobulin undetectable) or pre-B (cytoplasmic immunoglobulin-positive) lymphocytes or occasionally mature virgin B cells (surface immunoglobulin-positive), although it may involve the aberrant expression of normally quiescent genes. Approximately 80 per cent of patients with ALL have lymphoblasts whose phenotypes correspond to those of B-cell precursors. Only 2 to 3 per cent of these patients have mature B-cell leukaemia, which is thought to represent a disseminated form of Burkitt lymphoma. The prevailing concept is that lymphoid leukaemic cells are classified immunophenotypically according to their 'normal' developmental stage, as this convention provides a firm basis for the study of cell type-specific genetic alterations.

BCR–ABL

The first constitutively activated tyrosine kinase described in ALL results from fusion of 5' sequences of the *BCR* proto-oncogene to 3' sequences of *ABL* due to action of the t(9;22) translocation, leading to creation of the so-called Philadelphia (**Ph**) chromosome. Most investigators agree that the t(9;22) translocation occurs in haemopoietic stem cells possessing both lymphoid and myeloid differentiative potential. Differences between *BCR–ABL*$^{+}$ leukaemias in children and adults are striking. Found in only 3 to 5 per cent of newly diagnosed paediatric ALL cases, they represent at least 25 per cent of adult cases. Also, the *BCR* breakpoints on chromosome 22 in paediatric cases cluster mainly in the *m-bcr* (minor breakpoint cluster region), whereas in adults they can occur in either the *m-bcr* or the *M-bcr* (major breakpoint cluster region). Breaks in the former region lead to fusion genes encoding a 190-kDa protein (p190), while those in the latter generate a 210-kDa protein (p120).

Very little is known about the normal function of ABL, although as a nuclear protein with tyrosine kinase activity, it may stimulate p53-dependent growth arrest, suggesting a role as a cell-cycle checkpoint after damage to the cellular genome. Both the p190 and p210 forms of BCR –ABL are localized in the cytoplasm and have increased tyrosine kinase activity. Their enforced expression can transform haemopoietic cells *in vitro* and can induce a syndrome similar to chronic myeloid leukaemia in mice. The precise mechanism by which BCR–ABL transforms human haemopoietic cells is unclear, but this process almost certainly involves activation

of the *CRKL* gene, whose product stimulates JUN kinase and ultimately JUN through the RAS signalling pathway, as well as STATs, MYC, and cyclin D1.

Patients with *BCR–ABL*$^+$ ALL respond poorly to conventional therapy but are excellent candidates for bone marrow transplantation. A new drug, STI-571, has been identified that selectively inhibits the ABL tyrosine kinase and appears to be highly active in BCR –ABL$^+$ CML (see below). Trials are currently underway to test the activity of this drug in BCR–ABL$^+$ leukaemias that present initially as ALL.

TEL–AML1

One of the exciting recent developments in molecular genetics research of ALL was the identification of *TEL–AML1* (also termed *ETV6–CBFA2*) as the most common genetic alteration in leukaemic pro-B lymphoblasts. This chimeric oncogene is generated by the t(12;21), a translocation that is difficult to detect by standard Giemsa-banding, but which is identified in 25 per cent of cases by molecular assays. The resultant TEL –AML1 oncoprotein consists of the HLH domain of TEL, an ETS family transcription factor, fused to the DNA-binding and transactivation domains of AML1. AML1 is the DNA-binding component of the core-binding factor (**CBF**) transcription-factor complex, which is also the most frequent target of myeloid cell-associated translocations, including the t(8;21), t(3;21), and inv(16), and a critical participant in normal haemopoiesis.

The relative contributions of TEL and AML1 to leukaemia induction are only beginning to be understood. One attractive model suggests that the crucial pathogenic event is interference with AML1-mediated expression of *HOX* or other master control genes, which have pivotal roles in normal lymphopoiesis. Thus, the leukaemogenic role of TEL–AML1 may well depend on the DNA-binding and transactivating domains of AML1, although a definitive explanation will probably not be found until better *in vitro* transformation assays become available.

The prognostic impact of *TEL–AML1* expression is controversial. Some treatment centres claim long-term, event-free survival rates of approximately 90 per cent in patients with this genetic abnormality, while others report a lack of a favourable prognostic significance. Evaluation of the components of the treatment regimens suggest that TEL–AML1$^+$ cases respond better to drug combinations that rely on the intensive use of L-asparaginase and increased dosages of methotrexate with leucovorin (calcium folinate) rescue. Thus, the *TEL–AML1* fusion gene may identify a large, previously unrecognized subset of pro-B ALL cases that can be treated with regimens that rely on antimetabolites and an enzyme that depletes an essential amino acid in lymphoid cells, rather than genotoxic agents (for example, epipodophyllotoxins) that are associated with secondary AML.

E2A fusion genes

The *E2A* gene, which encodes a bHLH transcription factor on chromosome 19, is targeted by two reciprocal translocations in patients with ALL—the t(1;19) in 5 per cent of children and 3 per cent of adults, and the t(17;19) in approximately 0.5 per cent of children. The former generates one of the best-characterized fusion oncogenes in ALL, in which the two transcriptional transactivation domains of *E2A* are linked to the homeodomain of *PBX1*. *PBX1* is an orphan *HOX* gene that shares homology with the *exd* gene of *Drosophila*, which regulates in segment identity through direct interaction of its product with specific HOM proteins of the *Bithorax* and *Antennapedia* complexes.

E2A–PBX1, which binds to DNA in a site-specific manner, is clearly oncogenic in fibroblast transformation assays and in mice, and appears to induce programmed cell death (apoptosis) in lymphoid cells. Like its exd homologue, PBX1 is directed to its consensus DNA-binding site by a subset of interacting HOX proteins, whether or not it is fused to E2A. Surprisingly, these site-specific recognition sequences of PBX1 are not required for the transforming activity of E2A–PBX1. How, then, would the chimeric oncoprotein induce leukaemia, if not by disruption of gene expression normally regulated by HOX proteins? The answer appears to lie in a short peptide sequence that regulates the HOX-specific protein–protein interaction, and which is essential for leukaemogenic activity.

In about 0.5 per cent of childhood ALL cases, the t(17;19) translocation generates the *E2A–HLF* fusion gene, consisting of the amino-terminal transactivation regions of *E2A* and the C-terminal DNA-binding and dimerization domains of *HLF*, a member of the bZIP transcription factor gene family. E2A–HLF mediates leukaemic transformation by inhibiting a normal apoptotic pathway in pro-B lymphocytes, one that closely resembles the pathway responsible for eliminating extraneous neuronal cells in the nematode *Caenorhabditis elegans*. Of seven reported patients with ALL whose blast cells expressed *E2A–HLF*, each has died of leukaemia during or after aggressive treatment, suggesting a profound resistance to chemotherapy, which may arise from E2A–HLF-induced inhibition of drug-induced apoptosis.

MLL fusion genes

Structural abnormalities of chromosome 11, band q23, are found in 80 per cent of infants with ALL, but only 7 per cent of older children and adults with this disease. Recent findings of Greaves and co-workers in the United Kingdom, indicate that translocations affecting the 11q23 region can arise *in utero*, predisposing the child to the very early development of leukaemia. The vast majority of 11q23 translocations affect the *MLL* gene, which encodes a protein of 3968 amino acids with a predicted molecular mass of 431 kDa and with three regions of homology with the *Drosophila* trithorax protein (two central zinc-finger domains and a C-terminal segment of 210 amino acids). The N-terminal region, which is uniformly retained in reciprocal translocations, contains three A –T hook motifs that apparently bind A–T-rich sequences in the minor groove of DNA. The A–T hook motifs are separated from the zinc-finger regions by a 47-amino-acid sequence with homology to the non-catalytic domains of human DNA-methyltransferase, an enzyme that produces fully methylated double-stranded DNA from a hemimethylated substrate. The structural features of MLL indicate that its normal physiological function, as well as its role in leukaemogenesis, is mediated through direct interactions with DNA and other DNA-binding and signal-transduction proteins.

As with PBX1, the MLL protein appears to play a role in *HOX* gene regulation. Homozygous inactivation of the *MII* gene in mice is lethal during embryogenesis, with homeotic transformations of the skeleton reminiscent of the phenotype associated with *trithorax* mutation in flies. Knockout mice heterozygous for *MII* are small at birth, have retarded growth, and develop both anaemia and thrombocytopenia. Thus, loss of function of one *MLL* allele through chromosome breakage and translocation of the resultant fragment to a new site, together with a gain of function due to gene fusion, would be expected to interfere with the normal haemopoietic role of HOX proteins, thereby contributing to leukaemogenesis.

More than 30 discrete chromosomal sites participate in 11q23 translocations, most commonly 4q21, 9p22, and 19p13, resulting in fusion of the *AF4*, *AF9*, and *ENL* genes to *MLL*,. A recurring question has been whether the partner DNA fragments in *MLL* gene fusions are needed to induce leukaemia. In the case of *MLL–ENL*, created by the t(11;19), neither the *MLL* fragment alone nor a fusion gene lacking the *ENL* C-terminal region is sufficient to transform retrovirally transduced haemopoietic cells, suggesting that a gain of function due to the *ENL* C-terminus is required for *MLL–ENL*-induced leukaemia. Similar results have been obtained for *AF9*, in regions of the molecules required for transcriptional activation, which occurs through recruitment of co-activators like **CBP** to the transcriptional machinery. In fact, CBP itself has recently been identified as a fusion partner with MLL in rare leukaemia cases. Taken together, recent findings suggest a model in which CBP or related histone acetylases like p300 contribute in a highly regulated fashion to normal MLL function. MLL fusion proteins apparently result in aberrant gene regulation through the constitutive association of this enzymatic activity with the MLL DNA-binding domain.

The *MLL–AF4*, *MLL–AF9*, and other *MLL* fusion genes predict a dismal outcome in infants and adults treated exclusively with chemotherapy. Trials testing the efficacy of high-dose chemotherapy and radiation with stem cell replacement are currently underway.

MYC

Chromosomal translocations in B-lineage cells can also mobilize proto-oncogenes to sites adjacent to normally active enhancer or promoter elements of *IG* genes. The prototype for this mechanism in B-lineage ALL is the t(8;14), which arises in mature B cells and places the *MYC* proto-oncogene on chromosome 8 under the control of *IG* heavy-chain gene regulatory sequences on chromosome 14. Similar repositioning of *MYC* adjacent to the light-chain regulatory sequences results from the t(2;8) or the t(8;22), although in much smaller percentages of cases. Through one of these translocations, *MYC* expression becomes dysregulated, leading to abnormally increased amounts of the MYC protein, a transcription factor that forms a DNA-binding complex with another cellular protein (MAX), and eventually leads to disruption of gene expression involved in the control of cell proliferation.

Dysregulated *MYC* genes confer an exceptionally poor prognosis in children and adults with mature B-cell ALL who are treated with conventional regimens used for other types of ALL. Recent studies, however, indicate that at least 80 per cent of these patients can be cured with intensive short-term chemotherapy including high-doses of cyclophosphamide, methotrexate, and cytarabine. Thus, B-cell ALL provides the first example of a subtype of ALL requiring tailored therapy with a vastly different drug regimen for effective disease control.

T-Lineage ALL

Cell biology

First recognized as a distinct clinical entity in the early 1970s, T-cell ALL accounts for 10 to 15 per cent of acute lymphoid leukaemias in children and 20 to 25 per cent of cases in adults. The disease can arise in thymocytes at any stage of maturation, defined on the basis of reactivity with monoclonal antibodies (CD4/CD8 double-negative immature thymocytes, cytoplasmic CD3+ CD7+ CD2+ CD5+; CD4/CD8 double-positive common thymocytes, cytoplasmic CD3+ CD1+ CD2+ CD5+ CD7+ CD10+ CD4+ and CD8+; and CD4/CD8 single-positive late thymocytes, cytoplasmic CD3+ CD2+ CD5+ CD7+, CD4+ or CD8+).

Molecular oncogenesis

In contrast to the fusion oncogenes that drive the development of B-cell precursor ALL, oncogene activation in T-cell ALL reflects the mobilization of genes encoding structurally intact T-cell proto-oncogenes into the vicinity of transcriptionally active sites of the beta or alpha/delta loci of the T-cell receptor genes (TCRb or TCRa/†). Among the genes that are aberrantly expressed in thymocytes and cause leukaemic transformation through this mechanism are those representing the bHLH family of transcription factors (TAL1/SCL1, TAL2/SCL2, LYL1, and BHLHB1), the bHLH/ZIP family (MYC), other nuclear regulatory proteins (LMO1 and LMO2), homeotic proteins (HOX11), and a truncated and constitutively activated form of the human homologue of the *Drosophila* Notch 1 receptor (TAN1). The relationship of these genes to the pathogenesis of T-cell ALL has been established by their recurrent involvement in translocations that affect thymocytes or their precursors. Surprisingly, most of the T-cell oncogenes identified to date are not usually expressed in T cells; hence, their ability to induce leukaemia most likely reflects the misexpression of master transcriptional control genes with the disruption of normal T-cell developmental pathways. This is illustrated by *HOX11*, which is not normally expressed in lymphoid cells, but has been shown to be absolutely essential for normal development of the spleen.

Despite intensive cytogenetic research, chromosomal translocations have been identified in only about 25 per cent of T-cell ALL cases, suggesting that additional pathogenetic mechanisms remain to be identified. One intriguing possibility is that such cases harbour mutations (not attributable to translocations) that disrupt key transcriptional control networks in thymocyte development, leading to overt ALL. Support for this hypothesis comes from the existence of mechanisms that can induce misexpression of bHLH transcription factor genes, including *TAL1/SCL*, without a requirement for rearrangement to a site near the *TCRa/†* locus. Thus, *TAL1/SCL* may be abnormally expressed in as many as 60 per cent of T-cell leukaemias, in contrast to the 3 per cent accounted for by chromosomal translocations. Even so, it is unlikely that dysregulation of *TAL1/SCL* by itself would be sufficient to generate a fully malignant phenotype; rather, consistent misexpression of two or more T-cell oncogenes and their cooperative interaction, both among themselves and through a lack of other regulatory proteins encoded by tumour suppressor genes, is probably needed to induce clinically apparent leukaemia.

Therapeutic implications

With the availability of effective multidrug regimens, the prognostic importance of T-lineage leukaemia has disappeared in children. In adults, the addition of cyclophosphamide and cytarabine to first-line treatments boosted complete remission rates from 72 per cent to 85 per cent and improved the probability of continuous complete remission from less than 10 per cent to 46 per cent or more. The best prospect for accelerated therapeutic progress in this disease appears to lie in a fuller understanding of the molecular aspects of T-cell pathogenesis and how they relate to available modes of treatment. Ongoing studies to clarify these interactions should greatly enhance the value of molecular genetics in predicting the clinical responses of patients with T-cell ALL and, ultimately, could provide lucrative targets for novel drug therapies.

Acute myeloid leukaemia

The estimated number of new cases of acute myeloid leukaemia (**AML**) occurring annually in the United States is vastly higher in adults than in children (22 500 versus 500). Prognosis is poor in both age groups, especially in older patients with AML, although recent improvements in allogeneic bone marrow transplantation may boost cure rates above 50 per cent in those patients under 50 years of age with histocompatible donors. AML can develop from transformed cells within the granulocyte/monocyte lineage or from haemopoietic stem cells capable of differentiating into erythrocytes and megakaryocytes, as well as granulocytes and monocytes. Regardless of the cell of origin, AML pathogenesis is a multistep process, involving alterations of both proto-oncogenes and tumour suppressor genes. Although important tumour suppressors are thought to exist in regions of non-random loss of heterozygosity in this disease (for example, monosomy 7, 5q $^{-}$, 20q^{-}), current knowledge focuses on chromosomal translocations which activate transcription factor genes, reminiscent of those giving rise to ALL.

Differentiation stage in AML is best described in the context of the French–American–British (**FAB**) cell-classification system, which distinguishes among eight morphological subtypes of myeloid leukaemia, allowing useful cell type-specific comparisons of molecular genetic findings.

Acute promyelocytic leukaemia

Characterized by the clonal expansion of transformed myeloid cells blocked at the promyelocyte stage of development, the FAB M3 subtype of AML harbours a t(15;17) translocation that generates the *PML–RARa* fusion gene. *RARa* is a member of the nuclear hormone-receptor superfamily, functioning as a ligand-dependent, zinc-finger transcription factor with a critical role in normal myeloid cell differentiation. Much less is known about the normal biological function of PML, although it is a nuclear protein thought to function with p53 in cellular senescence induced by oncogene expression. The fusion protein contains nearly all the key functional domains of each molecule, including the protein–protein interaction motifs of PML and the DNA-binding, dimerization, ligand-binding, and transcriptional activation domains of RARa. The PML–RARa oncoprotein induces leukaemia by inhibiting, in a dominant fashion, the normal biological activities of both RARa and PML. The net effect is a blockade of differentiation with immortality and sustained proliferation among promyelocytes, the hallmark of acute promyelocytic leukaemia (M3 AML).

Treatment of *PML–RARa*+ AML with pharmacological dosages of the RARa ligand all-*trans*-retinoic acid (**ATRA**) results in the release of co-repressor complexes from the PML–RARa fusion protein, reversing the protein's inhibitory activity and enabling the leukaemic promyelocytes to proceed to terminal differentiation. The unique specificity of ATRA for the underlying molecular lesion in M3 AML affords a paradigm for molecularly targeted cancer chemotherapy.

Acute myeloblastic leukaemia

AML1–ETO

The *AML1–ETO* fusion gene results from the t(8;21) translocation in approximately 40 per cent of cases involving myeloblastic leukaemic cells with some evidence of differentiation (FAB M2 subtype). The oncogene product consists of the N-terminal portion of AML1, including its entire Runt homology domain (RHD), and the C-terminal portion of ETO, the mammalian homologue of the *Drosophila* protein, nervy. The AML1–ETO chimeric oncoprotein exerts its leukaemic activity by dominantly repressing the DNA-binding sites normally recognized by the AML1/CBFb core-binding factor transcriptional complex, whose function is essential for the development of all haemopoietic lineages.

Patients with *AML1–ETO*+ leukaemia respond more readily to chemotherapy than most other patients with AML, so that most experts advise reserving stem-cell transplantation for patients in first relapse. Multiple groups have documented the persistence of *AML1–ETO* fusion transcripts in patients with long-term remissions, suggesting that additional mutations within the leukaemic clone are essential for manifestation of the malignant phenotype. Since AML–ETO is a dominant-negative chimeric transcription factor that relies on co-repressor complexes, novel treatments that disrupt the formation, stability, or activity of such complexes, such as histone deacetylase inhibitors, might reverse the leukaemic phenotype, as seen with the use of ATRA in patients with acute promyelocytic leukaemia carrying the *PML–RARa* oncogene.

CBFb–MYH11

The *CBFb–MYH11* fusion product, due to inv(16) or t(16;16), is another frequent genetic lesion in newly diagnosed cases of AML. Once thought to be pathognomonic of cases with dysplastic eosinophilic precursors among myeloblasts and monoblasts (M4Eo subtype), this finding has since been made in acute myeloblastic leukaemia (M1 and M2 subtypes). These genetic rearrangements fuse the N-terminal portion of CBFb to a variable amount of the C-terminal a-helical rod domain of

MYH11, a smooth-muscle, myosin heavy-chain protein that possesses both actin binding and ATPase activity. *CBFb–MYH11* also inhibits the normal activity of the AML1/CBFb transcription factor complex, depriving the cell of requisite developmental signals. There are also suggestions that the oncoprotein generates positive signals resulting in abnormalities of cell growth. As with *AML1–ETO*, the *CBFb–MYH11* oncogene confers a better-than-average probability of achieving a sustained remission with chemotherapy.

Chronic myeloid leukaemia

Several forms of leukaemia are included under the generic term 'chronic myeloid leukaemia' (**CML**). About 90 per cent of patients with CML, both children and adults, harbour the classic t(9;22) translocation in myeloid cells, giving rise to the Ph chromosome and the *BCR–ABL* oncogene. In most patients the resulting disease is biphasic, with an initial (chronic) phase that lasts 3 years on average, and a terminal (blast) phase that is refractory to all treatment and is generally fatal within a median of 2 to 4 months. Children also can develop a juvenile form of CML (**JCML**) that often involves loss of the NF1 tumour suppressor.

Allogeneic bone marrow transplantation is the main curative treatment for CML. Patients with either the adult or juvenile form of the disease, who lack histocompatible sibling donors, may benefit from long-term treatment with interferon-a, which improves karyotypic responses, delays progression of the disease, and prolongs overall survival in randomized clinical trials. An exciting new development is the experimental agent STI-571, which targets the tyrosine kinase activity of BCR –ABL. STI-571 has produced striking improvements in each of 31 patients who were resistant to interferon and who then received STI-571 in cumulative doses of at least 300 mg per day. In three cases, the drug eradicated all cells with the t(9;22) chromosomal marker, and the malignant clone has remained undetectable in these patients for the relatively short duration of this trial.

Clinical summary

Molecular genetic changes at diagnosis are sensitive markers of potential leukaemia aggressiveness and therefore can be used as guides to treatment. Table 1 summarizes the clinical utility of recognized oncogenic transcription factors in the human leukaemias. Thus far, only two specific lesions, the *PML–RARa* fusion gene in acute promyelocytic leukaemia and the BCR–ABL kinase in CML and ALL, have been productive targets for molecular-oriented therapy, but this number will likely increase as we learn more about the genetic mechanisms that transform normal blood cells and maintain leukaemic phenotypes.

22.3.2 The classification of leukaemia

D. Catovsky

Introduction

The classification of leukaemia has evolved from a purely morphological approach, based on the appearances of the leukaemic cells in peripheral blood and bone marrow films, through cytochemical techniques and, more recently, with the use of monoclonal antibodies (**MAbs**) against cellular antigens. There has also been a major input from cytogenetic and molecular methods. The new methodologies are introducing greater precision and objectivity to the diagnostic criteria and in the assessment of prognosis in the well-defined disease entities. A new WHO classification on haemopoietic malignancies is a positive step forward and represents the consensus of most pathologists and clinicians in the field.

A broad classification of acute leukaemia includes two large groups, historically designated 'acute' and 'chronic'. Acute leukaemias represent malignancies with little evidence of differentiation; the characteristic cells are immature precursors or blasts. It is for this group where techniques other than morphology are essential for classification. The chronic leukaemias (lymphoid and myeloid) show maturation that is easily recognized morphologically, although in the diseases of lymphocytes the various subtypes can only be accurately defined by means of immunological methodology using panels of MAbs (Chapter 22.3.5).

Acute leukaemia

There are two major groups of acute leukaemia, lymphoblastic (**ALL**) and myeloid (**AML**) (Table 1). Both affect children and adults but with different frequency: 80 per cent of patients with AML are adults (over the age of 15 years) and 20 per cent children, including infants; in contrast, 85 per cent of those with ALL are children (under 15 years) and 15 per cent are adults. There are few differences in most disease features in AML between children and adults; conversely, the biological and clinical differences between childhood ALL and adult ALL are substantial.

For a diagnosis of acute leukaemia it is necessary to identify blasts as the major cellular component. With a few cytochemical reactions, namely myeloperoxidase (**MPO**), Sudan Black B, and a-naphthyl acetate esterase (**ANAE**), it is possible to distinguish the two main forms, ALL and AML. However, because cytochemistry is largely negative in ALL, it is essential to apply a battery of MAbs which can be used as markers for the two ALL cell lineages, B and T, and which can also characterize the AML blasts (Table 2). These MAbs define the immunophenotype of the disease. In immature cells some antigens are first expressed in the cytoplasm then in the cell membrane. This must be taken into account when testing blasts in suspension by flow cytometry as this method needs to be adapted for the detection of cytoplasmic antigens. Some of the markers that are specific for the T, B, and myeloid lineages, CD3, CD22, CD79a, and MPO (Table 2), are localized in the cytoplasm and not in the membrane.

Bone marrow trephine biopsies may be useful for the diagnosis of those rare cases that yield a dry tap or a hypocellular specimen in aspirates. This is the case in two uncommon forms of acute leukaemia: megakaryoblastic, or AML-M7, and hypocellular acute leukaemia, the blasts of which may be myeloid or lymphoid.

In the last decade it has become apparent that some of the acute leukaemias, both AML and ALL, can be defined by distinct chromosome translocations. These translocations often result in a fusion gene that encodes a new chimeric protein. The leukaemias so classified correlate with their response to therapy and their prognosis. For this reason, the new WHO classification has defined several types of AML and ALL by the molecular events crucial in their pathogenesis. It is therefore essential that, whenever possible, cytogenetic analysis and/or molecular methods—such as fluorescent *in-situ* hybridization (**FISH**), polymerase chain reaction (**PCR**), or Southern blots—should be part of the diagnostic procedures performed in all these cases.

Acute myeloid leukaemia (Table 3)

AML with cytogenetic abnormalities

There is now good evidence that four types of AML defined by reciprocal chromosomal translocations represent distinct disease entities: these are listed in Table 3.

The translocation t(8;21)(q22;q22) is seen in 10 per cent of cases of AML, most of which have the M2 morphology (myeloblastic with maturation). This form of AML is relatively more common in children than adults. In rare cases the percentage of blasts in the bone marrow is less than 20 per cent, which is currently the recommended threshold for the diagnosis of AML. The immunophenotype of this type of AML is similar to others (Table 2), except for the frequent expression of the B-lineage antigen CD19, in 70 per cent of cases. AML with t(8;21) is associated with a high complete remission rate and a long-term disease-free survival. In a proportion of cases, mainly children, t(8;21) presents as a chloroma (myeloid sarcoma), sometimes with little bone marrow involvement.

The translocation t(15;17)(q22;q21) is consistently associated with acute promyelocytic leukaemia (FAB M3). The chromosome abnormality is seen in both the typical or hypergranular form and the less common microgranular type or M3V. The translocation involves the *PML* and *RARa* (retinoic acid receptor) genes, resulting in a *PML/RARa* fusion gene. M3 represents 7 to 8 per cent of all AMLs. Typical cases can be recognized morphologically: the blasts are bilobed, heavily granular, and show bundles of Auer rods or 'faggots'. MPO and Sudan Black B are strongly positive, myeloid antigens are expressed but HLA-DR and CD34, a feature of myeloblasts, are negative. AML M3 affects young adults who present with low white blood counts (**WBC**) and a bleeding tendency. M3 variant cases have high WBC, and the blasts are deceptively hypogranular and may resemble monocytes but the nucleus is bilobed rather than reniform. Cytochemistry helps to exclude monocytic leukaemia by a strong MPO and weak or negative ANAE reaction. Patients with the rare variant translocations such as t(11;17)(q23;q21) also involving *RARa* usually lack typical M3 morphology and do not respond to treatment with all-*trans* retinoic acid (**ATRA**).

AML with myelomonocytic features and abnormal eosinophils (FAB M4Eo) is associated with abnormalities of chromosome 16, inv16, del(16) or t(16;16) (Table 3). The cytogenetic changes result in the fusion of the *CBFb* and *MYH11* genes and often require analysis by FISH or PCR as they may be missed by conventional karyotype analysis. The granules of the bone marrow eosinophils are often large and react with chloracetate esterase.

Analysis of more than 4000 AML cases entered into MRC AML trials (MRC AML 10, 11, and 12) showed that patients with t(8;21), t(15;17), or inv(16) represent 23 per cent of all cases, and have a significantly better prognosis and treatment outcome than those with normal karyotypes or other abnormalities. In contrast, a particularly unfavourable prognosis is seen in AML with abnormalities of chromosomes 3, 5, and 7.

Translocations involving the *MLL* gene at 11q23 take place with close to 20 other partner chromosomes. These abnormalities are more common in childhood AML and include the t(9;11)(p21;q23) and t(11;19)(q23;p13). The demonstration of *MLL* rearrangement, which is also affected in childhood ALL, is better shown by Southern blot and FISH than by conventional karyotyping. Abnormalities of the *MLL* gene are seen mainly in infants (<1 year) with AML and therapy-related AML (see below). Morphologically, these cases often have monocytic/monoblastic features and a strong ANAE reaction sensitive to inhibition by sodium fluoride.

AML not otherwise categorized

These represent more than two-thirds of cases of AML not included in the above group. Some have distinct chromosome abnormalities, but because they are uncommon they have not yet been considered as specific entities. The WHO classification has retained the FAB categories (M0 to M7) with some additions for this large group of AML (Table 4).

AML M0 represents the most immature form of myeloblastic leukaemia. The blasts are negative with MPO and ANAE cytochemistry, negative with B- and T-lymphoid markers, as distinct from ALL, and positive with one or more of the AML markers (Table 2), including anti-MPO which is more sensitive than the cytochemical method for MPO. The incidence of M0 is around 3 per cent of all AML. There is evidence that this disease has a poor prognosis with a lower remission rate and shorter survival than other forms of AML.

AML M1 is also poorly differentiated; it differs from M0 in the demonstration of myeloid features by the cytochemical reactions with MPO and Sudan Black B. The majority of cases have more than 25 per cent positive blasts and often show Auer rods. It is advisable, in cases with less than 10 per cent MPO-positive blasts, to confirm the diagnosis of AML with myeloid markers (Table 2; Fig. 1).

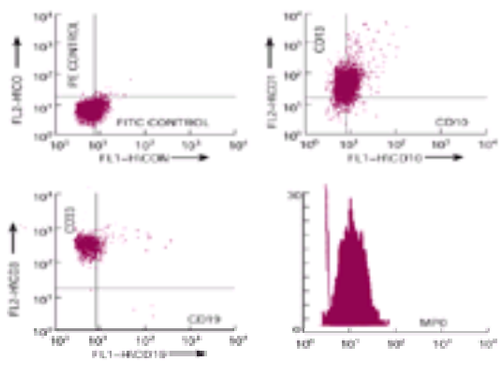

Fig. 1 Flow cytometry analysis of a case of AML using double MAbs conjugated with two different fluorescent dyes (phycoerythrin (**PE**) and fluorescein-isothiocyanate (**FITC**)) shown in the control panel (top left). The blast cells are CD13+ and CD10– (top right), CD33+ and CD19– (bottom left) and anti-MPO+ (bottom right). (See Table 2 and Farahat *et al*. (1994) for technical details).

Some one-third of cases with AML M2 will show t(8;21) and will therefore be included in the group defined by cytogenetic abnormalities. Other cases may have other changes, for example the rare variants of M2 and basophilia involving abnormalities at 12p or the translocation t(6;9)(p23;q34) with the chimeric fusion of the *DEK* and *CAN* genes.

The majority of cases of M3 and M3V recognized morphologically will have the t(15;17) described above. It has been retained here only for cases in which cytogenetic or molecular studies are not possible.

The myelomonocytic (M4) and pure monocytic (M5) leukaemias can be defined by morphology and cytochemistry. The variant M4Eo is associated with inv(16) and is included in the group with cytogenetic abnormalities.

There are two forms of M5 AML identified by morphology. M5a is immature, common in infants, and is recognized by a strong ANAE cytochemical reaction. In M5b the cells are more mature and lysozyme levels are raised. M5 is associated with high WBC, lymphadenopathy, gum hypertrophy, skin deposits, and central nervous system involvement. A rare form of M4 or M5 has heavily granular blasts, prominent haemophagocytosis, and a bleeding diathesis and is characterized by the translocation t(8;16)(p11;p13).

M6 (erythroleukaemia) may show features of trilineage dysplasia. The WHO recommends that the 20 per cent blasts required for the diagnosis of AML could be reached in M6 by excluding erythroblasts in the bone marrow differential count. The blasts in M6 are often myeloblasts. A rare pure form of AML M6 with erythroid precursors could be identified with MAbs against glycophorin A and Hb A.

AML M7 has a fibrotic bone marrow with more than 20 per cent blasts, abnormal megakaryocytes, and circulating blasts shown to be megakaryoblasts by their reactivity with MAbs against platelet glycoproteins, for example CD41/42/61. Bone marrow trephines are essential for diagnosis if there are insufficient blasts to examine with MAbs. Electron microscopy shows that the megakaryoblasts contain peroxidase activity in their nuclear membranes and endoplasmic reticulum. Both M6 and M7 are associated with a poor prognosis.

A subtype of AML seen in children with Down's syndrome has been described as a transient myeloproliferative disorder. If they develop acute leukaemia this is often megakaryoblastic in type.

Other rare forms of AML, acute basophilic leukaemia, acute panmyelosis with myelofibrosis (which may be indistinguishable from AML M7), and myeloid sarcoma (a myeloid tumour developing in an extramedullary site) are now incorporated in the WHO classification (Table 4).

AML with multilineage dysplasia

This form of AML is seen mainly in elderly patients and is defined by the presence of dysplasia in the three bone marrow lineages: granulocytic, erythroid, and megakaryocytic. Chromosome abnormalities, gains or losses, involving chromosomes 7 (–7,7q–) and 5 (–5,5q–), are common. These cases include those evolving from a myelodysplastic syndrome (**MDS**) or arising apparently *de novo*. The key element to distinguish from MDS is the presence of more than 20 per cent blasts in the bone marrow.

Therapy-related AML and MDS

This new category recognized in the WHO classification results from the increased number of patients developing AML and MDS following therapy for other malignancies. Two major types are recognized:

1. *Related to therapy with alkylating agents*. These cases occur late, 5 to 6 years following exposure. A phase of MDS often precedes AML. Morphologically, these cases have trilineage dysplasia and are difficult to classify in the types listed in Table 4. Abnormalities of chromosomes 5 and 7 are also common.
2. *Related to therapy with topoisomerase II inhibitors*. This form of AML is seen in patients treated with drugs targeting topoisomerase II, such as etoposide and teniposide, and also with anthracyclines. It has a short period of latency, usually from 12 to 50 months (median 33 months) and is rarely associated with MDS changes. Chromosome abnormalities often involve the *MLL* gene, e.g. t(9;11) and t(11;19), and also t(8;21), inv(16), and t(6;9).

Acute lymphoblastic leukaemia

ALL represents the clonal proliferation of immature lymphoid precursors. The characteristic cell is the lymphoblast, which has a high nuclear to cytoplasmic ratio and usually lacks cytoplasmic granules. Staining reactions with MPO, Sudan Black B, and ANAE are negative. Evidence of lymphoid differentiation towards a B or T lineage is provided by immunological markers (Table 2), including a positive terminal deoxynucleotidyl transferase (**TdT**) response.

In the morphological groups described by the FAB group, L1 is seen in 80 per cent of childhood cases, L2 in 20 per cent, and L3 (or Burkitt type) in 1 to 3 per cent. However, only the latter—which corresponds to membrane Ig-positive B-lineage ALL and has the same chromosome translocation, t(8;14), as Burkitt lymphoma—remains as a morphological/pathological entity described as Burkitt leukaemia/lymphoma (Table 5). The L1 and L2 types are no longer taken into consideration for classification purposes.

The current classification of ALL takes into account the cell lineage, B or T, which is based on the sequential appearance of B- and T-cell antigens during differentiation (Table 2), and distinct and consistent abnormalities that define discrete forms of the disease (Table 5). The immunophenotype of ALL correlates at the DNA level with the rearrangement of the immunoglobulin heavy-chain genes and T-cell receptor (**TCR**) genes in the B and T lineages, respectively. This type of analysis is not necessary for diagnosis or classification purposes, but it is important for monitoring minimal residual disease. Molecular techniques, such as PCR and FISH analysis, on the other hand, are also becoming more informative for the detection of rearranged genes and chimeric mRNA involved in the specific chromosome abnormalities of ALL.

Precursor B-lineage ALL

This is more frequent in children and the elderly. In infants with precursor B-ALL, there is a strong association with translocations of the *MLL* gene, which confers a poor prognosis.

An important marker of the B lineage is the common-ALL antigen recognized by MAbs of the CD10 cluster. CD10 is expressed in the blasts of 75 per cent of childhood ALL cases. Less mature lymphoblasts (early or pro-B ALL) do not express CD10, and this is seen in 10 per cent of childhood cases and in 30 per cent of adult patients. Pre-B ALL blasts express cytoplasmic μ chains (without light chains).

The various forms of B-lineage ALL have distinct prognostic features that are best characterized by the associated chromosome abnormalities (Table 5). The best two prognostic groups of precursor B-ALL defined by cytogenetic/molecular rearrangements are t(12;21)(q21;q22) and hyperdiploidy (51–65 chromosomes). The t(12;21) translocation is the most common, found in 25 per cent of cases, but it is difficult to detect by conventional cytogenetics and needs FISH analysis or Southern blotting to identify rearrangements of the *TEL* gene. Recent data show that at 5 years' follow-up the event-free survival of children with *TEL* rearrangements is 91 per cent. Similarly, 85 per cent of children with ALL and 51 to 65 chromosomes can be cured with current protocols. One of the possible explanations for this high cure rate is the propensity of lymphoblasts from hyperdiploid cases to undergo apoptosis.

The translocation t(1;19) is associated with the expression of cytoplasmic μ chain and immunologically it corresponds to a pre-B precursor. Although formerly associated with a poor prognosis, this has improved with newer modalities.

Poor prognosis in patients with ALL is associated with two molecular events: *MLL* rearrangement and the *BCR/ABL* fusion gene (Table 5). The *MLL* gene is rearranged in several translocations. The most common in infants is t(4;11)(q21;q23); this event is now known to occur before birth. The t(4;11) translocation is seen in 4 to 8 per cent of adult cases of ALL, 3 to 5 per cent of childhood ALL, and in up to 70 per cent of infants with ALL.

The t(9;22), which results in a short chromosome 22, the Philadelphia (**Ph**) chromosome, and the associated *BCR/ABL* fusion gene, increases in frequency with age. In childhood ALL up to 5 per cent of cases have been reported, but 25 to 30 per cent of adult patients with ALL have the translocation. There are important subtle differences between children and adults. In the latter, 50 per cent of the *BCR/ABL* fusion results in a p210 chimeric protein (as in all cases of Ph-positive CML), whilst in childhood ALL the common product is p190. In addition to the higher incidence of t(9;22) in adult ALL, their poor prognosis is compounded by the rarity of hyperdiploidy and of the t(12;21) translocation.

Precursor T-lineage ALL

T-lymphoblasts are defined by several T-cell markers (Table 2). In about one-third of cases, chromosome translocations involving the *TCRa/d* loci at 14q11 and the *TCRb/g* loci at 7q34. Examples are t(1;14)(p32;q11) involving the *TAL1* gene, t(10;14)(q24;q11) with the *HOX11* gene, and t(11;14)(p13;q11) involving the *RBTN2* gene. In 25 per cent of cases of T-ALL the *TAL1* locus (1p32) is dysregulated by submicroscopic deletion.

Precursor T-ALL comprises 15 per cent of childhood ALL and is more common in adolescents and males. In adult ALL it comprises 25 per cent of cases. Disease characteristics are a high WBC, large mediastinal mass, and less involvement of the bone marrow than precursor B cases.

Burkitt leukaemia/lymphoma

This leukaemia represents the leukaemic presentation of Burkitt lymphoma and is defined by evidence of membrane immunoglobulin (heavy and light chains); it is associated with L3 morphology and the translocation t(8;14)(q24;q32). In adults it may also represent the transformation of a pre-existing follicular lymphoma; in such cases t(8;14) coexists with t(14;18), but this is rare. The lymphoblasts have a deep basophilic cytoplasm and prominent nucleolus. L3 blasts are TdT- and CD34-negative and CD19-, CD20-, and CD22-positive; CD10 may be expressed, although it is more frequently absent.

Patients present with bulky disease and, biochemically, a high lactate dehydrogenase (**LDH**) level. Prognosis has now improved with very intensive protocols of short duration.

Biphenotypic acute leukaemia or acute leukaemia of ambiguous lineage

The wider use of MAbs has brought to light the existence of cases in which markers of different cell lineages (usually B and myeloid) are coexpressed on the same blast cells. Many of the markers used for defining the immunophenotype of acute leukaemia are not always lineage-specific. Hence, it is necessary to use restrictive criteria to define as 'biphenotypic' those cases that coexpress two markers of which at least one is lineage specific, for example: CD22, CD79a, and μ chain for the B lineage; CD3 for the T lineage; and MPO or CD117 for the myeloid lineage.

Some cases of biphenotypic leukaemia have all the features of ALL but coexpress two or more myeloid markers. Others present as typical AML and, in addition to myeloid antigens (Table 2), they express TdT and two or more B (or rarely T) antigens. Biphenotypic leukaemias may represent up to 5 per cent of all acute leukaemias and frequently show rearrangement of immunoglobulin and/or *TCR* genes, even in cases presenting as AML. Because of the distinct biological and molecular changes and current poor prognosis associated with these cases, it is relevant to recognize biphenotypic leukaemia as a distinct type using well-defined criteria. Cytogenetic changes include t(4;11) and other 11q23 abnormalities as well as t(9;22), which may explain the overall poor prognosis.

Chronic leukaemias

These are malignancies in which mature leucocytes are the predominant cells. As in the acute leukaemias, there are two main groups: myeloid and lymphoid, with two representative disorders, chronic myelogenous (**CML**) and chronic lymphocytic (**CLL**) leukaemia. The latter, as well as the less common forms of leukaemias of mature B and T lymphocytes, are described in Chapter 22.3.5. The chronic myeloid leukaemias reflect granulocytic or monocytic differentiation, or a combination of both: myelomonocytic (Table 6).

CML (Ph-positive)

CML (or CGL) has a distinct chromosome marker, the Ph chromosome, resulting from the reciprocal translocation t(9;22), found in 95 per cent of cases. Cases with similar haematological features, but which are cytogenetically Ph-negative, often have the same molecular rearrangement that results from the juxtaposition of the *BCR* and *ABL* genes to form a hybrid *BCR/ABL* gene. Understanding of the molecular biology of CML leads to significant advances in treatment (see Further reading

list).

The diagnosis of Ph-positive CML can be established by the morphological appearance of peripheral blood and bone marrow films, and confirmed by cytogenetic and/or molecular analysis. The leucocyte differential count in CML shows the full spectrum of granulocytic cells but with a predominance of myelocytes (about 30 per cent) and mature neutrophils (about 50 per cent), as well as almost invariably basophilia (approximately 5 per cent) and frequent eosinophilia; the percentage of monocytes is low, usually less than 3 per cent. Blasts represent 1 or 2 per cent of the circulating cells unless the disease is in accelerated phase or in transformation; myelodysplastic changes are minimal. The bone marrow aspirate is hypercellular with granulocytic hyperplasia and numerous megakaryocytes, and is less useful than the peripheral blood for a differential diagnosis between CGL and the other chronic myeloid leukaemias. The myeloid:erythroid ratio is greater than 10:1 with few erythroblasts. The bone marrow trephine is necessary to assess the degree of fibrosis and, occasionally, to distinguish from idiopathic myelofibrosis.

Atypical chronic myeloid leukaemia (Ph-negative)

Patients with high leucocyte counts who are Ph chromosome-negative (and *BCR/ABL*-negative) represent a slightly heterogeneous group. Most cases have atypical morphological features compared with those with Ph-positive CML: namely, slight monocytosis, absence of basophilia and eosinophilia, granulocytic dysplasia (Pelger and hypogranular neutrophils), and 2 to 3 per cent circulating blasts.

Chronic myelomonocytic leukaemia (CMML)

CMML has features of MDS and myeloproliferative disorders. The two main differences with atypical CML and Ph-positive CML are the proportion of monocytes, which ranges from 25 to 50 per cent in CMML, and the lower percentage of immature granulocytes (5–10 per cent) in the bone marrow. The erythroid cells in the bone marrow are also more prominent in CMML, with a lower myeloid:erythroid ratio than in the other conditions. CMML cases are always Ph-negative and *BCR/ABL*-negative, and show moderate to high levels of serum and urinary lysozyme and myelodysplastic changes in the bone marrow. The WHO includes CML in an MDS/myeloproliferative grouping and no longer purely as MDS.

Rare forms of chronic myeloid leukaemia

Chronic neutrophilia

This occurs in adults over 50 years of age. Haemoglobin and platelet counts are normal. The blood film shows predominantly neutrophils without immature forms. The neutrophil alkaline phosphatase score is high, in contrast with the very low levels in classic Ph-positive CML. Most cases were thought to be Ph-negative. Recent evidence suggests that some cases have the t(9;22), but, in contrast to CML, the *BCR/ABL* rearrangement results in a p230, rather than a p210, protein product.

Juvenile CMML

Juvenile chronic myelomonocytic leukaemia represents 2 per cent of the childhood leukaemias. Patients are under 5 years of age and have systemic symptoms. In contrast to CML, there is monocytosis without basophilia or eosinophilia. Characteristically, the levels of fetal haemoglobin are high. Cytogenetic analysis is important to distinguish juvenile CMML from Ph-positive CML in childhood and from the myelodysplastic syndrome with monosomy 7 seen in young children.

Chronic eosinophilic leukaemia (CES)

CES is now included together with the hypereosinophilic syndrome because a clear distinction between these conditions is currently not possible. A comprehensive review of the topic has recently been published (see Further reading list).

22.3.3 Acute lymphoblastic leukaemia

Philip J. Burke

Acute lymphoblastic leukaemia (ALL)

Some 40 years ago prednisone and vincristine were found to be effective in reducing visible leukaemia in children with ALL. The concepts of remission, consolidation, and maintenance therapies for all leukaemias evolved from trials in this disease, and until now have been the mainstay of tumour control strategies. Although the outcome in children has been excellent, outcomes in adults have so far been discouraging. However, with improved support, thereby permitting more intensive treatment modalities, the survival rate in patients at obvious poor risk has improved. Unfortunately, a significant increase in the cure rate without untoward early and late toxicity is unlikely using currently available drugs.

It is unclear how best to increase the cure rate in older patients. Real improvement may lie in applied molecular biology aimed at specific genetic targets. Subset identification will help to resolve the question of risk versus benefit in individual patients. The next step will be to obtain evidence supporting biological intervention with specific novel agents. The most appropriate candidates for study are patients with minimal leukaemia after initial tumour reduction and bone marrow homeostasis.

Diagnosis

Classically, acute lymphoblastic leukaemia has been categorized by morphology. There are three groups in the French–American–British (**FAB**) carcinoma staging classification, with L1 being defined by small monomorphic cells, L2 by large heterogeneous cells, and L3 by a Burkitt's cell-type with vacuoles. These distinctions are not as definitive as for acute myeloblastic leukaemia (**AML**), but flow cytometry has relieved some of the confusion with identification by phenotype. A prognosis in ALL can now be more accurately assigned with the addition of both immunophenotyping and cytogenetics (Table 1). Some 20 per cent of ALL are T cell, 75 per cent are precursor B cell, and 5 per cent are mature B cell in origin. In adults, 35 per cent of cases express both lymphoid and myeloid antigens. These more immature subtypes, early-pre-B-ALL and pre-T-ALL occur more frequently in adults than in children. Classification by immunological subtype is reviewed in Chapter 22.3.2. In brief, early pre-B-ALL expressing HLA-DR, terminal deoxynucleotidyl transferase (**TdT**), and CD19 occur in 10 per cent of adults and 5 per cent of children. Common ALL, found in 50 per cent of adults, is characterized by CD10 and CD19. Some 15 per cent of ALL are pre-B with expression of a cytoplasmic immunoglobulin absent in common ALL.

The T-cell phenotype is present in 25 per cent of adult ALL, with CD7, CD2, and/or CD1. In most, the T-cell receptor gene is rearranged. Bilineage or biphenotypic hybrid leukaemias which express both lymphoid and myeloid antigens account for 35 per cent of adult cases.

Cytogenetic analyses of lymphoblasts reveal clonal chromosomal aberrations in 50 to 75 per cent of ALL. Most are structural abnormalities with a balanced translocation. Other more random aberrations are classed by chromosomal number—hypo- or hyperploidy. This syndrome identification confers prognosis for outcome with standard therapy.

Pathophysiology

Clinical manifestations

The pathophysiology of ALL is the consequence of bone marrow failure caused by tumour-related suppression of normal haemopoiesis and the clinical expression of the malignant clone. The growth of lymphocytic precursors arrested at an immature stage of differentiation suppresses production of the normal bone marrow elements, resulting in anaemia, infection, and bleeding. Circulating leukaemic cells infiltrate the central nervous system, liver, spleen, testes, ovary, lymph nodes, skin, and gastrointestinal tract. Diffuse lymphadenopathy and hepatosplenomegaly occur in half the cases. Varied degrees of failure of each organ, and the metabolic effects of increased cell turnover, contribute to the overall symptom complex at presentation. Centripetal joint swelling and bone pain with rheumatic symptoms in the adult contrast with the distal bone involvement seen in children. Punched out bony lesions may be present on the radiograph.

In children, the history of a recent severe upper respiratory infection is frequently elicited. Although evidence for a viral aetiology is sketchy, immune stimulation may lead to proliferation of B-cell precursors. There are models in the lymphomas with similar theoretical pathogenesis.

Failure to obtain disease remission late in therapy involves either failure of support or tumour resistance, while early mortality relates to the pathophysiology of the tumour and its immediate management.

Infection

As seen with AML, clinical signs and symptoms are those of bone marrow failure and tumour mass, but because of a lack of normal lymphocytes there is an associated immunosuppression in addition to neutropenia. This loss of immune surveillance places the patient at risk for infections unique to the immunocompromised host. In addition to the infectious agents encountered in the myeloid malignancies with granulocytopenia, nosocomial and parasitic infections, such as *Pneumocystis carinii* and atypical fungal organisms, must be suspected with each new fever. Since therapy is prolonged in ALL, consistent monitoring for pathogenic organisms is necessary even during remission (Chapter 22.3.4).

Lymphoblastosis

The immediate challenge at presentation is the diagnosis of the leukaemia presenting with a high white blood cell (**WBC**) count. Acute causes of an increased WBC count which may be mistaken for lymphoid leukaemia include the FAB classifications M0 and M7 of acute myelocytic leukaemia, chronic myelocytic leukaemia, and chronic lymphocytic leukaemia.

The WBC can range from zero to more than 100×10^9/l, with a count of less than 5×10^9/l in 25 per cent of patients. The need for immediate intervention is less urgent with lymphoblasts because they are relatively small and deformable compared with young myeloid cells, lessening the probability of hyperviscosity. Their

rupture with chemotherapy, however, releases high levels of phosphates and urates which can cause tumour-lysis syndrome unless precautions are taken. An approach to hydration, leukapheresis, and possible early dialysis is reviewed in Chapter 22.3.4. If the diagnosis remains in doubt after slide review, flow cytometry will quickly distinguish between myeloid and lymphoid cells. The untoward effects of inappropriate chemotherapy prior to leukapheresis and fluid balance must be avoided in ALL.

Occasionally (less than 5 per cent of patients) the differential count shows reactive myelopoiesis with pseudo Pelger–Huët cells, but without circulating lymphoblasts. Normal lymphocytes may be absent. A bone marrow aspirate will provide the diagnosis in these cases of subleukaemic leukaemia.

Prognostic factors

Although statistics indicate considerable improvement in the treatment of adult ALL over the past decade, the majority of patients relapse and die of their disease. Certain subsets of patients are predicted to respond poorly with current therapies. For example, those with leukaemia characterized by the Philadelphia chromosome (Ph_1) or its molecular equivalent, the fusion gene *BCR–ABL*, have essentially no chance of cure without allogeneic bone marrow transplantation. Even then, only 40 per cent of patients who achieve remission will be cured.

Other adverse prognostic factors include over 60 years of age, WBC in excess of 30×10^9/l, absence of a mediastinal mass, L3 morphology, myeloid phenotype, and lack of expression of CD10. Combinations of these markers decrease the predicted survival. In one trial, the presence of three high-risk factors in B-lineage ALL decreased the 1-year survival rate from 75 per cent (one risk factor present) to 25 per cent. There were no long-term survivors among patients with four risk factors.

The strongest variable, genetic identification, now provides a reliable basis for assigning risk and selecting therapies (see cytogenetic and phenotypic classification, Chapter 22.3.1 and Chapter 22.3.2). Patients known to do poorly with childhood-type strategies, usually those with the chromosomal anomalies t(9;22), t(4;11), t(8;14), or 14q 11–13 (T-ALL), now respond to intensive initial treatment schedules.

Management

Therapy

The highly successful treatment of ALL in young children combines numerous drugs known to be active against malignant lymphoblasts. Therapy consists of a three-phase treatment induction, CNS prophylaxis, and maintenance. Induction therapy with prednisone, vincristine, L-aspara-ginase, and daunorubicin produces remission rates of 85 per cent. Maintenance therapy with 6-mercaptopurine, methotrexate, cyclophosphamide, and prednisone is given in a cyclical fashion for 2 or more years.

In contrast, complete remission (**CR**) rates in adults with ALL range from 65 per cent to 85 per cent, the time to remission is longer, the relapse rate is higher, and cure rates are between 20 per cent and 40 per cent. Multiple factors related to both the biology of leukaemic cells and ability of the host to tolerate treatment contribute to the inferior prognosis in adults as compared with childhood ALL.

A variety of strategies are designed to decrease the relapse rates in adults. Early intensive therapy to rapidly destroy more leukaemic cells that have not yet developed drug resistance is a logical approach. Increasing induction intensity with sequential high-dose cytotoxic agents results in an improved long-term outcome in poor-risk groups. In recent studies, the addition of early intensification therapy, particularly a timed sequence of daunorubicin and cytarabine, effectively prolongs remissions and prevents relapse. This approach in children results in a CR rate of 95 per cent, with 70 per cent of children remaining in CR beyond 5 years.

Intense therapy derived from AML models, given early in remission (consolidation) using drugs not previously employed and at high doses, effectively destroys residual leukaemic cells. Cyclophosphamide and cytarabine are examples of AML drugs of obvious value which are now better tolerated, and with a greater therapeutic advantage provided by effective support measures. The role of colony-stimulating factors remains unclear.

The present investigative approach focuses on intensification of therapy in all subgroups with ALL. Repeatedly given high-dose drugs rapidly reduce tumour mass, reduce the possibility of drug-resistance, and invade sanctuary sites to eliminate sequestered cells. With these more aggressive therapies, CNS relapse in adults is less than 5 per cent.

However, in contrast to the experience with two short, intensive courses in AML, long-term success in ALL requires prolonged chemotherapy with multiple courses similar to present lymphoma regimens. Long-term maintenance therapy remains standard in most group trials but long-term value is not proven (Table 2).

The model of high-dose chemotherapy is intense induction followed by bone marrow transplantation (**BMT**). The optimal indications for BMT in adult ALL remain to be determined. While a definitive role of allogeneic BMT during first remission in patients with high-risk features has been established, significant controversy exists regarding the indications for BMT in patients with standard-risk adult ALL. Autologous BMT has a failure rate similar to that of high-dose chemotherapy.

High-dose treatment in poor-risk patients with ALL

Below are examples of cytogenetically poor-risk groups of ALL which respond to aggressive therapies:

1. ALL-L3 (B-ALL) treated with intensive therapies with high doses of five drugs (vincristine, doxorubicin, cytarabine, methotrexate, cyclophosphamide) given in short repeated cycles now achieve CR rates of 70 per cent with 50 per cent long-term survival rates in patients with this rare (5 per cent) leukaemia. CNS prophylaxis with high-dose systemic therapy or intrathecal drugs is essential.
2. t(4;11) ALL with a pro-B-cell phenotype occurs in 5 per cent of adults and infants. Intensive therapy with high-dose cytarabine and mitoxantrone has improved the dismal outcome, with a predicted 50 per cent disease-free survival. Bone marrow transplantation is a reasonable alternative therapy.
3. t(9;22) ALL with *BCR–ABL* fusion gene occurs in 30 per cent of adults; 50 per cent of adults with B-lineage surface antigens have this fusion protein p190, in contrast to the p210 subtype of CML. Although remission rates of 75 per cent can be achieved with intensive therapy, even with BMT the relapse rate is between 40 and 80 per cent.
4. t(1;19), 11q23, t(12;21) are specific syndromes which have also demonstrated a significantly improved outcome with aggressive treatment.

Allogeneic bone marrow transplantation in poor-risk patients is a reasonable choice, since the median age in adults is 33 years. Relapse after BMT is 30 per cent, with a 15 to 20 per cent mortality from immediate and late toxicities.

With present support and intensive treatment, most patients can achieve a stable and durable remission. Most will relapse with resistant disease. A continued search for new approaches to the treatment of such patients with these non-random subsets of ALL is critical.

Proto-oncogene leukaemogenesis (seeTable 1)

Most of the lymphoid malignancies appear to be related to oncogene rather than tumour-suppressor malfunction. Oncogenes direct the synthesis of products that contribute to the malignant transformation of a cell. When a genetic alteration activates a particular proto-oncogene, it is implicated in malignant transformation. The mechanisms may also involve either a point mutation or insertional mutagenesis. The most mechanistically defined are those syndromes related to visible translocation of proto-oncogenes to active promoter sites, a coupling that results in production of a unique protein or overproduction of the normal product. The diseases may also be associated with a single-point mutation in cells committed to specific lineage. A number of the leukaemias have been fully characterized. Minimal numbers of leukaemia cells are quantifiable by detection of the residual fusion gene with the polymerase chain reaction.

Measuring cause and change in these specific and cytotoxic drug-responsive leukaemias may determine and remedy the oncogenic mechanism, and establish models for treatment strategies in similar, but less definable, tumours.

Regulation of lymphoid-cell growth

Biological modifiers of lymphoid-cell proliferation are being sought for therapy. These are best understood by reviewing the normal regulation of cell growth and survival. The proliferation and maturation of lymphocytes is ultimately determined by peptide growth factors that bind and activate specific receptors. These activated receptors propagate the signal through a series of protein interactions to the cell nucleus where the signals are converted into predetermined responses. Proto-oncogenes encode growth factors and growth-factor receptors, transcription factors, and cell-cycle proteins that determine the level of gene expression. Abnormalities of these functions are produced by genetic change in haematological malignancies.

The rate of proliferation versus its maturation and normal programmed cell death by growth factors is determined by the cell. In the nucleus, low levels of MYC cause apoptosis (cell death) in response to cytokines. MYC is an intracellular protein ordinarily sequestered in the cytoplasm by the retinoblastoma suppressor protein (**Rb**). MYC protein, functioning in the nucleus as a heterodimer with another molecule, MAX, regulates transcription and therefore gene expression and cell survival. BCL-2 allows MYC to drive the cells to proliferation by blocking the pathway to cell death, determining the ultimate expansion of the cell population. This activity of BCL-2 is balanced by an opposing protein, BAX, whose activity as a dominant regulator of BCL-2 is increased by expression of P53. P53 overcomes the BCL-2 block of cell death and inhibits cell-cycle traverse of mutated or damaged DNA. It blocks cyclin-dependent phosphorylation, forcing DNA repair, or apoptosis if repair is faulty. For example, elimination of excess lymphoid cells activated by antigenic stimuli via the programmed cell-death mechanism is a physiological event involved in normal immune responses.

The initial aim of intervention in the lymphoid tumours is to downregulate the overexpressed gene *BCL2*, and to force apoptosis in patients with leukaemias defined by this *BCL2* abnormality. In those without specific abnormalities in gene translocation and protein production, the transfer of lymphocytes to upregulate cytoplasmic antigens for tumour-specific attack is a testable thesis.

Novel agents

A few of many targets for investigation in patients with senescent leukaemia in remission are listed below. See Table 5 of Chapter 22.3.4 for a wider list of potential agents.

Drug resistance

Although most leukaemias are responsive to initial therapies, most patients relapse and die of drug-resistant disease. The refractory clone, either acquired or selected with chemotherapy, contains the multidrug resistance gene and its encoded 170-kDa P-glycoprotein. This mechanism may also protect normal bone marrow stem cells from cytotoxicity. Drugs that modulate the effect of this gene—the rapid pumping out of drug from the cell—are calcium-channel blocking agents such as verapamil and ciclosporin-A.

Telomerase

Telomeres are structures at the ends of chromosome which in normal cells progressively shorten with each cell division. Without telomerase action terminally short telomeres cause cell-growth arrest. Suppression of telomerase is a tumour-suppressor and ageing mechanism. In contrast, most cancer cells activate telomerase, resulting in stable telomeres and immortalization. Normal stem cells may express telomerase in the adult, allowing perpetuation, while tumours arising from stem cells may have a similar prolongation of survival. Telomerase inhibition is a therapeutic target to force cell senescence. Since telomerase levels reflect the persistent growth of AML, measurable suppression of telomerase activity in patients with minimal residual disease in remission may force tumour senescence and cell death.

Methylation

An imbalance of DNA methylation, involving widespread hypomethylation, regional hypermethylation, and increased cellular capacity for methylation is characteristic of human neoplasia. Beginning in preneoplastic cells, it becomes extensive in subsequent stages of tumour progression. This aberrant methylation, particularly of cytosine, may mark abnormalities of chromatin reorganization and mediate progressive losses of gene expression associated with tumour development.

Abnormal methylation sites have been detected in both myeloid and lymphoid malignancies. Drugs presently in trial to prevent leukaemic transformation or suppress relapse are the butyrates and cytidine analogues.

Angiogenesis

Leukaemia-cell growth requires the aggressive infiltration of capillaries into nests of tumour in excess of that seen in normal bone marrow. Relative selectivity of this neovascularization results in selective tumour regression on administration of antiangiogenic agents. These include angiostatin, endostatin, vasostatin, and other endogenous inhibitors of angiogenesis that block the effects of vascular endothelial cell-growth factor (**VEGF**). Other drugs act to block oncoprotein function by inhibiting signal transduction, for example Ras farnesyltransferase inhibitors. Such factors will prevent blood supply to new tumour growth when given at the time of maximal leukaemia-cell reduction.

Monoclonal antibodies

Cell-surface directed approaches are now in large clinical trials with encouraging responses. Constructs aimed directly at receptors include monoclonal antibodies (MAbs) specific for the cell-surface receptors CD20, CD19, and CD33 linked with a radionuclide, an endotoxin, or an antibiotic. All have achieved early success in relatively resistant leukaemias. Unequal expression of surface receptors in the leukaemic clone may require upregulation for sensitivity.

Monoclonal antibodies have achieved utility in the treatment on lymphoma and hold promise in ALL.

22.3.4 Acute myeloblastic leukaemia

Philip J. Burke

Introduction

Efforts in leukaemia research over the last 30 years or so have been rewarded with much success. Moreover, the principles of clinical research and their application to patient care are now defined.

With the availability of effective extrinsic haemopoietic support, leukaemia-induced bone marrow failure no longer restricts the intensity of therapy necessary to achieve maximal tumour kill. Pharmacologically deter-mined drugs and schedules combined with rational concepts of maximal therapy have improved the survival rates of patients with leukaemia. The identification of tools and specific targets heralds a new era of therapy in patients with small amounts of residual leukaemia.

Many new technologies—DNA hybridization, purified specific probes, monoclonal antibodies marking lineage specificity, genetic array, and rapid measures of hybrid proteins—permit the genetic classification and identification of the origin and activity of a tumour. For some types of leukaemias, a combination of these methods provides an accurate prognosis for tumour eradication with the utilization of enhanced chemotherapy regimens and the application of new biological modalities. Single-site genetic mutations, translocations or deletions on chromosomes, loss of suppression or overexpression of genes, and transcription of an abnormal product that induces a malignant phenotype are all obvious targets for unique approaches to tumour control. Future success depends on understanding genetic multistep pathogenesis and its control, ultimately with specific interdiction of the premalignant clone.

Pathogenesis of myeloid leukaemia

There is evidence for a multistep pathogenesis of solid tumours. Similarly, many of the acute myeloid leukaemias are the final stages of clonal homeopathies initially transformed by exposure to ionizing radiation, certain chemicals, some chemotherapeutic drugs—especially alkylating agents and topoisomerase inhibitors—or by progression (for example, in certain genetic disorders).

Leukaemogenesis proceeds after the deleterious effect of a chemical or environmental agent on chromosomes. In some cases amplification or modification of the gene product then perpetuates the process. These events can be subclinical and of long duration in the prodromal stage. Progression occurs, for instance, when DNA damage is not repaired in proliferating cells which then escape programmed cell death.

The prima-facie evidence of induced genetic instability comes from the leukaemias that developed in people exposed to high-dose radiation from the Hiroshima and Nagasaki atomic bombs. A similar leukaemogenic effect of alkylating agents was manifested in 10 per cent of patients treated with **MOPP** (mechlorethamine, Oncovin (vincristine), procarbazine, prednisone) for Hodgkin's disease. These therapy-related leukaemias (**tAML**; secondary AML, **sAML**) usually have non-random genetic deletions of -5, -7, 5q, and/or 7q, while those related to topoisomerase II inhibitors (etoposides and anthracyclines) have consistent abnormalities of chromosome 11 (11q,23), and FAB 4 to 5 morphology of the French–American–British carcinoma staging classification. Many evolve from trilineage bone marrow failure (myelodysplastic syndrome, **MDS**), suggesting a genetic instability of multistep origin. These syndromes of long duration culminate in an aggressive phase with a clonal cohort that escaped DNA repair. The increasing numbers of patients with MDS reflect the cumulative effects of a series of sporadic incidents having their ultimate expression in an ageing population.

Some 30 per cent of patients have leukaemic syndromes associated with a non-random loss or gain of DNA on chromosomes 5, 7, and 8. These are stem-cell derived, trilineage tumours classified by FAB as either M_6, M_7, transformed MDS, or secondary acute myelocytic leukaemia (**sAML**). As in colon cancer, sequential genetic alterations ultimately result in metastatic malignancy. Secondary leukaemia may take years to evolve (Fig. 1). This class of haematological malignancy—the loss of a tumour-suppressor gene(s)—only transiently responds to current therapeutic modalities. However, remissions of predictable duration are achievable with intensive therapy in 40 per cent of such patients. Once stable, these genetic carcinoma-like tumours are targets for specific novel agents.

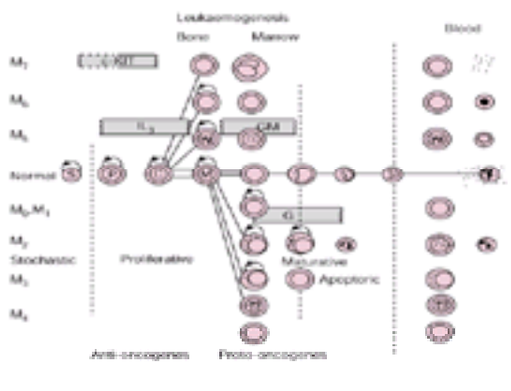

Fig. 1 Myeloid leukaemogenesis. Normal proliferation and maturation of granulopoiesis is contrasted to those leukaemias of proto-oncogene and antioncogene derivation. This is a conceptual model loosely relating FAB with a cytogenetic classification. The activities of growth factors relative to proliferation, maturation, and apoptosis are shown. The figure depicts the progression of leukaemia according to the FAB classification and ligand stimulation. During the stochastic kinetic period the stem cell reproduces itself, with some cells distributed to the committed pool in a random manner. While in this proliferative pool they are influenced by normal regulatory factors. The first legend, c-*kit*, affects the stem cell directly, with the subsequent committed cells filling various compartments. In the M7 through M5 leukaemias, this compartment consists of trilineage-derived cells. The disease reflects the activities of the cell type most prominently involved, i.e. megakaryocyte, erythrocyte, or monocyte. Leukaemias of FAB classification M1 through M3 are specifically derived from cells committed to the granulocytic pathway, while M4, a combination of monocytic and granulocytic phenotypes, is probably derived from one or more earlier cells. Normal growth factors, which modify proliferation and maturation, are c-kit, IL-3 (active early), and GM-CSF (active late) in the proliferation period; and G-CSF specifically affecting the more mature granulocytic precursors (GM-CSF, granulocyte–macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor). The resultant forms commonly released to the peripheral blood are blasts, some showing signs of maturation. The leukaemias with balanced translocations represent a loss of oncogene control, while those derived from earlier progenitors, more likely to be involved with a loss of DNA, relate to a loss of suppressor gene activity. Patients with balanced translocations or inversions comprise 20 per cent of the total AML population, while 50 per cent have grossly normal cytogenetics. Most of these are found within FAB classifications M0–5, while those antioncogene tumours with DNA loss occur in the FAB M5–7, secondary AMLs, and transformed MDS. This distribution is not absolute, and prognosis cannot be determined by FAB classification alone.

In contrast, myeloid leukaemias which occur spontaneously or with only brief incubation periods are probably clonal progeny with a single proto-oncogene, non-random genetic mutation. In these, chromosomal malfunction at the gene level follows transposition of genetic material to promoter areas and activation. These leukaemias, representing 20 per cent of all cases of AML, have either a chromosomal balanced translocation or an inversion. Some 50 per cent of patients with a normal karyotype have submicroscopic genetic mutations and overexpression. These alter nuclear oncogenes, many yet to be defined, which affect signal transduction, transcription, gene splicing, protein kinase C, and many other cellular activities.

Pretreatment management of acute leukaemia

Initial evaluation

The clinical signs and symptoms of acute leukaemia result from the suppression of normal haemopoiesis and the extramedullary expression of the malignant clone.

Bone marrow failure

Tumour suppression of the trilineage elements of the bone marrow produces pancytopenia. The signs and symptoms of anaemia result from the non-production of red blood cells, and may be associated with overt blood loss and with petechia and purpura at pressure sites in the skin. Variations in the dominance of loss of function of any the trilineage products relate to the specific type of AML (see FAB classification). Neutropenia is not commonly associated with infection in the rapid-onset subsets of AML. With a lymphoid-sparing pathogenesis, immunosuppression and its associated opportunistic infections are not frequently encountered in patients with AML. The incidence of compounding medical diseases is no greater that in the general population. Most signs and symptoms of acute multiorgan impairment disappear with adequate tumour control and homeostasis. The performance factor score is not a reliable indicator for making treatment decisions.

Extramedullary disease

A minority of patients present with a subleukaemia without circulating blast cells and require a bone marrow aspirate for diagnosis. The white blood cell (**WBC**) count may reach levels in excess of 100 000 × 10^9/l in 5 per cent of patients, although in the majority it is between 5 and 20 × 10^9/l. However, even in those patients with low WBC counts at presentation the initial decisions are urgent. Disseminated intravascular coagulation (**DIC**) can occur in promyelocytic leukaemia (M3) in young patients with pancytopenia. Emergency approaches have been designed to manage patients who will suffer the morbidity of leucostasis and tumour-lysis syndrome before and during treatment.

Diagnosis and supportive care

The advent of HLA typing, recognition of the risks of neutropenia, evidence of stem-cell resilience, availability of blood products, the acceptance of new aggressive chemotherapy regimens, recognition of genetic subsets, and identification of special training needs of staff now provide the basis for maximal levels of support for the patient presenting with acute leukaemia. These concepts of oncology care are essential for patients' survival throughout the intensive therapy required to reduce their leukaemic state to a minimum.

Support at presentation

Although the combination of bone marrow failure and tumour invasion determine the presenting clinical features of acute leukaemia, the aspects of clonal expression based on tumour mass, specific leukaemia-cell characteristics, and the rate of cell turnover determine the need for prompt intervention. Paradoxically, rapid cell killing with intensive drug treatment results in severe metabolic imbalances that are sometimes difficult to ameliorate. Survival depends on the prevention of both disease and treatment-related complications. The rational use of supportive measures combined with treatment permits both disease eradication and survival with treatment.

Immediate intervention is required in some cases. Efforts to decrease tumour mass both rapidly and safely entail awareness, rapid intervention, and aggressive treatment. Intense and appropriate critical-care management in emergency situations in patients with hyperleucocytosis, tumour-lysis syndrome, and DIC has now markedly reduced the historical early death rate of 50 per cent.

Hyperleucocytosis

Early mortality is related to the sheer mass of tumour cells. Patients with hyperleucocytic leukaemia (WBC count of more than 75 000 × 10^9/l), can suffer early death with central nervous system (**CNS**) haemorrhage and pulmonary capillary leakage sometimes due to a delay in treatment. These patients are at grave risk of vessel rupture. Clinically, high leukaemia blast-cell counts in AML and chronic myelocytic leukaemia (CML) are associated with fever and evidence of functional impairment of the lungs and brain. The most predictive sign of ongoing vascular rupture is a target purpura with a single, deep central nodule. The rigidity of the myeloblast causes stasis with expanding aggregates, arteriole infarction, and bleeding (Fig. 2 and Plate 1). Increased viscosity is offset by a concurrent anaemia. The combined haematocrit and leucocrit at presentation is usually no more than 45 per cent. Because this critical level is not exceeded unless iatrogenically increased by red blood cell transfusions, the incidence of clinical leucostasis in patients with WBC counts less than 75 × 10^9/l is low.

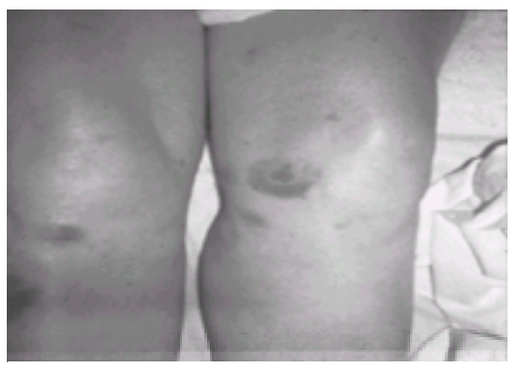

Fig. 2 Target purpura. Classic target appearance of purpura formed by infarction of an arteriole by a dividing cluster of leukaemic myeloblasts. Typically, a deep, firm nodule can be felt in the pale centre of the lesion. (See also Plate 1.)

Not all patients with an elevated WBC count are at risk of leucostasis. Those with acute lymphocytic leukaemia (**ALL**) and chronic lymphocytic leukaemia (**CLL**) are less likely to be affected, as are those with CML. Those in jeopardy are patients with myeloblasts having a high proliferative rate and short cell-cycle time. These patients form thrombi in the slow-flow microcirculation, with haemorrhage and necrosis of lung and brain tissue.

In a high percentage of patients CNS damage can be prevented with the rapid institution of a continuous infusion of high-dose cytarabine. Hydroxycarbamide (hydroxyurea) (6 g/m^2) and cyclophosphamide (3 g/m^2) are also of value in rapidly reducing the WBC count (Table 1).

Tumour lysis

An indwelling, triple-lumen catheter provides access for all necessary parenteral support throughout the treatment and recovery period. Initial platelet support and subsequent prophylactic antibiotics prevent the complications of bleeding and infection at the puncture site. Measures to allay the complications of rapid tumour kill and chemotherapy toxicity include hydration and diuresis. Allopurinol offsets the metabolic consequences of hyperuricaemia, particularly in lymphoid leukaemias, and aluminium hydroxide counters the opposing phosphataemia. The addition of bicarbonate is unnecessary. Furosemide (frusemide) given every 6 h is the critical component affecting the morbidity associated with the tumour-lysis syndrome and fluid overload. Low-dose dopamine helps to maintain renal blood flow and the

essential high urinary output. The toxicity of cytarabine when given by continuous infusion—namely, pulmonary vascular permeability—is prevented by rigorous control of the fluid balance. If major renal insufficiency does occur, then early dialysis effectively maintains the metabolic balance for the short at-risk period.

Disseminated intravascular coagulation (DIC)

An aggressive attack on ongoing or anticipated DIC has changed the dire prognosis of patients presenting with FAB M3, M3V, and occasionally M2 to M4 and M_5 myeloid leukaemias. Prophylactic infusion of heparin at 10 units/kg per hour in patients with M_3 and M_3V disease, together with close monitoring of changes in the prothrombin and partial thromboplastin times, fibrinogen, fibrin degradation products, and the platelet count, will prevent haemorrhage in these ultimately long-term survivors. Ongoing platelet consumption is countered with platelet infusions to maintain counts in excess of 50×10^9/l, and heparin to prevent the fibrinogen level from falling below 100 mg/ml. Some centres depend more heavily on the use of cryoprecipitate infusions.

Bleeding as a result of low-dose anticoagulation is seldom encountered; the risk of fatal haemorrhage is far greater without its use. This syndrome of DIC is driven by tumour-cell destruction, and should be monitored and treated throughout the initial days of chemotherapy. The WBC count will fall to 10 per cent of the presenting count within 72 h. The major cause of morbidity is any delay in the institution of leukaemic treatment.

Fever

At initial presentation, fever is related either to disease progression (B signs) or caused by a sensitive Gram-positive organism. Opportunistic and Gram-negative organisms and parasites are uncommon in patients with AML prior to their initial therapy. However, if a patient has been previously treated, the manifestations and organisms previously encountered must be anticipated.

Prophylactic antibiotics

If the patient is afebrile, prophylaxis is begun with an oral antiviral agent and vancomycin to prevent the first fever, most frequently caused by *Staphylococcus epidermitis* and/or *Corynebacterium* spp. This approach prohibits the use of empirical Gram-negative antibiotics for up to 5 days. The guidelines for antibiotic use at the Johns Hopkins' Oncology Center (**JHOC**) are outlined in (Table 2).

Laboratory monitoring

Laboratory data for tumour lysis, DIC, and chemotherapy-induced organ toxicity are determined daily until after tumour clearance, then twice a week.

Blood products

Once the WBC count is less than 50×10^9/l the haematocrit is maintained above 24 per cent. If evidence of bleeding and platelet deficiency is present on admission, and to anticipate DIC in all patients with AML, the platelet count is maintained at 50×10^9/l until measurements are reviewed and the leukaemia stabilized.

Hyperalimentation

Nausea and vomiting associated with intensive induction therapy limits a patient's oral intake to less than 500 calories/day. Parenteral feeding provides nourishment for normal bone marrow stem-cell regrowth and decreases the mitotic activity of the villus crypt cells of the gut, thereby eliminating them as a target for DNA synthesis-dependent drugs.

Three-step treatment

The immediate goal of therapy is to alter disease progression and stabilize the biology in favour of the patient by eradicating leukaemia and restoring bone marrow homeostasis. Currently, the use of potent chemotherapeutic agents is the first-choice therapy at diagnosis. Early and aggressive therapy, in contrast to the so-called 'standard' regimens, greatly improves survival.

Reviews of large randomized studies confirm that early intensive therapy with the few available drugs used at full dose cures a growing percentage of patients with myeloid malignancies, while providing a period of meaningful survival for many others (Table 3). This approach calls for an initial aggressive reduction of a large tumour mass with cautious management of tumour and therapy-related physiological instabilities, as well as chronic biological infirmities (stroke, myocardial infarction, DU, emphysema, etc.). When followed by greater intensification in remission this two-course sequence of rapid high-dose cytotoxicity results in a 40 per cent long-term survival in definable, selected populations. The key second course eliminates leukaemia in some, or substantially reduces it to small amounts in others, resulting in measurable and anticipated stable periods prior to relapse. These subgroups of patients with predicted outcomes furnishes the model for studies of novel therapeutic agents. Once homeostasis has been re-established and the patient is in remission, further interventions with novel agents are warranted in all groups, since there is a risk of relapse in all such patients. Many varied approaches now exist, or soon will, which are non-cytotoxic innovative modalities based in new biology.

Management of induction therapy—step 1

Drugs and dose

Variables predicting early failure must be taken into account when clinical instability is identified in patients presenting with leukaemia. However, since a delay in intervention is frequently not a valid option, it is important to select a dose schedule that provides stability and some therapeutic advantage based on the anticipated duration of bone marrow failure. The use of a moderately intense induction regimen (compared to the aggressive second course in remission) has reduced the clinical failure rate in successive studies. Examples of some two-step therapies are given in Table 4.

Support in remission

The interval between remission and the second course of therapy should be long enough to allow the patient to fully recover from all untoward consequences of the induction treatment. Those with FAB 1 to 5 disease usually recover without sequelae within a month, whereas those patients with FAB 6 to 7, SAML, and transformed MDS may be slower to recover. Any infections, but most importantly previous fungal infections, require treatment with appropriate antibiotics/antifungal agents prior to the patient receiving further chemotherapy: the use of amphotericin B will prevent the recurrence of fungal infections during the second course of therapy. On admission to hospital, patients should be treated with prophylactic antibiotics, since past infections in the patient will recur (Table 2).

Management of augmentation therapy—step 2

Intensive chemotherapy

Until recently it was assumed that cures could only be achieved in AML with therapy that destroyed both leukaemic and normal host bone marrow tissues. Requiring bone marrow transplanted from a suitable donor, this strategy is the ultimate aggressive single-course therapy. Although a high cure rate is apparent in those patients surviving allogeneic bone marrow transplantation, its application is limited by the age and availability of a suitable donor.

Another approach considers the infinite character of the bone marrow stem cell. With the development of four drugs effective in the treatment of AML, and the exploration of more intensive therapy, evidence accumulates that cures can be attained. Central to the success of these intensive regimens is the relative resistance of the host progenitor haemopoietic cell to tumoricidal doses of drugs. Such aggressive therapies contrast with those based on some of the principles developed in rodent lymphoid models and extrapolated to trials in children with lymphocytic leukaemia. These regimens initially reduce the tumour bulk to levels allowing the recovery of normal haemopoiesis, but they require continued long-term treatment to suppress tumour regrowth. These approaches using low-dose drugs are generally effective for only short periods in patients with AML. Conceptual change, using intensive high-dose therapy to eradicate residual leukaemia after its initial reduction,

has prompted a number of successful innovative studies that have matured sufficiently to allow comparison of the two approaches.

Patients with good-risk prognostic factors—normal genetics or balanced translocations with core-binding transcripts—are candidates for intensive non-ablative chemotherapy in remission. The data strongly support the use of a brief exposure to an intense regimen, high-dose cytarabine (**HDAC**) or timed sequential therapy (**TST**), which, with one or two courses, produce significant improvements over lesser therapies. There is no role for 'maintenance' therapy with similar cytotoxic drugs after the recovery of normal bone marrow function.

Alternately, patients with poor-risk prognostic factors (that is to say, genetic loss of a tumour suppressor) or with negative prognostic factors are candidates for bone marrow transplantation with stem-cell ablation.

Bone marrow transplantation (BMT)

The outcome, availability, and technology for BMT have all improved, and the indications for its use have increased in recent years. The number of bone marrow transplants performed annually has increased 10-fold since 1985, when essentially all transplants were allogeneic; 60 per cent are now autologous and 50 per cent use sources of stem cells other than from bone marrow.

Non-myeloablative BMT regimens are now used to produce mixed donor chimerism instead of full donor engraftment. This approach (referred to as 'minitransplants' or 'transplant-lite') can serve as a foundation for adoptive immunotherapy with donor lymphocyte infusions against leukaemias.

T-cell depletion and intensive immunosuppression can successfully prevent graft-versus-host disease, but these approaches are associated with an increased frequency of Epstein–Barr virus-associated lymphoproliferative disease.

High-dose cytotoxic therapy followed by BMT produces high response rates, prolongation of survival, and cures in some patients. It is indicated in patients with AML who are at risk of a poor response to non-ablative intensive chemotherapy. Autologous transplantation procedures are not as successful as intensive non-ablative chemotherapy.

Limitations of two-step treatment

Currently available drugs allow the most aggressive therapy to be rationally applied, and meaningful survival achieved. These brief intensive treatments aimed at leukaemia cure include doses of active drugs given to host tolerance levels, although some patients will require bone marrow rescue. Initial tumour reduction with a less intense regimen is followed by a more aggressive tumour-ablative treatment in a medically stable patient with normal bone marrow function. In an attempt to further reduce the amount of leukaemia while preserving host recovery capability, this approach, as in the ablative therapy for BMT, produces a large tumour kill while sparing host stem cells.

However, much more needs to be done for treating patients with all subsets of leukaemia. Only 70 per cent of adults with AML achieve complete remission (**CR**) following cytotoxic therapy. Further intensive chemotherapy or BMT during a patient's early first complete remission results in a longer than 5-year disease-free survival (**DFS**) in 35 to 50 per cent of adults treated in this manner. However, 30 per cent of all newly diagnosed AMLs are primarily refractory to induction therapy, in particular those evolving from myelodysplastic syndrome (**MDS**), an antecedent haematological disorder, and those linked to environmental/occupational exposures, including the secondary AMLs. The myelodysplastic syndrome-associated AMLs occur in older adults (over 60 years of age). Current treatment approaches to these AML variants yield CR rates of 40 per cent or less (however, the CR is brief, at less than 12 months), and low cure rates even with BMT.

At present, the cure rate for all adult acute leukaemias is only between 25 and 30 per cent. New approaches are needed to improve the clinical outcome of those adult leukaemias which are refractory to current therapeutic modalities.

Elimination of senescent leukaemia—step 3

New strategies with biological agents will test current approaches in all patients with minimal residual leukaemia. These new agents will probably be most effective after two courses of intensive timed sequential therapy, which reduces the tumour mass to minimal amounts, frequently to levels only detectable using PCR or fluorescent *in situ* hybridization (**FISH**) techniques.

Therapeutic strategies (novel agents)

Genetically engineered, human biological agents having minimal host toxicity and possessing activity at multiple levels of gene function are expanding the scope of applied medicine.

Brief, two-course, tumour-reduction therapy in all patients with AML provides a biologically stable array of genetically determined subgroups with predictable cell mass. These residual cells are vulnerable to designer agents. Coupled with the immunologically intact host, novel agents with a wide therapeutic advantage could annihilate the remaining 100 cells.

Examples of possible novel genetic agents of use in the treatment of varied leukaemias with minimal residual disease are outlined in (Table 5).

The ability to detect probable subtle differences in early outcome induced by the new biological agents is critical to expanding their trials, and hence rapidly moving to alternate treatments. These methods vary with the disease syndrome. In some good-risk patients, such as those with balanced chromosomal translocations, fluctuation of hybrid proteins may reflect and quantify any modifying effects of new agents. A prime example is the signal transduction inhibitor (STI571). Designed by flow-through and configuration technologies, this selected blocker of a tyrosine kinase specific for bcr-able has demonstrated significant antitumour effect and apoptosis in patients with CML in all stages. Persistent bone marrow depression and activity of STI571 against the rare gastrointestinal stromal tumours may relate to interaction with platelet derived growth factor and C-KIT as well as abl. Less effect in CML blast crisis may relate to the second-step genetic changes in that disease, with progressive proto-oncogenes characteristic of carcinoma.

In other groups of patients, the persistence of molecular abnormalities detectable in leukaemic cells (such as *RAS* mutations), kinetic responses to recruiting agents, or maturation effects may all be of specific value, but are as yet not clinically relevant to the study design. The duration of complete remission will be a valuable tool for measuring effect, particularly in that group of patients with leukaemic syndromes mirroring one-step carcinogenesis. Those with a loss or gain of DNA are predicted for relapse within a defined period. These genetic abnormalities promote biological instability and a tumour growth advantage. When minimal residual disease after induction therapy is achieved, any effective intervention that alters the time of relapse may be transferable to the management of patients with cancer, since the genetics of these leukaemias mimic those of carcinoma. Thus, the paradigm for the leukaemic model of cure of carcinoma is in those patients with an anti-oncogene with significant tumour reduction, but an anticipated short remission. Lengthening of this duration, or cure with genetically targeted novel biologies, will be of great significance.

22.3.5 Chronic lymphocytic leukaemia and other leukaemias of mature B and T cells

D. Catovsky

Advances in the last decade have revealed a greater recognition of the heterogeneity in leukaemias arising from immunologically mature B and T cells. These advances resulted mainly from the systematic use of monoclonal antibodies against lymphocyte differentiation antigens, greater attention to morphological detail, and a more consistent evaluation of the patterns of lymphocytic infiltration in the bone marrow, lymph nodes, and spleen. Precise diagnosis is critical because there are new treatment modalities for these disorders and the related low-grade non-Hodgkin's lymphomas.

The principal methods used for diagnosis and classification include: films of peripheral blood and bone marrow aspirates, bone marrow trephine biopsies, monoclonal antibodies against lymphocyte differentiation antigens and antibodies specific to immunoglobulin (**Ig**) heavy and light chains, histology of involved organs such as lymph nodes and spleen, and cytogenetic analysis, chiefly by means of fluorescence *in situ* hybridization (**FISH**), which allows the study of cells in interphase. DNA analysis may help to elucidate pathogenesis and demonstrate clonality in cases of uncertain diagnosis. Other investigations which may provide information are protein electrophoresis, tests for free light chains in the urine, and imaging techniques. Physical examination should include palpation of lymph nodes, liver, and spleen, and detection of any skin infiltration.

There are two broad disease categories to be considered: primary lymphoid leukaemias and leukaemia/lymphoma syndromes, which as a rule correspond to non-Hodgkin's lymphomas manifesting with peripheral blood and/or bone marrow involvement. Both groups can be subdivided, according to their cell derivation, into B- and T-cell types (Table 1).

Chronic lymphocytic leukaemia

This is the most common form of lymphocytic leukaemia, accounting for at least 50 per cent of cases presenting with a lymphocyte count of 5×10^9/l or higher. In Western countries chronic lymphocytic leukaemia accounts for 25 per cent of all cases of leukaemia. It is less common in the Far East, comprising 2 per cent of cases. It is estimated that 1000 new cases are diagnosed in the United Kingdom each year.

Chronic lymphocytic leukaemia affects adults over the age of 50 years, with only 5 per cent of patients aged between 30 and 50, and it is rare below the age of 30. The peak incidence is between 60 and 80 years. The male to female ratio is 2:1. This ratio is greater in younger patients and lower in older patients.

Diagnostic criteria include lymphocytosis greater than 10×10^9/l and more than 30 per cent lymphocytes in the bone marrow aspirates. With the use of membrane markers it is possible to make a diagnosis with lymphocyte counts of at least 5×10^9/l. The lymphocytes in chronic lymphocytic leukaemia have distinct morphology (Plate 1): small size, round nucleus, clumped nuclear chromatin, and scanty cytoplasm; smear cells are common. A minority of cells are larger with a prominent nucleolus and have been designated prolymphocytes. Cases with more than 10 per cent prolymphocytes have a progressive clinical course, a higher proliferation rate than stable cases, and a correspondingly shorter lymphocyte doubling time. This variant form of chronic lymphocytic leukaemia has been described as chronic lymphocytic leukaemia/prolymphocytic.

Clinical features

Almost one-third of patients are diagnosed by chance with lymphocytosis and no specific symptoms or physical signs. Others present with lymphadenopathy or symptoms of anaemia. The lymphadenopathy is usually symmetrical and of moderate size, involving the neck, axillas, and inguinal regions. Other nodal areas can be ascertained by chest radiography and abdominal CT scan. Splenomegaly of variable size is found in 50 per cent of cases; hepatomegaly is less common and more difficult to document as being of clinical relevance.

Systemic symptoms such as weight loss or night sweating are not common but, when present, they correlate with bulky abdominal disease. Fever in chronic lymphocytic leukaemia usually indicates infection, but if the latter is excluded it may suggest transformation (see below).

Membrane markers

Chronic lymphocytic leukaemia lymphocytes are clonal B cells with weak kappa or lambda light-chain expression (**SmIg**) in the membrane. The immunophenotype of chronic lymphocytic leukaemia is unique within the B-cell disorders: CD5 and CD23 positive, FMC7 negative, and weak or negative expression of CD22 and CD79b. These markers, including the weak SmIg expression, represent the typical immunophenotype of chronic lymphocytic leukaemia. In a majority of cases (about 90 per cent) chronic lymphocytic leukaemia lymphocytes will show the expected findings with four or five of the above reagents. The most consistent markers are CD5 and CD23, positive in 92 and 94 per cent of cases, respectively. This contrasts with observations in other B-cell leukaemias and non-Hodgkin's lymphoma in leukaemic phase (Table 2). Chronic lymphocytic leukaemia/prolymphocytic has the same membrane markers as typical chronic lymphocytic leukaemia although in 20 to 30 per cent of cases it departs from the expected phenotype by expressing strong SmIg or CD79b or FMC7. As CD5 is a marker of both B and T cells, it may be necessary to establish in cases with a low white blood cell count that another B-cell antigen, such as CD19, is coexpressed in the CD5+ lymphocytes by simultaneous double labelling.

The expression of CD38 on chronic lymphocytic leukaemia lymphocytes seems to provide a strong new marker of prognosis. To be accurate, the assessment of CD38 needs to be done simultaneously with CD5 and CD19 to identify chronic lymphocytic leukaemia cells. CD38 appears also to be a surrogate marker for two forms of chronic lymphocytic leukaemia: (i) a benign one, CD38 negative, which arises from post-follicular (memory) B cells as shown by somatic mutations of the IgVH genes; and (ii) a more active and progressive form of chronic lymphocytic leukaemia, CD38 positive, which usually requires treatment and is associated with unmutated IgVH

genes (naive B cells). The proportion of cases with one or other form of chronic lymphocytic leukaemia appears to be similar.

Bone marrow findings

A bone marrow trephine biopsy should always be performed in chronic lymphocytic leukaemia to complement the clinical staging (see below), to exclude other B-cell leukaemias and non-Hodgkin's lymphoma, and as a baseline to assess disease progression and/or response to therapy. Immunohistochemistry with CD20 and CD79a is useful to highlight the areas of leukaemic infiltration.

The patterns of bone marrow infiltration in chronic lymphocytic leukaemia are variable and correlate with clinical stages. Early chronic lymphocytic leukaemia shows minimal interstitial or nodular involvement; with disease progression the normal bone marrow fat spaces are gradually replaced by lymphocytes. There is a mixed interstitial and nodular pattern and in advanced disease, the involvement is diffuse or 'packed'. The latter correlates with the presence of anaemia and/or thrombocytopenia. A paratrabecular pattern characteristic of non-Hodgkin's lymphoma, follicular lymphoma in particular, is not seen in chronic lymphocytic leukaemia. A nodular pattern, on the other hand, is common in lymphoplasmacytic, mantle cell, and splenic lymphoma with villous lymphocytes.

Bone marrow aspirates are necessary to confirm lymphocyte morphology and to evaluate infiltration. A minimum of 30 per cent lymphocytes is required for a diagnosis of chronic lymphocytic leukaemia, but this needs to be confirmed by cell marker studies.

Examination of the bone marrow is important in chronic lymphocytic leukaemia for three reasons: (i) to assess the degree of infiltration, which is an independent prognostic factor; (ii) to establish the possible mechanism of anaemia or thrombocytopenia by assessing the normal haemopoietic reserves; and (iii) to distinguish chronic lymphocytic leukaemia from cases of low-grade non-Hodgkin's lymphoma by the pattern of involvement in trephine biopsy sections. In patients with cytopenias and a large spleen, assessment of the bone marrow is critical to decide whether splenectomy may be beneficial.

Staging

The course of chronic lymphocytic leukaemia is very variable. Some patients may never require treatment and others have a progressive course with short survival. A major advance in the management of chronic lymphocytic leukaemia was the development of staging systems which can predict prognosis. The first system, used in the United States, was described by Rai *et al*. (1975). A new, simplified proposal by Binet *et al*. (1981) was subsequently adopted by the International Workshop on Chronic Lymphocytic Leukaemia (1981) whilst retaining some aspects of Rai's staging.

Both systems use simple information: blood counts and physical signs, namely lymphadenopathy and hepatosplenomegaly. Findings by imaging techniques are not taken into account for staging but are useful for assessing accurately disease bulk and measuring response to treatment.

Binet's system is currently used in chronic lymphocytic leukaemia trials in the United Kingdom. Stages A and B have no anaemia (haemoglobin, **Hb** > 10 g/dl) or thrombocytopenia (platelets > 100 × 10^9/l) and have a different degree of organ enlargement. Patients with stage A disease have either no palpable nodes (including liver and spleen as nodal areas) or have one or two involved areas. Patients with stage B disease have three, four, or all five nodal areas involved, which include nodes in cervical, axillary, and inguinal regions, spleen, and liver. Patients with stage C disease have anaemia (Hb < 10 g/dl) and/or thrombocytopenia (platelets < 100 × 10^9/l) and correspond to stages III and IV of the Rai system. The relative distribution of stages at presentation in chronic lymphocytic leukaemia is as follows: stage A, 45 to 50 per cent; stage B, 25 to 30 per cent; and stage C, 20 to 25 per cent. The proportion of patients in stages A, B, and C varies between the sexes. More women are likely to present with stage A and more men with stages B and C. Stage A is also more common over the age of 70 years in both sexes. Stage is the single most important prognostic factor of the disease (see below).

Attempts have been made to identify, within the large stage A group, further prognostic substages. One is to retain Rai stage 0 (lymphocytosis with no physical signs) as stage A(0). The other, proposed by the French Cooperative Group on Chronic Lymphocytic Leukaemia (1990), is to separate stage A into patients with (i) haemoglobin greater than 12 g/dl and a lymphocyte count less than 30 × 10^9/l (stage A') or (ii) haemoglobin less than 12 g/dl and a lymphocyte count greater than 30 × 10^9/l (stage A''). The 5-year survival of the first group was 87 per cent and of the latter 60 per cent. This difference was confirmed in the analysis of the United Kingdom Medical Research Council (**MRC**) Chronic Lymphocytic Leukaemia 3A study, which also confirmed the survival advantage of patients with stage A disease with lymphocyte doubling times greater than 12 months.

Chromosome abnormalities

Progress in this area has resulted from the routine use of fluorescence *in situ* hybridization (FISH), which helps detect the abnormalities in chronic lymphocytic leukaemia with a higher frequency (80 per cent of cases) than conventional cytogenetic methods (30 per cent). The most common abnormality is the interstitial deletion of 13q14 (50 to 60 per cent of cases), followed by trisomy 12 (20 per cent), 11q23 deletion (20 per cent), 17p13 (p53 locus) deletion (10 per cent), and 6q21 deletion (5 per cent of cases). Chromosome translocations have been described in chronic lymphocytic leukaemia but with low frequency. None of the above abnormalities are unique to chronic lymphocytic leukaemia as they may also be seen in other low-grade non-Hodgkin's lymphomas. On the other hand, translocations seen in non-Hodgkin's lymphomas such as t(11;14)(q13;q32), a feature of mantle cell lymphoma, and t(14;18)(q32;q21) are not a feature of chronic lymphocytic leukaemia.

Some of the changes detected by FISH in chronic lymphocytic leukaemia have been associated with distinct disease characteristics, namely: trisomy 12 with high proliferative rate and increased number of prolymphocytes; p53 deletion, which correlates with p53 overexpression and gene mutation, is associated with chronic lymphocytic leukaemia/prolymphocytic and poor response to therapy; 11q23 with younger age, massive lymphadenopathy, and poor prognosis; and 6q21 with high lymphocyte counts and bulky disease. It is likely that most of the abnormalities described in chronic lymphocytic leukaemia are relatively late events in the evolution of the disease. The nature of the early genetic event triggering naive (unmutated IgVH genes) or memory (mutated IgVH genes) B cells to become neoplastic is unknown.

Prognostic factors

The main features of poor prognosis in chronic lymphocytic leukaemia are listed in Table 3. The most important one for predicting survival is clinical stage, assessed by either the Binet or Rai systems, followed by age, sex, and response to therapy. The median survival of patients with stage A disease is more than 10 years, with stage B disease it is 6 years, and stage C disease 4 to 5 years.

For patients with stage A disease, both the French substaging (A', A'') and the lymphocyte doubling time are important independent prognostic variables (see above). A period of close observation with blood counts every 2 or 3 months for the first year is recommended in newly diagnosed patients with stage A disease in order to assess the pace of the disease and calculate the lymphocyte doubling time. The degree of bone marrow infiltration is also an independent prognostic variable, particularly in patients with stage B disease. A packed bone marrow pattern is associated with worse prognosis. In contrast to the anaemia caused by bone marrow infiltration, autoimmune haemolytic anaemia is not necessarily considered to indicate poor prognosis. Because chronic lymphocytic leukaemia affects elderly people, it is essential to investigate thoroughly other causes of anaemia and exclude, as not related to chronic lymphocytic leukaemia, those caused by iron, folate, or vitamin B_{12} deficiency, before deciding that the patient has stage C disease and requires chemotherapy.

The prospective value of new prognostic factors such as CD38 expression, IgVH mutations, and cytogenetic changes as detected by FISH analysis is still being evaluated. However, they are likely to define or to be associated with distinct clinical behaviour and to explain in large part the contrasting evolution of chronic lymphocytic leukaemia seen in patients.

Complications

Infections, particularly of the upper respiratory tract, are the main cause of morbidity in chronic lymphocytic leukaemia. Pneumonia is the main cause of death in 30 per cent of cases, usually in patients with advanced disease. The major predisposing factor for infections is hypogammaglobulinaemia.

Autoimmune phenomena, commonly haemolytic anaemia with a positive direct antiglobulin test due to warm autoantibodies, is a feature in 5 to 7 per cent of cases at presentation. However, the proportion of cases with a positive Coombs' test is higher than the number with frank haemolysis. Not infrequently, the haemolytic anaemia

is precipitated by the initiation of therapy, particularly the nucleoside analogue fludarabine, which causes a drop in CD4+ T cells, or following a viral illness. Immune thrombocytopenia is seen in 2 per cent of cases.

Other malignancies are not uncommon in chronic lymphocytic leukaemia and it is not clear whether this relatively high incidence correlates with age or with a greater predisposition of the disease itself or its associated immunodeficiency. Up to 30 per cent of patients may die of causes unrelated to chronic lymphocytic leukaemia and in half of them the cause is another cancer. In patients with early chronic lymphocytic leukaemia (stage A), half of the causes of death are not due to the disease itself and are often age related, such as cardiovascular events. In contrast, in advanced stages (stages B and C) 80 to 90 per cent of deaths are a direct consequence of chronic lymphocytic leukaemia and its complications.

Treatment

Because of the variable outlook of patients, which relates to stage and other disease features, it is important to consider the treatment separately for patients with early and stable disease and for those with progressive, symptomatic, and/or advanced disease. For this purpose staging is the first criterion to take into account.

The majority of patients with stage A disease have no symptoms and may be observed for a while to determine, by the lymphocyte doubling time or other features, whether the disease has a stable pattern, before deciding whether treatment is necessary. A number of randomized trials have considered whether patients having stage A disease should be treated early with chlorambucil, with or without prednisolone, and these have been summarized in an overview (Chronic Lymphocytic Leukaemia trialists, 1999) which showed conclusively that patients treated early did not fare better and, if anything, show a trend towards shorter survival.

Treatment is indicated for patients with stage B and C disease or stage A with evidence of progression. Disease progression is defined as a downward trend in haemoglobin or platelets, rising lymphocyte counts, development of lymphadenopathy, and systemic symptoms, among other parameters. Most of the treatments listed in Table 4 have been, or still are, subject to clinical trials. It is accepted that the addition of prednisolone to an alkylating agent, chlorambucil or cyclophosphamide as in **COP** (cyclophosphamide/oncovin/prednisolone) does not confer a survival advantage. There is good evidence, on the other hand, that the use of prednisolone alone for the first 4 weeks in patients who present with stage C disease facilitates the subsequent introduction of other drugs and corrects more rapidly the cytopenias. One needs to be aware that the use of corticosteroids results in a significant rise in the lymphocyte count whilst lymph nodes and spleen are reducing in size.

The role of anthracyclines, as in the combination **CHOP** (cyclophosphamide/oncovin/ prednisolone/doxorubicin) or by adding epirubicin to chlorambucil (Table 4), has been tested in several trials, including recently MRC CLL 3, but no survival advantage has been shown in a large meta-analysis of randomized trials. Although the response rates are slightly higher with anthracycline-containing combinations in previously untreated patients, for example 80 per cent for partial plus complete remissions, against 70 per cent with chlorambucil or COP, this has not translated into a survival advantage. The 5-year survival in the MRC CLL 3 trial was 44 per cent with chlorambucil and 45 per cent with chlorambucil plus epirubicin.

One of the difficulties in assessing survival as the only end point in clinical trials of chronic lymphocytic leukaemia is that patients who do not respond to a first-line therapy may respond to another and whenever there is a response (partial or complete) the outlook improves. Only patients who do not respond to any modality, such as those with p53 deletion/mutation or 11q23 deletion, fare really badly with respect to survival.

A new generation of drugs, the nucleoside analogues (Table 4), have shown promise for the treatment of chronic lymphocytic leukaemia and other low-grade lymphoid malignancies. The agent with greater activity in chronic lymphocytic leukaemia is fludarabine. The encouraging findings with fludarabine result from higher complete remission rates, for example 33 per cent in previously untreated patients, which compares favourably with the 15 per cent rate of complete remission that is observed with other agents. Furthermore, there is no evidence for cross-resistance between fludarabine and chlorambucil or anthracyclines. This makes fludarabine the agent of choice for second-line therapy in chronic lymphocytic leukaemia. It is not yet clear whether using fludarabine as first-line treatment provides any survival advantage.

Trials carried out in previously untreated patients by American and French co-operative groups have shown a higher rate of complete remission with fludarabine over chlorambucil or the combination CHOP and a prolonged disease-free interval, but no survival advantage. The reason for the latter, as stated above, may be that crossover design allowed good responses to fludarabine in the non-responders to chlorambucil or CHOP.

Data from the MD Anderson group in Texas suggest that fludarabine inhibits DNA and RNA synthesis as well as DNA repair, thus being potentially beneficial in combination with DNA-damaging agents. The combination of fludarabine with cyclophosphamide is currently being tested as first-line therapy in the Chronic Lymphocytic Leukaemia 4 trial in the United Kingdom. The potential benefit of the monoclonal antibodies, anti-CD20 and CD52 (Table 4), is currently being explored in chronic lymphocytic leukaemia with promising results. High-dose methylprednisolone is an effective salvage therapy for highly resistant patients, including those with p53 abnormalities. Although complete remissions are rare, partial responses, including some reverting to a bone marrow nodular pattern, have been observed. We have used high-dose methylprednisolone alone or in combination with other agents, such as vinca alkaloids, depending on results of an *in vitro* cytotoxicity assay (Bosanquet *et al.* 1999).

Stem cell transplantation

Efforts to improve treatment results in younger individuals with chronic lymphocytic leukaemia led to protocols using allogeneic and autologous stem cell transplantation. Allogeneic transplants may be curative in a minority, but this procedure is limited to those with an HLA-identical donor and has been associated in chronic lymphocytic leukaemia with a high (about 35 per cent) treatment-related mortality. To improve treatment-related mortality, less intensive conditioning regimens ('mini' transplants) have been devised in an attempt to exploit the host versus leukaemia effect. Currently, the use of the patient's own stem cells harvested after a good remission has been achieved is the preferred method of transplant for chronic lymphocytic leukaemia. The treatment-related mortality of autografts worldwide is less than 10 per cent and is more likely to be less than 5 per cent with improvements in supportive care and the ability to mobilize peripheral stem cells using haemopoietic growth factors such as granulocyte colony-stimulating factor (**G-CSF**). Due to its low toxicity, the 3- to 5-year survival after autografts is in the order of 75 to 80 per cent. However, the event-free survival is shorter due to 40 per cent relapses in the first 3 years. Thus, autologous transplants seem to increase survival in chronic lymphocytic leukaemia but may not be considered a curative procedure. The MRC Chronic Lymphocytic Leukaemia Working Group has conducted a pilot study since 1996 in which 102 patients have been entered so far. Remissions were induced with fludarabine and stem cells were harvested after cyclophosphamide priming followed by G-CSF. A harvest was not possible in a minority (about 15 per cent). The projected 5-year survival of the 50 patients who received transplants is 80 per cent, with a high proportion of bone marrow samples after autograft showing no sign of chronic lymphocytic leukaemia by polymerase chain reaction (PCR) for IgH gene rearrangement. A European randomized trial is planned, to assess further the value of autografts in younger patients with chronic lymphocytic leukaemia.

Splenectomy in chronic lymphocytic leukaemia

There are three indications for splenectomy in chronic lymphocytic leukaemia. First, for therapy-resistant disease with significant residual splenomegaly. Second, in patients with evidence of hypersplenism, that is cytopenia(s) and active bone marrow haemopoiesis. Third, for autoimmune complications, haemolytic anaemia, or thrombocytopenia that do not respond to therapy with corticosteroids and immunosuppressive drugs. In our experience, splenectomy is always beneficial in any of the above indications. In patients in whom the spleen is the dominant organ, with little or no lymphadenopathy, splenectomy could revert the clinical staging from C to A with the corresponding improvement in survival.

Because of the poor humoral immunity in chronic lymphocytic leukaemia, the prophylaxis after splenectomy should rely on oral penicillin as well as on antipneumococcal vaccines. The latter should also be used in all patients with chronic lymphocytic leukaemia.

Supportive care

The recurrent infections in patients with chronic lymphocytic leukaemia, particularly with advanced disease, makes supportive care an important component of management. This includes long-term antibiotics and their availability as soon as signs or symptoms of infections appear, and intravenous gammaglobulin replacement therapy to prevent serious upper respiratory tract infections in selected patients. Co-trimoxazole should be used in all patients treated with fludarabine or other nucleoside analogues that cause lymphopenia. Blood products should always be irradiated after fludarabine. Annual influenza vaccinations are strongly recommended. Other measures include blood transfusions and vitamin supplements such as folic acid to correct deficiencies. Anaemia in chronic lymphocytic leukaemia should always be thoroughly investigated and it should not be assumed that it is caused by bone marrow infiltration. The treatment of autoimmune

complications includes corticosteroids, splenectomy, danazol, azathioprine, cyclophosphamide, and cyclosporin A.

Transformation

There are two forms of transformation in chronic lymphocytic leukaemia: a subtle one with increased proportion (usually more than 10 per cent) of prolymphocytes, known as chronic lymphocytic leukaemia/prolymphocytic, and a more dramatic change to a high-grade non-Hodgkin's lymphoma with diffuse large B-cell/immunoblastic histology, known as Richter's syndrome. Chronic lymphocytic leukaemia/prolymphocytic may be seen in 10 per cent of patients and Richter's syndrome in at least 5 per cent. The former has a progressive course and is associated with trisomy 12 and p53 abnormalities in about 50 per cent of cases. The immunophenotype of chronic lymphocytic leukaemia/prolymphocytic is identical to typical chronic lymphocytic leukaemia with occasional cases scoring 3 instead of the usual 4 or 5. Chronic lymphocytic leukaemia/prolymphocytic should not be confused with B-cell prolymphocytic leukaemia (see below), which is a distinct entity and in which the immunophenotype usually scores less than 2 (Table 2).

The large cell transformation may be localized or generalized; very rarely, it may resemble an acute leukaemia with circulating large blasts. Richter's syndrome is associated with deteriorating clinical status and the systemic symptoms of fever, weight loss, and sweating, particularly when large para-aortic nodes are involved. Systemic symptoms or rapidly enlarging asymmetric nodes should always raise the question of transformation and be properly documented. Hypercalcaemia, a rare feature of chronic lymphocytic leukaemia, has been documented in patients developing Richter's syndrome.

One question which has generated interest is whether Richter's transformation represents a new malignancy or a new change within the chronic lymphocytic leukaemia B-cell clone. Studies with anti-light-chain antibodies and DNA analysis with probes for heavy- and light-chain genes seem to indicate that in 50 per cent of cases the transformation occurs within the pre-existing chronic lymphocytic leukaemia cells; in the rest it represents a new B-cell clone. In cases arising from a separate clone, it has been suggested that the new malignancy may be mediated by the Epstein–Barr virus (**EBV**) as shown by the expression of the EBV latent membrane protein (LMP-1) and EBV mRNA in tissue sections. Severe immunosuppression, usually through CD4 lymphopenia such as caused by fludarabine, may be involved in the development of the new malignancy, which, in the strict sense, is not truly a transformation event. Cases which histologically resemble Hodgkin's disease have been documented with an incidence of 0.5 per cent. These may also relate to treatment with nucleoside analogues.

Richter's syndrome has been associated with poor prognosis with a median survival of less than 6 months following presentation. Alkylating agents are no longer effective at this stage and neither is fludarabine. Combinations of the type used in high-grade non-Hodgkin's lymphoma, such as CHOP, may induce remissions in some patients. If complete remission is obtained, the outlook may be favourable. Patients with localized transformation seem to respond better than those with generalized lymphadenopathy.

B-cell prolymphocytic leukaemia

B-cell prolymphocytic leukaemia was originally described by Galton in 1974 as a variant form of chronic lymphocytic leukaemia but is now recognized as a distinct clinicopathological entity. The main disease features are splenomegaly without peripheral lymphadenopathy, anaemia, and thrombocytopenia and a high white blood cell count, usually over 100×10^9/l. The diagnosis is made by examination of peripheral blood films in which the predominant cells are prolymphocytes (Plate 2); small lymphocytes, as in chronic lymphocytic leukaemia, are rarely seen. B-cell prolymphocytic leukaemia is rare, representing 1 per cent of cases of lymphocytic leukaemia. Most patients are over the age of 60, with a median age of 70 years.

The immunophenotype of B-cell prolymphocytic leukaemia (Table 2) is different from that of chronic lymphocytic leukaemia: most cases express strongly SmIg, FMC7, CD22, and CD79b; two-thirds of cases are CD5 negative and CD23 is also often negative. The differential diagnosis should be considered with chronic lymphocytic leukaemia/prolymphocytic, mantle cell non-Hodgkin's lymphoma, and a rare variant form of hairy cell leukaemia. In chronic lymphocytic leukaemia/prolymphocytic the proportion of prolymphocytes is less than 50 per cent, there are many small lymphocytes in the blood films, and the immunophenotype is similar to that of chronic lymphocytic leukaemia. The circulating cells in the leukaemic phase of mantle cell lymphoma have a pleomorphic appearance, the nucleolus is not prominent, and they often have stippled nuclear chromatin and an indented nuclear outline. The membrane phenotype may be similar to B-cell prolymphocytic leukaemia except for CD5 which is positive in most cases. The cells in variant hairy cell leukaemia have a prominent nucleolus resembling prolymphocytes but their cytoplasm is abundant and has distinct 'hairy' projections. Their immunological profile may be similar to that of B-cell prolymphocytic leukaemia.

Many cases of B-cell prolymphocytic leukaemia have been reported with break points at chromosome 14q32 including the translocation t(11;14)(q13;q32) in 20 per cent. Such cases need to be distinguished from blastoid forms of mantle cell lymphoma presenting with leukaemia, but this may not be easy; cases with t(11;14) in both conditions overexpress cyclin D1. Abnormalities of the p53 gene (loss of heterozygosity, overexpression, and mutations) have been reported in more than 50 per cent of cases of B-cell prolymphocytic leukaemia, the highest incidence reported in lymphoid malignancies. Deletions at 11q23 and 13q14 have also been shown by FISH.

Treatment and prognosis

In contrast to chronic lymphocytic leukaemia, the evolution of B-cell prolymphocytic leukaemia is always progressive with a median survival of 3 to 4 years. Several treatment modalities have been used with moderate success: splenic irradiation, the combination CHOP, and splenectomy. Recently the nucleoside analogues fludarabine and cladribine have been shown to induce remissions in 50 per cent of patients. Chlorambucil and other alkylating agents are largely ineffective. The high incidence of p53 abnormalities may underlie the resistance of B-cell prolymphocytic leukaemia to chemotherapy.

Hairy cell leukaemia

Hairy cell leukaemia is a rare disorder comprising 2 per cent of lymphoid leukaemias characterized by pancytopenia and splenomegaly in two-thirds of cases; monocytopenia is a consistent finding. Most patients have circulating hairy cells but leucocyte counts rarely exceed 10×10^9/l. Hairy cells are larger than lymphocytes, their nuclei show a homogeneous loose chromatin pattern without a visible nucleolus (except in variant hairy cell leukaemia) and have an abundant cytoplasm with broad-based projections or villi. The nuclear outline is often kidney shaped.

The bone marrow trephine biopsy is the main diagnostic test and shows a unique pattern of infiltration with characteristic clear zones in between the cells. This infiltration is usually interstitial but may be also be focal. Bone marrow aspirates are, as a rule, unsuccessful (dry tap) due to the heavy deposition of reticulin fibres.

Hairy cells are B cells positive with CD19, CD20, and SmIg with light-chain restriction. When tested with the five markers listed in Table 2, the immunophenotype is different from chronic lymphocytic leukaemia but similar to other B-cell disorders. Four other monoclonal antibodies, CD103, CD11c, CD25, and HC2, which have shown specificity for hairy cells, are positive in most cases. Cases of variant hairy cell leukaemia have high white blood cell counts and no monocytopenia. Histologically they resemble typical hairy cell leukaemia. The cells are CD11c+, CD103+ (in 50 per cent of cases), but always HC2 and CD25 negative.

A cytochemical property of hairy cells is the presence of tartaric acid-resistant acid phosphatase, which is still used for diagnosis. In paraffin-embedded sections of bone marrow, hairy cells are positive with the monoclonal antibodies CD20 and DBA44. These reagents can help monitor residual disease after treatment as recognition of clusters of hairy cells in histological sections may be difficult.

Treatment and prognosis

The prognosis of patients with hairy cell leukaemia has improved dramatically with the advent of three treatment modalities: interferon-a, pento-statin, and cladribine. Splenectomy is reserved for patients presenting with very large spleens that are disproportionate to the degree of bone marrow involvement. Interferon-a improves the blood counts and the bone marrow but does not induce prolonged remissions when treatment is discontinued. Pentostatin induces complete remissions in 85 to 90 per cent of patients with few (less than 5 per cent) non-responders. Once treatment is discontinued the majority of responders remain in remission for more than 5 years; 40 to 50 per cent of patients are still in remission after 10 years. The response to these agents in variant hairy cell leukaemia is usually poor and the survival significantly shorter than in the typical form.

Transformation

A subtle transformation takes place in patients with hairy cell leukaemia in the form of massive abdominal lymphadenopathy with few systemic symptoms. The overall incidence of abdominal nodes in hairy cell leukaemia is about 25 per cent and is documented by performing routine CT scan investigations. The proportion with lymphadenopathy is higher in patients who relapse after previously successful treatments and/or who had long-standing disease. Abdominal lymphadenopathy may be associated with resistance to further therapy and with the presence of large hairy cells in both the bone marrow and the enlarged lymph nodes, supporting the concept of transformation suggested by clinical findings.

B-cell lymphomas in leukaemic phase

Several types of low- or intermediate-grade non-Hodgkin's lymphoma of B-cell type present or evolve with a leukaemic blood picture, for example more than 5×10^9/l circulating lymphoid cells (Table 1). The types of non-Hodgkin's lymphoma that most commonly develop a leukaemic phase are follicular lymphoma (Plate 4), mantle cell lymphoma (Plate 3), and splenic marginal zone lymphoma with villous lymphocytes (**SLVL**) (Plate 5). The main differential diagnosis is with chronic lymphocytic leukaemia, other non-Hodgkin's lymphoma, and in the case of SLVL, with hairy cell leukaemia.

The circulating cells in follicular lymphoma are small, have no visible cytoplasm, the nuclear chromatin has a smooth pattern and shows regularly deep nuclear clefts or indentations and an angular or irregular nuclear shape. Leukaemia in follicular lymphoma is associated with widespread disease, such as hepatosplenomegaly and lymphadenopathy. The membrane phenotype is different from chronic lymphocytic leukaemia (Table 2) and the cells often express CD10. Lymph node biopsy is essential for a definitive diagnosis. Cytogenetic analysis will show the translocation t(14;18)(q32;q21) and rearrangement of the BCL-2 gene by molecular techniques. Cases with leukaemia tend to run a more aggressive course and require a more intensive treatment approach than those without leukaemia.

SLVL is a distinct low-grade non-Hodgkin's lymphoma characterized by splenomegaly, moderate lymphocytosis (10 to 30 × 10^9/l), a small monoclonal band, and/or free light chains in the urine in 50 per cent of cases. The circulating lymphocytes have a small nucleolus and a cytoplasm with conspicuous villous projections that are often seen polarized in one end of the cell (Plate 5). A minority of cells show plasma cell differentiation. The bone marrow is minimally involved early in the disease and the biopsies show a nodular pattern and intrasinusoidal infiltration highlighted in trephine biopsies by CD20 staining. The immunophenotype of SLVL cells can be distinguished from that of chronic lymphocytic leukaemia (Table 2) and hairy cell leukaemia, both diseases with which it can be confused. SLVL lymphocytes do not express HC2 and CD25 as typical hairy cells. The distinction with variant hairy cell leukaemia is difficult unless there is tissue histology.

Splenectomy is a useful treatment modality for SLVL and fludarabine has recently been shown to induce complete remissions. The spleen histology shows predominant white pulp involvement with a prominent marginal zone, which contrasts with the predominantly red pulp infiltration pattern in typical and variant hairy cell leukaemia. Most cases have somatic mutations of the IgVH genes, suggesting a disease derivation from late B cells. Chromosome abnormalities are not consistent but chromosome 7q21–32 deletion has been found in 40 per cent of cases with abnormalities of the CDK6 gene at 7q21. Trisomy 3, a feature of marginal zone lymphoma of MALT type, has been found in 17 per cent of SLVL cases. The disease course is indolent. Transformation to a high-grade diffuse large B-cell lymphoma has been observed in 5 per cent of cases.

Leukaemia is common in mantle cell lymphoma presenting with splenomegaly and lymphocytosis. The circulating cells in mantle cell lymphoma (Plate 3) are of medium to large size with an irregular nuclear outline. The bone marrow biopsy shows nodular or paratrabecular involvement (Plate 6). In addition to histology, mantle cell lymphoma is characterized by the translocation t(11;14)(q13;q32) in 80 per cent of cases, involving the BCL-1/PRAD-1 gene at 11q13. This chromosome translocation, which can be shown in interphase cells by FISH, results in the overexpression of cyclin D1 in the nucleus, which can be demonstrated by immunohistochemistry in tissue sections and by flow cytometry in cell suspensions.

Large granular lymphocytic leukaemia

Most cases with persistent T-cell lymphocytosis greater than 2×10^9/l lasting for more than 6 months without an identifiable cause are likely to represent clonal proliferations of large granular lymphocytes. Clonality can be demonstrated by the rearrangement of T-cell receptor genes and sometimes, also, by chromosome translocations, which are not consistent in every case. Large granular lymphocytes have abundant cytoplasm with prominent azurophil granules and an excentric nucleus without a visible nucleolus. Half of the patients have splenomegaly without lymphadenopathy and are neutropenic or, less frequently, suffer from other cytopenias, in particular red cell hypoplasia. Rheumatoid arthritis and the presence of autoantibodies are a feature of 25 to 30 per cent of cases. The membrane phenotype shows mature T cells which are CD4–, CD8+ and, characteristically, express one or more antigens associated with natural killer cells, such as CD11b, CD16, CD56, and CD57. Bone marrow involvement is variable but is usually present in true large granular lymphocyte leukaemia. The spleen involvement is in the red pulp with reactive normal follicles (white pulp) and frequent granuloma formation. The bone marrow involvement is variable, often with an interstitial pattern, but representing less than 50 per cent of the bone marrow cells. Although many patients do not require active treatment, a significant number (about 60 per cent) present a therapeutic problem related to the associated cytopenia. Treatments that have been effective in some patients are cyclosporin A, prednisolone plus an alkylating agent, and pentostatin.

T-cell prolymphocytic leukaemia

This aggressive form of T-cell leukaemia is characterized by hepatosplenomegaly, lymphadenopathy, and high leucocyte counts, usually rising fairly rapidly above 100×10^9/l, but cases with an initial indolent course have been recognized. There is skin infiltration in the dermis around the blood vessels and appendages in 20 per cent of cases and pleural effusions are often seen. The blood picture (Plate 7) may resemble B-cell prolymphocytic leukaemia but typical T prolymphocytes are smaller than B prolymphocytes and have some distinct features: irregular nuclear outline and a deep basophilic cytoplasm with protrusions or blebs. The nucleolus is often prominent, but it may be hidden in 20 per cent of cases when small cells predominate (small cell variant). In 5 per cent of cases the cells have a cerebriform configuration (Sézary cell variant), but erythroderma is not a feature in these patients. Serology for HTLV-I is always negative.

The membrane phenotype corresponds to that of mature (post-thymic) T lymphocytes, CD2+, CD3+, CD7+, with CD4+, CD8– markers. One-third of cases coexpress CD4 and CD8 or are CD4–, CD8+. The diagnosis is made by examination of peripheral blood and bone marrow films and confirmed by the appropriate markers. Ultrastructural examination has been used to define the morphology in cases with small cells.

Cytogenetic abnormalities

There are consistent non-random chromosome abnormalities in T-cell prolymphocytic leukaemia affecting 90 per cent of cases. The most commonly involved inversion is of chromosome 14 with break points at 14q11, the T-cell receptor (**TCR**) a/b locus, and 14q32.1, locus of the proto-oncogenes TCL1 and TCL1b, which are activated through the translocation. Other karyotypic changes include: idic(8)(p11), t(8;8)(p11–12;q12) and trisomy 8q, and deletions at 12p13. The translocation t(X;14)(q28;q11) is less common but also involves the TCR a/b locus and the MTCP1 gene, which has 70 per cent homology with TCL1. Both TCL1 and MTCP1 can induce a T-cell leukaemia with a CD4–, CD8+ immunophenotype in a transgenic mouse model. Deletions and missense mutations involving the ataxia telangiectasia mutated (ATM) gene at 11q23 have been documented in a high proportion of cases. It is of interest that patients with ataxia telangiectasia have circulating T-cell clones with inv(14)(q11;q32) and that some develop a T-cell leukaemia indistinguishable from T-cell prolymphocytic leukaemia.

Treatment and prognosis

The median survival of T-cell prolymphocytic leukaemia in our historical series has been 7 months. Responses can be obtained in 50 per cent of cases with pentostatin, but the majority of these are partial. Complete responses can now be obtained with the humanized monoclonal antibodies CAMPATH-1H in two-thirds of patients who are resistant and only partially responsive to other agents. Currently CAMPATH-1H should be considered the best first-line therapy for T-cell prolymphocytic leukaemia. Autologous stem cell transplantation has been used in patients achieving a complete remission, with some success.

T-cell lymphomas in leukaemic phase

T-cell non-Hodgkin's lymphomas develop leukaemia with higher frequency that B-cell lymphomas. Two diseases in particular regularly evolve with circulating lymphoma cells in the peripheral blood: adult T-cell leukaemia/lymphoma and Sézary syndrome.

Adult T-cell leukaemia/lymphoma has a distinct geographical distribution affecting mainly the south-west islands of Japan, the Caribbean basin, and some parts of

South America—Brazil and Chile. The serological demonstration of antibodies to HTLV-I, the causative agent of adult T-cell leukaemia/lymphoma, is one of the tests necessary for diagnosis. At genomic level there is evidence of clonal integration of HTLV-I in the malignant T cells. Diagnosis is further suggested by the demonstration of adult T-cell leukaemia/lymphoma cells in peripheral blood films (Plate 8). These cells have an irregular nucleus with polylobed configuration and many atypical forms including large transformed ones. These cells have been described as 'flower' cells. Patients with adult T-cell leukaemia/lymphoma have generalized lymphadenopathy, splenomegaly, and skin rashes. Leucocyte counts are variable but often less than 50×10^{9}/l. Hypercalcaemia is present in two-thirds of patients and tends to be difficult to control.

The pathogenesis of the T-cell malignancy by HTLV-I involves multiple steps. Infection with HTLV-I is essential but only 1 out of 2000 infected patients may develop full-blown adult T-cell leukaemia/lymphoma. Cases with non-specific symptoms and signs and minimal lymphocytosis are considered as smouldering disease. Lymphoma forms without blood or bone marrow involvement have been recognized in 20 per cent of cases.

Adult T-cell leukaemia/lymphoma cells may resemble Sézary cells. The latter have more uniform features and a cerebriform rather than a hyperlobulated nucleus. Lymph node histology in adult T-cell leukaemia/lymphoma shows diffuse infiltration with pleomorphic T cells of small, medium, and large size (Plate 10). The median survival of acute forms of adult T-cell leukaemia/lymphoma is less than 12 months. Patients are treated as those with high-grade non-Hodgkin's lymphoma, but remissions are transient and opportunistic infections are common. Some benefit has been reported using the combination of interferon-a and zidovudine.

Sézary syndrome is a distinct form of cutaneous T-cell lymphoma characterized by erythroderma and circulating Sézary cells, usually of small size (also known as Lutzner cells) (Plate 9). The skin infiltration is epidermotrophic with the formation of Pautrier microabcesses. Sézary cells, as well as adult T-cell leukaemia/lymphoma cells, are mature T cells with a CD4+, CD8– immunophenotype. The main difference is strong expression of the interleukin-2 receptor, demonstrated by the monoclonal antibodies CD25, in adult T-cell leukaemia/lymphoma but not in Sézary cells. Cases of T-cell leukaemia without skin involvement and with cells that resemble Sézary cells morphologically but lack skin involvement are now considered as part of the spectrum of T-cell prolymphocytic leukaemia (see above).

22.3.6 Chronic myeloid leukaemia

Tariq I. Mughal and John M. Goldman

Introduction

Chronic myeloid leukaemia (**CML**)—a term historically used interchangeably with chronic granulocytic leukaemia, chronic myelogenous leukaemia, and chronic myelocytic leukaemia—is a clonal malignant myeloproliferative disorder believed to originate in a single abnormal haemopoietic stem cell. It involves myeloid, monocytic, erythyroid, megakaryocytic, B-lymphoid, and sometimes T-lymphoid lineages. The first cases were described in the 1840s. A major landmark in the study of CML was the discovery of the Philadelphia (**Ph**) chromosome in 1960. Later it was established that the Ph chromosome was linked to the genetic events that cause CML. CML became the first human cancer in which a specific cytogenetic abnormality could be linked to its pathogenesis.

The past two decades have witnessed an enormous increase in our understanding of the molecular biology of CML. Such knowledge has enabled specialists to define precisely some of the molecular events and relate them to the prognostic factors of the individual patients with CML. During this period the prognosis of patients with CML has evolved from incurable to potentially curable by treatment with allogeneic haemopoietic stem-cell transplantation (allo- **SCT**). However, only a relatively small proportion of all patients with CML are eligible for allo-SCT, which still carries an appreciable risk of mortality and morbidity. For the majority of patients, interferon-alpha (IFN-á) have been found to suppress the CML cells and prolong survival in comparison to hydroxyurea. Adoptive immunotherapy using donor-lymphocyte infusions have proven valuable in treating selected patients with mini-SCT, and for rescuing those who relapse following a conventional allogeneic SCT. A new Abl-specific tyrosine kinase inhibitor, designated STI571 or imatinib mesylate, has recently been introduced and early clinical results are extremely encouraging.

Epidemiology

The annual incidence of CML is about 1 to 1.5 per 100 000 of the population. It accounts for approximately 15 per cent of all leukaemias in adults but less than 5 per cent of all childhood leukaemias. In the United Kingdom there are about 700 new cases each year. The median age of onset is 60 years and there is a slight male excess. With the possible exception of China there appears to be no clear geographical variation in the incidence.

Aetiology

Most cases of CML occur sporadically. No aetiological factor can be incriminated in the great majority of cases. A marginally increased risk of developing CML has been reported following exposure to high doses of irradiation, as occurred in survivors of the Hiroshima and Nagasaki atomic bombs in 1945. No familial predisposition or specific HLA genotypes have been recognized, but a small number of families with a high incidence of the disease have been reported.

Natural history

Characteristically CML is a biphasic or triphasic disease. Most patients present in the initial stable 'chronic' phase which typically lasts for 4 to 7 years. The natural history involves a spontaneous but largely predictable progression to an 'advanced phase', a term that covers the 'accelerated' phase and also 'blast crisis' or 'blastic transformation' (Table 1). About half of all patients in chronic phase transform directly into blast crisis, and the remainder do so following an intervening period of accelerated phase. In blastic transformation the CML cells fail to mature, and the blast cells resemble either the myeloblasts (myeloid blastic transformation) or lymphoblasts (lymphoid blastic transformation) found in patients with *de novo* acute myeloid or acute lymphoblastic leukaemia respectively.

Clinical features

Most patients typically present with lethargy and anorexia or abdominal discomfort due to splenomegaly, but 30 to 40 per cent of patients are asymptomatic and the diagnosis is made following a routine blood test. The principal physical finding is a palpable spleen, which is found in up to three-quarters of patients. Hepatomegaly and lymphadenopathy are uncommon. The clinical features of 430 patients referred to the Hammersmith Hospital in London are shown in Table 2. Occasional patients have 'chloromas' or 'granulocytic sarcomas' with subcutaneous deposits of extramedullary leukaemia.

In contrast to patients in the chronic phase, patients in the advanced phase are often symptomatic with fever, bone pain, bleeding, and/or excessive sweating. Splenic pain due to splenic infarct is not uncommon. During the accelerated phase patients often require increasing doses of hydroxycarbamide (hydroxyurea) to control the neutrophil counts.

Molecular biology

The Ph chromosome is an acquired cytogenetic abnormality present in all CML cells (Fig. 1). It is formed as a result of a reciprocal translocation of genetic material from the long arm of one of the two no. 9 chromosomes with material from the long arm of one of the no. 22 chromosomes, referred to as t(9;22)(q34;q11). This translocation involves transections of the *BCR* (breakpoint cluster region) gene normally on chromosome 22 and the *ABL* (Abelson) gene normally on chromosome 9 and so results in the juxtaposition of 5' sequences from the *BCR* gene with the 3' sequences from the *ABL* gene. The end results is the creation of a chimeric or 'fusion' *BCR–ABL* gene.

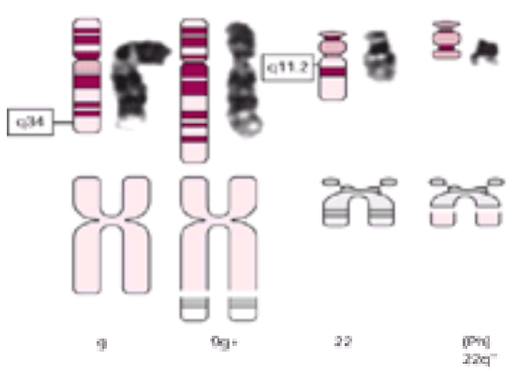

Fig. 1 Partial karyotype showing the Philadelphia chromosome translocation t(9;22)(q34;q11) with the positions of the breakpoints on chromosomes 9 and 22.

The classical Ph chromosome is easily identified in 80 per cent of patients with CML. Variant translocations are seen in a further 10 per cent of patients; these variants may be 'simple' involving chromosome 22 and a chromosome other than chromosome 9, or 'complex', where chromosomes 9, 22, and other additional chromosomes are involved. About 8 per cent of patients with classical clinical and haematological features of CML lack the Ph chromosome and are referred to as cases of Ph-negative CML. About half of such patients have a *BCR–ABL* chimeric gene and are referred to as Ph-negative, BCR-ABL-positive cases; the remainder are BCR-ABL-negative, and some of these have mutations in other genes. It is probable that these latter patients have a more aggressive clinical course than those with Ph-negative, BCR-ABL-positive disease. As the disease progresses patients may acquire additional cytogenetic abnormalities, including duplication of the Ph chromosome, trisomy 8, and isochromosome 17q. Mutations or deletions of tumour-suppressor genes such as *p16* and *p53* may contribute to the disease progression.

The *BCR–ABL* fusion gene transcribes an mRNA which encodes a protein that has a greater tyrosine kinase activity than the normal ABL protein. Depending on the site of the breakpoint in the *BCR* gene, the fusion protein can vary in size from 185 kDa to 230 kDa (Fig. 2). To date, three separate breakpoint locations on the *BCR* gene have been identified. When the break occurs in *major breakpoint cluster region* (**M-BCR**) it is nearly always in the intron between exons e13 and e14 or in the intron between exons e14 and e15 (toward the telomere). By contrast, the position of the breakpoint in the *ABL* gene is highly variable and may occur at almost any position upstream of exon a2 (toward the centromere). Most patients with the classical Ph chromosome have express transcripts with e13a2 or e14a2 junctions which translate as 210-kDa oncoproteins ($p210^{BCR–ABL}$) (Table 3). A break in the first intron of the *BCR* gene, between exons e1 and e2, in an area designated the *minor breakpoint cluster region* (m-bcr) results in the transcription of an e1a2 mRNA which encodes a 190-kDa protein ($p190^{BCR–ABL}$). This is found in about two-thirds of patients with Ph-positive acute lymphoblastic leukaemia. The third position for a break in the *BCR* gene is between exons e19 and e20, in an area designated *micro breakpoint cluster region* (**μ-bcr**). The associated mRNA product, e19a2, encodes a larger protein of 230 kDa ($p230^{BCR–ABL}$), which is found in the very rare cases of chronic neutrophilic leukaemia associated with a Ph chromosome.

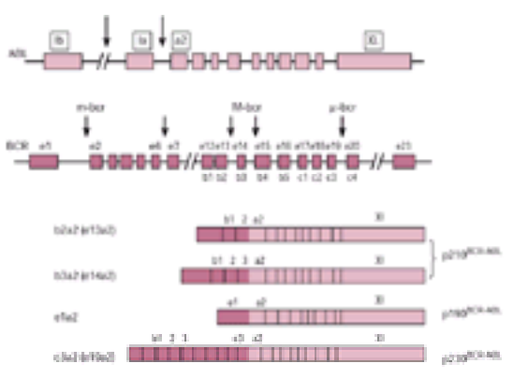

Fig. 2 Schematic representation of the various breakpoints in the *ABL* and *BCR* genes and the encoded proteins in the BCR–ABL-positive leukaemias

The different breakpoints in the M-BCR result in two slightly different chimeric *BCR–ABL* genes. A break occurring in the M-BCR intron between exons e13 and e14 yields an e13a2 (previously known as b2a2) mRNA, whereas a break occurring in the intron between exons e14 and e15) produces an e14a2 mRNA (previously known as b3a2). Most patients have either e13a2 or e14a2 transcripts, although both transcripts are present in about 10 per cent of cases. The type of BCR-ABL transcript has no important prognostic significance, altough patients with the e14a2 transcripts may have higher platelet counts.

It is believed that the various BCR–ABL transcripts play a central role in the pathogenesis of CML, though the precise details are still not fully understood. Various efforts to determine the function of the BCR–ABL proteins have established that, as a consequence of increased tyrosine kinase activity, the BCR–ABL protein can phosphorylate several substrate molecules, such as CRKL, p62Dok, paxillin, CBL, and RIN, thereby activating multiple signal-transduction pathways affecting cell growth and differentiation. The details of the pathways are incomplete, but a popular hypothesis is that the BCR–ABL protein activates the same pathways as are activated by cytokines that control the growth and differentiation of haemopoietic cells, thereby allowing CML cells to circumvent normal cellular growth and differentiation and become malignant. This would not, however, explain the mechanism by which the preferential proliferation and differentiation of myeloid progenitors occur. The molecular basis for transformation of CML from chronic phase to more advanced phases remains poorly understood, although several molecular changes, in particular mutations or deletions of p53, p16, retinoblastoma protein, and mutations or overexpression of Ras and EVI-1, have been identified.

Normal haemopoietic stem cells may be maintained in a resting state (designated G_0) as a result of the proliferation of CML cells. Under certain circumstances, however, these normal cells can be induced to proliferate, and this provides the rationale for autografting as a treatment of CML. There may also be a subpopulation of deeply quiescent Ph-positive CML cells, that might be relatively resistant to eradication by cycle-active cytotoxic drugs even when administered in high doses.

Diagnosis

The diagnosis of CML is commonly based on the characteristic appearances of the peripheral blood film and bone marrow aspirate and trephine biopsy. Cytogenetic analysis for the presence of the Ph chromosome is confirmatory. Molecular studies for the evidence of the BCR–ABL product provide additional confirmation.

The peripheral blood usually shows a leucocytosis which involves cells at all stages of differentiation within the myeloid lineage (Fig. 3 and Plate 1). Basophilia is an important diagnostic feature as its absence suggests other myeloproliferative disorders, particularly if the Ph chromosome and *BCR–ABL* gene are also absent. Eosinophilia may also be present but has no diagnostic relevance. There is a relative monocytopenia, although absolute numbers may be increased corresponding with the leucocytosis. This differentiates CML from chronic myelomonocytic leukaemia. Thrombocytosis with platelet anisocytosis and nucleated red cells are common.

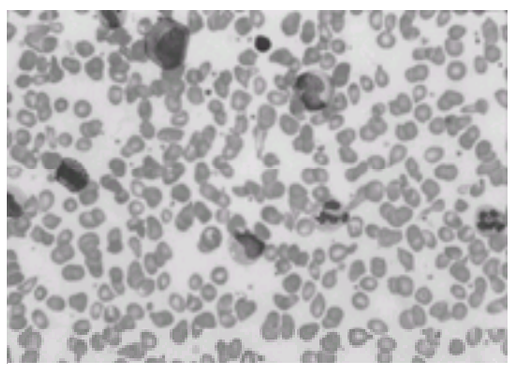

Fig. 3 Peripheral blood film from a patient with CML in chronic phase. (Photograph kindly provided by Professor Barbara Bain, Imperial College London.) (See also Plate 1.)

The bone marrow is markedly hypercellular with an increased myeloid to erythroid ratio due to the predominance of myeloid cells, particularly neutrophils and myelocytes. There may be no features of abnormal maturation in the precursors. Megakaryocytes are increased and may form clusters, which are less striking than those seen in essential thrombocythaemia. Reticulin fibrosis is usually absent or mildly increased at diagnosis.

Blastic transformation is often abrupt and striking with blast cells comprising up to 100 per cent of nucleated cells seen in the blood and marrow; it thus resembles an acute leukaemia arising *de novo*. These blast cells are of myeloid lineage in about 70 per cent of the patients, while in about 20 per cent the express lymphoid surface markers, have rearrangement of immunoglobulin genes and are presumably lymhoid in origin. The remaining patients in blast crisis have a blast population with a mixed or indeterminate morphology and immunophenotype.

Prognostic factors

Various efforts have been made to establish criteria definable at diagnosis that may help to predict survival for individual patients. Historically the most frequently used method was that proposed by Sokal, whereby patients can be divided into various risk categories based on a mathematical formula that takes account of the patient's age, blast-cell count, spleen size, and platelet count at diagnosis. The Sokal index has recently been updated by a retrospective study of patients treated with IFN-a in Germany — the new Euro or Hasford system is similar to the Sokal index but includes consideration of basophil and eosinophil numbers. Currently the best prognostic indicator may be the response to initial treatment with **IFN-a**; patients who achieve a degree of cytogenetic response have the best survival. These approaches help to predict survival with a non-transplant strategy. Other methods, such as the risk assessment proposals by Gratwohl *et al*. and Lee *et al*., are designed to calculate the risk of transplant-related mortality after an allo-SCT. Other possible prognostic factors are the presence or absence of deletions in the derivative 9q+ chromosome and the rate of shortening of telomeres in the leukaemia clone.

Management

The substantial recent developments in treating CML, including the introduction of IFN-a and allogeneic SCT in the 1980s and of STI571 very recently, have made management decisions for individual patients in chronic phase fairly complex. Thus some patients with CML can be cured by an allogeneic SCT, but the risks associated with it need to be carefully assessed. In contrast, IFN-a induces haematological control in a significant proportion of patients and confers some improvement in survival in comparison with hydroxyurea, especially for those patients who achieve a degree of cytogenetic response. It is rare, however, to achieve a molecular remission with IFN-a. STI571 induces haematological remission in almost all patients and is associated with a high incidence of cytogenetic response, but there is not yet information on its ability to confer molecular remission; neither is there any evidence as yet that it prolongs survival in comparison to the other treatments of CML. It is therefore prudent to discuss the relative merits of the various treatments with the patient at the time of diagnosis and to explain some aspects of the disease and the proposed management strategy.

Non-transplant treatment options

IFN-a is a member of a large family of glycoproteins of biological origin with antiviral and antiproliferative properties. It is active in reducing the leucocyte count and reversing the clinical features in 70 to 80 per cent of patients with CML. Five to 15 per cent of patients achieve a major reduction in the proportion of Ph-positive marrow metaphases. A number of prospective studies comparing IFN-a to hydroxycarbamide (hydroxyurea) and busulfan have been reported. The standard treatment for most patients with CML in the 1980s was hydroxycarbamide which had largely replaced busulfan. By the mid-1990s it was suggested that IFN-a was probably superior to both hydroxycarbamide and busulfan, and, more importantly, it appeared that IFN-a treatment resulted in prolongation of survival, in particular for patients achieving substantial cytogenetic responses. A meta-analysis of seven prospective randomized trials has confirmed the superiority of IFN-a over both busulfan and hydroxycarbamide. The meta-analysis involved over 1500 patients and found a 5-year survival of 57 per cent for the IFN-a treated patients compared to 42 per cent for the chemotherapy treated cohort. A major cytogenetic response (>66 per cent Ph-chromo-some negativity in the marrow) was seen in 10 to 38 per cent of all patients and occurred usually within 12 to 18 months of starting IFN-a therapy.

There are several key issues still unresolved with regard to IFN-a. The optimal dose remains a matter of some controversy although the recent study conducted by the UK Medical Research Council found no difference between 'high' and 'low' doses. Moreover, the optimal duration of IFN-a treatment remains undefined. Toxicity is common but is generally mild and reversible. Most patients suffer from influenza-like symptoms on starting treatment. Later they may experience lethargy and weight loss. Less common effects include autoimmune-mediated complications, such as thrombocytopenia and hypothyroidism. In an effort to improve the treatment results, several trials focused on combining IFN-a with cytotoxic drugs. Encouraging cytogenetic results have been obtained with the addition of cytarabine to IFN-a in French trial and a survival advantage in comparison to IFN-a was observed; this has not however been confirmed in a comparable Italian study. In an attempt to reduce the toxicity of IFN-a therapy, a pegylated form of IFN-a has also been investigated and preliminary experience is encouraging.

The precise mode of action of IFN-a remains uncertain. *In vitro* studies, mainly from long-term cultures of CML cells, suggest a prominent antiproliferative effect of IFN-a in CML. Some of this activity against CML cells may be mediated through the dendritic cells. IFN-a may also indirectly influence the survival of CML cells by restoring the defective cytoadhesion of the CML cells or by recruiting accessory cells of the immune surveillance system, by inhibiting other cytokines or by augmenting the action of natural killer cells.

Clinical trials designed to assess the efficacy and safety of STI571 in patients in all phases of CML began in 1998. In patients with CML in chronic phase refractory to or intolerant of IFN-a who receive at least 300mg of STI571 daily the incidence of complete haematological response is 98 per cent of the patients; about 40 to 45 per cent achieve cytogenetic responses. STI571 was administered orally and so far no important side-effects have been noted. The drug also demonstrated significant activity in CML in accelerated phase and in blast crisis. The follow-up is still relatively short, but if the responses are sustainable, this novel drug will become the preferred non-transplant treatment option. The drug is now licensed for these indications on both sides of the Atlantic and studies to compare STI571 alone with STI571 plus IFN-á and STI571 plus cytarabine are being designed. The combination of STI571 with pegylated IFN-á is also being tested.

Stem-cell transplantation

Allogeneic SCT, using blood- or marrow-derived stem cells derived from an HLA-matched sibling donor, performed in the chronic phase can cure a substantial proportion of patients with CML. International Bone Marrow Transplant Registry (**IBMTR**) showed that the leukaemia-free survival (**LFS**) at 5 years is 55 to 60 per cent. The probability of relapse at 5 years was 15 per cent. In contrast, the results of allogeneic SCT performed in the advanced phase of CML were generally poor. The probabilities of LFS at 5 years for those transplanted in the accelerated phase and blast crisis were 28 per cent and 10 per cent, respectively. The clinical results of transplantation using HLA-matched sibling donors appear to be relatively consistent worldwide.

The major determinants for survival, other than the phase of the disease, include the patient's age at transplant and the cytomegalovirus (**CMV**) status of the patient, and the age and sex of the donor. Survival appears to be best for patients who are transplanted within 1 year of diagnosis, are less than 40 years of age, have a young male donor, and both patient and donor are CMV-negative. For such a cohort, the 5-year LFS is probably 70 to 80 per cent; the relapse rate would be 10 to 20 per cent. It is possible that the precise details of the transplant procedure also influence the outcome. The cytoreductive regimens used prior to the transplant and the preventive measures for graft-versus-host disease (**GvHD**) appear especially important. The source of stem cells may also influence the result; following a peripheral-blood SCT patients achieve rapid engraftment, but there is a slight excess of chronic GvHD, perhaps due to the increased T-cell numbers in the peripheral blood compared to the bone marrow. There has also been some concern with regard to the effect of prior IFN-a therapy following an initial report suggesting a possible detrimental effect, further careful monitoring is therefore necessary.

Although allogeneic SCT using an HLA-matched sibling donor appears to cure some patients with CML, this treatment is only available to about 15 to 20 per cent of all patients with CML. This is largely due to a lack of suitable family donors and to age limitations. The rigors associated with SCT mean that most patients over the age of 60 years have a substantial incidence of transplant-related mortality (**TRM**). For these reasons, efforts have been made to identify suitable volunteer unrelated donors (**VUD**) and better conditioning regimens to reduce the toxicity. Historically, the results of VUD-SCT are inferior to those of HLA-matched sibling SCT due to an increased rate of graft failure, GvHD, and TRM. The presence of GvHD greatly increases the risk of TRM and morbidity post-SCT from infections. GvHD prophylaxis with a combination of ciclosporin and methotrexate is superior to ciclosporin alone. T-cell depletion of the allograft effectively abrogates GvHD, in particular in the VUD-SCT setting, but it is accompanied by a relapse rate of over 60 per cent. The observation that removal of donor T cells greatly increased the incidence of relapse was the unequivocal proof of the existence of a graft-versus-leukaemia (**GvL**) effect.

Current results of VUD-SCT from the Seattle group suggest an LFS of 74 per cent at 5 years in CML patients who are under the age of 50 years and are transplanted within a year of diagnosis. These and other similar results have led to further refinements toward the search for suitable VUDs to make SCT more available. Newer molecular techniques for subtyping the HLA class I genes should improve the chances of finding optimally matched or acceptably mismatched donors. Syngeneic SCT has comparable overall survival, but, due to the lack of a GvL effect, there is a higher relapse rate resulting in a lower LFS.

Efforts to minimize the toxicity of conditioning regimens have been benefited by the use of the purine analogues (for example, fludarabine) which are potent immunosuppressive drugs. These regimens are non-myeloablative but ensure engraftment and are designed to exploit maximally the GvL effect. These procedures have been termed reduced intensity conditioning SCTs (also mini-SCTs or non-myeloablative SCTs) and reflect the exciting advances in our understanding of how SCT actually works.

Treatment of relapse of CML post-transplantation

Most patients who relapse after allogeneic SCT (allo-SCT) do so within the first 3 years. This relapse tends to follow an orderly progression, with the patient initially demonstrating evidence of a molecular relapse with increasing positivity of BCR–ABL transcripts assayed by the polymerase chain reaction (**PCR**), followed by a cytogenetic relapse (finding of the Ph chromosome in marrow metaphases), and then by haematological and clinical relapse. Molecular monitoring of allo-SCT recipients is therefore valuable. For patients with molecular relapse, remission can be induced by withdrawing immunosuppression or by the infusion of lymphocytes collected from the original transplant donor (**DLI**) without any other antileukaemic measures. DLI can induce remissions in 60 to 80 per cent of patients with molecular or cytogenetic relapse. These important results lend further support to the concept that a GvL effect plays an important role in the cure of CML after allografting. Patients who fail to enter remission with DLI may be candidates for treatment with STI571 or a second allo-SCT but the risk of TRM is relatively high. The 4-year LFS for a second allo-SCT is around 28 per cent. The potential benefit of using STI571 initially instead of DLI is now being assessed.

The mechanisms by which T lymphocytes exert a GvL effect remain highly speculative. It is possible that they release cytokines, such as interleukin-2, IFN-a, or transforming growth factor-a, that selectively suppress the proliferation of Ph-positive cells. It is possible that T cells or natural killer cells act directly against leukaemia cells. A third possibility is that CML cells express leukaemia-specific antigens, possibly coded by the *BCR–ABL* chimeric gene, that provoke a true leukaemia-specific, T-cell response.

Autologous stem-cell transplantation

Despite the qualified success of allo-SCT, the majority of CML patients are not eligible for this therapy and a substantial number have a marginal survival benefit from IFN-a treatment. Autologous SCT following high-dose chemotherapy has a lower TRM and is available to more patients. Retrospective analyses suggest that autografting with blood- or marrow-derived stem cells can prolong survival. The fact that some Ph-negative stem cells survive at the time of diagnosis in most patients provides the rationale for developing techniques that favour reconstitution with Ph-negative haemopoiesis. The Genoa group has pioneered procedures where Ph-negative stem cells are harvested during the recovery phase after chemotherapy; they demonstrated successful engraftment resulting in Ph-negative haemopoiesis. In most cases, however, the Ph-positive haemopoiesis recurs. This recurrence may be due in some cases to residual Ph-positive cells in the autografted material and this provides the rationale for 'purging' techniques. Various *in vitro* and *in vivo* methods have been developed with variable degrees of success. The new generation of *in vitro* purging studies using tyrosine kinase inhibitors targeted against the *BCR–ABL* oncoprotein, such as STI571, may be informative. Although the clinical feasibility and safety of these differing autografting strategies have been demonstrated, the precise therapeutic role of autografting remains unclear.

Conclusions and a suggested therapeutic algorithm

The choice of therapy for the younger CML patient newly diagnosed in chronic phase now requires the benefits and risks of SCT to be balanced against the predicted results of non-transplant therapy. The decision to offer an allogeneic SCT early after diagnosis to a patient under the age of 40 years, in particular if an HLA-matched sibling donor is available, is probably straightforward. For most other patients it is useful to assess all the treatment options carefully. For the present, patients over the age of 60 years cannot safely be treated by SCT, but this may change in the near future following further experience with non-myeloablative SCT. For patients aged between 40 and 60 years who have a suitable molecularly matched unrelated donor and wish to be transplanted, the risk of TRM is such that a trial of STI571 in the first instance is reasonable. We suggest this form of an integrated approach in the therapeutic algorithm shown in Fig. 4. It is likely that some of the other new treatment strategies currently being investigated, such as immunotherapy to activate a leukaemia-specific immune response, will also be integrated in the treatment plans of patients with CML in the near future.

22.3.7 Myelodysplasia

Lawrence B. Gardner and Chi V. Dang

Definition

The myelodysplastic syndromes are a collection of acquired, clonal, haemopoietic disorders characterized by cytopenias and abnormal cellular morphologies. The vast majority of myelodysplastic syndromes (**MDS**) are marked by progressive, multilineage cytopenias, ineffective maturation of cells with dysplastic appearances and chromosomal abnormalities, and a tendency to degenerate into poorly responsive leukaemias. Historically, these syndromes have been referred to as preleukaemias, smouldering leukaemias, and refractory anaemias. In 1976 the French–American–British (**FAB**) Cooperative Group proposed a classification system of these heterogeneous disorders based on the histological appearance of the peripheral blood and bone marrow, with primary emphasis placed on the percentage of immature cells, or myeloblasts, present. This artificial classification has provided a helpful outline for physician communication and research. However, the presentation and prognosis of individuals with MDS vary greatly, depending on the biological impact of the genetic mutation(s) present in an individual's clone. MDS is more common in adults than any acute or chronic leukaemia. While MDS can occur at any age, it is primarily a disease of the old; over 80 per cent of those affected are older than 60 years, and after age 70 there is a prevalence of approximately 33/100 000. The incidence of the disease appears to be increasing, probably in part due to more common screening with complete blood counts, and an increase in secondary, treatment-related MDS. There is currently no effective cure for MDS, except for allogeneic bone marrow transplantation, which is often not an option for the older patient with MDS. Treatment therefore remains supportive, consisting of transfusion and antibiotic treatment for documented infections. Patients often die as a result of their cytopenias (for example, from bleeding or infection) or transformation to leukaemia.

Pathogenesis and pathophysiology

The biology of MDS is difficult to study, since disorders grouped under MDS probably include diagnoses of disparate aetiologies. It is clear from karyotypic analysis, including chromosomal studies, and X-linked inactivation of genetic markers, that MDS is a clonal disorder involving a defect in an early haemopoietic progenitor cell. Thus erythrocytes, platelets, neutrophils, and monocytes may all be affected in MDS. The ability of progenitor cells from patients with MDS to form colonies *in vitro* is markedly diminished. Haemopoietic growth-factor production by lymphocytes from these patients is often decreased, and growth-inhibitory cytokines may be increased. In addition to the abnormal growth characteristics found in MDS progenitor cells in culture, there appears to be a higher rate of programmed cell death, or apoptosis, in such cells, which may contribute to the peripheral cytopenias and ineffective haemopoiesis noted on bone marrow examination.

Chromosomes are often abnormal in MDS. In both therapy-related and *de novo*-acquired MDS, specific chromosomal abnormalities (including deletions of chromosomes 5 and 7, and trisomy 8) are relatively common. A specific chromosomal translocation resulting in an oncogenic fusion protein is often found in a subtype of chronic myelomonocytic leukaemia (**CMMoL**). While the regions of chromosome 5 and 7 often deleted in MDS contain several genes important for haemopoiesis, including granulocyte–macrophage colony-stimulating factor (**GM-CSF**), erythropoietin, interleukin-6 (**IL-6)**, and the receptors for several haemopoietic growth factors, no single gene, or group of genes, has been found to be consistently mutated in MDS. In addition, the pathogenic importance of specific deletions has not been well established. A number of genes important for proliferation and apoptosis have been described to be abnormally expressed in MDS, including the mutated *ras* oncogene which is present in up to 30 per cent of cases, but the importance of these abnormalities in the causation of MDS is unclear. Progression of MDS is often associated with the accumulation of additional chromosomal abnormalities. This stepwise accumulation of mutations, often found in many types of cancers, suggests the dominance of new clones with a proliferation and/or survival advantage.

Primary acquired sideroblastic anaemia is a unique subset of MDS. Other causes of an anaemia with the morphological appearance of ringed sideroblasts include an X-linked inherited form, and a secondary toxic form. Inherited and secondary sideroblastic anaemias are believed to result from a disruption in haem synthesis, producing ineffective haemopoiesis and iron overload. Alcohol, isoniazid, and pyrazinamide are among the common medications that can cause acquired sideroblastic anaemia.

Clinical features

While MDS has been described in children, it is uncommon and other congenital haemopoietic diseases should be strongly considered. And while secondary MDS may occur in younger adults, MDS is primarily a disease of the older adult. The clinical presentation of a patient with MDS depends on the specific cytopenias present, and the extent to which a lineage is depressed. Most commonly, patients present due to a symptomatic anaemia. Because the onset of MDS is gradual and progressive, patients typically present with signs and symptoms of chronic, not acute, anaemia, including fatigue and exertional dyspnoea. If the platelet count is are low, petechiae or other forms of bleeding, typically mucosal or gastrointestinal, may be present. Infections occur with suppressed numbers of white cells, particularly when the absolute neutrophil count is below 500/ml. One form of MDS, CMMoL, shares many characteristics with myeloproliferative diseases. In CMMoL the monocyte count can be quite high, resulting in pleural, pericardial, and peritoneal effusions, as well as splenomegaly. Rheumatological and autoimmune processes have been noted to occur with MDS.

Laboratory diagnosis

Because MDS is a chronic disease, obtaining old laboratory data documenting a progressive, often macrocytic anaemia, thrombocytopenia, and leucopenia, can be invaluable in making the diagnosis. All patients diagnosed with MDS have an anaemia, which is typically either normocytic or macrocytic, although extreme macrocytosis (mean corpuscular volume (**MCV**) >120 fl) is not common. Anaemia and leucopenia in the setting of a normal or elevated platelet count should lead one to consider a subtype of MDS, the 5q-syndrome. The hallmark of MDS is dysplasia, which is often noted on a peripheral blood smear (Fig. 1(a)). Erythrocytes may show anisocytosis (varying sizes), poikilocytosis (abnormal morphology) with bizarre shapes, and basophilic stippling. Polymorphonuclear neutrophils may be hyperlobulated or, more commonly, hypolobulated, sometimes showing the characteristic bilobed appearance of pseudo-Pelger–Huët cells. Hypogranulation may be present, and chromatin may be abnormally clumped. Myeloblasts may be seen in the periphery, and are a poor prognostic sign.

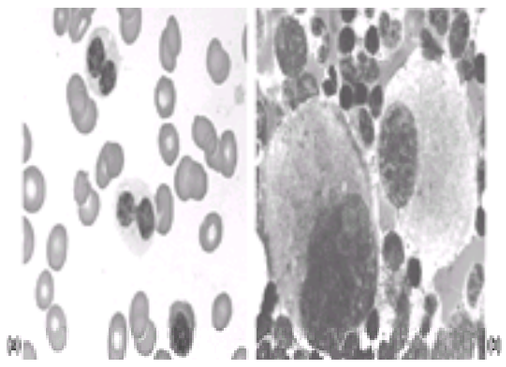

Fig. 1 (a) Peripheral blood smear and (b) bone marrow appearance in MDS. (a) Several dysplastic neutrophils, including a pseudo-Pelger–Huët neutrophil with a bilobed nucleus. The chromatin in the neutrophils is clumped, and the red cells show a range of sizes and appearances. (b) A bone marrow aspirate with a small, monolobed megakaryocyte, typical in MDS.

A bone marrow aspirate and biopsy, along with cytogenetics, are crucial for the diagnosis of MDS (Fig. 1(b)). Although the bone marrow biopsy may reveal a hypocellular bone marrow, this is rare, and should lead one to question the diagnosis and consider aplastic anaemia as the cause of a cytopenia. Typically, the bone marrow biopsy reveals a hypercellular marrow, consistent with the ineffective haemopoiesis common in MDS. The morphology of early progenitor cells shows a lack of maturation, with abnormal forms. Dyserythropoiesis, with multilobed erythroid progenitors, may be present. Megaloblastoid erythropoiesis is common; this is evidenced by an asynchrony of nuclear/cytoplasmic maturation, so that haemoglobin synthesis occurs while the erythroid nucleus is large and young. Megakaryocytes may be diminished, and/or be small and hypolobulated The bone marrow biopsy may show an abnormal localization of immature myeloid precursors (**ALIP**); typically, granulopoiesis occurs in a paratrabecular location, but in MDS there may be a shift to a central intratrabecular site. Depending on the stage of MDS, the number of blasts may be elevated. According to the FAB classification scheme, more than 30 per cent blasts in the marrow defines acute leukaemia, while less than 30 per cent are consistent with MDS. Staining the bone marrow biopsy for CD34+ cells may be helpful in the diagnosis.

Chromosomal abnormalities (deletions, additions, translocations) are very common in MDS. In MDS as a whole, chromosomal abnormalities are found 40 per cent of the time. While MDS may be associated with a normal karyotype, especially in an early stage with few blasts, some chromosomal abnormalities are so typical that their presence strongly suggests the diagnosis. Similarly, multiple complex chromosomal abnormalities leads one to strongly consider a diagnosis of MDS. Typically, the longer a patient has MDS, the more chromosomal abnormalities may occur, leading to a more aggressive clone. The most common abnormalities include monosomy 7, 7q-, monosomy 5, 5q-, trisomy 8, and 20q-. 11q23 is commonly found in secondary MDS due to treatment with topoisomerase II inhibitors, such as the epipodophyllotoxin, VP16 (etoposide). As discussed below, chromosomal abnormalities are important not only in suggesting the diagnosis of MDS, but also in its prognosis. Other diagnostic tests, such as abnormal growth of progenitor colonies in *in vitro* assays, are not widely utilized.

Differential diagnosis

When working up the possible aetiologies of a mild asymptomatic anaemia or pancytopenia in the older patient, where making a diagnosis may not change management, the extent of the work-up should depend on the patient's wishes. However, certain reversible diseases, several of which may be significant to the patient's overall health, must be ruled out. Aplastic anaemia also presents with pancytopenia; however, in contrast to MDS, the bone marrow is hypocellular, CD34+ early progenitor stem cells in the bone marrow are relatively diminished, and there is little evidence of dysplasia. In paroxysmal nocturnal haemoglobinuria the absence of the marker CD59 on the surface of cells, a lack of dysplasia, and low iron stores should differentiate this disease from MDS. Macrocytic, megaloblastoid anaemias as well as pancytopenias are common in patients with vitamin B12 and folate deficiency. These may be ruled out with serum and red cell measurements, respectively. Additionally, these defects should respond rapidly to replacement therapy. The anaemia of chronic disease is primarily a clinical diagnosis, but little dysplasia should be present. Alcoholism and/or hypersplenism can result in a mild pancytopenia, and an abnormal physical examination and normal bone marrow biopsy will rule these out. Bone marrow infiltration by a tumour or fibrosis usually presents with a myelophthisic blood smear consisting of nucleated red cells, teardrop red-cell forms, and a left-shifted myeloid series. Although both MDS and myeloproliferative diseases may present with a hypercellular marrow, it should not be difficult to delineate these two. Myeloproliferative disorders are not marked by dysplasia and bone marrow failure, but by increased proliferation and usually elevated cell counts.

Classification

The 1976 FAB classification divided MDS into five subgroups based on the morphological appearance of the peripheral blood and bone marrow (Table 1). While newer prognostic systems, including a modification of the FAB classification recently proposed by the World Health Organization, are becoming more popular, and aspects of the FAB MDS classification, especially the inclusion of CMMoL, have been criticized, this classification system remains helpful clinically and is the basis of patient stratification in most recent MDS research. In many patients, there is a gradual progression through the subgroups, eventually leading to acute leukaemia.

Refractory anaemia

Refractory anaemia accounts for approximately 25 per cent of all cases of MDS. By definition, less than 5 per cent blasts are present in the bone marrow, and less than 15 per cent ringed sideroblasts are seen with iron staining. Typically, dysplasia in the peripheral blood and bone marrow are minimal, and there are few chromosomal abnormalities. These patients have a relatively low risk of progressing to leukaemia, and may do well for prolonged periods of time.

Refractory anaemia with ringed sideroblasts (RARS)

Ringed sideroblasts are erythroblasts with iron-laden mitochondria encircling more than one-third of the nucleus. More than six Prussian Blue-stained iron granules must be noted, in more than 15 per cent of the cells to make the diagnosis of RARS. In addition, fewer than 5 per cent blasts must be found in the bone marrow. As alluded to above, several drug-induced and hereditary syndromes may also present with ringed sideroblasts: for example, alcohol- and isoniazid-induced and X-linked disease, respectively. It is important to differentiate these states, as their prognosis and treatment may be different than for RARS. For example, inherited RARS may sometimes be successfully treated with pyridoxine, and the most common complication is usually iron overload. RARS, like refractory anaemia, has a relatively low risk of progression to acute leukaemia (approximately 10 per cent), especially when only the erythroid series is suppressed. Median survival is 50 months.

Refractory anaemia with excess blasts (RAEB)

RAEB accounts for approximately 25 per cent of cases of MDS. While ringed sideroblasts may be present, a diagnosis of RAEB is made when the bone marrow contains 5 to 20 per cent blasts. Multiple lineages of cells are usually affected, and chromosomal abnormalities are often found. RAEB has a high rate of progression to acute leukaemia and of bone marrow failure.

Refractory anaemia with excess blasts in transformation (RAEBt)

A diagnosis of RAEBt is made when there are more than 5 per cent blasts in the peripheral blood, or 21 to 30 per cent blasts in the bone marrow. Auer rods (that is, abnormal, oblong lysosomes) may be present in these blasts. These patients have multiple chromosomal abnormalities and a dismal prognosis, with most progressing to acute leukaemia. Obviously the decision that 29 per cent blasts in the marrow confers a diagnosis of MDS, while 31 per cent blasts meet the criteria of leukaemia is artefactual and arbitrary. Even some cases of RAEB, where the bone marrow blasts are less than 20 per cent, clinically behave as—and might be better considered—an evolving acute leukaemia. Thus a proportion of RAEBt cases may be acute leukaemia diagnosed relatively early. The classification of RAEBt is most helpful in those with documented long-term cytopenias and MDS, and characteristic chromosomal abnormalities. Mortality of patients with RAEBt is not dramatically different than those with acute leukaemia, and in fact survivors whose acute leukaemia has evolved from RAEBt have a higher rate of relapse after aggressive chemotherapy.

Chronic myelomonocytic leukaemia (CMMoL)

CMMoL, characterized by fewer than 20 per cent bone marrow blasts and a peripheral monocytosis of more than 1000 monocytes/μl, has many similarities to myeloproliferative diseases such as chronic myelogenous leukaemia. The white blood cell count is typically very elevated, marrow fibrosis can occur, and extramedullary diseases (hepatosplenomegaly, skin) and serositis are common. Splenomegaly is found in approximately 20 per cent of the cases. However, similar to other MDS types, trilineage dysplasia is typically evident. Prognosis best correlates with the percentage of bone marrow blasts, not with the degree of peripheral monocytosis. Approximately 25 per cent of patients progress to acute leukaemia, and death due to cytopenia is common.

Other subtypes of MDS- 5q- and secondary MDS

The 5q- syndrome is a unique subtype of MDS with specific morphological, laboratory, and clinical characteristics. Platelet counts are typically normal, or even elevated. Megakaryocytes are small and hypolobulated. When the only chromosomal abnormality is a deletion of 5, patients have an excellent prognosis with a low risk of transforming to a leukaemic state.

Secondary, or treatment-related MDS, is becoming more prevalent. This is probably due to several factors. Patients with solid malignancies are being treated with more aggressive chemotherapeutic regimens, and they are living longer after these treatments. In addition, it has been postulated that haemopoietic growth-factor support during intensive chemotherapy may be a contributing factor to the development of MDS. Most cases of secondary MDS present within the first decade after treatment. Chromosomal abnormalities are common, occurring more than 90 per cent of the time. Chromosomes 5 or 7, are typically involved, with monosomy 7 occurring in 60 per cent of the cases. Alkylating agents and topoisomerase II inhibitors are the most commonly implicated in causing secondary MDS.

Treatment

With the exception of allogeneic transplant there is no curative treatment for MDS. In addition, once acute leukaemia has evolved from MDS, treatment with aggressive chemotherapy does not usually result in long-term, curative, remission. Although there are several treatments for MDS, there are little data to suggest that drug treatment of MDS prolongs survival over that of standard, supportive care. However, treatment can improve quality of life, and new treatments are being explored.

Because of the limits of therapy, there is no need to treat asymptomatic patients, except when an allogeneic bone marrow transplant is clinically possible and the patient wishes to undergo such a procedure. Thus, mild anaemia and thrombocytopenia without bleeding do not necessitate transfusion. There is no evidence that prophylactic antibiotics are beneficial. However, for symptomatic anaemia, or anaemia in the older patient with cardiovascular disease, and for severely thrombocytopenic patients with episodes of bleeding or who are at high risk for significant bleeds, supportive transfusions are the mainstay of care. Patients may need regular transfusions. It is important to recognize patients who will live for long periods with red cell transfusion; such patients should have their iron status followed, and be initiated on iron chelation therapy to avoid the side-effects of haemosiderosis.

A wide range of myeloablative chemotherapeutic regimens have been explored; for instance, regimens commonly used to treat acute myelogenous leukaemia (**AML**), including aplasia-inducing doses of cytosine arabinoside (**Ara-C**), anthracyclines, cytoxan, and topotecan. A few studies have suggested that selected patients with good-risk characteristics may do as well with such regimens as patients with AML, but the results have usually been disappointing. Complete responses have ranged from 10 to 50 per cent, but these are generally of short duration and accompanied by significant morbidity and mortality. This is probably due to several factors, including the relatively older age of most patients with MDS, the drug resistance of MDS due to the increased expression of multidrug resistance proteins, and limited reserves of normal, healthy marrow for recovery. Low-dose chemotherapy has also been used. While initially explored because these dosing regimens are better tolerated in the older MDS population, many of these agents may have differentiating as well as cytotoxic effects. Low-dose Ara-C, 5-azacytidine, and topotecan have been used. These have resulted in complete responses from 10 to 40 per cent, but again these responses are not durable. Trials with low-dose Ara-C or 5-azacytidine showed no improvement in survival over supportive care. There is still significant scientific enthusiasm for exploring other dosing regimens, other differentiating agents, alone or in combination with growth factors and cytotoxic agents, in the treatment of MDS. For CMMoL, hydroxycarbamide (hydroxyurea) and the control of peripheral monocytosis has been shown to be as effective as aggressive chemotherapy.

Although most patients with MDS are ineligible for an allogeneic stem-cell transplant (either because of their age, comorbid disease, or lack of suitable donor), for some this remains a viable option and hope for cure. Bone marrow transplantation has been successively carried out in highly selected 55- to 66-year-old patients with MDS. The 5-year survival rate for all patients undergoing transplantation ranges from 30 to 70 per cent, but early mortality is common. Patients with refractory anaemia and RARS and younger patients have the best outcomes with transplantation. Normal or good chromosomal abnormalities are also predictive of a better response with a transplant. All high-risk (see next section) young patients should be considered for allogeneic bone marrow transplantation.

Multiple trials have utilized haemopoietic growth factors, such as erythropoietin and granulocyte colony-stimulating factor (**G-CSF**) (or granulocyte–macrophage colony-stimulating factor, **GM-CSF**), sometimes in combination. Short-term (1–2 weeks) and prolonged treatment with erythropoietin and G-CSF or GM-CSF do not appear to increase the progression to acute leukaemia. In a majority of patients, neutrophil counts increase, sometimes with a documented decrease in infection, and there are often improvements in red cell and platelet counts with decreased transfusion requirements. Some patients may actually respond with a decreased platelet count, and some patients may not tolerate some of the side-effects of the injections. Current evidence suggests that overall survival does not appear to be improved. Generally higher doses of erythropoietin (>200 U/kg per day) may be necessary, and patients with lower serum erythropoietin levels (<500 mU/ml) tend to have better responses. Laboratory data has suggested that the combination of erythropoietin and G-CSF may be synergistic in promoting the growth of haemopoietic progenitor colonies. Several clinical studies have suggested that the combination of erythropoietin and G-CSF is more effective than either alone, especially in patients with low serum erythropoietin levels and in those with ringed sideroblasts. Ciclosporin, an immunosuppressant, has also recently been reported as effective in MDS, especially when the marrow is hypocellular. In general, treatment choices should be based on the patient's performance status and age, the prognosis of the disease, and, whenever possible, in the setting of a clinical research protocol.

Prognosis

The median survival of all those with MDS has been reported to be between 12 and 28 months. However, since MDS consists of a variety of diseases, prognosis varies widely. A number of prognostic factors have been studied. Many of the factors which have proven to be predictive in prospective and retrospective studies are intuitive. Because the most common causes of death in patients with MDS are transformation to leukaemia or symptomatic cytopenias, a poorer prognosis is seen in those with increased bone marrow blasts and with more severe cytopenias. Other important prognostic factors include age and specific karyotypic abnormalities.

Because the FAB classification is for the most part dependent on the percentage of bone marrow blasts, the FAB subtypes closely correlate with both overall survival and evolution to acute leukaemia (Fig. 2). Those with refractory anaemia (**RA**) and RARS have a low incidence of leukaemia, both within the first 2 years and overall, and an improved survival rate. Patients with increased blasts, seen in RAEB and RAEBt do worse, and the overall survival in RAEBt is not significantly different than AML. Virtually all patients with RAEBt evolve to acute leukaemia within 30 months. Univariate analysis has also indicated that those with two or three cytopenias do worse than those with none or just one cytopenia, probably because those with more cytopenias have increased blasts, and are more prone to bleeding and infection. Marrow cytogenetics have also been found to be important. A relatively good prognosis is found in deletions of 5q, 20q, -Y in men, or normal cytogenetics. Of note, when these deletions are accompanied with other chromosomal abnormalities, they do not connote a good prognosis. Those with complex chromosomal abnormalities, or deletions of 7 do particularly poorly, with a high progression to acute leukaemia.

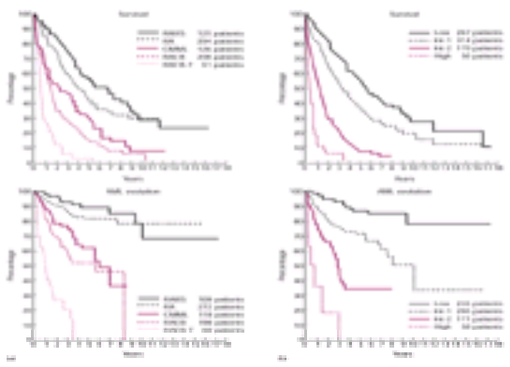

Fig. 2 Survival and evolution to leukaemia in MDS in groups defined by FAB classification (a) and IPSS (b). RA, refractory anaemia; RARS, refractory anaemia with ringed sideroblasts; RAEB, refractory anaemia with excess blasts; RAEBt, refractory anaemia with excess blasts in transformation; CMMoL, chronic myelomonocytic leukaemia. IPSS as defined in Table 2. (Figures taken from Greenberg P, *et al.* (1997). International scoring system for evaluating prognosis in myelodysplastic syndromes. *Blood* **89**, 2079–88, with permission from the publisher.)

Several of these prognostic indicators have been combined in various scoring systems to predict the survival of patients with MDS. One of the most accurate, and most widely used, is the International Prognostic Scoring System (**IPSS**) (Table 2). The IPSS assigns points for unfavourable characteristics, such as unbalanced chromosomal translocations, percentage of blasts in the bone marrow, and lineages affected by the MDS. Although the IPSS is somewhat cumbersome to use for clinicians, and no scoring system is perfect for individual patients, the IPSS is useful for investigators and for making general decisions regarding the aggressiveness of treatment.

Further research

Increasing information on normal stem-cell biology and haemopoiesis will clearly lead to increased understanding of the abnormal haemopoietic development seen in MDS. Particular areas of research being explored include the role of apoptosis in MDS, and specific genetic mutations (or groups of mutations) that are necessary for the development of MDS. The importance of individual mutations or chromosomal abnormalities for prognosis is still being explored. A major emphasis in the stem-cell transplantation field is on increasing the availability of transplants. This includes making transplantation less toxic through non-myeloablative induction strategies, capitalizing on the graft-versus-tumour phenomena, and increasing the number of potential donors with international registries and by minimizing the importance of HLA barriers. Clearly these improvements will aid in the treatment of MDS. The most active area of research in specific treatment of MDS, is in the role of non-toxic differentiating agents.

22.3.8 The polycythaemias

David M. Gustin and Ronald Hoffman

Introduction

Polycythaemia or erythrocytosis is associated with an aetiologically distinct group of disorders characterized by an abnormal increase in the numbers of red blood cells, leading to an elevation in the haemoglobin concentration and haematocrit. Absolute polycythaemias (increased red cell mass) can be attributed to either an intrinsic defect of haemopoietic stem cells (primary) or to the stimulation of progenitor cells by excessive levels of circulating growth factors (secondary). A pathophysiological classification of polycythaemia is offered in Table 1. Patients with absolute polycythaemias should be distinguished from individuals in whom a minimally elevated haematocrit is not accompanied by a corresponding absolute increase in the red cell mass (spurious polycythaemia, stress erythrocytosis, Gaisbock's syndrome), but rather by a contraction of plasma volume.

Erythropoiesis

Erythropoietin (EPO), a 34.4-kDa glycoprotein hormone, is the primary humoral regulator of red blood cell production. Erythropoiesis occurs at a low baseline level to replace normal, senescent red blood cells. Decreased tissue oxygen tension increases erythropoietin levels by enhancing expression of the *EPO* gene. The circulating, secreted erythropoietin binds to receptors present on erythroid progenitor cells, promoting the proliferation and differentiation of erythroid precursors, ultimately resulting in an increased red cell mass. This complex process enhances the oxygen-carrying capacity of blood, leading to elevated tissue oxygen tension and down-modulating erythropoietin production. A peritubular interstitial cell is the primary site of erythropoietin production in the kidney. An oxygen-sensing haem protein present in these cells is essential for the control of erythropoietin production. It induces the transcription of EPO mRNA, a phenomenon mediated by hypoxia-inducible factors (**HIF**), a group of nucleoproteins that interact with the enhancer element of the *EPO* gene. The kidney has no preformed stores of erythropoietin. Increases in plasma levels are primarily due to new hormone synthesis. Since anaemia or hypoxia does not seem to influence, to any significant degree, the plasma clearance of erythropoietin, the control appears to occur mainly at the level of gene expression. Erythropoietin production also occurs in the liver to a lesser degree. The severity of hypoxia required to induce its production is much greater than that required in the kidney.

Oxygen transport is a complex process dependent on a number of variables, such as ambient oxygen levels, minute ventilation, lung diffusion capacity, cardiac output, red cell mass, regional blood flow, tissue capillary density, and haemoglobin–oxygen affinity. Acute changes in tissue oxygen demands or in environmental oxygen levels are compensated not only by increased erythropoietin production but also in minute ventilation, cardiac output, blood flow distribution, and haemoglobin–oxygen affinity (thro-ugh the modulation of 2,3-diphosphoglycerate (**2,3-DPG**) production). Sustained hypoxia is required for polycythaemia to occur as a compensatory mechanism.

Relative polycythaemias

A common group of disorders is marked by an elevated haemoglobin or haematocrit as the result of the contraction in plasma volume. The red cell mass remains normal. There are two major groups of patients with relative polycythaemias. The first includes patients with more acute conditions associated with significant degrees of dehydration with a consequent decrease in extracellular volume: for example, gastrointestinal fluid losses, therapeutic diuresis, endocrine disorders such as Addison's disease, and hypercalcaemia. In most cases, the presence of volume contraction is clinically obvious. The aetiology of the increase in haematocrit does not usually present a diagnostic challenge.

The second group is associated with a chronic low-level increase in the haematocrit. These patients are frequently active, hard-working, middle-aged, mildly hypertensive, obese males subjected to considerable stress who present with persistent polycythaemia. Characteristically, they appear plethoric but without any of the other typical features of polycythaemia vera. The cause for the contraction in the plasma volume is poorly understood, but autonomic dysregulation with changes in venous capacitance have been suggested.

The usual range of haemoglobin in these individuals is between 18 and 20 g/dl with haematocrits ranging from 49 to 55 per cent. Most of these patients seek medical evaluation for an unrelated condition, and are incidentally found to have increased haemoglobin and haematocrit values.

Suitable advice regarding weight reduction, control of hypertension, and smoking cessation is usually given to these patients. Evidence associating the mild elevations in viscosity encountered in this condition with episodes of thrombosis is incomplete. It seems sensible to recommend phlebotomy for those patients who have already experienced thrombotic episodes and who have persistent elevations of their haematocrits. It is more difficult to justify phlebotomy in asymptomatic individuals with mild elevations in haematocrit.

Absolute polycythaemia

Absolute polycythaemias may be classified as being primary, due to autonomous cell growth or to an enhanced response to growth factors that promote the proliferation of developing erythroid cells, or secondary, due to excessive production of erythropoietin in response to a variety of stimuli. Primary polycythaemia caused by defects in haemopoietic stem cells, is accompanied by low levels of circulating erythropoietin. Germline mutations that lead to enhanced erythropoiesis cause primary familial congenital polycythaemias. Polycythaemia vera, the most common primary polycythaemia, is caused by an acquired defect in haemopoietic stem cells resulting in an excessive proliferation of myeloid cells. By contrast, secondary polycythaemia is generally associated with elevated erythropoietin production. Raised levels of plasma erythropoietin can accompany systemic hypoxaemia, certain neoplasms, and disorders that impair oxygen delivery to tissues.

Absolute polycythaemias are accompanied by an elevated red cell mass. Documentation of such a mass to confirm the presence of an absolute polycythaemia usually requires a blood volume study with direct quantitation of both the red cell mass and plasma volume. An haematocrit greater than 60 per cent in men and greater than 55 per cent in women, however, are almost always associated with absolute erythrocytosis. In such cases it is frequently unnecessary to perform blood volume studies to be assured that the patient has an absolute polycythaemia.

Secondary polycythaemias associated with appropriate erythropoietin secretion

This group of polycythaemias encompasses a number of conditions that are ultimately the result of tissue hypoxia and subsequent excessive erythropoietin production leading to erythrocytosis. These disorders are collectively regarded as hypoxic erythrocytoses.

Hypobaric hypoxia

At high altitudes the barometric pressure and, consequently, the ambient oxygen tension are reduced, resulting in alveolar and arterial hypoxia. Natives of the Andes mountains who live above 4200 metres have been reported to have haematocrits 30 per cent higher than individuals who live at sea level. Acutely, changes in minute ventilation, heart rate, blood flow, and haemoglobin–oxygen affinity occur as an individual reaches a high altitude. Serum erythropoietin is elevated initially, but

eventually returns to the normal range in the absence of extreme hypoxia. This decline will not prevent the increase in red cell mass, which will be sustained, because early unsustained elevations of erythropoietin promote expansion of the erythroid progenitor pool. Only very small quantities of the hormone are subsequently required to sustain the red cell mass under normal circumstances.

A decrease in the plasma volume frequently accompanies hypoxic erythrocytoses resulting in further elevation of the haematocrit. Some individuals who live at high altitudes for prolonged periods develop chronic mountain sickness. They suffer from headaches, fatigue, impaired exercise tolerance, cyanosis, clubbing, right heart failure, and absolute polycythaemia. These symptoms frequently resolve with therapeutic phlebotomy.

Chronic pulmonary disease

Pulmonary diseases are a common cause of secondary polycythaemias. Defects in gas exchange result in hypoxia, with consequent increases in erythropoietin and red cell mass. Not every patient with hypoxia secondary to respiratory disease develops polycythaemia. The presence of concurrent inflammation or infection may blunt the marrow response to hypoxia. It is important to be aware that smoking itself may also contribute significantly to the polycythaemia associated with chronic respiratory disease. Phlebotomy may be indicated in patients with relatively high haematocrits (55–60 per cent), given the known deleterious effects of increased viscosity on tissue perfusion.

Alveolar hypoventilation

Hypoventilation may lead to hypoxia and an erythropoietin-mediated increase in red cell mass. These disorders include the sleep apnoea syndrome and supine hypoventilation. In these conditions, significant degrees of hypoxia may occur without evident parenchymal pulmonary disease. Decreases in blood oxygen content may occur intermittently, consequently erythropoietin levels and arterial blood gas values may be normal. Diseases affecting the central nervous system may impair respiratory centre function and trigger hypoventilation. These defects have been described in association with encephalitis, cerebrovascular accidents, and drug intoxication (that is, barbiturates). Impaired skeletal muscle function of the chest wall or diaphragm may also sufficiently compromise alveolar ventilation to trigger polycythaemia. In these cases, correction of hypoxia is warranted. The role of phlebotomy is unclear, but not unreasonable in patients with significant elevations in haematocrit and associated cardiovascular or cerebrovascular disease.

Cardiovascular disease

Cyanotic congenital heart diseases with associated right-to-left shunt result in oxygen desaturation and an elevation of erythropoietin, causing secondary polycythaemia. After compensatory erythrocytosis in response to oxygen desaturation occurs, serum erythropoietin levels may return to normal levels. Characteristically, therapeutic phlebotomy is associated with marked increases in erythropoietin levels. Some children with congenital heart disease may develop extreme haematocrit values (80 per cent or higher), which lead to a clear risk of a thrombotic event, especially during periods of dehydration. Phlebotomy may be indicated in some instances: for example, in preparation for elective surgery. Further clinical information is required to establish the precise target haematocrit value for therapeutic phlebotomy in the management of these disorders.

Carbon monoxide intoxication

Chronic carbon monoxide intoxication most commonly occurs as a consequence of smoking. Elevated haematocrits have been reported in 3 per cent of all smokers. Other less common causes include work-related exposures such as those seen in caisson workers or tunnel toll-collectors. Carbon monoxide has a much higher affinity for haemoglobin than oxygen, thereby reducing the amount of oxygen that can be bound and transported by haemoglobin. It also shifts the oxygen–haemoglobin dissociation curve to the left, decreasing the ability of haemoglobin to release oxygen to peripheral tissues. Furthermore, carbon monoxide impairs normal compensatory mechanisms; carboxyhaemoglobin is known to decrease 2,3-DPG production by red cells and to reduce the affinity of haemoglobin for 2,3-DPG. Polycythaemia due to chronic carbon monoxide intoxication may be associated with an increased risk of thromboembolic phenomena. Phlebotomy may be indicated in patients with very high haematocrits (>55–60 per cent).

The decreased oxygen-carrying capacity associated with carbon monoxide intoxication is not detected by standard blood gas measurements, therefore a direct measure of carboxyhaemoglobin levels is required. Morning carboxyhaemoglobin levels ranging from 4 per cent to 20 per cent have been reported. Individuals with chronic carbon monoxide poisoning may experience neuropsychiatric and cardiac abnormalities. The treatment is smoking cessation or removal of the patient from the alternative source of carbon monoxide.

High-affinity haemoglobins

At least 50 haemoglobin variants exhibit increased avidity for oxygen. Oxygen transport by haemoglobin occurs as a function of the oxygen–haemoglobin affinity curve. This function is represented by a sigmoid-shaped curve and is a reflection of the initial binding of oxygen by deoxygenated haemoglobin occurring with significant difficulty. As oxygen molecules are bound to normal haemoglobin, further binding is facilitated by structural changes that occur to the haemoglobin molecule. High-affinity haemoglobin variants arise when mutations alter key amino acid residues in regions of haemoglobin that affect these rearrangements, or at the interface between a- and b-chains. Another group of mutations induces changes in oxygen affinity indirectly, by causing structural changes in haemoglobin regions that are critical for the binding of 2,3-DPG.

Increases in oxygen affinity result in a shift of the oxygen dissociation curve to the left. Consequently haemoglobin binds oxygen more readily and retains more oxygen at lower *P*O2 (partial pressure of O2) levels. This ultimately results in decreased delivery of oxygen to tissues where capillary *P*O2 is low (35–45 mmHg). Mild tissue hypoxia then triggers an increase in the production of erythropoietin with consequent polycythaemia.

Oxygen affinity by a variant haemoglobin is usually measured as the $P_{50}O_2$, which represents the partial oxygen pressure at which 50 per cent of haemoglobin is saturated with oxygen. This analysis is necessary for the identification of patients with high-affinity haemoglobins. High-affinity haemoglobins are associated with lower than normal values of $P_{50}O_2$. Haemoglobin electrophoresis may, on occasion, aid in the recognition of an abnormal haemoglobin, but many high-affinity haemoglobins display normal electrophoretic mobility. Conversely, the presence of an abnormal band *per se* does not provide information regarding oxygen affinity. A study of family members is important, but a negative family history does not negate the diagnosis since there is a high rate of spontaneous mutations.

Most patients with high-affinity haemoglobins have mild polycythaemia and are asymptomatic since the compensatory polycythaemia results in normal oxygen delivery to tissues. On rare occasions, very high haematocrits (>55–60 per cent) associated with elevated blood viscosity may be sufficient to warrant therapeutic phlebotomy.

Methaemoglobinaemias

Hereditary methaemoglobinaemia may be associated with a mild polycythaemia. Methaemoglobin results from the oxidation of ferrous ions (Fe^{2+}) to the ferric state (Fe^{3+}). Oxygen does not bind reversibly to methaemoglobin, so resulting in a left shift of the oxygen dissociation curve, impaired oxygen delivery, and chronic tissue hypoxia.

2,3-Diphosphoglycerate (2,3-DPG) deficiency

This rare familial form of polycythaemia is due to a deficiency of the enzyme diphosphoglyceromutase. Deficiency leads to a decrease in 2,3-DPG, resulting in the increased affinity of oxygen to haemoglobin, peripheral tissue hypoxia, and hypoxic erythrocytosis. This disorder should be suspected in patients with familial polycythaemia with a low $P_{50}O_2$ in the absence of a mutant haemoglobin. Measurements of 2,3-DPG in fresh red cells reveals reduced levels.

Chuvash polycythaemia

Chuvash polycythaemia is a recently recognized form of congenital and familial polycythaemia that is endemic to the Chuvash population of the Russian Federation. The extreme elevations of haemoglobin in this autosomal recessive disorder are accompanied by increased erythropoietin levels. Excessive elaboration of erythropoietin is thought to be due to an abnormality of the oxygen-sensing mechanism. These patients present with isolated erythrocytosis without elevations of white

cells or platelets. Death frequently occurs before the age of 40 due to thrombotic and haemorrhagic complications.

Secondary polycythaemias associated with the inappropriate secretion of erythropoietin

Enhanced erythropoietin levels and secretion occur in the absence of tissue hypoxia in this group of disorders. The erythropoietin response is therefore inappropriate to systemic oxygen requirements.

Polycythaemia of renal disease

As the kidney is the major site of erythropoietin production, it is not surprising that renal disorders may be associated with erythrocytosis or anaemia. Patients with hypertension and renal artery stenosis have a higher incidence of erythrocytosis than similarly hypertensive patients without renal artery disease. Other benign kidney diseases associated with an increase in erythropoietin production and erythrocytosis include polycystic kidney disease (acquired or familial) and renal cysts. Unusual patients with glomerulonephritis may also occasionally present with an elevated haematocrit. An uncommon cause of polycythaemia is Bartter's syndrome, an hereditary tubular disorder characterized by hypokalaemia secondary to renal potassium loss in association with elevated plasma renin activity and aldosterone secretion. Between 5 and 13 per cent of patients have been reported to develop erythrocytosis following renal transplantation. It has been postulated that the excessive erythropoietin response originates from the patient's own kidneys and not from the transplanted one. Angiotensin-converting enzyme inhibitors may prove useful in controlling post-transplantation polycythaemia. Phlebotomy may be required in patients with haematocrit levels over 55 to 60 per cent.

Tumour-associated polycythaemia

A number of tumours are associated with an inappropriately increased production of erythropoietin, including benign and malignant tumours of the kidney, hepatomas, cerebellar haemangioblastomas, and phaeochromocytomas. Polycythaemia occurs in 1 per cent of patients with renal carcinomas, 9 to 20 per cent of patients with cerebellar haemangioblastomas, and 10 per cent of patients with hepatomas. Resection of the tumour, if feasible, may be associated with regression of the polycythaemia. Therapeutic phlebotomy is recommended in patients with extreme increases in the haematocrit.

Endocrine disorders

Phaeochromocytomas and aldosterone-producing adenomas have been associated with increased levels of erythropoietin. Mild forms of polycythaemia have also been observed in some patients with Cushing's syndrome, probably related to marrow stimulation by steroid hormone.

Primary polycythaemia

Primary familial and congenital polycythaemia (PFCP)

PFCP is an inherited form of polycythaemia caused by mutations in the erythropoietin receptor, thereby resulting in the hypersensitivity of erythroid progenitor cells to erythropoietin and low serum erythropoietin levels. In the autosomal dominant form of the disease, family members have plethora, headaches, dizziness, nose bleeds, and exertional dyspnoea. These symptoms resolve with phlebotomy and reduction of the haematocrit. Not all cases of PFPC can be attributed to the mutations of the erythropoietin receptor, suggesting that other genetic defects can lead to a similar phenotype.

Polycythaemia vera

Polycythaemia vera is a malignancy characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic elements in the bone marrow. Its hallmark is an absolute increase in the red cell mass usually associated with leucocytosis, thrombocytosis, and splenomegaly. In contrast to other haematological malignancies, patients suffering from polycythaemia vera may enjoy prolonged survival, provided that the excessive production of red cells and platelets is controlled. This survival is occasionally punctuated by the development of myelofibrosis and/or acute leukaemia.

Epidemiology

Polycythaemia vera is a rare disorder, the estimated yearly incidence in the Western world is between 5 and 17 cases per 1 million of the population. Its true prevalence is unknown but it seems to be more common in Ashkenazi Jews and rarer in Afro-Americans. A very low incidence of 2 cases per year per million population has been reported in Japan. These differences suggest that environmental as well as genetic factors might be important.

Polycythaemia vera is slightly more common in males than in females, with a male to female ratio of 1.2:1. The average age at diagnosis is 60 years, it is very rare in individuals younger than 30 years of age. Only a handful of cases have being reported during childhood.

Biological and molecular aspects

The exaggerated production of red cells, granulocytes, and platelets in polycythaemia vera suggests that the fundamental defect occurs at the level of the pluripotent haemopoietic stem cell. The clonal, and thereby malignant, nature of polycythaemia vera was first established by the cellular analysis of blood cell production, in heterozygous Afro-American women, of X-linked glucose-6-phosphate dehydrogenase (**G6PD**) isoenzymes. These results have recently been confirmed using restriction fragment length polymorphisms (**RFLPs**) of the active X-chromosomes.

In patients with polycythaemia vera, erythropoietin levels often fall below the 95 per cent confidence interval for normal individuals. These low levels persist even after repeated phlebotomies, suggesting that excessive production of erythropoietin is not a critical component in the pathogenesis of this disorder. Using *in vitro* cell-culture systems, polycythaemia-vera bone marrow can form erythroid colonies in the absence of erythropoietin (endogenous colonies). Erythroid progenitor cells derived from normal individuals are incapable of forming such colonies in the absence of exogenous erythropoietin. In addition to the erythroid colonies, mixed-lineage colonies are frequently formed in the absence of exogenous erythropoietin, suggesting the involvement by not just erythroid precursors but also of more primitive haemopoietic progenitor cells. Both malignant and normal cells are present in the bone marrow of patients with polycythaemia vera, but the malignant cells have a growth advantage. Most peripheral blood elements are thus derived from the neoplastic clone. We now know that the clonal assay systems that were first used to produce endogenous erythroid colonies contained trace quantities of erythropoietin. In newer systems that are absolutely devoided of erythropoietin, the progenitor cells in polycythaemia vera require erythropoietin, but clearly demonstrate increased sensitivity to this growth factor.

Polycythaemia vera progenitor cells are also hypersensitive to other cytokines such as steel factor, interleukin-3 (**IL-3**), and granulocyte–macrophage colony-stimulating factor (**GM-CSF**). These responses require the presence of insulin-like growth factor-1 (**IGF-1**) or of its binding protein (**IGFBP-1**). At present, the primary signalling protein defect that underlies the characteristic hypersensitivity to this broad group of cytokines remains unknown.

Pathobiology

Patients with polycythaemia vera have an increased thrombotic tendency resulting from the expansion of the red cell mass. There is a direct relationship between the risk of thrombosis and age, suggesting that the presence of vascular disease might be important. Younger individuals are also at risk for thrombotic episodes, many of them life-threatening. The main rheological abnormality is elevated total blood viscosity. Cerebral blood flow is reduced in patients with polycythaemia vera and a haematocrit of 53 to 62 per cent. Reductions in blood flow are correctable by phlebotomy. Even small reductions in the haematocrit result in significant reduction in blood viscosity and cerebral blood flow. An increased haematocrit may facilitate the transport of platelets to the vessel wall, an event that may lead to thrombus formation. Elevation in blood viscosity also results in greater peripheral vascular resistance and a consequent reduction in organ blood flow, thereby increasing the likelihood of thrombus development. Thrombocytosis and functional platelet abnormalities are frequently present, and may play a role in the development of thrombosis. This relationship is still highly controversial.

Patients with polycythaemia vera are also at an increased risk of developing life-threatening haemorrhagic complications. Abnormalities in platelet function and number have been implicated. Qualitative platelet abnormalities include defective platelet aggregation *in vitro*, acquired storage pool disease, and dysregulated thromboxane A_2 metabolism. Patients with acquired von Willebrand syndromes have been described who have very high platelet counts (>1000 × 10^6/μl), in

association with life-threatening bleeding episodes. Leucocytosis, found in 50 per cent of patients, may impact negatively on the rheology of the microcirculation. No laboratory test has proven useful for the *a priori* identification of patients at an increased risk of developing haemorrhagic or thrombotic events.

The progression to the so-called 'spent phase' is a common cause of morbidity. This stage, also known as postpolycythaemic myeloid metaplasia (**PPMM**), is characterized by cytopenias, myelofibrosis, and extramedullary haemopoiesis. The fibroblastic component represents a reactive event, and may be due to the local release of growth factors, particularly platelet-derived growth factor. The association between the treatment modality and the development of myeloid metaplasia is as yet unclear. Clearer is the association between treatment type (alkylating agents and ^{32}P; see below), and the development of acute leukaemia. It must be emphasized, however, that even those patients treated with phlebotomy alone have a leukaemogenic risk significantly higher than that expected in the general population.

Clinical manifestations

The clinical manifestations of polycythaemia vera are the direct consequence of the excessive proliferation of cellular elements of the various haemopoietic cell lineages.

The routine and widespread use of laboratory screening tests during medical evaluations has led to an increased detection of asymptomatic patients. In contrast, symptomatic patients may present to their physician with a large array of non-specific complaints including headache, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paraesthesias, joint symptoms, and epigastric distress. Some one-third of patients will have lost 10 per cent of their body weight by the time they present, presumably due to the associated hypermetabolism. Joint disease is usually the manifestation of gout, due to the increased production of uric acid. The most important signs on physical examination include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension.

Patients left without appropriate treatment are at a particularly high risk of developing thrombotic or haemorrhagic events. In fact, thrombosis may be the cause of death in up to 30 to 40 per cent of patients. Thrombosis may occur in the deep venous system of the lower extremities, or present as a pulmonary embolism. Cerebrovascular, coronary, and peripheral vascular occlusions are not rare.

Thromboses at unusual sites are characteristic of polycythaemia vera. They include occlusion of the splenic, portal, hepatic, and mesenteric veins. Cardiac valve abnormalities affecting the aortic or the mitral valves are commonly seen, frequently in the form of leaflet thickening or frank vegetations. These lesions are associated with the occurrence of arterial thromboembolism. Hepatic venous or inferior vena caval thrombosis is known as Budd–Chiari syndrome. It is characterized by hepatosplenomegaly, ascites, oedema of the peripheral extremities, jaundice, abdominal pain, and distension of superficial abdominal veins due to portal hypertension. Some ten per cent of patients who present with Budd–Chiari syndrome have polycythaemia vera. At times, these patients will present with normal haemoglobin and haematocrit levels as a consequence of blood loss and expansion of the plasma volume. This phenomenon is regarded as 'inapparent polycythaemia vera' and requires direct quantification of the red cell mass for confirmation. Iron deficiency may also mask the expected erythrocytosis in some patients with polycythaemia vera. Leucocytosis, thrombocytosis, and splenomegaly are usually present. The definitive diagnosis of polycythaemia vera in this patient population requires the documentation of an elevated red cell mass.

Neurological abnormalities are also common and occur in up to 60 to 80 per cent of patients. They include transient ischaemic attacks, cerebral infarction, cerebral haemorrhage, confusional states, fluctuating dementia, and involuntary movement syndromes. Dizziness, paraesthesias, tinnitus, visual problems, and headaches are common symptoms attributed to the hyperviscosity state. Small infarcts in the basal ganglia region, also known as lacunae, might be related to some of the transient neurological manifestations. Symptoms of carotid or vertebral and basilar artery insufficiency occur frequently. Peripheral vascular insufficiency may be manifested by intense redness or cyanosis of the digits, burning, classical erythromelalgia, digital ischaemia with palpable pulses, or thrombophlebitis. Erythromelalgia consists of a burning pain in the digits of either the lower and/or upper extremities, an objective sensation of increased temperature, and relief by cooling. If left untreated it may evolve into gangrene. Antiplatelet aggregation therapy rapidly reverses the symptoms. Peripheral pulses are usually normal in these patients, as this phenomenon is due to changes in the microcirculation related to arteriolar activation and aggregation of platelets *in vivo*.

Haemorrhagic complications are the cause of death in 2 to 10 per cent of patients with polycythaemia vera: 30 to 40 per cent of patients will experience a haemorrhagic event sometime during the course of their disease. Peptic ulcer disease occurs frequently and contributes to the gastrointestinal tract being the most common source of bleeding. The bleeding diathesis may relate to abnormalities in platelet function, and thus occurs frequently after the ingestion of anti-inflammatory agents. Spontaneous bleeding is rare. Recent data suggests that low-dose aspirin might not increase the frequency of life-threatening haemorrhages.

The risk of postoperative complications is high in patients with polycythaemia vera. Bleeding, thrombosis, or a combination of both can occur. The risk is higher for those patients who undergo surgery with uncontrolled erythrocytosis. Generalized pruritus affects 50 per cent of all patients, but its aetiology is unknown. Increased blood and urine histamine levels have been implicated by some. Pruritus triggered by water contact is characteristic and tolerated very poorly. There is no relationship between the severity of the disease and the intensity of the pruritus. Up to 20 per cent of patients experience persistent pruritus in even after normalization of their counts.

Polycythaemia vera evolves to PPMM in up to 50 per cent of the patients 10 years, on average, after the initial diagnosis. It is characterized by increased splenomegaly, tear-drop red cells, a leucoerythroblastic blood picture, marrow fibrosis, and a normal or decreasing red cell mass. Fatigue, dizziness, weight loss, anorexia, progressive anaemia, and thrombocytopenia associated with bleeding are common. Patients with progressive anaemia should be evaluated for folate and iron deficiency. Occasional patients will respond to iron supplementation with resurgence of erythropoiesis. Severe hyperuricaemia may induce gout or uric acid nephropathy. PPMM portends a very grave prognosis with over two-thirds of patients dying within 3 years.

The evolution to acute leukaemia is probably the natural consequence of the malignant nature of polycythaemia vera, which can be accentuated by the therapeutic interventions commonly used for its treatment, such as alkylating agent use or radioactive phosphorus (^{32}P) administration. A randomized study conducted under the auspices of the Polycythaemia Vera Study Group (**PVSG**) comparing chlorambucil, ^{32}P, and phlebotomy is instructive. After 15 years of follow-up, 17.5 per cent of patients treated with chlorambucil and 10.9 per cent of those who received ^{32}P had developed acute leukaemia. Only 1.5 per cent of patients treated with phlebotomy alone developed acute leukaemia. This still represents a much higher incidence than the one expected in a normal age-matched population. Between 30 and 50 per cent of patients who develop leukaemia have previously entered the spent phase, whereas 50 per cent progress directly from the erythrocytotic phase. A significant number of patients experience a myelodysplastic interval before transforming. Large-cell lymphomas have been observed in roughly 3.5 per cent of patients treated with chlorambucil.

Laboratory evaluation

Polycythaemia vera is a panmyelosis. Some two-thirds of the patients present with leucocytosis and approximately 50 per cent with thrombocytosis. Red cell morphology usually reflects an underlying iron deficiency state: microcytosis, hypochromia, polychromatophilia, poikilocytosis, and anisocytosis are frequently seen. White blood cell morphology is usually normal. Increased numbers of basophils, eosinophils, and immature myeloid cells are observed. Megathrombocytes are often seen in the peripheral blood smear. Platelet counts are usually under $1 \times 10^6/\mu l$, but higher counts may be seen. The PPMM phase is characterized by a leucoerythroblastic response with the presence in the peripheral blood of tear-drop red cells (dacrocytes), immature myeloid cells, and nucleated red blood cells. Bleeding time and platelet aggregation studies are frequently, but not always, abnormal. Prolongation of prothrombin and partial thromboplastin times are frequently encountered, usually reflecting a laboratory artefact due to erythrocytosis (the volume of plasma in the collection tube might be too small relative to the amount of anticoagulant (citrate) present in these tubes).

Acquired von Willebrand factor (**vWF**) defects are frequently characterized by a significant decrease in large vWF multimers. This acquired defect resembles type II vWF disease. It occurs mainly in patients with very high platelet counts ($>1 \times 10^6/\mu l$), implicating the adsorption of larger forms of vWF multimers on to platelet membranes. The defect is corrected by normalization of the thrombocytosis. Elevations in leucocyte alkaline phosphatase (70 per cent), serum vitamin B12 levels (40 per cent), and serum vitamin B12 binding proteins (70 per cent) are common, as are hyperuricaemia and increased histamine levels.

Bone marrow examination reveals a hypercellular marrow with an increased number of megakaryocytes. The cellular elements are morphologically normal. Iron stores are usually absent prior to treatment. Reticulin is often seen, but is not predictive of evolution into the spent phase. At diagnosis, erythropoietin levels are either reduced or within the lower limits of normal. Low levels persist in two-thirds of patients after normalization of their haematocrit. Cytogenetic abnormalities have been described, but none are characteristic. Abnormalities in chromosomes 1, 5, 7, 8, 9, 12, 13, and 20 have been detected. The frequency and complexity of these

chromosomal abnormalities are a function of the disease longevity and duration of treatment.

Diagnostic criteria of polycythaemia vera

Clinical criteria for the diagnosis of polycythaemia vera have been developed. These criteria have proven useful in defining a homogeneous study population for incorporation into clinical studies, but, in our opinion, the previously utilized criteria have a number of shortcomings that are of clinical relevance. In Table 2 we offer what we believe to be a more flexible and useful criteria utilizing modern diagnostic tools for the diagnosis of polycythaemia vera.

Approach to the patient with polycythaemia

It is wise to avoid the temptation of diagnosing polycythaemia on the basis of a single blood count determination unless extremely high levels are identified. A rational diagnostic approach is required to avoid unnecessary emotional distress to the patient as well as expensive and unnecessary evaluations (see Fig. 1).

Fig. 1 Diagnostic approach to the patient with polycythaemia.

Dehydration from any cause can produce a spurious elevation in the blood counts. Heavy smokers with mild polycythaemias should be asked to stop smoking and their counts repeated after a few weeks. Once a genuine elevation of haemoglobin or haematocrit has been established, the next step is to decide whether this represents an absolute increase in total red cell mass, or just a relative phenomenon. A blood volume study with direct quantitation of both red cell mass and plasma volume is helpful in making this distinction. If absolute polycythaemia is confirmed, it is essential to elucidate whether it is the consequence of a primary myeloproliferative disorder such as polycythaemia vera or a secondary condition.

The determination of erythropoietin levels may prove to be of diagnostic utility. An elevated serum erythropoietin level is indicative of the presence of a secondary polycythaemia and a low level supports the diagnosis of polycythaemia vera, but a normal erythropoietin value excludes neither hypoxia nor the autonomous production of erythropoietin as the cause. Normal values may also be encountered in some cases of polycythaemia vera.

The presence of leucocytosis, thrombocytosis, or splenomegaly is suggestive of polycythaemia vera as the cause for the elevated red cell mass. Arterial blood gases and the direct determination of oxygen saturation in arterial blood, if decreased they may aid in the recognition of a chronic pulmonary or congenital cardiovascular abnormality. If blood oxygen saturation is normal, the quantification of haemoglobin's oxygen affinity ($P_{50}O_2$) may indicate the presence of a high-affinity haemoglobin variant. Otherwise, causes for a physiologically inappropriate polycythaemia should be sought.

There is a small but definite group of patients in whom a specific cause for polycythaemia remains elusive, despite appropriate diagnostic testing. Examining close relatives might disclose the presence of a hereditary polycythaemia, a rare condition caused by an abnormality in erythropoietin control. Regular, continued surveillance is recommended for all non-categorized patients, as some of them develop polycythaemia vera in the future.

Management of polycythaemia

The two major tasks in the management of polycythaemia involve the identification of a correctable cause and the reduction of the red cell mass. The untoward effects of an increased red cell mass on tissue blood flow occur independently from the specific cause of the polycythaemia. It is thus reasonable to recommend that all patients with uncorrectable erythrocytosis be offered phlebotomy. A haematocrit under 45 per cent represents a reasonable target.

Polycythaemia vera is an incurable disorder. The main therapeutic goals are the maintenance of well being and the prevention of complications for as long as possible. Several therapeutic strategies have resulted in dramatic increases in the survival of patients. Historical evidence suggests a median survival of approximately 18 months in untreated patients, whereas with appropriate management survival of over 10 years is now common. The main therapeutic objective is the reduction of the haematocrit to a safe level. This is usually accomplished by the implementation of repeated phlebotomies. Every possible effort should be made to discourage patients with polycythaemia vera from smoking. A regimen of phlebotomies should be prescribed as soon as the diagnosis has been clearly established. It is often feasible to remove between 350 and 500 ml of blood every other day until the desired haematocrit level is attained. Haematocrit levels of less than 50 per cent and preferably below 45 per cent are desirable. The removal of smaller aliquots might be necessary in older patients.

Once the target haematocrit level is achieved, a maintenance regimen should be instituted. Venesection is preferred in those younger individuals without critical elevations in their platelet counts. Myelosuppressive therapy should be considered in elderly patients who are intolerant of phlebotomies, and in younger individuals with repeated thrombotic episodes and extremely high platelet counts. There is controversy regarding what represents the optimal myelosuppressive agent. A major concern has been the growing evidence that supports the association between exposure to some of these agents and the development of leukaemia. A number of clinical studies have been conducted in order to clarify the risk/benefit ratios of some of these approaches.

The Polycythemia Vera Study Group conducted a randomized comparison of three interventions: (1) phlebotomy only; (2) chlorambucil supplemented by phlebotomy; and (3) ^{32}P supplemented by phlebotomy. Median survival was shorter for the chlorambucil group (9.1 years) and statistically similar for ^{32}P (10.9 years) and for the phlebotomy-only group (12.6 years). Chlorambucil treatment was clearly associated with an unacceptably large number of acute leukaemias. Thrombosis as a cause of death was much more common in the phlebotomy-only group, whereas the use of ^{32}P led to a higher incidence of leukaemias, lymphoma, and non-haematological malignancies. In a subsequent study, high-dose platelet antiaggregating agents (aspirin and dipyridamole) were added to phlebotomy and compared with ^{32}P. Surprisingly, a higher number of thrombotic and serious bleeding episodes were seen in the former group. In a recent study, however, 40 mg/day of aspirin was administered to patients with polycythaemia vera in order to prevent thrombosis and minimize the bleeding risk. This regimen was shown to be well tolerated, safe, and appeared to reduce the thrombotic risk. Hydroxycarbamide (hydroxyurea) is useful for the management of a number of patients with polycythaemia vera, despite emerging evidence suggesting a mild leukaemogenic potential. At present, hydroxyurea is the chemotherapeutic drug of choice in those patients who can not be treated with phlebotomy alone.

In younger patients, given their potential long-term survival, strong consideration should be given to the use of phlebotomy therapy in combination with low-dose aspirin, as well as with other apparently non-leukae-mogenic interventions such as interferon-a and anagrelide. In patients where uncontrolled thrombocytosis is a problem, anagrelide, an inhibitor of megakaryocytic maturation, has proven effective.

Elective surgery should only be undertaken after adequate and sustained control of the blood count has been achieved. When emergency surgery is required the patient should be phlebotomized rapidly until a normal haematocrit is achieved, and platelets should be available in case excessive operative bleeding occurs. Patients should be mobilized promptly, and the use of prophylactic doses of low molecular weight heparin should be considered unless contraindicated. Dental extractions are associated with an increased bleeding risk and should only be pursued in patients with good haematological control.

In the later spent phases of the disease the management is quite similar to that for primary myelofibrosis. It mainly consists of blood product replacement, folate and

iron replacement, and splenectomy if there is significant hypersplenism. The prognosis of patients with acute leukaemia that has evolved from pre-existing polycythaemia vera is very poor, with very few long-term survivors after aggressive combination chemotherapy.

Pregnant patients with polycythaemia vera experience an increased incidence of fetal wastage, with 30 per cent of pregnancies culminating in spontaneous abortions. Interestingly, pregnancy in patients with polycythaemia vera is frequently associated with a gradual normalization of blood values, and it is not unusual for a woman who has required extensive therapy for control of her disease to no longer require phlebotomies during pregnancy. Delivery appears not to be complicated by excessive haemorrhage or by an increased risk of venous thrombosis.

Prognosis

The outcome of patients with secondary polycythaemia is usually related to the prognosis of the underlying disorder. In polycythaemia vera, the nature and severity of the complications during the clinical course of the disease are the most important determinants of outcome. Disease duration is also important, as long-term survival is strongly associated with progression into the spent phase or acute leukaemia. As was previously emphasized, prompt and appropriate therapy results in dramatic improvements in survival. Young patients should be initially managed with phlebotomy and low doses of aspirin. Supplemental therapy with interferon, anagrelide, or hydroxyurea might be required in patients with serious haemorrhagic or thrombotic episodes. The use of either hydroxyurea or ^{32}P appears warranted in the treatment of elderly patients who, because of their age, have a limited survival.

Jerry L. Spivak

Introduction

Idiopathic myelofibrosis (also called myelofibrosis with myeloid metaplasia, agnogenic myeloid metaplasia, primary myelofibrosis, or primary myelosclerosis) is a chronic clonal disorder of unknown aetiology, involving a multipotent haemopoietic progenitor cell that results in abnormalities in red cell, white cell, and platelet production in association with marrow fibrosis and extramedullary haemopoiesis. Although myelofibrosis in association with leucoerythroblastosis and splenomegaly are the clinical hallmarks of idiopathic myelofibrosis, these abnormalities can also be seen in other chronic myeloproliferative disorders such as polycythaemia vera and chronic myelogenous leukaemia as well as in a variety of benign and malignant disorders that involve the bone marrow (Table 1). Since there is no specific clonal marker for idiopathic myelofibrosis and since many of the disorders listed in Table 1 are responsive to specific therapies not effective in idiopathic myelofibrosis, the diagnosis of this disorder is one of exclusion.

Aetiology

The aetiology of idiopathic myelofibrosis is unknown. Analysis of glucose-6-phosphate dehydrogenase (**G6DP**) isoenzyme expression and X-linked gene inactivation patterns in informative women, as well as N-*ras* mutations, have established the clonality of idiopathic myelofibrosis and its origin in a multipotent haemopoietic progenitor cell. In some patients, T lymphocytes express the same clonal marker as B lymphocytes and myeloid cells, suggesting involvement at the level of the pluripotent stem cell. Non-random chromosome abnormalities primarily involving chromosomes 13 (del. 13q), 20 (del. 20q), and 1 (partial trisomy 1q) occur, but are found in fewer than 40 per cent of patients at the time of diagnosis. No abnormalities of the known tumour suppressor genes associated with these chromosomes have yet been identified.

The basis for the myelofibrosis has proved equally problematic. Marrow fibroblasts in idiopathic myelofibrosis are polyclonal, suggesting that the fibrosis is a reactive process initiated by expansion of the monoclonal malignant clone. Marrow collagen is argyrophilic, so that changes in its distribution and content can be analysed histochemically by silver staining. Under normal circumstances, the connective tissue stroma of the bone marrow is composed of collagen types I, III, IV, and V together with non-collagen proteins such as fibronectin, laminin, vitronectin, and the proteoglycans. Collagen types I, III, and V form a delicate and usually non-continuous supporting network for haemopoietic cells, while type IV collagen, laminin, and fibronectin are localized in the basement membranes of arteries in a continuous fashion and along marrow sinusoids in a discontinuous fashion. With increasing marrow cellularity, the collagenous supporting network also increases. In myelofibrosis, however, there is both an increase in the collagen network and a change in its physical characteristics. Condensation of the interstitial fibres results in the formation of thick, continuous and often wavy bundles in association with an increase in reticular or fibroblastic cells. Sinusoidal basement membrane collagen becomes continuous, leading to sinusoidal dilatation and obliteration with an associated capillary neovascularization. The content of basement membrane fibronectin as well as stromal fibronectin and vitronectin also increases. While best studied in idiopathic myelofibrosis, the types of collagen involved in marrow fibrosis in this condition do not appear to differ from those involved in the marrow fibrosis associated with the other disorders listed in Table 1.

Neither the stimulus nor the molecular basis for the increase in marrow collagen and non-collagenous extracellular matrix proteins in idiopathic myelofibrosis is understood. The commonality of the types of collagen involved and the similarity of the histological process, regardless of disease association, implies that marrow fibrosis *per se* represents a final common pathway involved in the response to diverse immunological, metabolic, toxic, or infectious stimuli (Table 1). Megakaryocytic hyperplasia, dysplasia, and clustering is characteristic of idiopathic myelofibrosis. These cells produce proteins such as platelet-derived growth factor (**PDGF**) and transforming growth factor-b (**TGF-b**) that promote fibroblast proliferation, and platelet factor 4, which, like TGF-b, inhibits collagenase. These findings suggest that inappropriate release of these fibrogenic proteins by dysfunctional megakaryocytes is the stimulus for myelofibrosis. In support of this contention, elevated levels of PDGF and TGF-b as well as basic fibroblast growth factor have been observed in platelets and megakaryocytes from patients with idiopathic myelofibrosis. Circulating levels of TGF-b are also increased in idiopathic myelofibrosis, as is the urinary excretion of basic fibroblast growth factor and calmodulin, another potential fibroblast stimulant present in platelets.

However, these findings must be reconciled with the observations that neither overexpression of PDGF nor high levels of circulating TGF-b alone are associated with marrow fibrosis, presumably because PDGF in the circulation is inactivated by a2-macroglobulin and TGF-b usually circulates in an inactive from. Furthermore, in some studies the appropriate control populations were not examined, while in others there was significant overlap in the overexpression of these proteins when they were examined. Importantly, there was no correlation between marrow TGF-b content and megakaryocyte number, nor was there a correlation between marrow fibrosis and platelet number, although such a correlation existed between the extent of fibrosis and granulocyte number. Nevertheless, given what is known about the process of tissue fibrosis in other organs, it is likely that a combination of cytokines and growth factors such as TGF-b, PDGF, basic fibroblast growth factor, interleukin-1, and tumour necrosis factor (**TNF**) acting in synergy are required to initiate and perpetuate collagen deposition. In addition, thrombopoietin may also have a role, since overexpression of this hormone can cause myelofibrosis in animal models. Neither the cells responsible for the elaboration of these cytokines nor their targets, whether reticulum cells or fibroblasts, have been defined but recent evidence suggests that monocytes may be an important source of cytokine production. What has been learned, however, is that myelofibrosis is reversible by chemotherapy or bone marrow transplantation and occasionally spontaneously resolves.

Clinical features

Although considered to be an uncommon disorder with an incidence of approximately 1/100 000 person-years, clinical studies of more than 1000 patients have been reported over the last 40 years. In contrast to the other chronic myeloproliferative disorders, the median age at diagnosis of myelofibrosis, 61 years (range 15–94), is much older. No gender differences exist and familial clustering is sufficiently unusual that another myeloproliferative disorder such as polycythaemia vera should be considered when this occurs. The presenting manifestations depend on the state of the illness but are often bland. Many patients are asymptomatic at the time of discovery. Fatigue is the commonest presenting complaint followed by weight loss, night sweats, fever, dyspnoea, and abdominal discomfort due to splenomegaly. Hearing loss due to otosclerosis is an interesting but often non-elicited symptom. Easy bruising or bleeding and acute gout or renal stones are other presenting manifestations that are reasonably common and directly related to the underlying disease process. Rarely, periostitis may occur.

Splenomegaly is present in virtually every patient with idiopathic myelofibrosis at diagnosis. When absent, one should consider other causes for the clinical abnormalities. The degree of splenomegaly varies but is frequently substantial. Moreover, the rate of splenic enlargement is also variable; spleen size cannot be used as an indication of disease duration. Hepatomegaly, invariably of a lesser extent than the splenomegaly, is present initially in approximately 50 per cent of patients and is usually proportional to the degree of splenomegaly. Lymphadenopathy is uncommon. With substantial splenomegaly, wasting may be prominent.

Laboratory studies

Because of its origin in a multipotent haemopoietic progenitor cell, idiopathic myelofibrosis affects all cell lines but not in a predictable manner. Anaemia, usually mild, is the most consistent abnormality. Indeed, a normal haemoglobin or haematocrit in the presence of substantial splenomegaly should lead to immediate consideration of polycythaemia vera, since the expanded plasma volume associated with splenomegaly can mask a substantial increase of the red cell mass. The leucocyte and platelets counts can be low, normal, or high without reference to spleen size. Inevitably, due to extramedullary haemopoiesis, metamyelocytes, myelocytes, promyelocytes, myeloblasts, and nucleated red cells will be present in the circulation together with the tear drop-shaped red cells characteristic of this situation (Fig. 1). While this so-called leucoerythroblastic reaction is not specific for idiopathic myelofibrosis, its absence should challenge the clinical impression. Abnormalities in liver function tests are not uncommon, usually mild and most often involve a reduction in serum albumin and an elevation of the alkaline phosphatase, an abnormality

that is magnified by splenectomy. The lactate dehydrogenase (**LDH**) level is usually mildly increased and correlates best with the leucocyte count. Hyperuricaemia is not infrequent. The leucocyte alkaline phosphatase concentration can be low, normal, or high and so cannot be recommended as a diagnostic test.

Note, in addition, the abnormal platelet morphology and platelet clumps.

Perhaps the most intriguing laboratory abnormalities in idiopathic myelofibrosis are those linked to autoreactivity, such as circulating immune complexes, complement activation, elevations in antinuclear antibody (**ANA**) and rheumatoid factor titres, and a positive Coombs' test in the absence of an overt connective tissue disorder. Although marrow fibrosis has been documented in patients with systemic lupus erythematosis, the linkage between autoimmune abnormalities and marrow fibrosis is unclear. It does, however, provide another therapeutic option as discussed below.

The presence of marrow fibrosis is essential for a diagnosis of idiopathic myelofibrosis and usually results in a 'dry tap' or the inability to aspirate marrow from a properly placed needle. A prefibrotic phase of idiopathic myelofibrosis has been described retrospectively. However, given the similarity of the histopathology of polycythaemia vera, essential thrombocytosis, and premyelofibrotic myelofibrosis, prospective substantiation of the latter disorder is not possible in the absence of marrow fibrosis and/or a specific clonal marker. Even the presence of myelofibrosis, while mandatory, is not in itself sufficient for diagnosis. This is because polycythaemia vera and chronic myelogenous leukaemia and other disorders such as hairy-cell leukaemia, myelodysplasia, and acute leukaemia can present with myelofibrosis. Thus, it is essential to employ the appropriate diagnostic tests (cytogenetics, *BCR–ABL* polymerase chain reaction (**PCR**), flow cytometry, and immunohistochemistry) to exclude these and the other disorders listed in Table 1 that can cause myelofibrosis.

Marrow cellularity in idiopathic myelofibrosis may be increased with trilineage hyperplasia and erythroblastic and megakaryocytic islands, decreased with scattered areas of hyperplastic marrow embedded in a collagenous matrix, or hypoplastic with intense osteomyelosclerosis and residual megakaryocytic islands (Fig. 2). While there is a correlation between the degree of fibrosis and osteosclerosis, there is no correlation between bone marrow histology and disease duration, platelet count, or splenomegaly; marrow fibrosis does, however, appear to correlate with the leucocyte count. In general, marrow fibrosis and extramedullary haemopoiesis with myeloid metaplasia appear unrelated, and the latter abnormalities cannot be considered as compensation for the former. Increased marrow angiogenesis is a recently recognized feature of idiopathic myelofibrosis which correlates with increased cellularity and extramedullary haematopoiesis independently of marrow fibrosis.

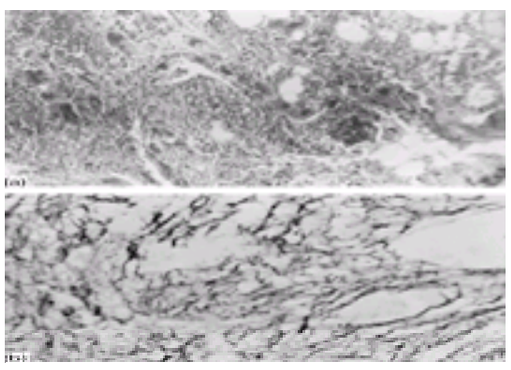

Fig. 2 Bone marrow appearances in myelosclerosis. (a) A biopsy showing a hyperplastic fragment with marked megakaryocytic hyperplasia; (b) silver stain showing the marked increase in reticulin.

In conjunction with the most severe form of marrow fibrosis, osteosclerosis, radiographic abnormalities become apparent. These primarily involve the axial skeleton but can include the skull, with thickening of bony trabeculae and patchy or coalescent sclerosis. With obliteration of axial marrow, extension of the marrow into the long bones occurs. Interestingly, the increase in trabecula bone formation in idiopathic myelofibrosis is not accompanied by an increase in either osteoblastic or osteoclastic activity. This feature distinguishes the osteosclerosis of idiopathic myelofibrosis from that associated with metabolic causes of osteosclerosis.

Course and prognosis

Idiopathic myelofibrosis is a chronic progressive disorder with a median lifespan (5.5 years) that is much shorter than for polycythaemia vera and essential thrombocytosis. However, the heterogeneity characterizing the initial clinical presentation is also evident with respect to survival, which can range from less than a year to more than 30 years. Death is usually a consequence of bone marrow failure (haemorrhage, anaemia, or infection), transformation to acute leukaemia, portal hypertension, heart failure, cachexia, or myeloid metaplasia with organ failure. Retrospective analysis of the adverse prognostic value of presenting manifestations has identified a number of factors that may be useful for both prognostic and therapeutic purposes. These include age at onset (>64 years), anaemia (haemoglobin <10 g/dl), constitutional symptoms, white cell count abnormalities (<4000/μl or >12 000/μl), thrombocytopenia, circulating blast cells (>1 per cent), and cytogenetic abnormalities. A number of scoring systems have been devised for identifying long- and short-term survivors based on the presence of more than one adverse presenting manifestation. Two such scoring systems that are useful in separating patients of any age with myelofibrosis into low- and high-risk groups with respect to survival are shown in Table 2.

Complications

The major complications of idiopathic myelofibrosis are the consequences of bone marrow failure and extramedullary haemopoiesis.

Anaemia may be the result of ineffective erythropoiesis, but haemodilution due to the expanded plasma volume associated with splenomegaly, iron deficiency due to gastrointestinal blood loss, folic acid deficiency due to the increased demands of haemopoiesis, haemolysis due to autoimmune phenomena or hypersplenism, and, rarely, pyridoxine deficiency are also considerations. In some patients, erythropoietin production may be inappropriately low for the degree of anaemia but in this instance haemodilution needs to be excluded. Red cell survival and splenic sequestration studies can be useful in determining the splenic contribution to anaemia. Ferrokinetic studies, although no longer easily obtained, provide a means of assessing effective marrow erythropoiesis.

Hyperuricaemia is a consequence of increased cell turnover and can provoke acute gout or renal stone formation if left untreated.

Splenic enlargement is inevitable and can lead to splenic infarction, malnutrition due to early satiety, plasma volume expansion, hypersplenism, portal hypertension,

extreme discomfort due to its mass, and eventually cachexia (Fig. 3). Hepatomegaly is associated with splenomegaly. Impaired hepatic function is a consequence of extramedullary haemopoiesis, which can lead to hepatic fibrosis and portal hypertension.

Fig. 3 Autopsy showing massive splenomegaly together with a splenic infarct on the medial surface of the spleen in a patient with advanced myelosclerosis.

Although myeloid metaplasia due to exuberant extramedullary haemopoiesis is most common in the spleen and liver, it can occur at any site and compromise organ or tissue function. For example: peritoneal involvement can lead to ascites; epidural involvement to spinal cord compression; retroperitoneal involvement to obstructive uropathy or portal hypertension; and intravascular haemopoiesis to pulmonary thrombosis. The reason why myeloid metaplasia is more aggressive in some patients than in others is unclear.

Approximately 20 per cent of patients with idiopathic myelofibrosis develop acute leukaemia as a terminal event. Although some clinicians do not distinguish acute leukaemia presenting with myelofibrosis (malignant myelosclerosis) from idiopathic myelofibrosis, they are clinically distinct entities. The extent to which therapeutic intervention with mutagenic drugs such as hydroxycarbamide (hydroxyurea), alkylating agents, or irradiation predisposes patients with idiopathic myelofibrosis to progress to acute leukaemia (as it does in patients with polycythaemia vera or essential thrombocytosis) is unknown. Again for unknown reasons, splenectomy also appears to be a predisposing factor for the development of acute leukaemia.

Platelet dysfunction is a common feature of the chronic myeloproliferative disorders and can lead to spontaneous haemorrhage as well as increased bleeding during surgical procedures. Although abnormalities in platelet morphology, prolongation of the bleeding time, and abnormal platelet aggregation are frequently observed in patients with idiopathic myelofibrosis, no consistent biochemical abnormality has been identified and no platelet function test is predictive for the risk of haemorrhage.

Therapy

There is no specific therapy for idiopathic myelofibrosis. Treatment should be individualized based on the patient's risk group and age. Asymptomatic, low-risk patients without hyperuricaemia or a remedial cause of anaemia require no therapy, although the oral administration of folic acid (1 mg per day) and a trial of oral pyridoxine (250 mg per day for 3 months) appears reasonable. Anaemia associated with an inappropriately low endogenous erythropoietin level may respond to recombinant erythropoietin therapy but the hormone can cause an increase in splenomegaly or hepatomegaly. Hyperuricaemia should be treated with allopurinol. Asymptomatic leucocytosis or thrombocytosis requires no therapy. Patients of appropriate age, who are in a high-risk category and who have a matched, related donor should be considered for allogeneic bone marrow transplantation. In the absence of a suitable donor, therapy with recombinant a-interferon should be employed. This can alleviate splenomegaly and reduce myeloid metaplasia but may not reverse marrow fibrosis. Interferon therapy can be limited by the induction of leucopenia or thrombocytopenia and by its side-effects in elderly patients, in whom interferon therapy should be initiated at a low dose.

Given the known sensitivity of patients with polycythaemia vera to chemotherapeutic agents and irradiation, these forms of therapy should be used judiciously in the treatment of idiopathic myelofibrosis. Hydroxycarbamide, while easy to use and with a low incidence of acute toxicity, is leukaemogenic and should not be employed before a trial of interferon. Busulfan is another effective agent that has been demonstrated to reduce organomegaly, reverse marrow fibrosis, and improve blood counts, occasionally in a durable fashion. However, busulfan has significant toxicities, not least of which is prolonged marrow aplasia. Its influence on the development of acute leukaemia in patients with idiopathic myelofibrosis is unknown.

Splenomegaly is the most distressing complication of idiopathic myelofibrosis, leading to mechanical discomfort, inanition, splenic infarction, portal hypertension, and blood cell sequestration. Reduction in splenic size can be achieved with interferon, alkylating agents, hydroxcarbamide, splenectomy, and splenic irradiation. Interferon is the treatment of choice followed by chemotherapy with either busulfan or hydroxycarbamide. Splenic irradiation can be effective at alleviating splenic pain and temporarily reducing spleen size. However, its use should be restricted to inoperable patients since there is an unpredictable risk of severe cytopenias as well as an increased risk of haemorrhage if the irradiation precedes splenectomy. Local irradiation is, of course, appropriate for the management of patients with symptomatic extramedullary haemopoiesis.

Splenectomy in idiopathic myelofibrosis is a prodigious procedure, given the large size of the spleen and its vessels, the inevitable presence of adhesions, the haemorrhagic tendency of patients with idiopathic myelofibrosis, and their often poor nutritional status. Evaluation for portal hypertension should precede surgery and, if necessary, parental hyperalimentation should be employed to avoid postoperative complications. Epsilon-aminocaproic acid should be used if bleeding is a problem.

Leucocytosis, thrombocytosis, and postoperative hepatic enlargement are the usual consequences of splenectomy, as is elevation of the alkaline phosphatase. Postoperative splenic and portal vein thrombosis occur in approximately 10 per cent of patients, most often in the first few weeks after surgery and presumably due to the size of the splenic vein remnant. However, there is no correlation between splenic or portal vein thrombosis and the platelet count. Surveillance by sonography or computed tomography may useful in identifying this complication with the intent of administering anticoagulants or thrombolytic agents. Although most patients tolerate splenectomy well, the incidence of the transformation of idiopathic myelofibrosis to acute leukaemia is increased postsplenectomy, for unknown reasons.

Finally, as mentioned earlier, both autoimmune phenomena and capillary neovascularization are features of idiopathic myelofibrosis. The use of antiangiogenetic and immunosuppressive agents such as thalidomide are currently undergoing clinical trials. Corticosteroids may also be beneficial if autoimmune phenomena are clinically significant. Finally, tuberculosis was a frequent complication of idiopathic myelofibrosis early in the nineteenth century. Thus, constitutional symptoms in these patients should not be attributed to the myeloproliferative disease without first excluding an infectious process.

Thrombocytosis

David M. Gustin and Ronald Hoffman

Thrombocytosis refers to a platelet count elevated above the accepted normal range (more than 500 × 10^9/l). The widespread use of automated cell counters has made the identification of platelet count abnormalities a relatively common event requiring further evaluation. The clinical consequences are usually determined by the cause of the thrombocytosis, ranging from the uneventful recognition of a laboratory abnormality, to medical emergencies such as life threatening thrombosis or haemorrhage.

Pathophysiology and classification

An understanding of the disorders of platelet production requires knowledge of the regulatory events that occur during normal megakaryocytopoiesis. Megakaryocyte development is a complex process in which a wide variety of regulatory signals work in concert to direct a highly specific response to thrombopoietic demand. A large number of cytokines including interleukins (IL-3, IL-6, IL-9 and IL-11), c-kit ligand, granulocyte–macrophage colony stimulating factor (GM-CSF), thrombopoietin (TPO) and, possibly, erythropoietin have been shown to stimulate megakaryocyte development, but TPO and its receptor, c-mpl, are the primary physiological regulators of *in vivo* magakaryocytopoiesis. The liver and the kidney contribute most of the basal, constitutive production of TPO. Levels are regulated by the total mass of platelets and megakaryocytes. TPO binding to its receptor on these cells, and its subsequent degradation, represents its main pathway of clearance. During times of thrombopoietic stress, there is increased TPO production by the spleen and bone marrow. Inappropriately elevated levels of TPO may be observed in primary thrombocythaemia. This is probably not due to excessive production but rather impaired TPO clearance associated with decreased expression of the TPO receptor by megakaryocytes and platelets. Molecular abnormalities in the TPO gene, however, have been recently identified in several families with an autosomal dominant form of hereditary thrombocytosis where serum TPO levels are significantly elevated. This syndrome has been shown to be due to a mutation in a portion of the TPO gene which plays a crucial role in regulating its expression.

Thrombocytosis can occur in response to many underlying clinical conditions (secondary or reactive), or as an expression of a primary abnormality in bone marrow function (primary). A classification of the causes of thrombocytosis is offered in Table 1. Reactive or secondary thrombocytosis account for over 80 per cent of all recognized cases of thrombo-cytosis (platelet count more than 500 ×10^9/l). Short-lived, secondary thrombocytosis may be observed in situations such as trauma, acute bleeding, major surgery, or after strenuous physical exercise. Longer-term thrombocytosis is associated with the presence of chronic disorders such as malignancy, inflammation, chronic infections, and iron deficiency anaemia. The pathophysiology of reactive thrombocytosis is not fully understood but probably involves the increased generation of inflammatory cytokines such as IL-1, IL-6, GM-CSF and, possibly, TPO. Primary thrombocytosis by contrast is associated with a group of bone marrow disorders including chronic myeloid leukaemia, primary thrombocythaemia, polycythaemia vera, myeloid metaplasia with myelofibrosis, and the myelodysplastic syndromes. The level of elevated platelet numbers is not helpful in differentiating a reactive from a primary process.

For the most part, the presence of an underlying cause for reactive thrombocytosis can be identified by clinical criteria. A number of laboratory tests can be useful in distinguishing primary from secondary thrombocytosis. C-reactive protein synthesis in the liver is mediated by IL-6, with C-reactive protein levels being high in those patients with elevated IL-6 levels. Elevated levels of both IL-6 and C-reactive protein are strongly indicative of the elevated platelet count being reactive. The presence of 'endogenous erythroid colonies' (erythroid progenitor cells that proliferate *in vitro* without the addition of erythropoietin) and of megakaryocyte progenitor cells that are hypersensitive to certain stimulatory cytokines *in vitro* may be helpful in the identification of myeloproliferative disorders. Assays using probes for genes located on the X chromosome might help identify clonal haemopoiesis. In a number of female patients with a primary thrombocytosis, this can indicate the malignant origin of these underlying disorders.

The natural history and prognosis of reactive thrombocytosis is defined by its underlying cause. The thrombocytosis per se is probably inconsequential and does not require specific therapy. The thrombocytosis usually resolves after the treatment of the underlying cause. In contrast, the thrombocytosis due to underlying myeloproliferative disorders can cause life-threatening thromboembolic phenomena and bleeding episodes, and frequently requires specific cytoreductive therapy, emphasizing the need for accurate recognition. Primary or essential thrombocythaemia is the most important cause of primary thrombocytosis.

Primary thrombocythaemia

Primary thrombocythaemia, also known as essential thrombocythaemia or essential thrombocytosis, is a chronic myeloproliferative disorder characterized by marked megakaryocytic hyperplasia. The clinical course is punctuated by episodes of thrombosis and/or bleeding. In 1951, Dameshek suggested that primary thrombocythaemia represented a myeloproliferative disorder and hypothesized its clonal nature. The myeloproliferative disorders are currently thought to represent primary stem cell disorders.

Aetiology and pathogenesis

The causative factors of primary thrombocythaemia are poorly understood. Its pathogenesis involves the abnormal proliferation of a blood cell precursor that differentiates mainly towards the megakaryocytic/platelet compartment. Current evidence suggests that hypersensitivity to stimulatory cytokines such as IL-3, IL-6, TPO, and GM-CSF, coupled with relative insensitivity to inhibitory soluble factors such as transforming growth factor-b (TGF-b), might provoke the expansion of the megakaryocytic progenitor pool. Its clonal origin was initially established through biochemical isoenzyme characterization of the blood cells of affected women who were heterozygous for glucose-phosphate dehydrogenase (G-6PD). More recently, analysis of X-linked restriction fragment length polymorphisms in affected women has confirmed a clonal pattern in some cases. Recent evidence, however, suggests hat a significant number of patients have polyclonal myelopoiesis and that these non-clonal cases may have a decreased risk for thrombosis. This information therefore suggests that primary thrombocythaemia, as diagnosed by the currently accepted clinical and laboratory criteria, is a heterogeneous disorder in terms of clonality. The pathogenesis of such sustained non-reactive polyclonal thrombocytosis is as yet unclear.

Epidemiology

The true incidence of primary thrombocythaemia is unknown. Approximately 6000 new cases are identified each year in the United States. There seems to be a slight female predominance and the usual age at onset is between 50 and 60 years. Approximately 20 per cent of all cases occur in individuals younger than 40, but it is very rarely seen during childhood.

Pathobiology

The characteristic clinical features are dominated by the thrombocytosis and abnormalities in platelet function. The association between increased numbers of circulating platelets and ischaemic episodes remains unclear, but duration of thrombocytosis may play a role. Microvascular thrombosis results in a variety of clinical

syndromes associated with digital and cerebrovascular ischaemia. Abnormalities in platelet aggregation occur in 35 per cent to 100 per cent of patients, and prolongation of the bleeding time in 7 per cent to 19 per cent. Despite being common, these abnormalities are poor predictors of bleeding and/or thrombotic risk. This is in contrast to the acquired von Willebrand syndrome and erythromelalgia, clinical entities not infrequently seen in association with primary thrombocythaemia. In acquired von Willebrand syndrome, extreme thrombocytosis (more than 1000×10^9/l) induces the adsorption of larger von Willebrand multimers on to platelet membranes and their subsequent degradation, triggering a haemostatic defect that induces a bleeding diathesis quite similar to that observed in Type II von Willebrand disease. Erythromelalgia refers to redness and burning pain in the extremities which results from platelet-mediated thrombosis of the arterial microvasculature. If left untreated it may progress to frank gangrene. Its exquisite response to cyclo-oxygenase inhibitors such as aspirin and indomethacin suggests that prostaglandin endoperoxides produced by the metabolism of arachidonic acid play a major role in the generation of platelet-associated thrombosis.

Clinical features

As many as two-thirds of patients are asymptomatic when diagnosed. Most symptomatic patients present with either a thrombotic episode or a minor bleeding episode. Bleeding can occur spontaneously but is frequently associated with the recent use of a non-steroidal anti-inflammatory drug. Common sites of haemorrhage include the gastrointestinal and the genito-urinary tracts as well as easy bruisability of the skin. Thrombosis leads to the most common presenting symptoms and can occur in arteries and veins, large or small. Occlusion of the splenic vessels and of the superficial and deep veins of the lower extremities is common. Pulmonary emboli may also occur. An occasional patient presents with thrombosis of the hepatic veins causing the Budd–Chiari syndrome or with occlusion of the renal veins manifesting clinically as nephrotic syndrome.

When the microcirculation is involved, a number of clinical syndromes may occur. Palpable lesions with small areas of gangrene indistinguishable from vasculitic lesions of rheumatoid arthritis or systemic lupus erythematosus may be observed. Erythromelalgia may occur in association with transient ischaemic attacks or acute episodes of cardiac angina. Peripheral pulses are usually preserved; this helps differentiate erythromelalgia from atherosclerotic-related ischaemia. Neurological symptoms are common and include headaches and paresthesias of the extremities. Transient ischaemic attacks may present with symptoms of unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine headaches, and seizures. On occasion, transient ischaemic attacks may progress to established infarcts. Myocardial ischaemia with normal angiograms occurs occasionally. Thrombotic non-bacterial endocarditis, usually affecting the mitral or aortic valves, may manifest with findings of distal emboli. Splenic enlargement is often seen. Patients unaware of their diagnosis who have undergone splenectomy as part of the diagnostic work-up for splenomegaly will predictably develop extreme increases in their platelet counts with a consequent increased risk for bleeding and/or thrombosis.

Laboratory diagnosis

Elevated platelet counts, often above 600 to 1000×10^9/l are characteristic. The absolute number of platelets, even if higher than 1 million/µl, is not diagnostic of primary thrombocythaemia. Extreme increments have been observed in reactive thrombocytosis. Marked changes in platelet morphology, which include large and bizarre-looking platelets sometimes forming aggregates, are also characteristic and may be more useful in helping distinguishing primary from reactive thrombocytosis. The bone marrow is hypercellular with megakaryocytic hyperplasia. Clusters of megakaryocytes are often observed. Absent or diminished iron stores are seen frequently. This may be an epiphenomenon of an underlying myeloproliferative disorder or a true expression of iron depletion in patients with chronic bleeding. Reticulin is present in one-quarter of bone marrow specimens but collagen is usually absent. Mild leucocytosis is common.

Platelet function abnormalities are commonly found and include defective platelet aggregation in response to adrenaline, ADP, and collagen. Aggregation in response to arachidonic acid and ristocetin is often normal. An acquired platelet storage pool disease also occurs due to abnormalities in the content and release of a granules associated with a state of increased platelet activation. The bleeding time is occasionally prolonged but does not predict bleeding risk. Cytogenetic evidence for a Philadelphia chromosome and/or the molecular identification of the *brc/abl* fusion gene aids in distinguishing primary thrombocythaemia from chronic myeloid leukaemia. The presence of dyspoietic changes in bone marrow precursor cells and of characteristic chromosomal abnormalities suggests the diagnosis of myelodysplasia. The diagnostic criteria and management of the other myeloproliferative disorders associated with thrombocytosis are outlined in other chapters. Cytogenetic abnormalities occur in approximately 5 per cent of patients with primary thrombocythaemia. The most common chromosomal alterations include 1q–, 20q–, 21q–, and 1q+. Elevated vitamin B-12 levels occurs in 25 per cent of patients.

Diagnostic criteria and differential diagnosis

Diagnostic criteria are listed in Table 2. The exclusion of an identifiable cause of reactive thrombocytosis is a necessary condition. Primary thrombocythaemia is mainly a diagnosis of exclusion. Any condition associated with elevations in circulating platelets is part of the differential diagnosis. Thrombocytosis may be the consequence of primary bone marrow disorders associated with increases in platelet production (non-reactive thrombocytosis), or a secondary response to an underlying disorder (reactive thrombocytosis). Table 1 summarizes the most important. Clearly, secondary causes of thrombocytosis occur more frequently (more than 80 per cent). Infection, hyposplenism, malignancy, trauma, and non-infectious inflammation are the most commonly encountered disorders. Chronic myelogenous leukaemia and primary thrombocythaemia are the most frequent causes of primary thrombocytosis.

Risk assessment

Primary thrombocythaemia is associated with a very low risk of life-threatening complications. Most patients enjoy survival fairly similar to that of their unaffected peers. Exposure of every patient with primary thrombocythaemia to myelosuppresive therapy is unwarranted. A risk-based decision approach to therapy is outlined in Table 3. Advanced age (60 years or older) and previous history of thrombosis clearly define a group at high risk for the development of life-threatening complications. The degree of thrombocytosis and the presence of associated cardiovascular risk factors, particularly smoking and obesity, is also taken into consideration when making treatment decisions.

Treatment

A number of agents can lower the platelet count of patients with primary thrombocythaemia. There is now firm evidence that cytoreduction using hydroxyurea, at least in high-risk patients, results in a significant reduction in the number of thrombotic episodes. However, only a handful of randomized clinical trials have been conducted given the relatively small number of patients diagnosed with this disease each year. Alkylating agents have been extensively used in the past to treat primary thrombocythaemia. Within this group of agents, busulfan has been shown to be quite effective and relatively non-toxic, with predictable cytopenias as its major untoward effect. It is usually prescribed at 4 mg/day until a platelet count of 400 000/µl is reached. Additional 2-week courses are given if and when the platelet count rises over 400 000/µl. Extensive experience has also accumulated with radioactive phosphorus (^{32}P). Its advantages include ease of administration and the relative absence of significant, acute side-effects. It is usually given as a single dose of 2.3 mCi/m^2 that may be repeated in 3 to 6 month. Its effects are seen 4 to 8 weeks after administration. Excessive doses of ^{32}P can be associated with cytopenias. Alkylating agents and ^{32}P have been associated with significant increases in the risk of leukaemic transformation.

The use of hydroxyurea, an antimetabolite that interferes with DNA repair, decreased the number of thrombotic events in a randomized study of high risk patients when given at 15 mg/kg initially with subsequent adjustments based on initial response. In this study, the target was a platelet count of less than 600 000/µl, but it is possible that tighter control (less than 350 000) may be more effective. Onset of action is usually 3 to 5 days. Frequent side-effects include dose-related neutropenia, nausea, stomatitis, hyperpigmentation, rash, nail changes, leg ulcers, and hair loss. Its leukaemogenic potential when given as a single agent is still a subject of major controversy although it is clearly less leukaemogenic than alkylating agents or ^{32}P.

Interferon-a, a biological response modifier, also is useful in treating patients with primary thrombocytosis. Ninety per cent response rates with median times to response of approximately 3 months are seen when 3 to 5 million units are administered subcutaneously 3 to 5 days per week. It is non-mutagenic and does not cross the placenta. Frequent side-effects include flu-like symptoms, fatigue, lethargy, and depression. Its long-term use is associated with mild weight loss, alopecia, autoimmune thyroiditis, and autoimmune haemolytic anaemia. Interferon's extensive toxicity profile and the need for parenteral administration limit its use as initial therapy, particularly in elderly patients.

Anagrelide is at present the treatment of choice for younger patients and acts by selectively inhibiting megakaryocytic maturation. Responses have been documented in over 90 per cent of treated patients with a median time to response of 2.5 to 4 weeks and an onset of action of 6 to 10 days. It is non-mutagenic and its use has not been associated with the development of acute leukaemia. The usual initial dose is 0.5 mg, two to four times per day, which is increased at 0.5-mg increments per week according to response. Excessive dosing predictably causes thrombocytopenia. The current recommendation is not to exceed a total of 10 mg/day or 2 mg

(single) doses. The average daily maintenance dose is 2 mg in divided doses. The most common side-effects include headaches, dizziness, fluid retention, palpitations, nausea, abdominal pain, and diarrhoea. They develop within 2 weeks of use and usually improve within 2 weeks of continued treatment. It may also, on occasion, trigger episodes of tachyarrhythmias and heart failure. For this reason, it should be used carefully in the elderly and avoided in patients with known heart disease.

Recent evidence suggests that the administration of low doses of aspirin (250 mg daily, or less) is safe, and may decrease the recurrence of microcirculatory events (erythromelalgia/ transient ischaemic attacks) and prevent the development of other thrombotic phenomena, especially in combination with myelosuppressive agents. These data are still preliminary and require further study in large, randomized trials. In order to minimize the risk of iatrogenic bleeding, only patients with platelet counts less than 1 000 000/µl and without evidence of an acquired von Willebrand syndrome should be considered for low-dose aspirin administration.

Given the number of available therapeutic options and their different toxicity profiles, the choice of the appropriate cytoreductive drug for a given individual requires the consideration of a number of variables. These include age, childbearing potential, projected life expectancy, co-morbid-ities, and cost of treatment. Furthermore, the overall low risk for the development of life-threatening complications that affects patients with primary thrombocythaemia highlights the need for systematic, risk-based approaches to therapeutic decision making (see Table 3). The optimal therapy for patients with primary thrombocythaemia remains unclear. All patients should stop smoking. Indiscriminant use of high doses of non-steroidal anti-inflammatory agents should be avoided. Their excessive use is clearly associated with bleeding episodes.

Low-risk patients have a risk of thrombosis similar to that of the age and sex-matched population and a very low risk of life-threatening bleeding, supporting close observation without cytoreductive therapy as the most sensible approach. Hydroxyurea is an adequate choice for patients 60 years of age or older who are otherwise in good health. For elderly patients with limited projected survival (less than 10 years) and who have problems with either drug compliance or are too ill to comply with the minimum follow-up requirements during cytoreductive therapy, ^{32}P administration might be appropriate. Anagrelide should be offered to younger patients (less than 60) who are at high risk by virtue of a prior history of thrombosis or to patients at intermediate risk who the physician feels the necessity to treat. This drug should be used with extreme caution in elderly individuals and should be avoided in patients with cardiac disease. a-Interferon may be an acceptable option in the younger population of patients but is usually not used initially given the need for parenteral administration and its prominent side-effect profile. Alkylating agents, ^{32}P, and hydroxyurea are usually avoided in younger patients given their known (alkylators and ^{32}P) and possible (hydroxyurea) leukaemogenic potential. If a young patient, however, is resistant or intolerant to a-interferon and/or anagrelide, and requires treatment, we feel comfortable prescribing hydroxyurea at this point. In patients at intermediate risk based on platelet numbers at or more than 1 000 000/µl and who have the acquired von Willebrand syndrome, platelet reduction therapy is indicated to avoid the high risk of haemorrhage.

Smokers and obese individuals, unless symptomatic, should be managed by risk modification. In patients who suffer from thrombotic episodes, especially episodes involving the microcirculation or large vessels, we usually administer low-dose aspirin (100 mg/day). This dose appears safe and is effective in the treatment of thrombotic events, and is usually given in addition to cytoreductive therapy. In severe, life-threatening episodes, rapid cytoreduction may be achieved by plateletpheresis or by the administration of a single dose of 0.4 mg/kg of nitrogen mustard. In patients who present with a life-threatening, acute bleeding episode, the site of bleeding should be promptly identified and any antiplatelet agent should be stopped. Those suffering from an acquired von Willebrand's syndrome, can be treated with desmopressin (DDAVP) and factor VIII concentrates that contain high concentrations of von Willebrand factor. Cytoreductive therapy with hydroxyurea must be promptly initiated. In bleeding patients who fail to respond to DDAVP and factor VIII administration, the bleeding frequently resolves following platelet transfusions.

The management of patients who are or want to become pregnant requires special consideration. The risk of fetal loss is quite high (approximately 40 per cent). No clinical features other than the previous history of a miscarriage are predictive. Patients at low or intermediate risk should be managed by observation. Specific treatment should be considered during subsequent pregnancies if fetal loss were to occur. Uncontrolled studies have suggested that the careful use of heparin, aspirin, or a-interferon may decrease the chance for miscarriages. These data require further confirmation. Patients at high risk (for maternal thrombosis) are candidates for cytoreduction. Despite the lack of endorsement by the manufacturers of a-interferon, it may be the drug of choice during pregnancy given its lack of mutagenic potential and its inability to cross the placenta. Hydroxyurea, given its mechanism of action, could theoretically cause fetal malformations and anagrelide, due to its small molecular size, probably crosses the placenta and may cause life-threatening thrombocytopenia and haemorrhage in the fetus. Despite these concerns, recent case reports have described first trimester exposures to these two drugs resulting in the delivery of normal newborns. We therefore do not consider unintended exposures to hydroxyurea or anagrelide as absolute indications for the termination of pregnancy.

Prognosis

The probability that a patient with primary thrombocythaemia will survive 10 years is within the range of 64 to 80 per cent and is not substantially different from that of a control age- and sex-matched population. The actual risk for the development of a catastrophic thrombotic or haemorrhagic event in an asymptomatic patient is quite low. The majority of deaths come from thrombotic complications. Transformation to myelofibrosis and/or acute leukaemia has been reported with increasing frequency at a rate of transformation of 3 to 10 per cent. Prior administration of cytotoxic therapy is the strongest predictor of evolution to leukaemia but spontaneous transformations also occur, as in other myeloproliferative disorders. In rare instances, primary thrombocythaemia may also evolve into a clinical picture that resembles one of the other chronic myeloproliferative disorders.

Future directions

Better means to establish thrombotic and/or bleeding risk are required, and will help to improve the individualized risk-based selection of therapy. It is now clear that high-risk patients do benefit from cytoreductive therapy. Randomized comparisons to establish the efficacy of a-interferon and anagrelide in younger individuals at high risk is still needed. Although there is clear evidence that low-dose aspirin is safe and useful for the treatment of microcirculatory events such as erythromelalgia and transient ischaemic attacks, its additional therapeutic contribution when used in combination with anagrelide, hydroxyurea, or a-interferon requires further confirmation. The ideal therapeutic target in terms of the most desirable platelet number also requires better definition. A better understanding of the mechanisms involved in the regulation of platelet production and of the molecular abnormalities specifically associated with primary thrombocythaemia will offer rational targets against which to develop new and more specific therapies.

22.3.11 Aplastic anaemia and other causes of bone marrow failure

E. C. Gordon-Smith

Introduction

The concept of bone marrow failure as a cause of peripheral blood cytopenias is imprecise but convenient. Broadly, it indicates that the cause of the peripheral blood disturbance lies within the dividing pool of cells in the marrow itself. Fundamental to the classification of disorders within this group is the idea that normal development of cells within the bone marrow and release of cells into the peripheral blood depend upon an interaction between haematopoietic cells and the environment in which they proliferate and differentiate (see Chapter 22.2.1). The pathogenesis of most of these disorders is unknown and their separation depends mainly upon morphological criteria. The classification shown in Table 1 attempts to group the syndromes where there is a failure of circulating cell production according to the presumed cell stage involved and indicates inherited or congenital syndromes which mimic the acquired disorders.

Aplastic anaemias

Aplastic anaemia is defined by peripheral blood pancytopenia associated with a hypocellular marrow in which the normal haematopoietic tissue is replaced to a greater or lesser extent by fat cells. Remaining cells, both in the peripheral blood and bone marrow, appear morphologically normal and there is neither fibrosis nor infiltration by malignant cells in the marrow. Vitamin B_{12} and folate levels are normal and the disorder is not associated with other dietary deficiencies.

Classification

As defined above, aplastic anaemia may occur in a number of ways. There is no universally acceptable classification but a number of more or less well-defined entities may be identified (Table 2). In each of these, the pathogenesis seems to involve damage to the early haemopoietic progenitor cells, either stem cells or early lineage-committed progenitor cells.

Inevitable aplastic anaemia

Myelosuppression occurs following exposure to cytotoxic drugs or irradiation. The severity and duration of aplasia depends upon the nature of the cytotoxic agent and is dose related. Recovery usually occurs 1 to 6 weeks after the cytotoxic agent is discontinued. With very-high-dose radiation and certain cytotoxic agents, which do not depend on cell cycling for their action, stem cell killing may be complete and recovery does not occur.

Acquired aplastic anaemia

Incidence and epidemiology

Aplastic anaemia is a rare disease. In Europe and the United States, the incidence is probably between 2 and 4 per million of the population per year. All age groups may be affected, possibly with peaks between 20 and 30 and again in older patients. There is a slight preponderance of males, possibly reflecting the greater risk of exposure to toxic substances at work amongst men. In the Far East, the incidence of aplastic anaemia is two to three times higher and the male preponderance much more obvious. The risk factors seem to be environmental rather than genetic since people of the same ethnic groups in the West have a lower incidence.

Aetiology

In about two-thirds of cases of aplastic anaemia it is not possible to identify any likely cause. Amongst the rest, drugs, viruses, and environmental toxins may be identified as probable causes. There is no test to pinpoint the cause of the aplastic anaemia. The implication of any particular agent depends upon temporal associations and previous reports. Drugs have been implicated in the aetiology for 50 years or more and the list of drugs is long. In many cases, the association is weak and often confounded by the patient having received other drugs at the same time. The agents most commonly implicated are some antibiotics, of which chloramphenicol is the best known, and drugs used in the treatment of rheumatoid arthritis including non-steroidal anti-inflammatory agents (NSAIDS) and disease modifying agents in rheumatoid disorders (DMARDs). Table 3 includes a list of the more frequently reported drugs.

Viruses are also implicated. Up to 10 per cent of patients in Western and Japanese series of aplastic anaemia, particularly in the younger age group, give a history of jaundice and/or hepatitic symptoms some 6 weeks before the pancytopenia develops. In many instances, disturbances of hepatocellular function consistent with viral hepatitis have been demonstrated. However, a specific hepatitis virus is not usually identifiable. Aplastic anaemia has occurred following liver transplantation for fulminant infectious hepatitis but not other causes of liver failure. Occasional reports of aplastic anaemia following Epstein–Barr or other viruses have been published.

Various domestic and recreational drugs and chemicals have been implicated, though the evidence against any particular agent is not always very convincing. Wood preservatives, pesticides, and various organic solvents have been associated with the disease. Benzene is known to produce proliferative dysplasias, including acute leukaemias, when exposure is high. Its part in causing aplasia is not so certain.

Pathogenesis

The way in which the various agents bring about aplastic anaemia is unknown. The main defect is a failure of the pluripotent haematopoietic stem cells in the bone marrow to proliferate and differentiate into mature blood cells. *In vitro* experiments with long-term bone marrow culture show that aplastic marrow stroma cells are able to support haemopoiesis from normal stem cells but aplastic stem cells continue to grow abnormally on normal stroma. There is indirect evidence that cellular immune reactions play a role in the pathogenesis or at least the perpetuation of stem cell damage. The strongest evidence for this is the response of aplastic anaemia to

immunosuppressive treatment.

Diagnosis and pathology

The diagnosis of aplastic anaemia is made on the basis of the peripheral blood and bone marrow findings and by excluding other causes for pancytopenia. In the peripheral blood there is pancytopenia with no abnormal cells present. The anaemia is usually normocytic at presentation but becomes macrocytic, even strikingly so, in chronic cases. The reticulocyte count is low. Neutrophils are invariably reduced and the count may be very low. Circulating neutrophils may have rather heavy granulation, so-called 'toxic' granulation, and have a high alkaline phosphatase content. The eosinophils, basophils, and monocytes are usually also depleted. The reduction in the lymphocyte count is more variable; in children particularly it may be relatively high so that the total white cell count may be normal. The platelet count is reduced.

Aspiration of bone marrow is usually easy, fragments are obtained which are fatty, and there is a reduction of haematopoietic cells in the trails. The cellularity of the marrow may be judged to some extent from the marrow aspirate, but a so-called 'dry-tap' (no material obtained from an aspirate) or 'blood-tap' (no fragments obtained) does not allow an assessment of bone marrow activity. In aplastic anaemia, there may be a patchy loss of cellularity throughout the marrow so that an aspirate may yield relatively normal-looking marrow. The diagnosis cannot therefore be made on a bone marrow aspirate alone. Assessment of cellularity is made on a trephine biopsy, which shows replacement of the normal cellular marrow by fatty marrow (Fig. 1). The reticulin network of the marrow is reduced commensurate with the reduction in the general overall cellularity. Focal areas of preserved cellularity may be seen in the bone marrow trephine, so called 'hot pockets' (Fig. 1). The morphology of remaining haematopoietic progenitor cells is broadly normal though there may be some changes in the erythroid precursors which constitute mild dyserythropoiesis. Erythro-phagocytosis by macrophages may be prominent, especially early in the disease. Megakaryocytes are often absent but when present have normal maturation and morphology.

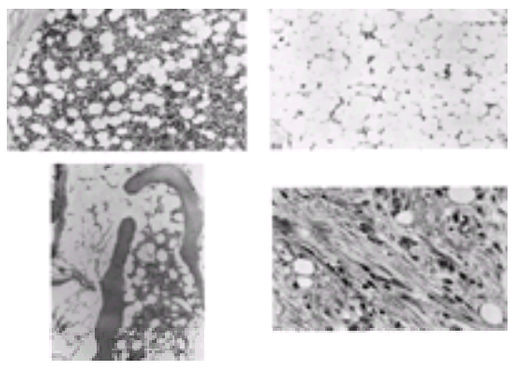

Fig. 1 Trephine biopsies of adult posterior iliac crest: (a) normal marrow; (b) severe aplastic anaemia; (c) cellular focus in severe aplastic anaemia; (d) proliferative dysplasia with fibrosis.

Clinical features

The clinical features of aplastic anaemia arise from the deficiencies of the cellular elements of the blood. There are no specific physical signs. Haemorrhagic manifestations are common at presentation. The development of thrombocytopenia takes place over a matter of weeks or months so that catastrophic haemorrhage as a presenting feature is unusual; minor signs of the bleeding tendency, easy bruising, gum bleeding, or purpuric rash, are more usual. Haemorrhages in the buccal mucosa may occur; retinal haemorrhages may be a portent of serious bleeding. The anaemia also develops slowly and the patient may complain only of mild fatigue or shortness of breath on marked exertion. Infections, particularly of the oropharynx or upper respiratory pathways, may be a presenting feature. Infections anywhere aggravate the effect of thrombocytopenia, particularly in the mouth. If the aplastic anaemia has followed an episode of apparent hepatitis, there may be some residual jaundice with enzyme abnormalities consistent with post-hepatitic cholestasis.

The progression of the disease is variable and depends upon the severity and completeness of the marrow damage. In earlier series of patients with aplastic anaemia where only support in the form of transfusions and available antibiotics was given, about half the patients died within 3 to 6 months as a result of infection or haemorrhage. Patients alive at a year, however, had a better chance of surviving, at least for the next 2 or 3 years. This suggested that there was a group of patients with severe disease with a very poor chance of recovery and another group with a milder disorder. This lead to the establishment of criteria for severe aplastic anaemia (Table 4) which have proven to be useful in stratifying patients when different treatments have been compared. The designations severe aplastic anaemia (neutrophils less than 0.5 but more than 0.2×10^9/l) and very severe aplastic anaemia (neutrophils less than 0.2×10^9/l) are useful in planning therapy.

The natural history of the disease has been so modified by improvement in transfusion support and infection control that it is difficult to decide, in some cases, whether subsequent events are part of the disease or the consequences of treatment. Spontaneous recovery, apparently to complete normality, may occur even after several years of pancytopenia. Other patients may remain stable for many years before haematopoietic activity decreases further. The emergence of abnormal clones, both benign and malignant, transient or progressive, is common. Paroxysmal nocturnal haemoglobinuria (PNH) is the most frequent. PNH arises from a somatic mutation involving a gene on the X chromosome which codes for a protein involved in the assembly of phosphatidyl inositol glycan (PIG), which anchors many proteins to the surface of cell membranes. Two enzymes which inactivate complement complexes, decay accelerating factor (DAF; CD59) and membrane inhibitor of reactive lysis (MIRL; CD55) are absent in PNH red cells, which then become sensitive to lysis by complement. PNH may be recognized by the Ham's test or directly by using fluorescence-activated cell scanning to identify populations which lack the PIG anchored proteins. Myelodysplastic syndromes and acute myeloid leukaemia may also develop following aplastic anaemia and the relationship between these blood diseases is discussed below.

Until platelet transfusions became readily available, the usual cause of death in these patients was haemorrhage. Most patients who fail to respond to treatment now succumb to infection or a mixture of infection and haemorrhage, often after many months of treatment with antibiotics. It is virtually impossible to eradicate infection in the severely neutropenic patient until such time as neutrophil production returns.

Treatment

The treatment of aplastic anaemia has two main components. The first is to protect and support patients from the consequences of pancytopenia. The second is to try to accelerate the recovery of the bone marrow by whatever means without eradicating the chance of spontaneous recovery.

Support and protection

For the aplastic patient this depends upon reducing potential sources of infection to a minimum and replacing deficient cells by transfusion (see Section 7). Infections may arise from the environment or from sources of bacteria and other agents with the patient. As with all immunosuppressed patients, significant and lethal infections may arise from contamination with organisms which are not normally pathogenic. Exogenous infections are more likely in a hospital environment than at home, so any patient with aplastic anaemia admitted to hospital must be nursed in a clean, and preferably sterile, area. Measures to prevent nosocomial infections should be of the highest standards. Virus infections are not in themselves especially likely in the neutropenic host, but if they occur they produce an environment in which secondary bacterial infections may flourish. When the neutropenic patient is also immunosuppressed in other ways, virus infections assume a very important role in causing morbidity. Patients with non-severe aplastic anaemia are not at greatly increased risk of opportunistic infection.

Endogenous infections arise from organisms carried within the patient, particularly the upper respiratory passages and the gastrointestinal tract. Scrupulous attention to oral hygiene minimizes the risk of infection from this source and diminishes gum bleeding. The extent to which potential pathogens should be removed from the gastrointestinal tract is debatable. Mostly these are aerobic organisms which are easily eliminated by antibiotics. Some would argue that removal of anaerobic bacteria may actually be harmful. So-called complete decontamination of the gut is achieved by giving a variety of non-absorbable antibiotics together with antifungal agents such as nystatin or amphotericin. Co-trimoxazole or ciprofloxacin, together with an antifungal agent, may be equally effective in eliminating most aerobic pathogens although it has yet to be demonstrated conclusively that this prevents infections. Recolonization of the bowel by potential pathogens can be avoided by

using freshly cooked, low bacterial food. It should be remembered that patients with aplastic anaemia may require months of protective isolation and therefore measures must be practical as well as effective.

Once an infection is established, it is essential to treat it as soon as possible. Systemic antibiotics, particularly to treat Gram-negative organisms, must be given as soon as fever or signs of infection occur and appropriate samples have been sent to the laboratory. Delay in the severely neutropenic patient may be fatal. Gram-positive infections, mainly with coagulase-negative staphylococci, are now common because of the extensive use of indwelling central venous lines, but rarely lead to rapidly progressive endotoxic shock. Since the most common exogenous infections arise from *Pseudomonas* or *Klebsiella* spp. and the endogenous ones from aerobic organisms of the gastrointestinal tract, the antibiotics used in the first instance must be appropriate to those organisms. Most centres use a combination of aminoglycoside with a second antibiotic likely to have activity against *Pseudomonas* or a third-generation cephalosporin (suitable regimens are described in Section 7). A difficulty in aplastic anaemia is to decide when to discontinue the antibiotics. The patient may become afebrile and apparently well, but when the antibiotics are stopped, infection by the original organism is all too likely to return unless the neutropenia recovers. Granulocyte stimulating cytokines, filgrastim or lenograstim, or granulocyte–macrophage stimulating cytokine, rhGM-CSF, may stimulate the remaining bone marrow sufficiently to raise the neutrophil count enough to eradicate the infection. Granulocyte transfusions do not seem to be helpful (see Section 7).

Transfusion of red cells and platelets is the other main standby in the management of aplasia. Red cell transfusions usually present few problems, but it must be remembered that the platelet count will fall and haemorrhage may occur during such transfusions. Platelets should always be given with red cell transfusion in the severely pancytopenic patient. Repeated platelet transfusion leads to the development of antibodies and resistance to platelet concentrates in about 40 per cent of patients. This complication is reduced by using white-cell-depleted products. The antibodies may be anti-HLA or antiplatelet-specific antigens. Resistance is indicated by an inability to raise the platelet count by platelet transfusion. Conventionally, platelets are only transfused when there is a clinical indication for their use. Indications include the rapid development of purpura, extensive bleeding from the gums and in the buccal mucosa, retinal haemorrhages, and headache. In aplastic anaemia, particularly when the patient is being managed on an outpatient basis, catastrophic and fatal haemorrhage may be the first indication of severe bleeding, particularly so if the patient develops an infection. For this reason centres manage their outpatients with regular platelet transfusions to maintain a count above 15 × 10^9/l.

Further details of the management of patients with marrow failure are given elsewhere.

Specific measures

There are two main approaches to the treatment of aplastic anaemia. Haematopoietic stem cell transplantation is curative but carries a high risk of treatment-related mortality and morbidity and is only available to patients with a suitable HLA-matched allogeneic donor. Immunosuppressive treatment, with antilymphocyte or antithymocyte globulin (ALG, ATG) and/or cyclosporin, is the other treatment option. The choice of treatment for any individual with aplastic anaemia depends on the age of the patient, the severity of the disease, and the availability of a suitable donor.

Haematopoietic stem cell transplantation

Recolonization of the aplastic bone marrow with normal stem cells from a suitable donor has long been considered the most rational treatment for aplastic anaemia. The first successful transplants from HLA-matched siblings for severe aplastic anaemia were carried out in Seattle in 1969 by E. Donall Thomas and colleagues. Subsequent, world-wide experience has shown that such transplants are the most effective treatment for very severe aplastic anaemia and severe aplastic anaemia in patients of suitable age. Patients up to the age of 55 years and, in certain instances, older, with very severe aplastic anaemia should be considered for stem cell transplantation. Children and young adults with severe aplastic anaemia should be offered transplantation as the first choice. The problems of stem cell transplantation for aplastic anaemia are the same as for other conditions, namely graft rejection and graft-versus-host disease. Graft rejection may be increased by sensitization to multiple blood transfusions, so transplants are best carried out early, once the diagnosis has been confirmed, the severity established, and a suitable donor identified. Stem cells for transplantation may be obtained from the bone marrow or from the peripheral blood following mobilization of the stem cells from the marrow by granulocyte colony stimulating factor (G-CSF). Peripheral blood stem cell transplants lead o quicker recovery of peripheral blood counts (at about 14 days compared with 20) but may cause more chronic graft-versus-host disease. On-going trials may establish the superior outcome for one or other source in the future. Conditioning of the patient for sibling transplant is relatively mild in that irradiation is not required. Various regimen have been used, the most wide experience being with intravenous cyclophosphamide 50 mg/kg per day for 4 days before the transplant. Commonly this is combined with ALG given for 4 or 5 days before the cyclophosphomide and continuing up to the transplant. The cell dose given is important. Graft rejection is uncommon after transfusion with greater than 3.0 × 10^6 nucleated cells per kg recipient body weight. Cyclosporin is given for graft-versus-host disease prophylaxis, initially intravenously and subsequently orally, and continued for up to 1 year to prevent late graft rejection. Successful outcome is achieved in about 70 to 80 per cent of cases overall with an incidence of chronic graft-versus-host disease of about 10 to 15 per cent. Children have a success rate of 90 per cent or better. Growth rate, endocrine development, and fertility appear to be normal following this type of transplant and the recovered marrow behaves normally without an increased risk of leukaemia or other clonal disorder.

Problems of bone marrow transplantation are considered further elsewhere.

Immunosuppression

Immunosuppressive treatment for aplastic anaemia was introduced in Europe in 1977, following observations by Georges Mathé in Paris and experimental work by Bruno Speck in Basel. Subsequent controlled trials confirmed that 5 days treatment with ALG was an effective way of achieving remission in all degrees of severity of aplastic anaemia and for all ages. Immunosuppression is the treatment of choice for all patients who are not suitable for transplantation. Recovery following treatment is usually slow with little response before about 3 months and often up to 6 months. Many patients treated in this way still require some transfusion support for this time and may continue with neutropenia and/or thrombocytopenia for many years, though independent of transfusion or hospital care. If the patient fails to respond to the first course of ALG, a second course using an alternative ATG may be given. Some 60 per cent of patients respond to the first course with partial or complete remission and about 40 per cent of non-responders will achieve some improvement with a second. The optimum timing of a second course still has to be determined but most groups wait about 4 to 6 months before a second course. Further courses may be tried in non-responders if they have not been sensitized to the animal protein. There are several preparations of ALG/ATG which are not necessarily bioequivalent so treatment schedules may vary. Reactions during infusion of ALG or ATG are common and may be severe. Serum sickness occurs in some 75 per cent of patients, requiring treatment with corticosteroids. The routine addition of high-dose methylprednisolone (5 mg/kg per day) has no obvious therapeutic advantage and produces a high incidence of avascular necrosis of the hip.

Cyclosporin, 5 mg/kg per day, the dose then adjusted to individual requirement, appears to increase the speed of remission when given after ALG and may also be used alone as an alternative to ALG, though the proportion of responders is less. Recovery, as with ALG, is slow and may be incomplete.

Relapse, or the emergence of PNH or myelodysplastic syndrome clones, leading to a requirement for transfusion, occurs in about 25 per cent of remitting patients over a 10-year period, though some patients respond to further course of immunosuppression. Relapse may follow virus infections, immunizations, or in pregnancy. Some patients seem to be dependent on a continuing dose of cyclosporin post ALG.

Anabolic steroids

Anabolic steroids may be useful in non-severe aplastic anaemia when immunosuppressive therapy fails. The virilizing side-effects make their use unpopular and hepatotoxicity is a problem. A trial of oxymethalone, 2.5 mg/kg per day, or other anabolic steroid in equivalent dose, may be warranted.

Congenital aplastic anaemias

There are a number of inherited disorders which may be associated with bone marrow failure. Table 5 lists the better characterized disorders; familial pancytopenias, which do not fit these diagnoses, sometimes occur.

Fanconi anaemia

The commonest of the inherited disorders which produce aplastic anaemia is that described by Fanconi in 1927. The disorder is inherited as an autosomal recessive and is associated with multiple developmental abnormalities, particularly of the skin and skeleton (Table 6). There is wide genetic and phenotypic heterogeneity.

Cases have been described in all populations.

Genetic basis of Fanconi anaemia

Somatic cell fusion studies have shown that there are at least seven distinct genes identifiable, *FANC(A–G).* Four of these genes have been cloned, *FANCA* (16q24.3), *FANCC* (9q22.3), *FANCF* (11p15), *FANCG* (9p13). For each of these genes, multiple mutations have been described. *FANCG* is identical to a gene, *XRCC9,* which is thought to be involved in cell cycle regulation or postreplication repair but the function of the other genes is unknown and the products of the cloned genes have no homology to each other or to other known proteins. It is presumed that the various gene products are part of a pathway involved in chromosome protection, probably through the formation of a functional complex. The genetic heterogeneity accounts for much of the phenotypic heterogeneity.

Cytogenetic findings

The diagnostic test for Fanconi anaemia is the appearance in metaphase of multiple chromosome breaks in phytohaemagglutinin-stimulated peripheral blood lymphocytes. Breakage rate is increased in baseline cultures but is markedly enhanced when cultures are exposed to clastogens such as diepoxybutane or mitomycin C (Fig. 2). Other inherited disorders which are thought to have underlying chromosome instability and a defect in DNA repair also have an increased tendency to develop acute leukaemia, though not usually with an aplastic phase (see Table 7).

Fig. 2 Chromosomes from a metaphase preparation of peripheral blood lymphocytes from a patient with Fanconi anaemia incubated in the presence of diepoxybutane (DEB) show multiple breaks and rearrangements. ctg, chromatid gap; csg, chromosome gap; ctb, chromatid break; csb, chromosome break. Rearrangements: cte, chromatid exchange; tr, triradial; qr, quadriradial.

Haematological features

Patients with Fanconi anaemia usually have a normal or nearly normal blood count at birth and during infancy. Bone marrow failure develops slowly. The age at which it is manifest clinically depends in part on the underlying genetic cause. In many cases the failure appears between 5 and 10 years, in other families the defect becomes apparent in adolescence whilst in some cases it presents in adult life. A severe form caused by a mutation in *FANCC*, the IVS-4 mutation found in Ashkenazi Jews, has a particularly rapid development of aplasia and a very high transformation to acute leukaemia. In all cases the bone marrow becomes progressively hypocellular, eventually being indistinguishable from acquired aplastic anaemia. Early on, macrophages showing active phagocytosis are prominent, perhaps indicating the removal of cells in apoptosis. Granulopoiesis may be relatively well-preserved. Dyserythropoiesis may be prominent. Evolution to acute leukaemia is common, particularly in some gene types. Patients may present with acute leukaemia, usually myeloid, without a prior period of aplasia. Red cells are macrocytic but there are no specific features in the peripheral blood to suggest the diagnosis.

Clinical features

The features of the full-blown Fanconi anaemia are characteristic (Table 6). There is marked phenotypic variation between patients in different families but considerable similarities within families, which reflects the genetic variation. In some cases, diagnosis may be difficult because of absence of the characteristic skeletal and skin features. Infants are of low birth weight and most remain small-for-age after birth. The skin is often mildly pigmented with areas of deeper pigmentation producing café-au-lait spots, sometimes with areas of depigmentation. Skeletal abnormalities involve particularly the bones of the forearm and thumbs. Abnormalities in the anatomy of the kidneys are also common. Intellectual development is usually normal.

Prognosis and treatment

The outlook in Fanconi anaemia is poor. Untreated, the disease is usually relentless. Despite support with transfusions over many years most patients die of haemorrhage, infection, or of acute leukaemia. Fanconi anaemia should also be suspected in all children and adolescents presenting with acute myeloid leukaemia. Identification of the familial nature of the disease is important for genetic counselling. The median interval between presentation and death is about 2 to 4 years. Patients who survive to adult life have an increased risk of solid tumours of squamous origin, particularly of the tongue, oesophagus, vulva, cervix, and breast. Most adult females are fertile whilst most males are infertile.

Treatment with anabolic steroids may bring about a remission of variable duration. Several years free from transfusion requirements may be obtained, but at the price of virilization and liver toxicity. Hepatocellular carcinoma, often accompanying peliosis hepatis, seems to be particularly common in children treated for years with 17a-alkylated anabolic agents (Fig. 3).

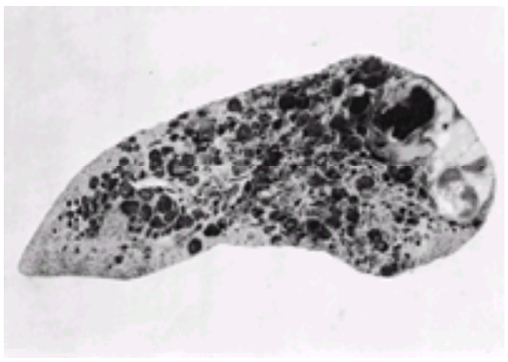

Fig. 3 Hepatocellular carcinoma in the liver of a patient with Fanconi anaemia treated for 4 years with anabolic steroids; the liver also shows multiple venous lakes (peliosis hepatis), another side-effect of anabolic steroids.

Bone marrow transplantation is the only curative form of treatment but carries special risks. The Fanconi anaemia cells are very sensitive to cyclophosphamide and irradiation used to immunosuppress patients prior to transplant and the doses given to these patients have to be greatly reduced. With these modifications, the success of bone marrow transplantation from HLA-matched sibling donors is similar to that for acquired aplastic anaemia. Transplantation from unrelated, HLA-matched donors is less successful but given that no other treatment is effective, should be offered whenever possible.

Dyskeratosis congenita

Dyskeratosis congenita is an inherited disorder involving the mucocutaneous system with the development of bone marrow failure in about 50 per cent of cases. The inheritance is X linked in the majority of cases with the defective gene located at Xq28. The gene mutated in these cases is designated *DKC1*, the protein dyskerin. Dyskerin may take part in the assembly of ribosomes and their export from the nucleus to the cytoplasm. Some families show recessive inheritance with female members also being affected.

Patients have reticular skin pigmentation of the upper body; leukoplakia and nail dystrophy usually appearing in childhood. There is a high incidence of squamous carcinoma of the oropharynx and gastrointestinal tract but not an increased risk of leukaemia. Marrow aplasia develops in the second or third decade. Treatment with anabolic steroids may be temporally effective in some patients as with Fanconi anaemia but most patients become refractory. Stem cell transplantation should be considered as the only possible cure for the haematological problems but results are poor. Late complications post-transplantation include renal failure, pulmonary fibrosis, and diffuse vasculitis.

Aplastic presentation of malignant disease

Aplastic anaemia is one response to bone marrow damage and acute leukaemia is another. At presentation, the distinction between the two may not always be clear, at least on histological and morphological criteria.

Acute lymphoblastic leukaemia (ALL)

ALL may present in a form indistinguishable from aplastic anaemia, usually, but not exclusively, in children. Blasts are not seen in the peripheral blood, and the bone marrow aspirate and trephine are hypocellular without any obvious infiltration by malignant cells. Presentation with severe infection, often of the pharynx, is more common than in acquired aplastic anaemia. The aplasia usually recovers spontaneously, sometimes in response to steroids. Some 6 to 8 weeks later there is the emergence of leukaemic cells in the peripheral blood. Whilst ALL in childhood is the commonest association, aplasia preceding acute myeloid leukaemia in this way has been described, and adults are occasionally affected.

Hypoplastic myelodysplasia

Hypoplastic myelodysplastic syndrome is a disease characterized by a hypocellular marrow in which a small proportion of blasts may be seen, sometimes with occasional blasts in the peripheral blood. The proportion of blasts in the marrow is less than 5 per cent but there may be abnormal aggregations of primitive precursors. Circulating granulocytes, reduced in number, are hypogranular in contrast to the toxic granulation of aplastic anaemia. The condition differs in a number of ways from aplastic anaemia, but the differences may be subtle and there is considerable overlap. The distinction by morphological criteria is subjective. The presence of cytogentically abnormal metaphases has been used to distinguish hypoplastic myelodysplastic syndrome from aplastic anaemia but transient clones may appear in the latter. The condition may remain stable for months or years during which the patient requires transfusions but is otherwise well. The prognosis is in the low-risk group of the international prognostic scoring system. If a suitable bone marrow donor is available, transplantation is indicated. Recent trials have shown that as many as two-thirds of patients may achieve meaningful remissions with ALG, indicating another link with aplastic anaemia.

Proliferative dysplasia with fibrosis

Occasionally, fibrosis of the bone marrow appears without evident underlying cause and in the absence of hepatosplenomegaly or extramedullary haemopoiesis. The condition is characterized by pancytopenia sometimes with the presence of red cell and white cell precursors in the peripheral blood, a leucoerythroblastic picture. Bone marrow aspirate is usually unsuccessful, and a trephine biopsy shows a variable degree of reduction in haemopoietic cells with the marrow replaced by reticulin and fibroblasts. Primitive cells are not seen at this stage of the illness. Some of these patients probably have an unusual form of myelofibrosis, particularly those who present in childhood. Others may have hypoplastic failure in which abnormal megakaryocyte development leads to the fibrosis.

Bone marrow failure affecting single cell lines

There are a number of conditions in which anaemia, neutropenia, or thrombocytopenia develop in isolation as a result of the failure of production by the marrow. The conditions may be inherited or acquired and the main disorders are listed in Table 8. The majority of acquired cytopenias are immune in origin with peripheral destruction so do not represent examples of bone marrow failure.

Amegakaryocytic thrombocytopenia

Thrombocytopenia caused by deficiency of megakaryocytes may be acquired or inherited. Inherited syndromes include amegakaryocytic thrombocytopenia with total absence of radii (TAR syndrome) and other congenital cases with normal skeleton. If children with TAR survive the first year of life, when cerebral haemorrhage is most likely, the platelet count usually increases spontaneously to safe levels and the outlook is good. Acquired amegakaryocytic thrombocytopenia is probably a variant of aplastic anaemia or myelodysplastic syndrome. The condition is rare. About one-third of patients remain thrombocytopenic, another third progress slowly to aplasia, and the remainder develop myelodysplastic syndrome. Immunosuppressive therapy may produce remission and stem cell transplantation may be curative for appropriate patients.

Pure red cell aplasia (PRCA)

PRCA is defined by anaemia with a marked reduction or absence of reticulocytes in which the neutrophil and platelet count are normal. The bone marrow is cellular with normal granulopoiesis and megakaryocytes. There may be a complete absence of red cell precursors or there may be red cell precursors present up to a certain stage of development but not beyond, so-called 'maturation arrest'. Apart from the changes in the red cell series, there are no other abnormalities in the peripheral blood and there is no evidence of peripheral destruction of red cells. The patients are in other respects normal. Both congenital and acquired forms exist.

Congenital pure red cell aplasia—Diamond–Blackfan anaemia

This has also been called rather confusingly 'congenital hypoplastic anaemia' but is better known by its eponym, the Diamond–Blackfan syndrome. In most instances, anaemia is present at birth or is detected shortly afterwards. There is a profound reticulocytopenia often with no reticulocytes present in the peripheral blood. There is macrocytosis and raised HbF. Red cell adenosine deaminase is increased. There is no hepatosplenomegaly. The white count and platelet counts are normal. Skeletal abnormalities may be present, particularly of the head and upper limb. About 50 per cent have no dysmorphic features. There may be disturbances of growth, either inherent in the disease or brought about by anaemia, iron overload, or steroid therapy. There are no abnormalities of the skin or other organs as seen in Fanconi anaemia.

Pathogenesis

There seem to be a number of genetic abnormalities underlying the disorder. About 20 per cent of patients have a family history, usually in earlier generations, suggesting dominant inheritance. The remainder has no such history but adenosine deaminase may be elevated in first degree relatives and sporadic cases may go on to have affected children. One gene in which mutations are associated with Diamond–Blackfan anaemia is located on chromosome 19 and codes for RPS19, a ribosomal protein. The function of the protein in the pathogenesis of Diamond–Blackfan anaemia is unknown. About a quarter of Diamond–Blackfan anaemia families have this defect. At least two other unrelated defects produce the phenotype.

Treatment

Treatment presents many problems. Most of these children, if treated early enough with corticosteroids, will respond. However, if the condition is steroid-dependent, major problems may result from the continued use of corticosteroids in the doses necessary to maintain remission. Patients may become steroid resistant. Some patients fail to respond to corticosteroids, and this seems to be particularly true if the corticosteroids are instituted late in the illness. These patients rely on blood

transfusions for survival. Transfusion will permit normal growth but produces all the problems of iron overload, including delayed or absent puberty. Chelation therapy is required from an early stage. Stem cell transplantation should be considered if there is a matched family donor but the potential donor should be checked for raised adenosine deaminase levels as well as anaemia before being accepted.

During the course of the disease, the spleen may enlarge and transfusion requirements increase. In these patients, splenectomy may reduce transfusion requirements and occasionally is associated with a marked increase in steroid responsiveness or even complete remission. This only seems to apply to those patients whose spleen is enlarged, and relapse may occur after a few years.

Transient erythroblastopenic anaemia in childhood (TEC)

Transient erythroblastopenia of childhood may have a viral aetiology though this is not always clearly demonstrated. The anaemia with reticulocytopenia most often occurs in children from 6 months to 5 years with a peak incidence around 2 years. There is usually a history of preceding viral illness. More than one member of the family may be affected making distinction from Diamond–Blackfan anaemia difficult. The anaemia is normocytic and adenosine deaminase levels are normal. Neutropenia is common. Recovery occurs within a few weeks of diagnosis though the patient may need transfusion in the meantime.

Parvovirus infection

'Aplastic crises' may occur in patients with haemolytic anaemia who develop infection with Parvovirus B 19. The term is confusing because only the red cell series is affected. The virus is tropic for red cell precursors and prevents differentiation. Red cell precursors are large and vacuolated. As antibodies to the virus develop, so the inhibition is removed. The reticulocytopenia lasts for up to 7 days so that the effect is trivial or unnoticed in people with red cell survival of 120 days. In patients with short red cell survival, such as patients with sickle cell disease and other congenital haemolytic anaemias, the effect may be devastating. Anaemia develops rapidly and transfusion may be required urgently. Antibodies to the virus are lacking in the serum initially, followed by an IgM response. The presence of IgG antibodies precludes the diagnosis.

Acquired pure red cell aplasia

This may occur *de novo*, following administration of various drugs, or in association with lymphoma, and about one-third are associated with a thymoma. PRCA may precede, accompany, or follow the development of the thymoma and excision of the tumour has variable effect with no guarantee of recovery of the anaemia. The haematological features of the disorder are similar to that seen in the congenital red cell aplasia, with anaemia and reticulocytopenia associated with absence of red cell precursors or maturation arrest of the red cell series in the bone marrow. There is an unpredictable responsiveness to corticosteroids. Immunosuppression with azathio-prine or cyclophosphamide may be effective. Autoantibodies are thought to play a role in the pathogenesis and occasionally immunoglobulins have been identified which inhibit haem synthesis or prevent the development of red cell colonies *in vitro*. Very rarely antierythropoietin antibodies have been found.

Acquired PRCA may occur in association with common variable hypogammaglobulinaemia and in association with other autoimmune diseases. The presence of such autoimmune phenomena suggests that the patient has a better chance of responding to corticosteroids than in their absence. PRCA may be associated with lymphomas and evidence of an underlying lymphoma may be obtained by finding evidence of immunoglobulin or T-cell receptor gene rearrangement in the marrow even when histological proof is lacking. Occasionally, splenectomy may increase responsiveness to corticosteroids or immunosuppression. An enlarging spleen, which increases transfusion requirements, is an indication for splenectomy. A chronic transfusion regimen with iron chelation may be required for non-responding patients.

Isolated defects in white cell or platelet production

These conditions are described elsewhere and are summarized in Table 7.

22.3.12 Paroxysmal nocturnal haemoglobinuria

Lucio Luzzatto

Definition

Paroxysmal nocturnal haemoglobinuria (**PNH**) is an acquired chronic disorder characterized by persistent intravascular haemolysis, subject to recurrent exacerbations, often associated with pancytopenia, and with a distinct tendency to venous thrombosis. The triad of haemolytic anaemia, pancytopenia, and thrombosis makes PNH a truly unique clinical condition: however, even in the absence of one or more of these manifestations a conclusive diagnosis can be made by appropriate laboratory investigations (see below).

Epidemiology

PNH is encountered in all populations throughout the world, and it can affect people of all socioeconomic groups. The prevalence of PNH is not accurately known: however, it is more rare than the related disorder, acquired aplastic anaemia (**AAA**). A rough estimate of the frequency of PNH is between 1 in 100 000 and 1 in 1 million. It has been suggested that, like AAA, PNH may be somewhat less rare in South East Asia and in the Far East. Most patients present as young adults, but we have seen PNH in a 2-year-old child and in people in their seventies. PNH has never been reported as a congenital disease, and there is no reported evidence of inherited susceptibility. The sex ratio is not far from even.

Clinical features

The patient may seek medical attention because, one morning, she or he has 'passed blood instead of urine'. This distressing or frightening event—the direct evidence of haemoglobinuria—may be regarded as the classical presentation; however, not infrequently the haemoglobinuria may be initially less spectacular, or it is suppressed. Indeed, the patient often presents simply as a problem in the differential diagnosis of anaemia, whether symptomatic or discovered incidentally; this may be associated with jaundice, immediately suggesting it may be a haemolytic anaemia. Sometimes the anaemia is associated from the outset with neutropenia, or thrombocytopenia, or both. Venous thrombosis may be the first clinical manifestation in other patients. Although any vein may be affected, the most common localization is intra-abdominal: indeed, recurrent attacks of severe abdominal pain defying a specific diagnosis, and eventually found to be related to thrombosis, have given to PNH the attribute of being a great impostor. On the other hand, when thrombosis affects the hepatic veins it may produce acute hepatomegaly and ascites—that is to say, a fully fledged Budd–Chiari syndrome.

The natural history of PNH can extend over decades. Without treatment the median survival is estimated to be about 8 to 10 years (see Fig. 1); in the past—but unfortunately even today—the most common causes of death have been thrombosis, or infection associated with severe neutropenia, or haemorrhage associated with severe thrombocytopenia. PNH may evolve into AAA, and PNH may manifest itself in patients who previously had AAA. Rarely (estimated 1–2 per cent of all cases), PNH may terminate in acute myeloid leukaemia. On the other hand, full spontaneous recovery from PNH has been also well documented.

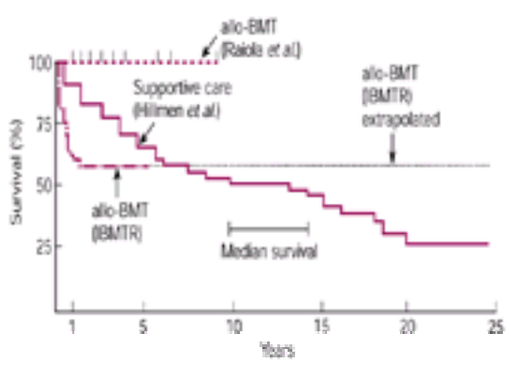

Fig. 1 PNH is a chronic disorder, the time course of which is often measured in decades. From a series of 80 patients who received only minimal supportive treatment we estimate a median survival of about 10 years. Allogeneic BMT has still been associated with significant mortality, and therefore may have reduced the survival of some patients; but recently more encouraging data have been reported on a small series from a single centre.

Laboratory investigations and diagnosis

The most consistent blood finding is anaemia, which may range from mild to moderate to very severe. The anaemia is usually normomacrocytic; if the mean cell volume (**MCV**) is high it is usually largely accounted for by reticulocytosis, which may be quite marked—up to 20 per cent. The anaemia may become microcytic if the patient is allowed to become iron-deficient as a result of chronic urinary blood loss through haemoglobinuria. The red cell morphology is otherwise usually normal. Neutropenia and/or thrombocytopenia may or may not be present from the outset, or may develop subsequently. Unconjugated bilirubin is mildly or moderately elevated; lactate dehydrogenase (**LDH**) is typically markedly elevated; haptoglobin is usually undetectable. All these findings make the diagnosis of haemolytic anaemia compelling. Haemoglobinuria may be overt in a random urine sample: if it is not, it may be helpful to obtain serial urine samples, since haemoglobinuria can vary dramatically from day to day, and even from hour to hour (it is more common, but not always, in the early morning: hence the adjective 'nocturnal'). Obviously, haemoglobinuria must be distinguished from haematuria. Surprisingly, even today a patient may undergo extensive urological investigations before it is realized that the patient has PNH. There may be free haemoglobin in the serum, and sometimes this is so high as to interfere with clinical chemistry. These findings clearly indicate intravascular haemolysis, thus increasing, by an order of magnitude, the likelihood that the haemolytic anaemia is in fact PNH (see Table 1). The bone marrow is usually cellular, with marked to massive erythroid hyperplasia, often with mild to moderate dyserythropoietic features. However, at some stage of the disease the marrow may become hypocellular or even frankly aplastic (see below).

The definitive diagnosis of PNH must be based on the demonstration that a substantial proportion of the patient's red cells have an increased susceptibility to complement, due to the deficiency on their surface of proteins that normally protect the red cells from activated complement. Classically, this is proven by the Ham test (acidified serum test): if appropriately carried out with all the necessary controls this test is still valid. By contrast, the sucrose haemolysis test can give both 'false-negatives' and 'false-positives', and therefore must be regarded as obsolete. Nowadays, the presence of a PNH red blood cell population can be easily demonstrated and quantified by flow cytometry, using anti-CD59 or anti-CD48. This analysis can also be carried out on granulocytes with a higher sensitivity (see Fig. 2).

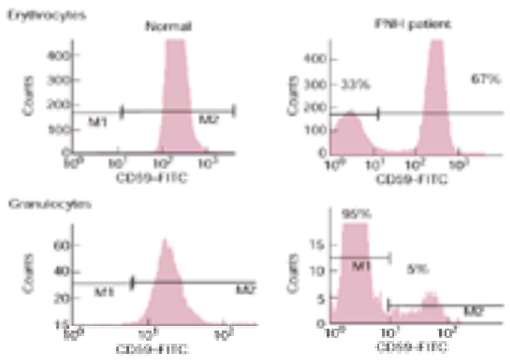

Fig. 2 Flow cytometry analysis of blood cells in a patient with PNH. On the left, red cells and granulocytes from a normal person display a unimodal distribution of surface expression of the GPI-linked protein CD59, which protects red cells against complement-mediated lysis. On the right, a similar analysis reveals, in a patient with PNH, a clearly bimodal distribution: from this analysis the size of the PNH cell population can be quantitated. (Figure by courtesy of Dr David Araten.)

Pathophysiology

Haemolysis

Haemolysis in PNH is due to an intrinsic abnormality of the red cell, which makes it exquisitely sensitive to activated complement, whether it is activated through the alternative pathway or through an antigen–antibody reaction. The former mechanism is probably the reason why there is chronic intravascular haemolysis in PNH. The latter mechanism explains why the haemolysis can be dramatically exacerbated in the course of a viral or bacterial infection. Hypersusceptibility to complement is due to the deficiency of several protective membrane proteins, of which CD59 is the most important, because it hinders the insertion into the membrane of C9 polymers.

The molecular basis for the deficiency of these proteins has been pinpointed not to a defect in any of the respective genes, but rather to the shortage of a unique glycolipid molecule, glycosyl phosphatidyl inositol (**GPI**), which, through a peptide bond, anchors these proteins to the surface membrane of cells. The shortage of GPI is due in turn to a mutation in an X-linked gene, called *PIG-A*, required for an early step in GPI biosynthesis. In virtually each patient the *PIG-A* mutation is different. This is not surprising, since these mutations are not inherited: rather, each one takes place *de novo* in a haemopoietic stem cell (in other words, they are somatic mutations). As a result, the patient's bone marrow is a mosaic of mutant and non-mutant cells, and the peripheral blood always contains both PNH cells and normal (non-PNH) cells (see Fig. 2).

Thrombosis

This is one of the most immediately life-threatening complications of PNH, and yet one of the least understood pathogenetically. It could be due to impaired fibrinolysis, because the urokinase plasminogen activator receptor (**uPAR**) is a GPI-linked protein; alternatively, complement activation could cause hypercoagulability, or hyperactivity of platelets, or both. For instance, it could be speculated that deficiency of CD59 on the PNH platelet could lead to abnormal insertion of the C5b–9 complex in the platelet membrane, as is the case with the red cell.

Bone marrow failure and the relationship between PNH and AAA

PNH has an intimate link with AAA, for several reasons. (1) As stated above, sometimes a patient with PNH becomes 'less haemolytic' and 'more pancytopenic' and ultimately evolves to frank AAA. (2) In terms of pathogenesis, it is believed that AAA is essentially an organ-specific autoimmune disease mediated by 'activated' cytotoxic (CD8+) T lymphocytes, which are able to inhibit haemopoietic stem cells. Recently, skewing of the T-cell repertoire, indicating the presence of abnormally expanded T-cell clones, has also been observed in cases of PNH. (3) Most important, intensive immunosuppressive treatment is the standard of care in those with AAA, and a beneficial response to the same treatment can also be obtained in patients with PNH (see below).

In view of these facts, it seems that an element of bone marrow failure in PNH is the rule rather than the exception: an extreme view is that PNH is a form of AAA, in which bone marrow failure is masked by the enormous expansion of the PNH clone that populates the patient's bone marrow. In other words, it appears that two different mechanisms co-operate in producing PNH (see Fig. 3): autoimmune damage to stem cells, and a somatic mutation in the *PIG-A* gene. This notion is supported by two further lines of evidence. (1) By targeted inactivation of the *pig-A* gene in mouse embryonic stem cells one can produce mice with a PNH cell population. However, this population does not grow further, as it does in patients with PNH. (2) By using refined flow cytometry technology, PNH cells harbouring *PIG-A* mutations can be demonstrated in normal people at a frequency in the order of 10 per million. Both these findings indicate that some other factor is required, in addition to a somatic mutation in the *PIG-A* gene, in order to cause PNH. Most likely, the same cytotoxic damage to stem cells that would otherwise cause AAA spares the PNH stem cells, thus allowing the PNH clone to grow to the size when it gives clinical PNH. The mechanism whereby the PNH cells escape damage is not yet known.

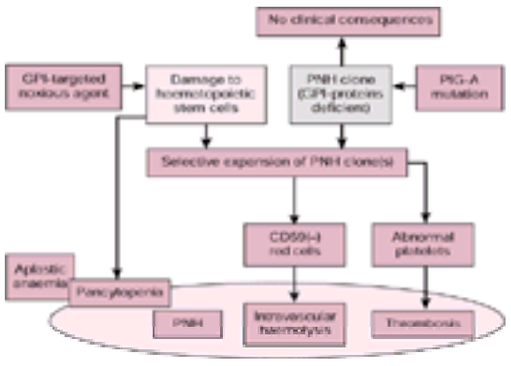

Fig. 3 The role of somatic mutation and bone marrow failure in causing PNH. This cartoon aims to emphasize that two separate factors are required to bring about PNH as a clinical disease. On the one hand, a *PIG-A* mutation on its own will produce a PNH clone, but there will be no basis for it to expand; on the other hand, damage to haemopoietic stem cells (HSC) can cause aplastic anaemia without PNH. When both factors co-operate, and if the damage to HSC is GPI-mediated, then there will be selective expansion of the PNH clone.

Complications

Given the chronic course and the complex nature of PNH, many events can cause concern and sometimes threaten life. The most important complication is certainly thrombosis, which is nearly always venous, and mostly affects the abdominal veins (see Fig. 4). The Budd–Chiari syndrome has already been mentioned: because of its characteristic clinical picture it is usually easy to recognize. However, in PNH it is sometimes associated with portal vein thrombosis, and this may limit the extent of liver enlargement. Thrombosis of the splenic vein should be suspected whenever a patient with PNH has, or develops, splenomegaly. Thrombosis of one of the mesenteric veins is much more difficult to diagnose clinically. Appropriate investigations include Doppler ultrasound, contrast-enhanced computer tomography (**CT**), and magnetic resonance imaging (**MR**I): in our experience, the most sensitive methodology is MR venography. Another life-threatening site of thrombosis is in the cranial veins, particularly the sagittal and transverse sinuses. Assessment of the location and extent of these complications is of great practical importance, because thrombolytic therapy with tissue plasminogen activator (Fig. 4) has been carried out successfully even after 3 weeks from the onset of signs and symptoms.

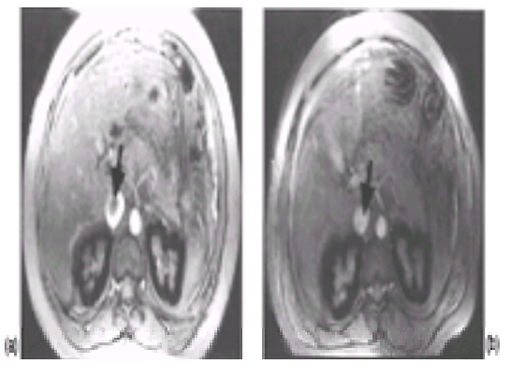

Fig. 4 Abdominal vein thrombosis in PNH can resolve with thrombolytic therapy. (a) shows extensive thrombus in the inferior vena cava in a patient with known PNH who had developed Budd–Chiari syndrome a few days earlier: it is not infrequent in PNH for thrombosis to involve multiple veins in the abdomen all at once. (b) shows a thrombus-free vena cava 2 days after an intravenous infusion of tissue plasminogen activator.(Figure by courtesy of Dr Raymond Thertulien.)

Treatment (see Fig. 5)

In the management of patients with PNH it is important to keep in mind two cardinal points: (1) unlike other acquired haemolytic anaemias, PNH may be lifelong; and (2) in view of the unique pathophysiological features reviewed in the section above, we may have to deal with any or all of three components: haemolysis, thrombosis, bone marrow failure. At the moment, the only form of treatment that can provide a cure for PNH is allogeneic bone marrow transplantation (**BMT**): when an HLA-identical sibling is available, BMT should be offered to any young patient with PNH, especially if there is severe pancytopenia. Results similar to those for AAA can be expected, with long-term disease-free survival ranging from 60 to 100 per cent in the few series that have been published (see Fig. 1: by contrast, the past record of BMT from unrelated donors in PNH is poor). The majority of patients will not have a potential sibling donor, and some of those who do may not wish to undergo BMT. Given the common pathogenesis of PNH and AAA, a logical alternative is immunosuppressive treatment with antilymphocyte globulin (or antithymocyte globulin) and ciclosporin A. Although no formal trial has ever been conducted, this approach has particularly helped to relieve severe thrombocytopenia and/or neutropenia in patients in whom these were the main problem(s): by contrast, there is often little beneficial effect on the haemolysis itself. For all patients, supportive management supervised by somebody who has previous experience of PNH can help the patient to 'live with PNH' for years, sometimes for decades, and sometimes with a good quality of life. The mainstay of support is the transfusion of filtered red cells whenever necessary. Folic acid supplements (at least 3 mg/day) are mandatory; the serum iron concentration should be checked periodically and iron supplements added as indicated. Prednisone (often administered at a dose of 15–30 mg on alternate days) is still quite popular; however, there is no evidence that prednisone decreases the rate of haemolysis, and long-term administration of prednisone, even at a low dosage, is **contraindicated**, in view of the serious potential side-effects. By contrast, a short course of prednisone may sometimes appear helpful during the course of an episode of massive haemoglobinuria associated with intercurrent infection. Any patient who has had a deep vein thrombosis at any one site in the abdomen or in a limb should be given anticoagulant prophylaxis.

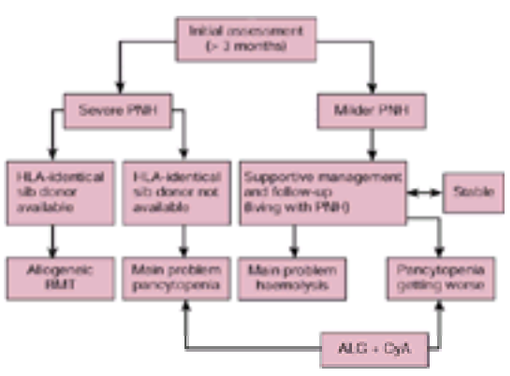

Fig. 5 An algorithm for the management of PNH. This algorithm is based on the consideration that patients with this condition vary considerably (1) in terms of clinical severity, and (2) in terms of the contributions of the PNH clone and of bone marrow failure, respectively, to determining the overall clinical picture. Some patients have been cured by bone marrow transplantation (BMT); other patients who for a long time have been 'living with PNH' have eventually experienced spontaneous recovery (see Hillmen *et al*., 1995).

22.4.1 Leucocytes in health and disease

Joseph Sinning and Nancy Berliner

Introduction

Leucocytes perform a critical role in the host defence against pathogens. They mediate inflammation and modulate the immune response. Leucocytes can be divided into granulocytes (neutrophils, eosinophils, and basophils) (Plate 1), monocytes, and lymphocytes. This chapter will focus on the role of granulocytes and monocytes in the normal host response and pathological manifestations of abnormalities of their number and/or function. Lymphocytes are discussed elsewhere.

Neutrophils

Morphology

Under normal conditions neutrophils make up over half of the leucocytes in the peripheral blood. The morphological hallmarks of these cells include heterogeneous granules and a multilobated or segmented nucleus. The two predominant types of granules in the neutrophil's cytoplasm are the azurophilic (or primary) granules and the specific (or secondary) granules. Azurophilic granules arise at the promyelocytic stage of differentiation. They contain myeloperoxidase, proteases, acid hydrolases, and microbicidal proteins. Specific granules and their content proteins are synthesized at the myelocytic stage of differentiation. Their contents include lactoferrin, lysozyme, vitamin B_{12} -binding protein, gelatinase, and neutrophil collagenase. The specific granules are not a uniform population, and vary by their content with the time of their formation. Those formed early in the myelocyte stage contain abundant lactoferrin, while those formed later are enriched for gelatinase, and are often referred to as 'tertiary' granules or gelatinase granules. The specific granule membrane contains the cytochrome b-558 component of the respiratory burst oxidase, as well as chemotactic and opsonic receptors, which are transferred to the plasma membrane upon activation of the neutrophil. Finally, the neutrophil cytoplasm also contains secretory vesicles that are endocytic vesicles containing primarily plasma proteins, and are the most rapidly mobilized fraction of cytoplasmic granules in the neutrophil. The membrane of secretory vesicles is rich in receptors and cytochrome b, and the vesicles contribute these proteins to the plasma membrane upon neutrophil activation.

Common variants of neutrophil morphology include the Pelger–Huet anomaly, hypersegmentation of the nucleus Dohle bodies, and toxic granulations. The Pelger–Huet anomaly is a dominantly inherited defect in nuclear segmentation that results in a dumb-bell- or rod-shaped nucleus. Neutrophils with nuclei similar to this ('pseudo-Pelger–Huet anomaly') may be seen in acquired myelodysplastic syndromes. Hypersegmented nuclei (containing five or more segments) are characteristic of megaloblastic haematopoiesis due to folic acid or vitamin B_{12} deficiency. Dohle bodies are large basophilic inclusions that may be seen in sepsis, pregnancy, and following cytotoxic chemotherapy. Toxic granulations are abnormally staining primary granules that arise when neutrophils are released prematurely from the marrow, as in severe bacterial infections.

Maturation

There are three cellular compartments that contain myeloid cells: the marrow, the intravascular compartment, and the extravascular space. Maturation from the haematopoietic stem cell occurs in the bone marrow and takes from 10 to 14 days. The marrow compartment can be subdivided into the mitotic compartment and the post-mitotic and storage compartment. In the marrow mitotic compartment neutrophils arise through serial division of myeloid precursors. The mitotic compartment contains myeloid cells with the ability to replicate: myeloblasts, promyelocytes, and myelocytes. The marrow post-mitotic and storage compartment contains myeloid elements that have lost the ability to divide, including metamyelocytes, bands, and segmented neutrophils. Neutrophils are released from the storage pool into the intravascular space, where they remain for 4 to 12 h. Within this space approximately half of the neutrophils circulate freely in the peripheral blood while half remain 'marginated' along the vascular endothelium. The marginated and circulating cells are in dynamic equilibrium with one another. Neutrophils then migrate through the vascular endothelium into the extravascular space, where they survive for 1 to 3 days. At any given time approximately 90 per cent of neutrophils are in the marrow compartment and 2 to 3 per cent are in the intravascular space, with the remainder in the extravascular space.

Neutrophilia

Neutrophilia is defined as an elevation of the circulating neutrophil count (greater than 7.5×10^{6}/μl). Although it may reflect a primary haematological process, it usually occurs as a secondary manifestation of an underlying disease process or drug. The causes of an elevated neutrophil count are summarized in Table 1.

Hereditary neutrophilias

Hereditary neutrophilia

This is a dominantly inherited syndrome manifested by leucocytosis, splenomegaly, and widened diploë of the skull. Laboratory evaluation reveals a white blood count of 20 000 to 70 000/μl with a neutrophilic predominance, and an elevated leucocyte alkaline phosphatase. Its clinical course is benign.

Chronic idiopathic neutrophilia

This is a sporadically occurring condition manifest as a white blood count of 11 000 to 40 000/μl with a neutrophilic predominance. Patients are otherwise well and have been followed for up to 20 years without the development of significant pathology.

Leucocyte adhesion deficiency

This is a rare inherited disorder characterized by recurrent life-threatening bacterial and fungal infections, cutaneous abscesses, gingivitis, or periodontal infections. Expression of the CD11b/CD18 integrin is deficient, resulting in the inability of neutrophils to migrate to sites of infection (see below under disorders of neutrophil function for further discussion).

Acquired neutrophilias

Infection

The most common cause of an elevated leucocyte count is infection. Acute infection often causes a modest rise in the white blood count, which may be accompanied

by an increase in circulating immature precursors ('left shift'). This occurs more commonly with bacterial infection but can also occur with viral processes. Along with a left shift, morphological changes in the neutrophil may be seen with bacterial infection, including toxic granulation, Dohle bodies, and cytoplasmic vacuoles. Neutrophilia resolves with treatment or resolution of the infectious process. In chronic inflammation, marrow granulocyte production is stimulated, resulting in moderate neutrophilia, sometimes with monocytosis. Chronic infections such as osteomyelitis, empyema, and tuberculosis can also give rise to a leukaemoid reaction with white blood counts markedly elevated (greater than 50 000/μl), usually associated with a marked left shift.

Drugs

Drugs can cause leucocytosis by several different mechanisms. Steroids increase the release of mature neutrophils from the marrow and should not cause a left shift. b-Agonists acutely raise the neutrophil count by inducing the demargination of neutrophils adherent to the vascular endothelium, and may result in a neutrophil count twice that of baseline. Acute stress also results in demargination of neutrophils, which is probably mediated by adrenergic stimulation. Stresses that can cause this include exercise, surgery, seizure, and myocardial infarction. The cytokines granulocyte colony-stimulating factor (**G-CSF**) and granulocyte–macrophage colony-stimulating factor (**GM-CSF**) stimulate marrow production of neutrophils and can cause dramatic elevations in the white blood count. The majority of white cells formed are neutrophils and a left shift is often seen. The use of these cytokines therefore requires careful monitoring.

Primary haematological conditions

In other situations, neutrophilia may reflect a primary haematological condition. Marrow hyperstimulation in the setting of autoimmune haemolytic anaemia, immune thrombocytopenia, or recovery following chemotherapy or toxic insult to the marrow may result in a reactive leucocytosis. In autoimmune haemolytic anaemia and immune thrombocytopenia, neutrophilia may reflect disease activity, but steroid therapy or splenectomy may contribute. Splenectomy or hyposplenic states (for instance sickle-cell disease) may also result in modest neutrophilia at baseline with more marked neutrophilia at times of stress or infection, reflective of the loss of the spleen as a site of margination and sequestration of leucocytes.

Myeloproliferative disorders

Neutrophilia is a common feature of the myeloproliferative disorders chronic myelogenous leukaemia, polycythaemia vera, and agnogenic myeloid metaplasia, as well as familial myeloproliferative disorders. Elevated eosinophil and basophil counts are also often seen in these disorders. Leucocyte alkaline phosphatase may be low or undetectable in chronic myelogenous leukaemia. The myeloproliferative disorders are discussed in further detail elsewhere.

Non-haematological malignancies

Various non-haematological malignancies including lung and breast tumours may also cause neutrophilia. Tumours may secrete colony-stimulating factors or may cause a leukaemoid reaction. Tumour metastatic to the bone marrow may cause leucoerythroblastic changes, characterized by fragmented erythrocytes, teardrops, and nucleated red cells (myelophthysic changes), as well as leucocytosis with a left shift.

Evaluation of neutrophilia

The evaluation of neutrophilia should take account of the fact that leucocytosis is usually reactive, and that primary haematological aetiologies are relatively rare. The abnormal laboratory value should be verified to rule out laboratory error or a transient unexplained leucocytosis that resolves spontaneously. A careful history and physical examination are essential to evaluate for potential infectious processes, and to obtain a history of medication use. Examination of the bone marrow is usually not necessary for the evaluation of neutrophilia, but examination of a peripheral smear may be very helpful. Evidence of leucoerythroblastic changes warrants examination of the bone marrow to rule out granulomatous disease or tumour infiltration of the marrow. If a bone marrow biopsy is performed, evaluation should include culture of the marrow for fungus or mycobacteria.

Features that raise the question of myeloproliferative disease include concomitant elevation of platelets and haematocrit, basophilia and/or eosinophilia, and splenomegaly. In that setting, evaluation should include stem cell culture of the peripheral blood or bone marrow to assay for cytokine-independent colony growth. Evaluation for myeloproliferative disease is discussed in detail elsewhere.

Neutropenia

Neutropenia is defined as an absolute neutrophil count (**ANC**) of less than 1.5×10^6/μl. In some populations, such as Africans and Yemenite Jews, normal absolute neutrophil counts are lower, with a lower limit of normal of 1.2×10^6/μl. Neutropenia may pose a risk of serious bacterial infection, and this risk is directly related to the degree of neutropenia. In mild neutropenia (ANC 1000 to 1500 × 10^6/μl) the risk of life-threatening infection is not increased, and in moderate neutropenia (ANC 500 to 1000 × 10^6/μl) the risk of severe infection is only mildly elevated. Severe neutropenia (ANC < 500 × 10^6/μl) markedly increases the risk of life-threatening infection. The duration and acuity of neutropenia may also be important, as the acute onset of severe neutropenia is associated with a higher risk of serious infection than is chronic neutropenia of similar severity. Neutropenia in the setting of marrow failure is more threatening than neutropenia with an intact marrow, as the marrow reserve pool may afford protection. Fever of new onset in the setting of severe neutropenia is a medical emergency requiring immediate evaluation and treatment. Common causes of infection in these patients include Gram-negative enteric pathogens such as *Escherichia coli*, *Pseudomonas* spp., and *Klebsiella pneumoniae*, as well as *Staphylococcus aureus.* The causes of neutropenia are summarized in Table 2.

Congenital neutropenia

Congenital agranulocytosis (Kostmann's syndrome)

This is characterized by severe persistent neutropenia, and the early onset of frequent, life-threatening infections. Bone marrow aspirate reveals a maturation arrest at the promyelocyte stage. This syndrome was originally described as an autosomal recessive disorder, but recent evidence suggests that most cases are autosomal dominant or sporadic. These patients respond to G-CSF with increases in their absolute neutrophil count and decreased incidence of infection. Haematopoietic cell transplantation is another viable treatment option.

With the prolongation of life offered by G-CSF therapy, it has become apparent that patients with Kostmann's syndrome have an increased incidence of acute myeloblastic leukaemia (AML) and myelodysplastic syndrome (MDS). These malignancies develop in association with an acquired mutation in the G-CSF receptor. A relationship has been speculated to exist between G-CSF therapy and the development of these mutations in the G-CSF receptor, but this connection remains unproven, as has the pathogenetic role of the mutations in the subsequent development of acute myeloblastic leukaemia (AML) and myelodysplastic syndrome (MDS). Recent studies have established that Kostmann's syndrome is linked to mutations in the gene encoding neutrophil elastase, a neutrophil primary granule protein. How mutations in the elastase gene give rise to agranulocytosis remains to be elucidated.

Cyclic neutropenia (cyclic haematopoiesis)

This is a rare, dominantly inherited, marrow disorder characterized by cyclic fluctuations in neutrophil counts approximately every 21 days and lasting 3 to 7 days. Along with the neutropenia, cyclic drops in the reticulocyte and monocyte counts are also observed. This suggests that the entire pattern of haematopoiesis is cyclic in these patients, although because of the short half-life of the neutrophil, only neutropenia is clinically significant. Episodes of neutropenia may be severe, often with an absolute neutrophil count less than 200 × 10^6/μl, and may be accompanied by fevers, pharyngitis, stomatitis, and other bacterial infections. Cyclic neutropenia has also been linked to mutations in the neutrophil elastase gene, although why some mutations give rise to cyclic haematopoiesis and others to agranulocytosis is still a matter of speculation. Cyclic neutropenia can be treated safely and effectively with G-CSF. Unlike Kostmann' s syndrome, cyclic haematopoiesis is not associated with an increased incidence of AML and MDS.

Acquired neutropenias

Postinfectious neutropenia

This is commonly seen following viral infections. It usually occurs several days after the onset of infection and may last several weeks. Varicella zoster, measles, Epstein–Barr, cytomegalovirus, influenza A and B, and hepatitis A and B are some of the viruses most commonly associated with postinfectious neutropenia. The neutropenia resolves spontaneously. Transient neutropenia may also be seen with parvovirus infection. Neutropenia occurs commonly in patients with HIV. The causes are multifactorial and may be related directly to the viral infection, to opportunistic infections or associated conditions, or to the treatment of the virus or its complications.

Several bacterial infections can cause neutropenia, including rickettsial infections, typhoid fever, brucellosis, and tularaemia. Bacterial sepsis of any cause can result in acute neutropenia. This occurs both as a result of marrow suppression and increased destruction of neutrophils. Acute severe neutropenia in bacterial infections suggest that egress to tissue exceeds the capacity of the marrow reserve pool. The neutropenia may be severe and it portends a poor prognosis. Fungal infections, such as disseminated histoplasmosis, and mycobacterial diseases may also cause neutropenia.

Nutritional deficiencies

Nutritional deficiencies of vitamins B_{12} and folic acid result in megaloblastic haematopoiesis with ineffective myelopoiesis. Deficiency of copper is a rare nutritional cause of neutropenia seen in the setting of severe malnutrition or long-term parenteral alimentation. Mild neutropenia may also be seen with anorexia nervosa.

Drugs and toxins

Numerous drugs and toxins are known to cause neutropenia. Mechanisms of drug-induced neutropenia include: (i) direct marrow suppression, (ii) immune destruction with antibody- or complement-mediated damage of myeloid precursors, and (iii) peripheral destruction of neutrophils. In most cases direct marrow suppression is dose dependent. Common offending drugs that cause dose-dependent neutropenia include cancer chemotherapeutic agents, phenothiazines, anticonvulsants, and ganciclovir. Alcohol can also cause neutropenia by marrow suppression. If a drug is suspected of causing dose-dependent neutropenia, it is best to stop the suspected offending agent when possible. However, if it is not possible to stop the drug and the neutropenia is not severe, the drug may be continued with careful monitoring. Neutropenia is often related to the dose and duration of therapy. In contrast, those drugs that cause immune neutropenia usually cause profound agranulocytosis, resulting from both intramedullary destruction of myeloid precursors and peripheral destruction of mature neutrophils. Such drugs include antithyroid medications, sulphonamides, and semisynthetic penicillins. Examination of the bone marrow shows a maturation arrest of the myeloid lineage, reflecting immune destruction of myeloid precursors. The offending agent must be stopped. Recovery of the neutrophil count can be accelerated by the administration of G-CSF.

Autoimmune neutropenia

This may occur in association with collagen vascular disorders such as systemic lupus erythematosis and rheumatoid arthritis, as well as with immune thrombocytopenia and autoimmune haemolytic anaemia. Destruction may be mediated by IgG or IgM antibodies. The neutropenia may be severe but the degree of neutropenia frequently does not correlate as well with the risk of infection as in other conditions. The marrow typically is hypercellular with a late myeloid maturation arrest. Treatment is indicated in the setting of severe, recurrent infections.

Treatment options include intravenous immunoglobulin, splenectomy, and other therapies directed at the underlying collagen vascular disorder. In Felty's syndrome, neutropenia accompanies rheumatoid arthritis and splenomegaly and neutropenia probably reflects both immune destruction and splenic sequestration. Granulopoiesis is inhibited by either antibodies or T cells. This can lead to severe and recurrent infections. It may be managed with G-CSF. Splenectomy relieves the neutropenia in the majority of cases.

Large granular lymphocytosis

This may cause profound neutropenia accompanied by severe infections. It occurs in an older population, and is frequently seen in association with rheumatological diseases such as rheumatoid arthritis. Because of the association with systemic inflammatory disease, large granular lymphocytosis was originally hypothesized to be a polyclonal abnormal immune response. However, gene rearrangement studies have confirmed that large granular lymphocytosis is frequently a clonal disease representing a form of T-cell lymphoma. There are two distinct subtypes, with cells expressing either an unusual Tg phenotype (CD3+,CD8+, CD56–) or an natural killer phenotype (CD56+). When seen in association with rheumatoid arthritis, the disease may be confused with Felty's syndrome. Neutropenia related to large granular lymphocytosis is associated with a myeloid maturation arrest in the marrow, consistent with immune-mediated neturophil destruction. Surprisingly, however, the neutrophil count will often respond to G-CSF. The course of lymphoma in large granular lymphocytosis varies from indolent to rapidly progressive.

Other causes

Aplastic anaemia reflects a primary failure of haematopoiesis with neutropenia, anaemia, and thrombocytopenia. In the myelodysplastic syndromes and acute leukaemias the marrow does not produce adequate numbers of neutrophils.

Isoimmune neutropenia occurs in 1 in 500 babies born alive. It is caused by placental transfer of maternal IgG directed against fetal neutrophils, and it presents in the first days of life.

Hypersplenism usually causes mild or moderate neutropenia along with anaemia and thrombocytopenia. Normal myeloid maturation is seen in the marrow. The neutropenia is rarely severe.

Evaluation of neutropenia

In contrast to the evaluation of neutrophilia, most patients with confirmed neutropenia require bone marrow examination. A comprehensive history and physical examination may identify the occasional patient with mild neutropenia and no other evidence of disease that may warrant close observation only. However, recurrent infections, including oral and mucosal infections, abnormalities observed in a peripheral blood smear, or severe neutropenia increase the likelihood of significant marrow pathology and marrow aspiration and biopsy is indicated. If neutropenia is accompanied by anaemia or thrombocytopenia, marrow examination is required to rule out aplasia, leukaemia, myelodysplasia, or other primary marrow malignancy. A marrow that shows hyperplastic myeloid precursors and a maturation arrest supports a diagnosis of peripheral neutrophil destruction and/or immune neutropenia, which should lead to a search for an underlying collagen vascular disorder or drug-induced neutropenia.

Management of neutropenia

Fever of new onset in the setting of severe neutropenia (ANC < 500×10^6/µl) is a medical emergency. A careful history and physical examination should be performed in a timely fashion. Because of the lack of neutrophils, sites of infection may be difficult to find as significant inflammation or tissue infiltration by neutrophils may not occur. Blood and bodily fluids should be cultured. Empirical broad-spectrum antibiotics should be initiated without delay. In patients with fever in the setting of neutropenia that is expected to resolve (usually neutropenia induced by chemotherapy or drug reaction), antibiotics should be continued until the neutrophil count recovers to over 500/µl. In patients with chronic neutropenia that is expected to persist indefinitely, antibiotics should be continued for several days past the resolution of fever. If fever persists for more than 1 week despite antibiotic therapy, empirical antifungal therapy should be given. Granulocyte transfusion should be considered in culture-positive Gram-negative sepsis not responsive to antibiotics in the setting of continued neutropenia.

Granulocyte colony-stimulating factor (G-CSF)

G-CSF (Filgrastim) is a haematopoietic growth factor that has effects primarily on the neutrophilic myeloid lineage. G-CSF reduces the time of maturation of committed neutrophil precursors, prolongs the lifespan of mature neutrophils, and primes them for enhanced function of the respiratory burst, phagocytosis, and chemotaxis. Clinically, G-CSF is used in the treatment and prevention of neutropenia. When used in conjunction with myelosuppressive chemotherapy, G-CSF has been shown to reduce the severity of neutropenia, shorten the duration of neutropenia, reduce the risk of developing neutropenic fever, and reduce the length of stay in hospital. G-CSF has also been utilized successfully in the treatment of severe neutropenia secondary to congenital disorders such as cyclic neutropenia and Kostmann's syndrome, and may be useful in the treatment of autoimmune neutropenia as seen in Felty's syndrome and systemic lupus erythematosis. The

neutropenia of marrow failure states, such as the myelodysplastic syndromes, may respond to G-CSF.

Neutropenia secondary to the treatment of HIV infection can also be controlled with G-CSF. The other major use of G-CSF is in the mobilization of haematopoietic progenitor cells from the bone marrow to the peripheral blood. While in the peripheral blood, these cells can be collected by cytopheresis for use in haematopoietic cell transplantation.

Disorders of neutrophil function

Chronic granulomatous disease

Chronic granulomatous disease is a heterogeneous group of rare disorders characterized by defective production of superoxide (O_2^-) by neutrophils, monocytes, and eosinophils. The majority of cases are inherited in an X-linked fashion, but autosomal recessive inheritance also occurs. The genetic lesions causing chronic granulomatous disease have been characterized, and involve mutations in any of four genes encoding the proteins of the respiratory burst oxidase. These include the 91-kDa (X-linked) and 22-kDa (autosomal) components of the membrane cytochrome b-558 complex, and the 47- and 67-kDa soluble components (autosomal) of the oxidase complex. Patients usually present in childhood with severe infections, often with catalase-negative pathogens. The most common infection in patients with chronic granulomatous disease is pneumonia, with *Staphylococcus aureus*, *Burkholderia cepacia*, *Aspergillus* spp., and enteric Gram-negative bacteria often implicated. Other common infections in chronic granulomatous disease include lymphadenitis, cutaneous infections, hepatic abscesses, and osteomyelitis. Aphthous ulceration of the oral mucosa is common, as are chronic mucosal inflammation, perirectal abscesses or fissures, and granulomas of the gastrointestinal and genitourinary tract. The diagnosis of chronic granulomatous disease should be considered in an individual with a history of multiple severe bacterial and fungal infections or a family history of the disorder. The diagnosis is established by confirming abnormal neutrophil oxidative metabolism with tests such as the nitroblue tetrazolium (NBT) slide test or measurements of superoxide or peroxide production. The management of chronic granulomatous disease is based on aggressive prophylaxis and prompt treatment of infection. Prophylactic trimethoprim–sulphamethoxazole or dicloxacillin can significantly decrease the number of bacterial infections in patients with chronic granulomatous disease. Potentially serious infections require the prompt initiation of parenteral antibiotics. Surgical interventions including drainage of abscesses and resection of infected tissue are in important adjunct to antimicrobial chemotherapy. Prophylaxis with recombinant human interferon-g has been shown in a phase III trial to decrease substantially the number of serious infections in patients with chronic granulomatous disease.

Leucocyte adhesion deficiency

Leucocyte adhesion deficiency is an inherited disorder of neutrophil function. Two types of leucocyte adhesion deficiency have been characterized. Type 1 deficiency is a rare autosomal recessive disorder resulting from mutations in CD18, the gene encoding for the b-chain of leucocyte function antigen-1 (LFA-1, CD11a/CD18), Mac-1 (CD 11b/CD18, CR3, the receptor for the opsonin C3Bi), and gp150,95 (CD11c/CD18). Deficient expression of these three integrin complexes on the neutrophil cell surface results in decreased neutrophil adhesion to the endothelium, impaired chemotaxis, and defective C3Bi-mediated pathogen ingestion, degranulation, and respiratory burst activation. Patients with leucocyte adhesion deficiency typically present in early childhood with recurrent pyogenic infections of the skin, respiratory and digestive tracts, and mucosal membranes. A history of delayed umbilical cord separation is also often noted. Common pathogens in patients with type 1 leucocyte adhesion deficiency include *Staphylococcus aureus* and Gram-negative enterics. Foci of infection notably lack neutrophil infiltration. A mild leucocytosis persists due to impaired margination. The diagnosis is confirmed by flow cytometric measurement of neutrophil CD11b/CD18 expression. The treatment of type 1 leucocyte adhesion deficiency includes aggressive use of parenteral antibiotics for pyogenic infections. Prophylactic trimethoprim–sulphamethoxazole may benefit some patients. Patients with a severe phenotype often die in the first 2 years of life, but patients with mild disease may survive to early adulthood. Type 2 leucocyte adhesion deficiency is caused by a deficiency of Sialyl–Lewis X moieties on neutrophil selectins. In addition to neutrophil function abnormalities, this extremely rare syndrome also is characterized by mental retardation, short stature, and the rare Bombay erythrocyte phenotype.

Myeloperoxidase deficiency

Myeloperoxidase deficiency is a relatively common, autosomal recessively inherited, disorder of neutrophil function. Complete deficiency occurs in 1 in 2000 individuals and partial deficiency occurs twice as frequently. Myeloperoxidase catalyses the production of hypochlorous acid, which is an antimicrobial agent. Myeloperoxidase deficiency is often of no clinical consequence because other host defence mechanisms can adequately compensate for the defective myeloperoxidase; however, when myeloperoxidase deficiency coexists with another defect in host defence, such as diabetes mellitus, disseminated candidal or fungal infections may occur. The diagnosis of myeloperoxidase deficiency is made by histochemical staining of neutrophils and monocytes. Therapy consists of aggressive treatment of fungal infections as well as careful control of glucose levels in patients with diabetes. An acquired form of myeloperoxidase deficiency occurs in some myeloid leukaemia.

Chediak–Higashi syndrome

Chediak–Higashi syndrome is a rare disorder of neutrophil function. Neutrophils and monocytes contain giant primary granules and demonstrate impaired degranulation and fusion with phagosomes. Chemotaxis is also defective. Neutropenia results from defective granulopoiesis. Chediak–Higashi syndrome is inherited in an autosomal recessive manner. The gene responsible has been cloned, and is homologous to a murine lysosomal trafficking protein. Chediak–Higashi syndrome manifests in childhood or infancy with infections of the skin, lungs, and mucous membranes. *S. aureus*, Gram-negative enterics, *Candida*, and *Aspergillus* species are responsible for most infections in this syndrome. Non-haematological manifestations of Chediak–Higashi syndrome include partial oculocutaneous albinism, progressive peripheral and cranial neuropathies, and in some cases, mental retardation. The majority of patients will develop an accelerated phase of the syndrome, manifested by lymphohistiocytic proliferation in the liver, spleen, bone marrow, and lymphatics. The diagnosis of Chediak–Higashi syndrome is made by the demonstration of giant peroxidase-containing granules in peripheral blood or bone marrow myeloid cells, outside of the setting of myelogenous leukaemia. Chediak–Higashi syndrome is treated in the early or stable phase with prophylactic antibiotics and aggressive parenteral antibiotics for infections. Ascorbic acid may also be of benefit. The accelerated phase is treated with vinca alkaloids and glucocorticoids, but often responds poorly to these measures. Allogeneic haematopoietic cell transplantation from HLA-compatible donors is the only potentially curative therapy for Chediak–Higashi syndrome.

Specific granule deficiency

An extremely rare disorder, neutrophil specific granule deficiency is characterized by absent or empty neutrophil specific granules. Specific granule deficiency is manifested clinically as recurrent skin and pulmonary infections resulting from the absence of antimicrobial neutrophil granule proteins such as lactoferrin and defensins. An inability to upregulate the expression of integrins stored on the specific granule membrane may also be responsible for the impairment of host defence. The diagnosis of specific granule deficiency is made by microscopic examination of neutrophils. With appropriate antibiotic prophylaxis and aggressive treatment of infections, patients may live to adulthood. A truncation mutation in the transcription factor C/EBPe has recently been demonstrated to be responsible for some, but not all, cases of specific granule deficiency.

Monocytes

Monocytes are large circulating cells with a non-segmented nucleus and cytoplasmic granules. They function as phagocytes both in antimicrobial defence and in clearing cellular debris. Their granules are essentially identical to neutrophil azurophilic granules, and contain acid hydrolases and myeloperoxidase. Monocytes are also capable of producing reactive oxygen and nitrogen compounds with microbicidal activity. Monocytes play a critical role in the immune response as they present antigens in the context of MHC to T cells. They also produce a variety of immunomodulatory cytokines including interleukins 1 and 6, tumour necrosis factor-a, and b-interferon.

Monocytes arise from bone marrow stem cells. They share a common myeloid precursor with granulocytes. The differentiation to the monocyte is modulated by several cytokines, most importantly monocyte colony-stimulating factor and granulocyte–monocyte colony-stimulating factor. The majority of monocytes are marginated to the vascular endothelium. Upon stimulation, they migrate to the tissue where they develop into macrophages. In the tissue they kill bacteria, mycobacteria, fungi, and protozoa. They are especially important in defence against intracellular pathogens. Specialized resident tissue macrophages include the Langerhans cells of the skin, dendritic cells of lymph nodes, Kupffer cells of the liver, and alveolar macrophages.

Monocytosis is defined as a monocyte count of greater than $0.9 \times 10^6/\mu l$. Disorders causing monocytosis are heterogeneous. Recovery of the marrow following chemotherapy or agranulocytosis is heralded by monocytosis prior to the return of neutrophils. Monocytosis is also seen in syndromes such as cyclic neutropenia,

Kostmann's syndrome, and idiopathic neutropenia.

The most common causes of monocytosis include chronic infection, inflammation, or tumour, as well as some primary haematological disorders (Table 3). Chronic infections leading to monocytosis include subacute bacterial endocarditis and mycobacterial diseases. Monocytosis is typically moderate and resolves with treatment of the infection. Autoimmune processes such as systemic lupus erythematosis, rheumatoid arthritis, and vasculitis also cause moderate monocytosis. Monocytosis may arise from primary malignancies of the marrow or in the setting of marrow infiltration with solid tumours (myelophthysis).

Primary marrow disorders causing monocytosis include acute monocytic leukaemia, chronic myelogenous leukaemia and other myeloproliferative disorders, and chronic myelomonocytic leukaemia, which has features of both myelodysplastic and myeloproliferative disorders. Juvenile chronic myelogenous leukaemia is a rare disorder occurring in children less than 4 years of age. Lymphadenopathy and splenomegaly are also prominent features.

Monocytopenia in isolation is uncommon. Monocytopenia is sometimes seen following steroid administration, endotoxaemia, or in marrow failure syndromes such as aplastic anaemia.

Eosinophils

Morphology

Eosinophils have a bilobate nucleus and contain characteristic elliptical granules that stain with eosin. There are three types of eosinophil granules. Primary granules are round in shape. Secondary granules are abundant and contain crystalloid material, and account for the eosinophil's staining properties. The third type of granule is small and contains lysosomal enzymes. Granules contain high concentrations of eosinophil major basic protein, histaminase, eosinophil cationic protein, hydrolases, and peroxidase. Eosinophils are capable of phagocytic function but more commonly release their granule contents to the environment. Eosinophils are also capable of producing reactive oxygen species, and produce prostaglandins, thromboxane A_2, and leukotriene C_4. Eosinophils play a prominent role in defence against helminths and parasites. They arise in the marrow from a common myeloid precursor, and their production is dependent on GM-CSF, IL-3, and IL-5.

Congenital eosinophilia

Job's syndrome is an inherited disorder characterized by recurrent cold abscesses, eczema, and coarse facies. Patients typically have eosinophilia and significantly elevated levels of IgE.

Acquired eosinophilia

Allergic reactions

These are the most common cause of eosinophilia, including allergies to drugs and environmental agents (Table 4). Moderate eosinophilia is common in collagen vascular diseases including rheumatoid arthritis, vasculitis, and eosinophilic fasciitis. Malignancies such as Hodgkin's disease, non-Hodgkin's lymphoma, and various solid tumours may present with eosinophilia. Moderate eosinophilia is commonly seen in chronic myelogenous leukaemia.

Eosinophilic leukaemia

This is an extremely rare disorder. It presents with extreme eosinophilia, and may be difficult to differentiate from the hypereosinophilic syndrome. However, in eosinophilic leukaemia, the eosinophils are clonal and may contain clonal cytogenetic abnormalities. Furthermore, eosinophilic leukaemia is often associated with cytopenias, infections, and an increase in marrow blasts.

Idiopathic hypereosinophilic syndrome

This is characterized by prolonged eosinophilia and end-organ damage secondary to tissue infiltration by eosinophils. Organs commonly involved include the heart, lungs, central nervous syndrome, kidneys, gastrointestinal tract, and skin. Eosinophilia may be severe (> 50–100 × 10^6/μl). Eosinophils deposit toxic proteins in the infiltrated tissues which lead to thrombosis and fibrosis. In the heart the fibrosis results in restrictive cardiomyopathy. The diagnosis of an idiopathic hypereosinophilic syndrome requires eosinophil counts greater than 1.5 × 10^6/μl for 6 months, organ dysfuncton secondary to eosinophilic infiltration, and no other cause to explain the eosinophilia.

Churg–Strauss syndrome

Primary hypereosinophilic syndrome may be difficult to distinguish from Churg–Strauss syndrome, an eosinophilic vasculitis associated with eosinophilia, pulmonary infiltrates, asthma, and neuropathy. The presence of Churg–Strauss syndrome is suggested by the presence of asthma, which is not characteristic of hypereosinophilic syndrome, and the diagnosis can be confirmed by the finding of necrotizing vasculitis of small vessels, often in association with extravascular granulomas.

Eosinophilia–myalgia syndrome

This is a disorder associated with the ingestion of L-tryptophan supplements from a single source. Affected individuals have eosinphilia and severe myositis. Tissues are infiltrated with eosinophils. In many cases the syndrome responds to steroids, but in some cases it is fatal.

Eosinopenia

Eosinopenia is seen in the setting of steroid use, stress, and acute infection. It typically is clinically benign.

Basophils

Basophils are rare circulating cells, accounting for less than 0.1 per cent of white blood cells. They are non-phagocytic granulocytes. Their large heterogeneous granules account for their purple-black staining. Their granules contain histamine, heparin, tryptase, chemotactic factors for neutrophils and eosinophils, leukotrienes, prostaglandins, and platelet-activating factor. They arise in the marrow from the same myeloid precursor as eosinophils. Basophils function in immediate-type hypersensitivity. They are structurally similar to mast cells but the exact relationship between these cell types is not clear. Basophilia (> 0.2 × 10^6/μl) is seen in myeloproliferative disorders such as chronic myelogenous leukaemia and polycythaemia vera, hypersensitivity reactions, and with some viral infections including varicella and influenza. Mast cell leukaemia is a rare disorder with a poor prognosis.

22.4.2 Introduction to the lymphoproliferative disorders

Barbara A. Degar and Nancy Berliner

The human immune system has the capacity to identify and respond specifically to invading pathogens. It can also 'remember' the exposure, such that subsequent exposure to the same pathogen results in a more rapid and potent immune response. Lymphocytes play the key role in the adaptive immune response, mediating both specificity and memory.

Lymphocytes

The lymphocytes can be divided into two morphologically indistinguishable types, which play different and complementary roles in the immune system. Both are derived from lymphohaemopoietic stem cells that reside in fetal liver and in adult bone marrow. B cells develop in the marrow (the human equivalent of the avian bursa of Fabricius) and their principal role is to generate immunoglobulin (antibodies). B cells represent about 20 per cent of the lymphocyte population in peripheral blood. T cells mature within the thymus. T cells orchestrate the immune response: they are capable of cell-mediated cytotoxicity, they generate inflammatory cytokines, and they provide help for B-cell function. T cells account for approximately 80 per cent of the lymphocytes in the peripheral circulation. A much smaller population of lymphoid-appearing cells express neither B-cell nor T-cell markers. These null cells, also known as natural killer (**NK**) cells and large granular lymphocytes (**LGLs**), are capable of cell-mediated cytotoxicity, especially against tumour cells and virally infected cells. NK cells are a component of the innate immune response, as they do not demonstrate immunological memory.

Lymph nodes

In their role in infection surveillance, lymphocytes circulate through the body via a network of lymphatic and blood vessels. At strategic locations, lymphoid cells are organized to allow direct interaction among lymphocytes and other specialized cells of the immune system.

These interactions permit the production of specific, functional effector cells. The network includes approximately 500 to 600 discrete lymph nodes, lymphoid populations in the oropharynx (Waldeyer's ring), bronchial tree and gut, as well as in the thymus, the bone marrow, and the spleen.

Within lymph nodes, lymphocytes are arranged in a central medulla surrounded by an outer cortex contained within a connective tissue capsule (Fig. 1) Afferent lymphatics penetrate the cortex and lymphocyte-rich fluid filters toward the medullary sinusoids and the efferent lymphatics at the hilum of the node. The vascular supply to the lymph node includes specialized postcapillary venules that allow the passage of peripheral blood lymphocytes into the node. Lymphocytes are ultimately returned to the bloodstream via the thoracic duct.

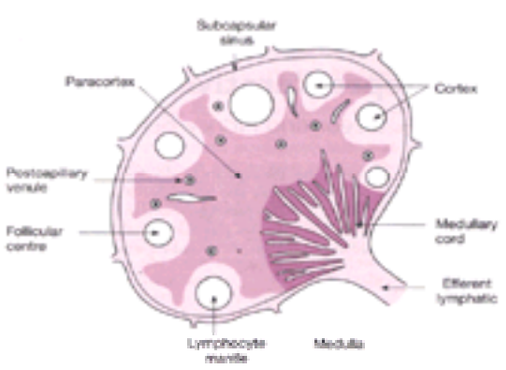

Fig. 1 Functional architecture of a normal lymph node. (Reproduced from Arno J (1980). *Atlas of lymph node pathology*, with permission.)

Roughly spherical follicles are found in the lymph node cortex and predominantly comprise B cells. Primary follicles contain clusters of naïve, unstimulated B cells. Secondary follicles, with pale 'germinal centres' surrounded by a darker 'mantle' zone, represent foci of B cells proliferating and differentiating in the presence of antigen-bearing dendritic cells and activated 'helper' T cells (T_H cells). The interfollicular and paracortical zones of the lymph node are densely populated by T cells. Macrophages, follicular dendritic cells, and interdigitating reticulum cells all process and present antigen to the lymphocytes within the node.

The design of the lymph node facilitates the process whereby the subpopulation of lymphocytes capable of responding to a specific antigen is expanded. Antigens are delivered to the subcapsular sinus of the node via afferent lymphatics, and are taken up by reticulum cells and presented on their surface in the context of the major histocompatibility complex (**MHC**) proteins. Specific T-lymphocyte responses require that peptide antigens, which are derived from 'foreign' proteins, appear on the surface of antigen-presenting cells in close association with a 'self' MHC molecule. B cells, on the other hand, are capable of responding to some antigens in solution. Optimal B-cell responses require the 'help' of T cells both via direct cell–cell contact and in response to cytokines secreted by T cells. Only those T cells and B cells that have been genetically preprogrammed to interact with a specific antigen will proliferate and differentiate in response to it.

Antigen receptors

Both B and T cells express transmembrane proteins on their cell surfaces, these proteins bind antigen and define the antigenic specificity of the cell. In the case of B cells, the immunoglobulin molecule represents the B-cell receptor (Fig. 2) Each immunoglobulin molecule is a bivalent tetramer comprising a pair of heavy chains bound to two light chains (of either kappa or lambda type). Genetic recombination of approximately 400 immunoglobulin gene segments (located on chromosomes 2, 14, and 22), generates about 10^{15} distinct antibody specificities. The expression of recombination activating genes (*RAG1* and *RAG2*) early in B-cell development mediates the random rearrangement of variable (**V**), diversity (**D**), and joining (**J**) gene segments. Terminal deoxyribonucleotidyl transferase (**TdT**) contributes to the diversity of immunoglobulin molecules by inserting additional nucleotides during the splicing of gene segments. This process gives rise to a vast repertoire of antibody molecules, each with a unique antigen-binding cleft. All of the progeny cells of a B cell that has rearranged its immunoglobulin genes have the same antigenic specificity and are referred to as a clone. Most protein antigens are complex and contain many different epitopes (structures capable of binding an antigen receptor). Therefore, most pathogens stimulate many lymphocyte clones to proliferate: that is to say, they result in polyclonal responses. As B-cell clones mature, the isotype of the antibodies they produce 'switches' from IgM/IgD to IgG, IgA, or IgE.

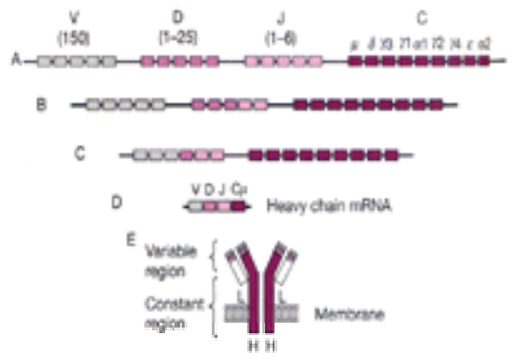

Fig. 2 Immunoglobulin gene rearrangement. The top line (A) represents the germline pattern of the immunoglobulin heavy chain locus found on human chromosome 14. B-cell progenitors express recombination activating genes which mediate the random, sequential rearrangement of gene modules (lines B and C) such that only one of several variable $(V)_1$ diversity (D), and joining (J) segments is expressed by a B-cell clone (line D). As the gene components are spliced, terminal deoxynucleotidyl transferase (TdT) randomly inserts additional nucleotides at splice junctures. Diverse antigenic specificity is thus somatically generated from a relatively small amount of genetic material. The immunoglobulin molecule (line E) is a tetramer of two heavy and two light chains which may be cell-associated (as shown) or secreted. The region of the molecule which interacts specifically with antigen is the variable region. The constant region of the light chain are of either the _ or l types. The constant region of the heavy chain determines the isotype of the antibody (IgM, IgD, IgG, IgA, IgE).

In an analogous fashion, T-cell precursors rearrange the T-cell receptor (**TCR**) genes. The TCR consists of a heterodimer of a and b chains, or g and † chains in a minority of T cells. The a and b genes are encoded on chromosomes 14 and 7, respectively, while the g and † chains are on chromosomes 7 and 14, respectively. T-cell precursors randomly assemble variable, joining, and diversity gene segments to generate a vastly diverse array of antigen-specific T-cell clones. When the T cell encounters antigen to which it can productively bind, the cell undergoes clonal expansion, and generates both activated effector cells and long-lived memory cells.

Lymphocyte ontogeny

As lymphocytes develop and mature from multipotent progenitors to terminally differentiated effector cells, they express a sequential pattern of surface proteins. Some of these cell-surface molecules subserve known, critical functions in the cells that bear them. Others are of less clear biological significance, but are useful markers of cell type and status of differentiation and activation. Malignant lymphomas and lymphoid leukaemias are frequently classified and understood on the basis of their expression of cell-surface markers (Fig. 3) In some cases, the stage of differentiation at which malignant transformation occurred can be inferred from the pattern of the surface antigens expressed by the malignant cells.

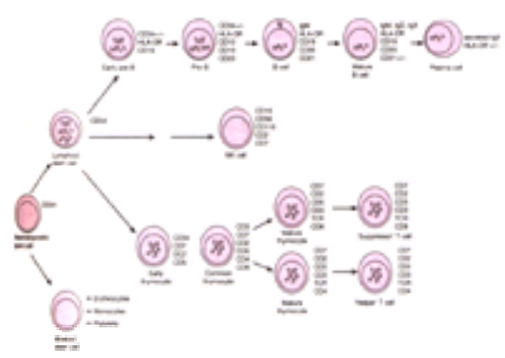

Fig. 3 Simplified depiction of lymphocyte ontogeny. Lymphocytes derive from lymphoid progenitors in the bone marrow, which in turn are derived from multipotent haemopoietic stem cells. B-lymphoid progenitors are recognized by their expression of terminal deoxynucleotidyl transferase (TdT) and the rearrangement of the immunoglobulin heavy chain locus. As B cells mature, the light chain is rearranged and immunoglobulin is expressed first within the cell cytoplasm, then on the cell surface, and is ultimately secreted. T-lymphoid progenitors migrate to the thymus where they express TdT and rearrange the b-subunit followed by the a-subunit of the T-cell receptor (TCR). An overlapping sequence of cell-surface proteins are expressed as the cells differentiate, these have been numerically classified using cluster of differentiation (**CD**) designations. The status of the immunoglobulin and *TCR* genes are represented as follows: H, immunoglobulin heavy chain; L, light chain; a, TCR-a; b, TCR-b; G, germline; R, rearranged.

Lymphocytes develop from haemopoietic stem cells. Although the surface characteristics of these elusive cells are not well understood, it is likely that human stem cells express the cell-surface glycoprotein CD34. The first recognizable sign of commitment to the B-lymphoid lineage is the expression of TdT and the rearrangement of the immunoglobulin heavy chain. As differentiation progresses, B-cell progenitors turn on the expression of class II MHC molecules (HLA-DR) as well as CD19 and then CD10 (the latter is also known as 'common acute lymphoblastic leukaemia antigen', **CALLA**). The immunoglobulin light chain is rearranged and the cells (now termed pre-B cells) express the μ heavy chain within their cytoplasm. As the cells progress to the early B-cell stage, CD34, TdT, and CD10 expression are extinguished, and CD19, CD20, and CD21, as well as IgM are expressed on the cells' surface. Mature B cells express surface IgM and/or IgD, in addition to CD19 and CD20. Plasma cells, the end result of B-cell differentiation, produce cytoplasmic as well as secreted immunoglobulin, but do not express surface immunoglobulin. They lack CD19 and CD20 expression.

Similarly, as T cells mature they progress through an orderly cascade of genetic and cell-surface events. CD34-positive progenitors that are destined for a T-lymphoid fate migrate from the marrow to the thymus and express TdT as well as CD7. Next, the cells express the CD2 molecule, which, among other things, mediates the binding of T cells to sheep erythrocytes. The T-cell receptor genes are then rearranged and subsequently expressed on the surface of the thymocyte in association with the CD3 molecule. Distinct populations of mature thymocytes emerge: those that express CD4 and function as cytokine-secreting 'helper' cells and those that express CD8 and function as cytotoxic 'killer' cells. Rare 'double-positives' (CD4+CD8+) and 'double-negatives' (CD4–CD8–) also exist. The CD4 molecule mediates the binding of T cells to MHC class II molecules, whereas CD8 binds MHC class I proteins.

The third descendant of the lymphoid stem cell, the NK cell, is characterized by its expression of CD7, CD2, CD16, and CD56, in addition to other surface proteins. NK cells are distinguished from T cells by the fact they do not express CD3 (and therefore the T-cell receptor).

Lymphoproliferative disorders

A variety of conditions that span the spectrum of benign, reactive processes to frank malignant transformation result in the expansion of lymphocyte populations. Lymphoproliferative diseases are typically manifested by lymphocytosis and/or lymphadenopathy. Distinguishing these processes clinically and pathologically is not always easy. The lymphoproliferative disorders are a loosely defined group of malignant and non-malignant entities characterized by the autonomous, poorly controlled proliferation of lymphoid cells. Malignant tumours are clonal in nature; they result from the uncontrolled proliferation of a single transformed cell. In contrast, non-malignant lymphoproliferation contains polyclonal lymphocyte populations. Lymphoproliferative disorders may result from chronic antigenic stimulation, certain viral infections, or from an imbalance among interacting lymphocyte populations, as may occur in congenital or acquired immunodeficiency syndromes. In addition, lymphocytes are prone to the acquisition of chromosomal translocations, particularly involving the immunoglobulin and T-cell receptor genes, and such changes may contribute to malignant transformation (see Table 1).

Lymphocytosis

Normal peripheral blood usually contains approximately 1000 to 5000 lymphocytes/μl, accounting for approximately 40 per cent of the circulating leucocytes. Infants and young children typically have higher absolute lymphocyte values. Increased numbers of circulating lymphocytes (lymphocytosis) and/or the appearance of abnormal (or atypical) lymphocytes in the blood are usually caused by either viral infection or lymphoid malignancy. The appearance of the circulating lymphocytes on a peripheral blood smear may provide clues to the pathogenesis of the elevated lymphocyte count. For example, infectious mononucleosis results from primary infection with the Epstein–Barr virus (**EBV**), and gives rise to large numbers of 'atypical' lymphocytes with abundant cytoplasm in the peripheral blood. Chronic lymphocytic leukaemia (**CLL**) leads to an increase in circulating normal-appearing 'mature' lymphocytes. CLL is also frequently associated with the appearance of 'smudge' cells in the peripheral smear, a preparation artefact caused by the destruction of the fragile CLL cells. Follicular lymphoma may be associated with the circulation of characteristic cells with a cleaved nucleus.

Lymphadenopathy

Enlargement of one or more lymph nodes (lymphadenopathy) is an extremely common clinical finding. With the exception of inguinal nodes, normal lymph nodes are non-palpable. Nodes that are palpable and/or exceed approximately 1 × 1 cm on imaging studies are considered pathological. Lymph node enlargement often results from the body's normal and adaptive response to an immunological challenge; however, it may signify a pathological inflammatory or malignant disease. The causes of lymphadenopathy fall into three main categories: infectious, inflammatory (reactive), and neoplastic (Table 1) Younger patients, especially children, are more likely to develop adenopathy as a result of infection, while the likelihood of haematological or metastatic malignancy increases with age.

Approach to the patient with lymphadenopathy

The history of the patient with lymphadenopathy should take into account the age and general health of the patient, the duration of the adenopathy, the coexistence of fever, weight loss, night sweats, pruritis, and cough, and any recent infections, medications, travel, and animal exposures. The physical examination should make note of the location (generalized versus regional), the texture (hard versus rubbery), and the mobility of the nodes (fixed versus mobile), and the presence or absence of signs of inflammation (warmth, tenderness, erythema). The skin and oropharynx should be examined and the size of the liver and spleen should be assessed. Additional screening studies may include a complete blood count, and measurement of the erythrocyte sedimentation rate (**ESR**). Serological studies for certain viral pathogens and for rheumatological diseases can be diagnostically helpful. Radiographs of the chest should be obtained if mediastinal adenopathy is suspected. Ultrasound may demonstrate central suppuration, which is characteristic of acute lymphadenitis. A computed tomography (**CT**) scan is required to diagnose intra-abdominal adenopathy.

Lymph node biopsy

In the absence of an obvious infection or underlying illness associated with lymphadenopathy, or when malignancy is suspected, a lymph node biopsy is recommended. Depending on the clinician's level of concern, a trial of observation with or without empirical antibiotics (usually an antistaphylococcal agent) is sometimes chosen. Empirical treatment with steroids should be avoided because it may undermine the diagnosis and proper therapy of lymphoid malignancy. If there is no resolution within 2 weeks, then a lymph node biopsy should be strongly considered. The largest accessible node is most often selected for biopsy. A fine-needle aspiration of lymph nodes is adequate for diagnosis in a restricted set of clinical circumstances: for example, diagnosis of recurrent disease or metastatic carcinoma or melanoma. Culture of a lymph node aspirate may yield a microbiological diagnosis in infective lymphadenitis. Most pathologists prefer an excisional biopsy, when possible, because nodal architecture is preserved. A portion of the sample should be reserved fresh (that is, not fixed in formalin) for flow cytometry and cytogenetic studies, if indicated.

Histopathology

Histological examination of lymph nodes is the mainstay of diagnostic studies, however non-diagnostic or non-specific inflammatory findings are frequently encountered. Reactive lymph nodes demonstrate characteristic, but by no means specific, histological patterns which involve the three functional domains of the lymph node: the follicles, the paracortex, and the medullary sinuses.

An increase in the size and/or number of lymphoid follicles (which contain proliferating B cells,) is termed 'follicular hyperplasia'. The specific cause is rarely identified. This pattern of lymph node reactivity is characteristic of rheumatological conditions and of HIV infection and Castleman's disease. Castleman's disease is a rare and poorly understood non-neoplastic cause of lymphadenopathy that occurs in localized and multicentric forms. The multicentric form is a systemic illness without defined therapy that is associated with infection with human herpesvirus-8 (HHV-8, also known as Kaposi's sarcoma herpesvirus).

Paracortical expansion accompanies T-cell proliferation and is characteristic of certain viral causes of lymphadenopathy, such as EBV infection. Paracortical expansion with granuloma formation is typical of mycobacterial infections and sarcoidosis. In Kikuchi's disease and Kawasaki's disease (mucocutaneous lymph node syndrome), paracortical necrosis is seen in involved lymph nodes.

Sinus hyperplasia is caused by an increased number of histiocytes in the medullary sinuses. This pattern of lymph node reactivity is seen in the histiocytic syndromes and in the storage diseases. A rare condition known as sinus histiocytosis with massive lymphadenopathy or Rosai–Dorfman disease is characterized by an extreme polyclonal proliferation of macrophages. This entity often involves the cervical lymph nodes, but may occur in virtually any nodal or extranodal site and is usually, but not always, self-limited.

Involvement by a malignant lymphoma leads to effacement of the lymph node structure to a greater or lesser degree. Histology correlates with clinical behaviour and will be described in subsequent sections focused on the classification of lymphoma.

Immunohistochemistry and flow cytometry

Histology alone may be inadequate to distinguish the malignant from the non-malignant lymphoproliferative disorders. Supplemental information from flow cytometry, cytogenetics, and immunoglobulin/TCR gene rearrangement studies demonstrate the clonal nature of malignant disease and provide data with prognostic and therapeutic significance. Immunohistochemistry is used to characterize the pattern of surface marker expression in fixed or frozen tissue samples. Flow cytometry is performed on cells in suspension, such as peripheral blood or bone marrow, or on cell suspensions prepared from a lymph node or other solid tumour. For flow cytometry, solid specimens should not be fixed or frozen but kept refrigerated until processing. Both techniques detect the binding of monoclonal antibodies of known specificity to the clinical sample. Using a panel of antibodies, these studies demonstrate the types of cells present in the sample. Non-haemopoietic metastatic tumours can be identified. The lineage of lymphoid malignancies can be revealed, for example B cell versus T cell versus NK cell. In the case of B-cell lymphoproliferation, the relative expression of kappa and lambda light chains can be measured. As described above, B cells express either the kappa or the lambda light chain, but not both. Predominant expression of either the kappa or lambda light chain by a population of B cells, a phenomenon known as light-chain restriction, suggests a clonal process. Using flow cytometry, lymphoid neoplasms can be placed within the hierarchy of normal lymphocyte ontogeny, and clinical behaviour, such as response to cytotoxic therapy, can often be predicted. These studies may be used to demonstrate the presence of a surface antigen to which monoclonal antibody-based therapy has been developed (for example, CD20 and rituxumab). Sometimes, malignant cells demonstrate lineage infidelity, with expression of a pattern of surface markers that does not correspond to a normal cellular counterpart. This may fortuitously provide an immunophenotypical fingerprint to detect small amounts of disease, early relapse, or minimal residual disease after therapy.

Genetic studies

The high proliferative rate of lymphocytes and the genetic events that occur within them, sets the stage for the development of chromosomal translocations which are aetiologically linked to malignant transformation. Increasingly, haemopoietic cancers are being defined genetically by the presence of specific, non-random chromosomal translocations. The detection and study of these translocations has increased diagnostic precision, has provided insights into the molecular mechanisms of oncogenesis, and has revealed molecular targets for rational therapeutic design. Chromosomal translocations can be demonstrated using classical cytogenetic techniques. When cytogenetics is technically unsuccessful, specific translocations may also be detected using the polymerase chain reaction (**PCR**) and fluorescence *in situ* hybridization (**FISH**). In addition, these methods may be used to identify the presence of specific viral sequences, such as those encoded by EBV and HHV-8. These highly sensitive and specific techniques are increasingly being applied to the detection of minimal residual disease.

As described above, the hallmark of lymphocyte differentiation is the somatic rearrangement of the antigen-receptor genes, immunoglobulin in the case of B cells and

the TCR in the case of T cells. Each lymphocyte clone has a unique arrangement of the components of the antigen-receptor genes, while cells of non-lymphocyte lineage preserve the germline structure of these genes. Lymphoproliferative malignancies are composed of clonal proliferations arising from a single cell with a rearranged antigen-receptor locus. The pattern of gene rearrangement helps to characterize the lineage and stage of differentiation of the tumour. For example, pre-B-cell acute lymphoblastic leukaemia cells usually contain rearranged heavy-chain genes with germline light-chain genes, whereas B-CLL cells usually have a rearrangement of both heavy- and light-chain genes and express surface immunoglobulin. Furthermore, since clonal populations of lym-phocytes all contain the same antigen-receptor rearrangement, these cells possess a 'molecular signature' that is unique to the malignant clone.

Consequently, antigen-receptor rearrangements have become the target of DNA diagnostic techniques for diagnosing and following lymphoproliferative malignancies. Antigen-receptor rearrangements can be detected by several methods including Southern blot and PCR-based techniques. The genetic detection of clonal B-cell populations was first achieved using Southern blotting. For Southern analysis, DNA is digested with restriction endonucleases, blotted on nitrocellulose membranes, and hybridized with probes specific for the immunoglobulin loci. Somatic rearrangement of the immunoglobulin loci, with concomitant excision of the intervening DNA, results in loss of the normal restriction endonuclease sites that lie within the immunoglobulin locus. Clonal populations of B cells then give rise to restriction fragments of altered size when probed with immunoglobulin gene sequences. This technique is still the 'gold standard' for determining B-lymphoid clonality of confusing lymphoproliferations. It has also been used for the detection of minimal residual disease (**MRD**). However, PCR-based techniques have largely supplanted Southern analysis for the detection of MRD. For these studies, PCR is performed using oligonucleotide primers based on conserved sequences within the immunoglobulin heavy-chain locus; approximately 70 to 90 per cent of rearrangements can be detected by this approach. To detect MRD with maximal sensitivity, such rearrangements are then subjected to sequence analysis to determine the antigen-specific sequences unique to the tumour rearrangement. An allele-specific oligonucleotide can then be synthesized and used in a PCR analysis that can detect residual clonal populations representing as few as $1:10^{5}$ cells.

22.4.3 Lymphoma

James O. Armitage

Introduction

Lymphomas represent malignancies of lymphoid cells and almost always present as solid tumours, ranging from among the least to among the most aggressive of the human malignancies. They have in common a frequent response to available therapies, and a significant subset of patients who develop lymphomas can be cured.

Lymphomas are usually divided into Hodgkin's disease and non-Hodgkin's lymphomas. The non-Hodgkin's lymphomas are much more frequent, with almost 60 000 new cases being diagnosed in the United States annually and approximately 8000 new cases diagnosed each year in the United Kingdom. Non-Hodgkin's lymphomas are increasing in incidence at a higher rate than almost all other malignancies; for instance, in the United States the incidence has increased at a rate of approximately 4 per cent per year since 1950. In contrast, Hodgkin's lymphomas occur approximately 7500 times per year in the United States and 1200 times per year in the United Kingdom. The incidence of Hodgkin's disease appears to be stable.

Presenting manifestation

Patients with lymphoma most commonly present with lymphadenopathy. However, a variety of presentations are possible. These include systemic symptoms such as fevers, night sweats, weight loss, and pruritus, which are believed to be the result of the release of cytokines by normal or malignant cells. Patients can present with symptoms secondary to a mediastinal or retroperitoneal mass such as superior vena cava obstruction, pleural effusion, pericardial tamponade, abdominal or back pain, intestinal obstruction or perforation, gastrointestinal bleeding, or renal failure from urethral obstruction. Central nervous system presentations include primary brain tumours and signs of meningeal involvement and spinal cord compression. Patients might present with cytopenia secondary to either bone marrow involvement or autoimmune destruction of the formed elements of the blood. Symptoms secondary to the overproduction of a monoclonal immunoglobulin or hypogammaglobulinaemia can be seen. In short, the possible presentations of lymphomas are so varied that the diagnosis should be considered in almost all patients and not just restricted to those presenting with lymphadenopathy or splenomegaly.

Establishing a diagnosis

The diagnosis of lymphoma should always be based on evaluation by an expert haematopathologist of, preferably, an adequate lymph node biopsy, or an extranodal tumour mass if lymph nodes are unavailable. Needle aspirates or small biopsies should be avoided as the basis for diagnosing lymphoma whenever possible. As one of the major challenges that pathologists face is the diagnosis of lymphoma, it is important not to handicap the haematopathologist by providing inadequate material. The differential diagnosis that the pathologist considers when diagnosing a lymphoma includes benign proliferations of lymphoid tissue, malignancies of myeloid cells, non-haemopoietic malignancies, viral infections, and unusual disorders such as Castleman's disease and giant lymph node hyperplasia. Having tissue available for immunological studies and/or genetic studies will frequently help to confirm the diagnosis.

Patient evaluation

Once the diagnosis of a type of lymphoma has been established, a series of studies should be carried out to determine the extent of disease. The anatomical spread of disease is usually expressed as an Ann Arbor Stage (Table 1). This staging system was originally developed for Hodgkin's disease and divides patients into those with disease confined to one lymphatic site, multiple lymphatic sites on one side of the diaphragm, lymphatic involvement on both sides of the diaphragm, and those with bone marrow involvement, liver involvement, or other extensive extranodal disease. The Ann Arbor Stage also includes a suffix A or B indicating the absence (A) or presence (B) of unexplained fevers above 38 °C, weight loss of more than 10 per cent of the body weight in the preceding 6 months, or drenching night sweats. Additional factors can also have an impact on a patient's response to therapy and survival. For non-Hodgkin's lymphomas, these factors are incorporated into the International Prognostic Index. In this system, the Ann Arbor Stage represents one factor with an adverse risk associated with stage III or IV. Other adverse risk factors include an elevated serum lactate dehydrogenase (**LDH**) level, age of 60 years or greater, multiple sites of extranodal disease, and a reduced performance status. The International Prognostic Index Score is determined by adding the adverse risk factors.

The laboratory and radiological evaluation of patients with lymphoma typically involves a standardized series of tests, such as a complete blood count, erythrocyte sedimentation rate determination, chemistry studies reflecting major organ function, computed tomography scans of the chest, abdomen, and pelvis, and a bone marrow biopsy (Table 2). In patients with non-Hodgkin's lymphoma, serum LDH, serum b_2-macroglobulin, and serum protein electrophoresis are often useful adjuncts. A gallium scan performed before therapy can identify sites of involvement in the majority of patients with Hodgkin's disease and those with aggressive non-Hodgkin's lymphoma. In addition to potentially altering the diagnostic stage, this technique allows a more accurate restaging of disease at the completion of therapy than can be obtained simply with computed tomography (**CT**) scans. However, CT scans only show anatomical findings, and some patients with lymphomas in the mediastinum and retroperitoneum do not have complete regression of their initial masses because of a sclerotic reaction to the tumour. Moreover, in patients who have actually

achieved a complete remission, the gallium scan (that is to say, a functional as opposed to an anatomical study) will typically have reverted to normal. Other studies can be useful in particular situations. Most patients will be given a chest radiograph. This offers an easy way to follow mediastinal or pulmonary involvement. Magnetic resonance imaging (**MRI**) studies are particularly useful in evaluating suspected bone or central nervous system sites of involvement by a lymphoma. Technetium scans of bone or the liver and spleen are occasionally valuable in detecting occult sites of involvement by a lymphoma. In some patients, abdominal ultrasonography will provide a more economical way to follow intra-abdominal disease.

Bilateral, lower limb lymphangiography was formerly used to evaluate pubic and retroperitoneal node involvement in most patients with lymphoma. However, this study is difficult to perform and is used only occasionally today. Patients with Hodgkin's disease and many patients with non-Hodgkin's lymphoma once routinely underwent staging laparotomy before the initiation of therapy to search for occult intra-abdominal disease. This approach is rarely used today because of the quality of available non-invasive staging procedures and the effectiveness of therapy. The one remaining place for staging laparotomy is for a patient with supradiaphragmatic disease who wants to be treated with limited radiotherapy alone. A laparotomy provides the surest evidence of the absence of intra-abdominal disease in this patient.

The studies necessary to evaluate a new patient with lymphoma and provide prognostic information and a therapy plan are presented in Table 2.

Pathobiology of lymphoma

Introduction

Increased understanding of the biology of the immune system has allowed the various lymphomas to be subclassified, and provided new prognostic information and new potential targets for therapy. Since lymphomas are malignancies of lymphocytes, the surface proteins involved in cell recognition and intercellular signalling can be expected to be important. Although the genetics of lymphomas are complicated, they too are beginning to be unravelled. Information gleaned from all these studies is likely to further change both the classification and therapy of the lymphomas.

Immunology

The recognition of new surface antigens has improved the ability to recognize specific subtypes of lymphoma. For example, discovery of the Ki-1 (CD30) antigen by investigators in Germany provided a marker for the Reed–Sternberg cells in classical Hodgkin's disease. However, it was soon discovered that this antigen was found on the surface of cancers that were previously felt to be undifferentiated carcinomas and malignant histiocytosis. This observation allowed the description of anaplastic large T/null-cell lymphoma as a diagnostic entity and, more importantly, allowed some patients with lymphoma to receive appropriate therapy.

The recognition of specific antigens by standardized antibodies has improved the accuracy of diagnosis. Some of the more commonly recognized antigens are presented in Table 3. A characteristic pattern of occurrence can be a key factor in making an accurate diagnosis. Some types of lymphoma, such as follicular lymphoma and nodular sclerosing Hodgkin's disease, can be diagnosed accurately without immunological studies. Others such as all T-cell lymphomas, diffuse large B-cell lymphoma, and mantle-cell lymphoma can only be accurately diagnosed with immune markers.

Genetics

A theme common to malignant disorders is the abnormal expression of specific genes. The search for these genes was facilitated by the frequent occurrence of chromosomal abnormalities detectable by cytogenetic studies. These abnormalities include chromosomal deletions or deletions of parts of a chromosome, chromosomal duplications, and translocation of genetic material from one chromosome to another. Chromosomal translocations, through studying the sites of chromosome breakage, led to the discovery of a number of genes that appear to be important in lymphomagenesis or in determining the character of a particular lymphoma. The best documented chromosomal translocations associated with lymphomas along with the involved oncogenes are presented in Table 4.

Genetic abnormalities determine the nature of the lymphoma by leading to the overexpression, underexpression, or abnormal expression of specific genes. The genes involved, termed 'oncogenes', are typically those that regulate the cell cycle or differentiation. Since the work of genes is done by the proteins for which they code, the underexpression, overexpression, or abnormal expression of specific proteins is an increasing source for study. In some cases, protein expression might be abnormal despite no obvious translocation. For example, diffuse large B-cell lymphoma displays the t(14;18) in approximately 30 per cent of patients. This translocation involves the *BCL-2* gene on chromosome 18, whose protein product is involved in suppressing apoptosis (that is, the mechanism of cell death usually triggered by chemotherapeutic agents). Tumours can overexpress the BCL-2 protein with or without the t(14;18). Overexpression of BCL-2 protein might be expected to lead to the increased survival of lymphoma cells when they are exposed to therapeutic agents. In patients with diffuse large-cell lymphoma, an increased relapse rate has been associated with overexpression of the BCL-2 protein, rather than with the t(14;18).

Specific chromosomal translocations are highly associated with certain subtypes of lymphoma and thus are useful in diagnosis. These include the t(2;5) and anaplastic large T/null-cell lymphoma, the t(14;18) in follicular lymphoma, the t(8;14), t(2;8), and t(8;22) in Burkitt's lymphoma, and the t(11;14) in mantle-cell lymphoma. Cytogenetic studies in most patients with non-Hodgkin's lymphoma display a large number of chromosomal abnormalities. However, only a few have been shown to be of diagnostic or prognostic significance. No such abnormalities have been consistently identified in patient's with Hodgkin's disease.

Future genetic studies in lymphomas are likely to focus on specific gene expression. The new 'lympho chip' technology will allow the several thousand genes typically expressed in lymphoid cells to be studied simultaneously. Patterns of gene expression may well provide new methods of classifying lymphomas, provide new prognostic information, and direct therapy or provide new targets for therapy.

The general principles of therapy of lymphoma

Those treatments effective in the management of patients with cancer include surgery, radiotherapy, cytotoxic chemotherapy, and a variety of new approaches developed through increasing understanding of the biology of the immune system. The latter include cytokines, antibodies, and attempts to direct an immune reaction against cancer. Because few patients with lymphoma have truly localized disease, surgery has not been a major treatment modality. Radiotherapy, since its utilization in medicine in the first part of the twentieth century, has been a major treatment modality for patients with lymphoma. Radiotherapy is limited in its application by toxicity. Its curative potential depends upon being able to achieve a tumoricidal dose (typically 3000–4000 cGy) without irreversibly injuring normal organs. Thus, the site of involvement by a lymphoma, as well as the number of sites involved, can limit the effectiveness of this treatment, since toxicity increases with the volume of tissue radiated. If a lymphoma is truly localized, radiotherapy is often a curative. Two approaches have been utilized to make radiotherapy a 'systemic' treatment. One involves radiation of the total body. When this is part of a bone marrow transplant regimen, a total dose of 1000–1500 cGy can be administered. More recently, it has been demonstrated that it is possible to give higher doses of radiotherapy to multiple areas by attaching radioactive molecules to antibodies that home to sites of involvement by lymphoma.

Cytotoxic chemotherapeutic agents were first discovered in the 1940s when mechlorethamine (that is, the nitrogen mustard gas used in warfare) and, subsequently, methotrexate were found to cause regressions in immune system malignancies. A wide variety of agents have since been shown to be able to cause regressions in a significant proportion of patients with lymphomas (Table 5). Unfortunately, early studies showed that regressions induced by single agents were almost invariably followed by regrowth of the tumour and eventual death of the patient. In an attempt to circumvent this, combinations of chemotherapeutic agents were first utilized in the 1960s and early 1970s. The drugs were combined by attempting to choose agents with different mechanisms of action and non-overlapping toxicities to allow the administration of doses that were near to the maximum tolerated dose with an individual agent. In both childhood acute leukaemia and Hodgkin's disease this approach was validated by the cure of a significant number of patients. Today, several combination-chemotherapy regimens with acceptable toxicity have been shown to be effective and are widely used worldwide (Table 6). All regimens are not equally good for treating all types of lymphoma.

Increasing knowledge of the immune system has further led to the recognition that a number of biologically active molecules can cause regression of lymphomas and, in some cases, impact on survival. The first such agent to be widely used was interferon-alpha, which has some activity in both non-Hodgkin's lymphoma and Hodgkin's disease. When administered at an adequate dose (at least 36 units per month), it has been shown to prolong survival in patients with poor-prognosis follicular lymphoma who received an anthracycline-containing chemotherapy regimen as their initial treatment. The ability to produce monoclonal antibodies has provided new therapeutic molecules. In B-cell non-Hodgkin's lymphomas, antibodies directed against the CD20 molecule have been incorporated into clinical practice. Rituximab has been shown to be active in a variety of B-cell lymphomas, and the new radiolabelled antibodies such as tositumomab will soon become available. An

antibody directed against CD25 has been introduced into therapy for patients with cutaneous T-cell lymphoma.

Very high doses of cytotoxic chemotherapeutic agents with or without radiotherapy and biologically active molecules have been utilized in the treatment of patients with lymphomas as part of the bone marrow transplantation procedure. This involves the administration of very high doses of antilymphoma therapy in an attempt to overcome presumed treatment resistance. Patients are rescued from the toxicity of treatment by the reinfusion of haemopoietic stem cells. The patient's own haemopoietic stem cells (an autologous transplant) or those from another individual with identical HLA genes (an allogeneic transplant) can be utilized. Cells for this procedure can be obtained from either bone marrow or peripheral blood. Autologous transplantation has been widely used for patients with lymphoma and shown to be able to cure patients with relapsed Hodgkin's disease and aggressive non-Hodgkin's lymphoma. In aggressive non-Hodgkin's lymphomas, a probable increased cure rate has been demonstrated by utilizing adjuvant transplantation following initially effective standard chemotherapy in patients with a poor prognosis. Transplantation is being widely utilized in patients with follicular lymphoma, but the curability of autologous transplantation in this setting remains a point of controversy, and allogeneic transplantation, while apparently curative, has a high mortality rate.

Various new treatments are being studied for patients with lymphoma. These include attempts to stimulate the patient's endogenous immune system to develop antibodies against lymphomas; such 'tumour vaccines' are now in clinical trials. Another approach has been called 'antisense therapy', which involves the use of antisense oligonucleotides aimed at interrupting the transcription and expression of key genes.

A number of factors need to be taken into account when formulating a treatment recommendation for a patient with lymphoma (Table 7). These include the patient's age, general health, extent of disease, likelihood of cure, coexisting illnesses, long-term goals, and concerns about treatment toxicity. This decision should be made in conjunction with the patient, and requires good judgement in addition to technical knowledge. The aggressiveness of the treatment that is finally chosen will often depend upon the physician's interpretation of the chances for cure. It is obvious that more toxicity would be acceptable if the goal was cure rather than palliation. For this reason, patients with definitely curable lymphomas, such as diffuse large B-cell lymphoma and Burkitt's lymphoma, are almost always treated promptly with intensive regimens. In contrast, the best treatment for patients with follicular lymphoma remains a point for intense debate. Since the curability of this disease is in question, many physicians would favour no initial therapy in an asymptomatic patient. However, as discussed below, this is not a simple decision.

For most patients, the goal of therapy is to achieve a complete remission. This implies the disappearance of all symptoms and objective evidence of lymphoma. In practice, a complete remission is documented by repeating all abnormal staging studies after several cycles of therapy or at the completion of the planned therapy. Sometimes, persisting masses visualized on CT scans represent residual fibrosis rather than persisting tumour. In certain patients, a previously abnormal gallium scan reverting to normal would resolve this dilemma, but, on rare occasions, a biopsy might be required. Documentation of complete remission is important. Patients who achieve a complete remission have a chance for cure; those who do not achieve a complete remission with initial therapy will often go directly to second-line treatments.

Patients who fail to be cured with initial therapy, either because they do not achieve an initial remission or they relapse from remission, are candidates for what has been termed 'salvage therapy.' These second-line regimens can regularly cause tumour regression in most patients with lymphoma and can occasionally produce long-term, disease-free survival. However, for most patients, the only curative approach in this setting is bone marrow transplantation. The toxicity of bone marrow transplantation limits its use to patients under certain ages (under 70 years of age for autologous transplantation and under 55 years for allogeneic transplantation), who have a good performance status, without serious compromise of major organ function, and to patients who do not have bulky/chemotherapy-refractory disease.

Hodgkin's disease

In 1832, Thomas Hodgkin of Guy's Hospital, London, reported seven patients who died from a disorder involving lymph node and spleen enlargement. Then, early in the twentieth century, Sternberg and Reed independently described the characteristic giant cells that now bear their name. This made it possible for pathologists to separate the disorder we now know as Hodgkin's disease from other lymphomas.

Incidence and epidemiology

Unlike non-Hodgkin's lymphomas, the incidence of Hodgkin's disease appears to be stable with approximately three new cases per 100 000 per year in western countries. As demonstrated in Fig. 1, this illness displays a peculiar bimodal distribution of occurrence with peaks in young adulthood and older age. This dual peak has led some to propose that Hodgkin's disease actually represents two illnesses, with the earlier peak being related to an infectious aetiology and the latter representing a true malignancy. However, there is little evidence to support this distinction.

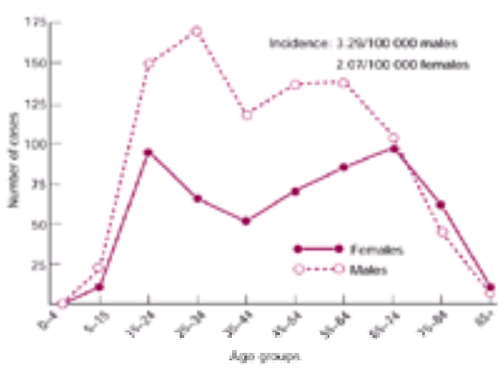

Fig. 1 Age distribution of Hodgkin's disease expressed as new cases registered in England and Wales in 1973.

A strong association has been demonstrated between the occurrence of Hodgkin's disease and infection by the Epstein–Barr virus (**EBV**). Monoclonal or oligoclonal proliferation of EBV-infected cells is found in 20 to 40 per cent of patients with Hodgkin's disease. Patients infected by the human immunodeficiency virus (**HIV**) are at an increased risk for Hodgkin's disease in addition to non-Hodgkin's lymphomas.

The subtypes of Hodgkin's disease vary geographically and by age group. Patients in western countries who develop Hodgkin's disease in young adulthood usually have the nodular sclerosis subtype. Patients from Third-World countries, elderly patients, and those infected with HIV usually have mixed-cellularity or lymphocyte-depletion Hodgkin's disease.

Hodgkin's disease is approximately 100 times more likely in an identical twin of an infected patient. Numerous instances of case-clustering have been described. While these might be taken as evidence of a genetic or infectious aetiology, the cause of Hodgkin's disease remains unknown.

Pathology

The diagnosis of Hodgkin's disease requires the identification of Reed–Sternberg cells in a characteristic cellular background; however, the cell of origin for the Reed–Sternberg cell remains unknown. The subtypes of Hodgkin's disease are presented in Table 8. Nodular sclerosing Hodgkin's disease is characterized by bands of fibrosis that are often visible to the naked eye when a slide is held to the light. Mixed-cellularity Hodgkin's disease typically displays a larger number of Reed–Sternberg cells in a mixed-cellular background including lymphocytes, macrophages, and eosinophils. Lymphocyte-depletion Hodgkin's disease can present with a very large number of Reed–Sternberg cells and atypical mononuclear cells, or a background of diffuse fibrosis with occasional Reed–Sternberg cells. Lymphocyte-predominance Hodgkin's disease is characterized by large numbers of small lymphocytes and histiocytes with occasional Reed–Sternberg cells. The growth pattern can be nodular or diffuse.

It is now clear that patients with nodular lymphocyte-predominance Hodgkin's disease have a different illness that is, in many ways, more like a B-cell non-Hodgkin's lymphoma. The Reed–Sternberg cells in nodular lymphocyte-predominance Hodgkin's disease express the leucocyte common antigen and other B-cell markers including CD20. Typical Reed–Sternberg cells do not express the leucocyte common antigen, but are CD15- and CD30-positive. Staining for CD15 and CD30 can

resolve difficult diagnostic problems in some cases.

Clinical features and evaluation

Patients with classical Hodgkin's disease usually present with palpable non-tender lymphadenopathy. In most patients, lymph nodes are discovered in the cervical, supraclavicular, and axillary regions. More than half the patients have mediastinal lymphadenopathy at diagnosis, and symptoms from a large mediastinal mass are often the initial presentation. Subdiaphragmatic presentation of Hodgkin's disease is unusual and more common in older males. Approximately one-third of patients with classical Hodgkin's disease present with fevers, night sweats, and/or weight loss.

Hodgkin's disease can present as a fever of unknown origin. Presentation as a 'fever of unknown origin' is more common in older patients who have mixed-cellularity or lymphocyte-depletion Hodgkin's disease and who present with disease in abdominal nodes. Fevers associated with Hodgkin's disease occasionally persist for days to weeks, followed by afebrile intervals, and then reoccurrence of the fever. This pattern is known as Pel–Ebstein fever. Unusual presentations of Hodgkin's disease include severe and unexplained pyloritis, paraneoplastic cerebellar degeneration, nephrotic syndrome, immune haemolytic anaemia and thrombocytopenia, hyper-calcaemia, and pain in lymph nodes on alcohol ingestion.

The diagnosis of Hodgkin's disease is based on a review of an adequate biopsy by an expert haematopathologist. Subsequent evaluation should include a careful history and examination, complete blood count, erythrocyte sedimentation rate determination, serum chemistry studies including serum lactate dehydrogenase, chest radiograph, computer demography of the chest, abdomen, and pelvis, and bone marrow biopsy. Gallium scans can be performed to document radioisotope uptake by the tumour, which can then be repeated at the completion of therapy to document remission. Bipedal lymphangiograms can be useful if radiologists expert in carrying out the procedure are available. Staging laparotomies are now rarely indicated.

Nodular lymphocyte-predominance Hodgkin's disease, as noted above, is a different clinical entity from classical Hodgkin's disease. These patients represent less than 5 per cent of all patients found to have Hodgkin's disease. The evaluation of such patients is carried out in a similar way to that for classical Hodgkin's disease. However, nodular lymphocyte-predominance Hodgkin's disease tends to follow a chronic, relapsing course and sometimes transforms to diffuse large B-cell lymphoma.

Prognostic factors

The major factors determining treatment outcome for patients with Hodgkin's disease include the Ann Arbor stage, the presence or absence of systemic symptoms, age, and gender. Patients with asymptomatic, localized disease who are young and female have the best outlook. Histological subtypes do not appear to have major independent prognostic significance. Patients with nodular sclerosing Hodgkin's disease have a better outcome than those with mixed-cellularity or lymphocyte-depleted Hodgkin's disease. However, adverse prognostic factors are more commonly found in patients with the latter histological subtypes. The results of several laboratory studies can predict outcome in patients with Hodgkin's disease. These include anaemia, an elevated erythrocyte sedimentation rate, and a low albumin level. The erythrocyte sedimentation rate is sometimes used to follow the course of patients with Hodgkin's disease since it tends to normalize with successful treatment.

The most important factor in predicting outcome for patients with Hodgkin's disease is their response to therapy. Patients who have a prompt, complete response to chemotherapy and/or radiotherapy have the best outlook and are most likely to be cured. It is important to note that residual masses do not always represent persisting disease. This is particularly true for residual mediastinal and retroperitoneal masses. These sites tend to be associated with a considerable amount of fibrosis that can persist after effective therapy. Normalization of a gallium scan can be used to document remission. Patients who relapse after initial successful treatment for Hodgkin's disease can sometimes be effectively treated with further chemotherapy or radiotherapy. The chances for successful treatment, in part, depend upon the duration of initial remission in addition to other prognostic factors present at relapse. Patients with a longer initial remission are more likely to be successfully retreated.

Primary therapy

Patients with localized Hodgkin's disease (stage I or non-bulky stage II) can be cured with extended-field radiotherapy. Patients with supradiaphragmatic disease are typically treated with a radiotherapy port that is often referred to as a mantle. This involves treatment of the cervical, supraclavicular, axillary, and mediastinal lymph nodes. In the absence of a staging laparotomy before therapy, upper abdominal nodes and spleen are also often treated. A dose of 3500 to 4400 cGY is usually administered in fractions of 175 to 200 cGy daily, 5 days per week for approximately 4 weeks.

Patients with otherwise localized Hodgkin's disease who present with a large mediastinal mass pose special therapeutic problems. A large mediastinal mass is often defined as one whose maximum diameter is greater than one-third of the maximum thoracic diameter. Treatment with radiotherapy alone, or chemotherapy alone, is associated with a high relapse rate. Large mediastinal masses are one definite indication for combined modality therapy.

Patients who present with B-symptoms or stage III or IV disease are best treated initially with a combination-chemotherapy regimen. If complete remission is documented after completing a course of chemotherapy, the majority of patients will be cured. Patients who have large masses often receive adjuvant radiotherapy to the sites of previous bulky disease after completing the chemotherapy regimen. While the original **MOPP** (mechlorethamine, Oncovin (i.e. vincristine), procarbazine, prednisone) regimen was effective in the treatment of Hodgkin's disease, it has now been shown that regimens which include **ABVD** (doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine) are associated with a better outcome (Table 6).

Elderly and pregnant patients pose special therapeutic problems. In Hodgkin's disease, the elderly have a much worse prognosis than younger patients: patients over 60 years of age at the time of diagnosis have a survival rate less than half that of younger patients. Elderly patients with localized disease seem to benefit from radiotherapy in a manner comparable to younger patients. However, older patients tolerate aggressive chemotherapy regimens much less well and, even if the drugs can be administered, have a higher relapse rate.

Hodgkin's disease, since it occurs frequently in young adults, is not rarely diagnosed in pregnant women. It is now clear that Hodgkin's disease can be treated with chemotherapy at any point during pregnancy with a chance of a good treatment outcome and a surviving infant. However, the risks are higher in the first trimester. Most physicians would favour delaying therapy past the first trimester, if possible, and would discuss the possibility of a therapeutic abortion with the patient. If the decision is made to treat a pregnant patient with chemotherapy, it must be remembered that the fetus will be myelosuppressed in a manner similar to the mother. This must be taken into account when planning delivery of the baby. Radiotherapy is generally not used in pregnant patients because of its teratogenic potential.

The optimal treatment for lymphocyte-predominance Hodgkin's disease is unclear. Some clinicians favour no initial therapy in asymptomatic patients. However, potentially curative radiotherapy to localized disease seems wise. The clinician must be alert for transformation to diffuse, large B-cell lymphoma.

Treatment of relapse

Approximately 25 to 35 per cent of patients treated with chemotherapy for stage III or IV Hodgkin's disease will suffer relapse after achieving a remission. A small proportion of patients will fail to enter initial complete remission. Patients who fail to enter complete remission or relapse within 1 year of completing therapy have a poor prognosis with further standard chemotherapy. Autologous bone marrow transplantation can be curative in 25 to 50 per cent of such patients, and is the treatment of choice. Patients who have an initial remission of longer than 1 year pose a more complicated therapeutic problem. These patients are likely to achieve a second remission with a standard chemotherapy regimen. However, long-term follow-up has demonstrated that the majority of these remissions are not durable, and many physicians would recommend autologous transplantation to such patients. The occasional patient with a localized relapse after chemotherapy can sometimes be cured with radiotherapy. Patients who relapse after treatment with initial radiotherapy have an excellent result with standard chemotherapy regimens and a high likelihood of cure.

Treatment complications

The treatment of Hodgkin's disease is associated with both short-term and long-term complications. Prominent short-term complications include hair loss, emesis, fatigue, anaemia, and infection due to chemotherapy-induced neutropenia. Hair loss is usually transient. Emesis can be prevented in almost all patients by 5-hydroxytryptamine antagonists such as ondansetron and granisetron. Anaemia and fatigue do not usually limit the administration of therapy. Chemotherapy-induced

neutropenia is a major problem and neutropenic fever needs to be managed aggressively with intravenous antibiotics after cultures are obtained. Even so, treatment for Hodgkin's disease is administered entirely on an outpatient basis.

Delayed toxicity from the treatment of Hodgkin's disease has become a major problem for young patients who are cured of Hodgkin's disease and have been followed for extended periods. In fact, for patients with good-prognosis Hodgkin's disease, long-term complications might lead to a higher mortality rate than the Hodgkin's disease itself.

Most of the serious complications of radiotherapy appear after long follow-up. In the first few months after treatment, some patients will develop an electric shock sensation down the spine and into the legs on flexion of the neck. This represents Lhermitte's syndrome and needs to be recognized so that further evaluation is not carried out. It is usually transient. In some patients, delayed pulmonary fibrosis or cardiac injuries are associated with thoracic radiotherapy. Modern radiotherapy techniques have minimized the risk of these problems, but accelerated coronary artery disease is a significant problem and leads to a number of treatment-related deaths. The major delayed problem with radiotherapy is the development of secondary cancers. This risk begins to appear beyond 10 years post-therapy, and by 20 years after therapy leads to a significant number of deaths. Patients treated with thoracic radiotherapy for Hodgkin's disease should be strongly encouraged not to smoke to reduce the risk of lung cancer. Young women should have screening mammography instituted 5 to 10 years earlier than for women not irradiated, or by 10 years after completing treatment.

Patients who receive radiotherapy to the neck have a high risk of developing subsequent hypothyroidism. Follow-up in such patients should include periodic quantitation of their thyrotropin levels to anticipate this problem. Some patients treated with either radiotherapy or chemotherapy will develop herpes zoster. This diagnosis does not necessarily signify a relapse of Hodgkin's disease.

Long-term problems associated with chemotherapy include treatment-related leukaemia, infertility, and aseptic necrosis of bone. Infertility is most likely in patients who receive alkylating agent-containing regimens. Most young males who received MOPP become infertile. In women, the risks of infertility are age-related. Women over 30 years of age are much more likely to be permanently infertile than those under 30 years. However, in any patient, resumption of fertility is possible and the patient should be aware of this. Infertility is less of a problem in patients who receive the ABVD regimen. Males very anxious to retain fertility can be offered semen storage and women, in extraordinary cases, can be offered egg storage.

Treatment-related leukaemia is most frequent in patients who receive chemotherapy regimens containing alkylating agents and who are treated on more than one occasion. Young patients treated with only one chemotherapy sequence are unlikely to develop leukaemia. The incidence of leukaemia rises dramatically in patients over 40 years of age, and in those who receive alkylating agents on more than one occasion. Leukaemia is unusual in patients treated with ABVD. The combination of chemotherapy and radiotherapy seems to increase the risk of leukaemia. The leukaemias that occur in this setting usually present with myelodysplasia and typically have genetic abnormalities involving chromosomes 5, 7, and 8. Etoposide can lead to the development of acute leukaemia without a preceding myelodysplasia that involves abnormalities on chromosome 11.

Patients who receive corticosteroid treatment as part of a combination therapy are at risk for aseptic necrosis of the femoral heads. Those who develop hip pain on follow-up should be evaluated for this possibility.

Non-Hodgkin's lymphoma

Incidence

In much of the world, it appears that the incidence of non-Hodgkin's lymphoma is increasing, but the incidence still varies widely between countries. The incidence appears to be approximately 2 cases per 100 000 per year in the Orient, 10 per 100 000 per year in the United Kingdom, and more than 15 per 100 000 per year in the United States. In the United States, the disease increased in frequency by approximately 4 per cent per year between 1950 and the mid-1990s. This increased incidence is seen in patients of all ages but more striking in the elderly. However, recent data suggest that the rate of increase may be slowing.

A recent study showed that the specific types of non-Hodgkin's lymphomas vary in occurrence between countries. For example, follicular lymphoma is more common in North America than in Europe or Asia. T-cell lymphomas have been seen more frequently in Asia, and certain types of T/NK-cell lymphomas (**NK**, natural killer) such as angiocentric nasal lymphomas seem restricted to only a few countries in Asia and Latin America. The explanation for this difference in different geographical settings is unclear.

Aetiology

Various aetiological factors, either proven or suggested to be associated with the development of non-Hodgkin's lymphoma, are listed in Table 9. It is now clear that exposure to certain agriculture chemicals does increase the risk of this disease. A variety of immune deficiencies, such as those associated with immunosuppression following organ transplantation and various inherited immune deficiencies, are also associated with an increased risk of developing non-Hodgkin's lymphoma. Patients with rheumatoid arthritis and systemic lupus erythematosus appear to be at increased risk.

A variety of infectious agents have been shown to be associated with the development of non-Hodgkin's lymphoma. Gastric *Helicobacter pylori* infection is associated with the development of gastric **MALT** (mucosa-associated lymphoid tissue) lymphoma. In the case of MALT lymphomas, eradication of the *Helicobacter pylori* infection by antibiotics can lead to regression of the lymphoma in a significant number of patients. **HTLV**-1 (human T-cell lymphoma/leukaemia virus-1) appears to be the cause of a specific type of non-Hodgkin's lymphoma, seen predominantly in southern Japan and the Caribbean, called adult T-cell lymphoma/leukaemia. The Epstein–Barr virus has been associated with Burkitt's lymphoma in Africa, the development of aggressive B-cell lymphomas in immunosuppressed patients, Hodgkin's disease, and certain aggressive T-cell lymphomas. HHV-8 (human herpesvirus-8) has been closely associated with a rare, diffuse, large B-cell lymphoma called effusion lymphoma. HIV (human immunodeficiency virus) infection can lead to the development of aggressive B-cell lymphoma. It is likely that the future will see more associations between lymphomas and specific infectious agents.

REAL/WHO classification

The classification of non-Hodgkin's lymphomas has changed several times during the twentieth century. The first popular classification proposed by Gall and Mallory divided lymphomas into giant follicular lymphoma, reticulum-cell sarcoma, and lymphosarcoma. Both the lack of adequate clinical correlation and clear definitions of the entities led to further proposals. Henry Rappaport recognized the importance of growth pattern in the prognosis of non-Hodgkin's lymphomas, and put forward his system that divided patients into those with nodular (i.e. follicular) or diffuse lymphomas and those with large- or small-cell lymphomas. However, this system was proposed before the recognition that lymphomas were all malignancies of lymphocytes and before the discovery of the existence of subtypes of lymphocytes. The advent of modern immunology led to new classification systems proposed by Carl Lennert and colleagues in Europe and Lukes and Collins in the United States. The Kiel classification proposed by Lennert and colleagues became the most widely used system in Europe. An attempt to unify the classifications of lymphomas led to the development of the Working Formulation. This is a compromise system taking major elements from the Rappaport classification, Kiel classification, and the Lukes/Collins classification. It became widely used in the United States but less so in Europe.

In the 1990s a group of haematopathologists from Europe, North America, and other parts of the world proposed a new system based on not just morphology and immunophenotyping, but taking into account other genetic and biological information that had become available. In the 1990s, a number of 'new' lymphomas were discovered that did not fit into previous classification systems. These included mantle-cell lymphoma, anaplastic large T/null-cell lymphoma, and MALT lymphomas. The Revised European/American Lymphoma classification (**REAL**) classified lymphomas based on clinical pathological syndromes (in other words, real diseases) rather than simply morphology. This system was tested in a large international study and shown to be more accurate than previous systems and to have high clinical relevance. Leaders in the fields of both haematopathology and clinical haematology/oncology agreed on a modified REAL classification to be endorsed by the World Health Organization and published as the WHO classification (Table 10). This, with modifications, is likely to be the major lymphoma classification for at least the next decade. The incidence of major lymphoma subtypes according to the WHO classification are listed in Table 11. Knowledge of 10 to 12 specific subtypes of non-Hodgkin's lymphoma will allow a clinician to care for almost all patients.

International Prognostic Index

Knowledge of the specific subtype of non-Hodgkin's lymphoma is only one of two pieces of information necessary to plan the intelligent management of patients with

these disorders. The other that must be available involves the delineation of the prognostic characteristics of the individual patient. While it is true that follicular lymphoma has a higher median overall survival than diffuse large B-cell lymphoma, individual patients with follicular lymphoma might have a much worse survival because of adverse prognostic characteristics than an individual patient with diffuse large B-cell lymphoma who has good prognostic characteristics. Codification of these prognostic characteristics into a practical clinical tool was accomplished by a large international study that yielded the International Prognostic Index (**IPI**) (Table 12). The IPI is a summation of a number of specific adverse prognostic factors in an individual patient. The important factors include age greater than 60 years, Ann Arbor Stage III/IV, serum lactate dehydrogenase level greater than normal, reduced performance status, and multiple extranodal sites of involvement by lymphoma. The impact of the IPI score on the survival of patients with follicular lymphoma and diffuse large B-cell lymphoma are presented in Fig. 2. As mentioned above, the treatment plan for a patient with lymphoma must always include knowledge of the specific subtype of lymphoma and the patient's prognostic characteristics.

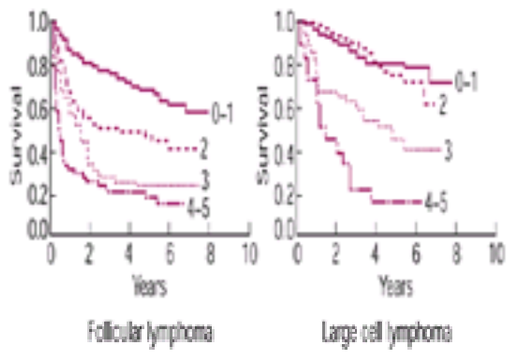

Fig. 2 The survival of 275 patients with follicular lymphoma and 388 patients with diffuse large B-cell lymphoma are shown by International Prognostic Index score.

Lymphoblastic lymphoma of B-cell and T-cell origin

Lymphoblastic lymphoma is a tumour of the precursor cells of T- and B-lymphocytes. It is intimately related to the acute lymphoid leukaemias, with the difference being the method of presentation. Sometimes it is difficult to determine when a patient should be said to have acute lymphoid leukaemia or lymphoblastic lymphoma, since bone marrow involvement is frequent with a lymphomatous presentation and lymphadenopathy and mediastinal mass are common in patients who present with leukaemia.

Most patients with lymphoblastic lymphoma have tumours derived from T-lymphoblasts, but approximately 10 per cent are B-cell in origin. The differential diagnosis of lymphoblastic lymphoma includes a blastic variant of mantle-cell lymphoma, acute myeloid leukaemia, and small round-cell lymphoma in children and young adults.

The median age of patients with lymphoblastic lymphoma is the late twenties and the majority of patients are male. Most patients have widely disseminated disease and an elevated serum LDH level. Approximately 50 per cent of patients will have bone marrow involvement. The IPI predicts outcome in lymphoblastic lymphoma. However, it has been suggested that patients can be divided into two prognostic groups. One group includes patients who have stage IV disease, elevated LDH levels, and bone marrow or central nervous system involvement; adults with these characteristics have a poor outlook. The second group comprises patients without these adverse characteristics, and these patients have a high cure rate.

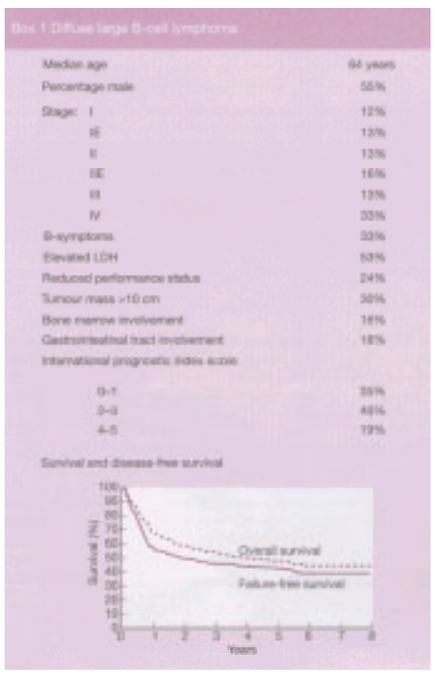
Most patients with lymphoblastic lymphoma will be treated with a leukaemia-like regimen. This includes an intensive induction therapy along with central nervous system prophylaxis, and an ongoing maintenance or consolidation phase of treatment. The majority of children and young adults can be cured with this treatment approach. Patients who present with adverse risk characteristics or who relapse after initial therapy are candidates for bone marrow transplantation.

Diffuse large B-cell lymphoma

Diffuse large B-cell lymphoma is the most common non-Hodgkin's lymphoma, representing approximately one-third of all patients. It most commonly presents *de novo*, but also can develop after histological transformation of a small-cell lymphoma such as follicular, small lymphocytic, and MALT lymphoma. This tumour can arise in lymph nodes or essentially on any extranodal site including the central nervous system. Rare presentations include pleural effusions from involvement of serosal surfaces (effusion lymphoma) and multiple organ system dysfunction secondary to endothelial involvement (intravascular lymphomatosis).

B-cell lymphomas will display the CD20 antigen. Several cytogenetic abnormalities are frequently associated with diffuse large B-cell lymphoma including t(14;18) t(3;14) and t(8;14). The differential diagnosis includes undifferentiated carcinoma, acute myeloid leukaemia, and Hodgkin's disease. Occasional patients with diffuse large B-cell lymphoma have a large number of infiltrating T cells, and so can be confused with a peripheral T-cell lymphoma.

The clinical characteristics of patients with diffuse large B-cell lymphoma are presented in Box 1. The median age at presentation is 64 years and there is a slight male predominance. Approximately 50 per cent of patients will have stage I or II disease and approximately 50 per cent will have a more widely disseminated lymphoma. Approximately two-thirds of patients will have some sign of extranodal involvement. B-symptoms are seen at presentation in approximately one-third of patients and approximately half of the patients have an elevated LDH. Bone marrow involvement is seen in approximately 15 per cent of patients.

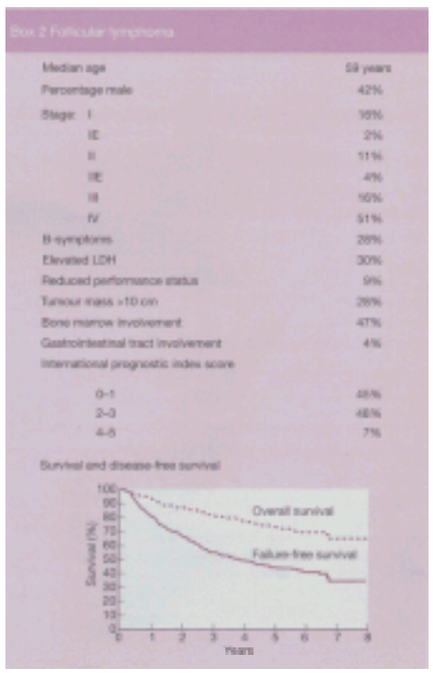


Since the early 1970s it has been known that patients with diffuse large B-cell lymphoma could be cured with combination chemotherapy—even those with disseminated disease. The most popular regimen in use today is **CHOP** (cyclophosphamide, doxorubicin, vincristine (Oncovin), and prednisone), although a number of other regimens including **ACVBP** (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone) are at least as active. A recent randomized trial in older patients found that adding rituximab to CHOP improved both the failure-free and overall survival. When a staging evaluation shows disease confined to one site (that is, stage I) or two nearby sites (minimal stage II) a brief course of chemotherapy followed by radiotherapy gives the highest cure rate. In patients with more disseminated disease, a complete course of one of the combination-chemotherapy regimens mentioned earlier is appropriate. In patients who present with the multiple adverse risk factors listed in the IPI, adjuvant autologous haemopoietic stem-cell transplantation after achieving an initial remission seems to yield a higher cure rate.

Approximately 75 per cent of patients with localized disease can be cured with abbreviated chemotherapy and radiotherapy, and approximately 35 to 40 per cent of patients with more disseminated disease can be cured with combination chemotherapy. Patients who relapse from complete remission can be cured with autologous transplantation. Patients who remain chemotherapy-sensitive after relapse have an approximately 40 per cent cure rate with autologous transplantation, while chemotherapy-resistant patients are cured only approximately 10 per cent of the time.

Follicular lymphoma

The second most common type of non-Hodgkin's lymphoma is follicular lymphoma. The clinical characteristics of patients with this disease are presented in Box 2. The differential diagnosis of follicular lymphoma includes benign follicular hyperplasia and the follicular variant of mantle-cell lymphoma. Patients with follicular lymphoma are subdivided based on the number of large cells in the tumour. In general, a higher proportion of large cells is associated with a higher proliferative rate, more rapid tumour progression, and, perhaps, a better response to anthracycline-containing combination-chemotherapy regimens. The natural history of follicular lymphoma involves a reduction in the degree of follicularity in the tumour over time and an increase in the proportion of large cells. At autopsy, the majority of tumours will be found to have undergone transformation to diffuse large B-cell lymphoma. This is recognized during life in approximately 50 per cent of patients. Histological transformation to diffuse large B-cell lymphoma is associated with a poor prognosis in most patients.



Follicular lymphomas are B-cell lymphomas that display the CD20 antigen. Most patients' tumours will display the translocation t(14;18) and overexpress the *BCL-2* oncogene. Transformation to diffuse large B-cell lymphoma is frequently associated with additional cytogenetic abnormalities and the expression of other oncogenes such as *p53*.

Treatments commonly utilized in the management of patients with follicular lymphoma are presented in Table 13. Asymptomatic patients are often managed with no initial therapy—a strategy that is sometimes called 'watchful waiting'. When followed in this manner, approximately 25 per cent of patients will undergo at least a partial spontaneous regression, although these regressions are not durable. The most popular treatment worldwide for follicular lymphoma is probably single-agent oral chlorambucil. This is particularly true in elderly or infirm patients requiring therapy. Combination chemotherapy with **CVP** (cyclophosphamide, vincristine, and prednisone) or **CHOP** (cyclophosphamide, doxorubicin, vincristine, and prednisone) causes a more rapid response and a higher proportion of complete remissions. Approximately 20 per cent of completely responding patients have remissions that last more than 10 years. Recently, a meta-analysis was conducted of all available trials of interferon incorporated into primary therapy in follicular lymphoma, which demonstrated an improved survival of patients who received adjuvant interferon if they presented with poor risk characteristics and received an anthracycline, such as doxorubicin, as part of their primary therapy. Using **PCR** (polymerase chain reaction) technology, bone marrow specimens from patients with follicular lymphoma frequently test positive for the *BCL-2* gene rearrangement. The goal of some treatment regimens is to eradicate any evidence of *BCL-2* gene rearrangement in the bone marrow, but what the ultimate effect of this will be on survival has not been proven.

Patients with localized follicular lymphoma are often treated with radiotherapy alone. These patients have an excellent outlook with a 10-year survival of 70 to 90 per cent in most series.

Most patients with follicular lymphoma will eventually fail their initial treatment regimen. There is a high response rate to retreatment utilizing single-agent chemotherapeutic agents such as chlorambucil or fludarabine, many combination-chemotherapy regimens, antibodies such as rituximab, and bone marrow transplantation. Both autologous and allogeneic bone marrow transplantation have been demonstrated to produce long-term, disease-free survival in a proportion of patients with follicular lymphoma. Allogeneic transplantation is associated with a higher mortality rate, but there is more convincing evidence that the procedure might be curative.

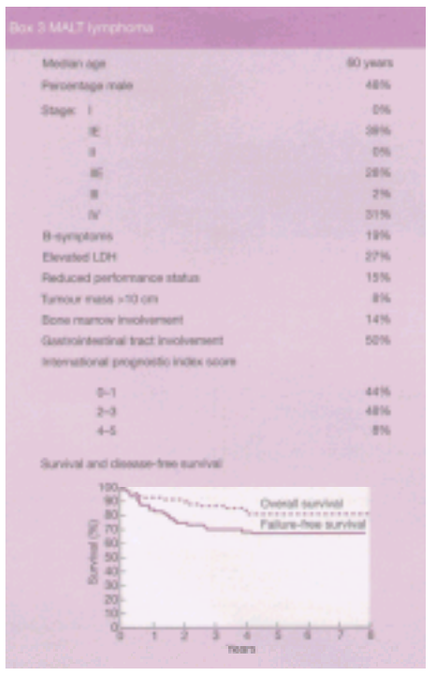
The median survival in series of patients treated for follicular lymphoma is approximately 10 years, although the median time to relapse is only 3 years. Prolonged survival after relapse is a characteristic of this disease, as are late relapses. This has made study of the treatment of patients with follicular lymphoma difficult and led to controversy of the curability of this illness.

MALT (mucosa-associated lymphoid tissue) lymphoma

This lymphoma, also known as the extranodal marginal-zone B-cell lymphoma of MALT-type, always presents in extranodal sites. A nodal presentation of a similar lymphoma is referred to as nodal marginal-zone lymphoma or monocytoid B-cell lymphoma (see below). Before the recognition of the existence of MALT lymphomas, orbital, pulmonary, and gastric presentations were sometimes referred to by pathologists as pseudolymphoma. The differential diagnosis of MALT lymphoma includes benign lymphocytic infiltration of extranodal organs and other small-cell B-cell lymphomas.

MALT lymphomas are tumours of CD5– and CD23– B cells that express CD20. The commonly seen cytogenetic abnormalities include trisomy 3 and t(11;18). Gastric MALT lymphomas are associated with infection by *Helicobacter pylori*. Thyroid MALT lymphomas are frequently associated with Hashimoto's thyroiditis, and orbital MALT lymphomas are sometimes associated with Sjögren's syndrome. MALT lymphomas can undergo histological transformation to diffuse large B-cell lymphomas. After this transformation, the patient should be treated for diffuse large B-cell lymphoma.

MALT lymphomas have a slight female predominance with a median age at presentation of approximately 60 years. The symptoms of the disorder are those associated with involvement of the extranodal site. The disease is usually localized and the presence of systemic symptoms or elevated LDH is unusual. The characteristics of patients with this lymphoma are presented in Box 3.



Gastric MALT lymphomas are the first example of a lymphoma that can be treated by eliminating a chronic infection. If the tumour does not transform to a large-cell lymphoma, and has not deeply invaded the stomach, the majority of patients will have their tumour regress with the eradication of *Helicobacter pylori* using antibiotics, proton-pump inhibitors, and bismuth. It appears that in some patients this treatment might be curative. Other local therapies are also effective, and patients with MALT lymphomas can be treated with local radiotherapy or, in some cases, surgery if radiotherapy would be contraindicated. These lymphomas also respond to single-agent chemotherapy or combination chemotherapy. Patients with disseminated MALT lymphoma regularly respond to therapy, but are rarely curable.

The majority of patients with localized MALT lymphoma can be cured, and the 5-year survival in such patients is approximately 90 per cent. However, patients with disseminated disease have a more serious illness and those with a high International Prognostic Index score have a 5-year survival of only 40 per cent.

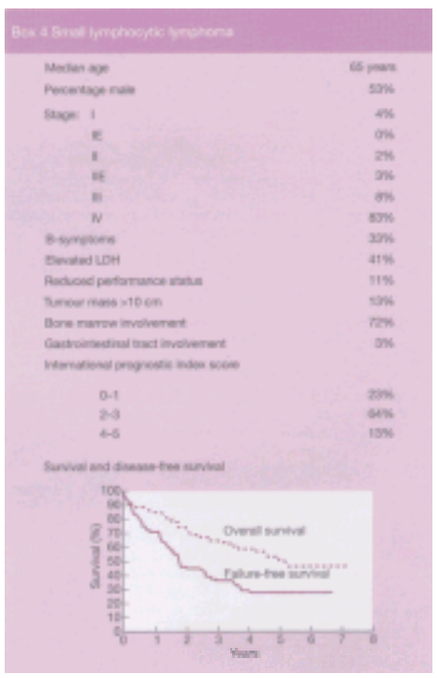
Small lymphocytic lymphoma/chronic lymphocytic leukaemia

Small lymphocytic lymphoma is the tissue manifestation of chronic lymphocytic leukaemia. Patients who present predominantly with blood and bone marrow involvement will have chronic lymphocytic leukaemia and those who present with lymphadenopathy will have small lymphocytic lymphoma. These are CD5+ B-cell lymphomas. Patients with plasmacytoid differentiation and monoclonal IgM protein in the serum can present the syndrome of Waldenström's macroglobulinaemia. Small lymphocytic lymphoma makes up approximately 7 per cent of non-Hodgkin's lymphomas worldwide, although it is more often seen in western countries.

The differential diagnosis of small lymphocytic lymphoma includes other small B-cell lymphomas. Patients with small lymphocytic lymphoma can undergo histological transformation to diffuse large B-cell lymphoma. This syndrome is seen in approximately 3 per cent of patients and is called Richter's syndrome. It is associated with a poor prognosis.

Chronic lymphocytic leukaemia/small lymphocytic lymphoma is a B-cell neoplasm that typically expresses CD20 and CD23. Approximately 30 per cent of cases have trisomy 12, but there is no specific chromosomal translocation associated with small lymphocytic lymphoma.

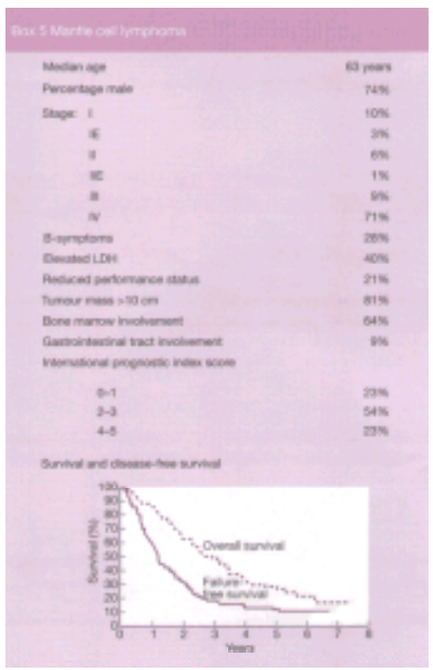
The clinical characteristics of patients with small lymphocytic lymphoma are presented in Box 4. Unusual immunological manifestations are sometimes seen, including hypogammaglobulinaemia, autoimmune thrombocytopenia, and autoimmune haemolytic anaemia. When present, these immune abnormalities should be specifically treated, in addition to any treatment given for the lymphoma. Hypogammaglobulinaemia should be treated with intermittent immunoglobulin interfusions and autoimmune cytopenias should be treated with prednisone and/or splenectomy.



Patients with small lymphocytic lymphoma can be followed with no initial therapy if they are symptomatic, but most patients will require treatment within the first few years. The two most popular treatments for small lymphocytic lymphoma/small lymphocytic leukaemia are single-agent oral chlorambucil and single-agent fludarabine. Fludarabine is associated with a higher complete response rate, but is somewhat more difficult to administer. Neither treatment is curative. Patients frequently respond to further treatment after relapse. Only a small proportion of patients are candidates for bone marrow transplantation. However, occasional patients seem to have a long-term, disease-free survival following allogeneic bone marrow transplantation.

Mantle-cell lymphoma

The clinical characteristics of patients with mantle-cell lymphoma are presented in Box 5. This lymphoma was recognized as a specific entity because of its characteristic cytogenetic abnormality. These tumours regularly express the t(11;14) that involves the *BCL-1* gene on chromosome 11 and the tumour cells overexpress the BCL-1 protein. This can be useful in diagnosis. Before the recognition of mantle-cell lymphoma, patients with this disorder were placed in many other histological categories. In the Kiel classification, mantle-cell lymphoma was usually called centrocytic lymphoma. An expert haematopathologist is important in making the diagnosis, since this lymphoma can be confused with small lymphocytic lymphoma, follicular lymphoma, and lymphoblastic lymphoma.



Extranodal sites of involvement by mantle-cell lymphoma are not unusual. Large bowel involvement with mantle-cell lymphoma presents as the syndrome of lymphomatous polyposis. Patients with distal gastrointestinal tract lymphoma often have Waldeyer's ring, and the converse is also true.

Mantle-cell lymphoma responds poorly to available therapies. Combination therapy regimens lead to a complete remission in less than 50 per cent of patients, and most complete responders relapse quickly. The median survival is 3 to 4 years and the 5-year survival for all patients is approximately 25 per cent. Patients who present with a high International Prognostic Index score rarely survive 5 years. Because of the poor outlook, autologous and allogeneic bone marrow transplantation have been increasingly utilized in younger patients.

Less common B-cell lymphomas

Burkitt's lymphoma was originally described by Dennis Burkitt while studying an aggressive lymphoma that occurred in the jaw of children in Central Africa. An association has been demonstrated between infection by the Epstein–Barr virus and this lymphoma. It is much more frequent in children than in adults and in patients infected by HIV. This very rapidly progressive lymphoma is associated with specific chromosomal translocations involving the heavy chain immunoglobulin gene on chromosome 14 or the light chain immunoglobulin genes on chromosomes 2 and 22. In each case, the associated oncogene is the c-*myc* gene on chromosome 8 (namely, t(8;14), t(2;8), and t(8;22)). Burkitt's lymphoma can present as acute leukaemia. This lymphoma can frequently be cured utilizing short courses of very intensive regimens that incorporate high doses of cyclophosphamide.

Nodal marginal-zone lymphoma or monocytoid B-cell lymphoma is immunologically related to MALT lymphoma (see above), but presents in a manner similar to follicular lymphoma. These patients respond to therapy and have an overall survival similar to those with follicular lymphoma. Splenic marginal-zone lymphoma is a rare disorder also known as splenic lymphoma with villous lymphocytes. This rare and indolent lymphoma often responds to splenectomy.

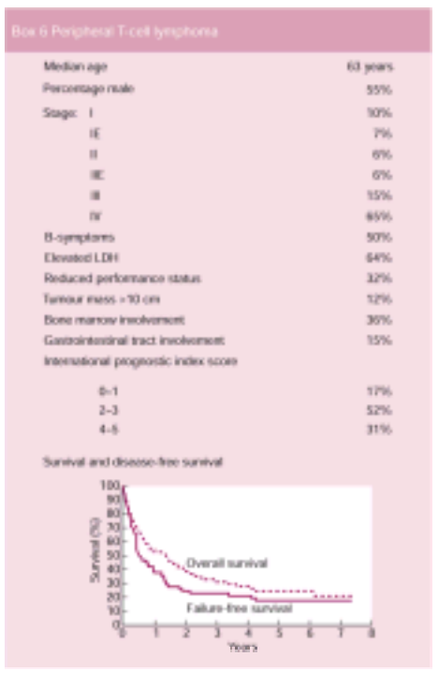
Primary, mediastinal, diffuse large B-cell lymphoma varies from other diffuse large B-cell lymphomas in that it occurs at a younger age and has a striking female predominance. However, the treatment and response to therapy are similar to other diffuse large B-cell lymphomas.

Lymphoplasmacytic lymphoma is a subtype of small lymphocytic lymphoma, which is a tissue manifestation of Waldenström's macroglobulinaemia.

Peripheral T-cell lymphoma

The illnesses classified together as 'peripheral T-cell lymphoma, unspecified type', are a heterogeneous group of non-Hodgkin's lymphomas. The accurate diagnosis of peripheral T-cell lymphoma involves the review of adequate histological material by an expert haematopathologist who has tissue available for immunophenotyping. The diagnosis cannot be made accurately in the absence of immunophenotyping. These tumours are generally CD3- and CD4-positive, although a few will be CD8-positive. Some display CD57 and an NK-cell immunophenotype. Cytogenetic abnormalities are frequent, but there is no consistent genetic abnormality. In occasional cases, demonstrating a T-cell receptor gene rearrangement will help to resolve a difficult diagnostic dilemma and confirm the diagnosis. The differential diagnosis of peripheral T-cell lymphoma includes diffuse large B-cell lymphoma and T-cell hyperplasia as seen in viral infection and drug reactions.

The clinical characteristics of patients with peripheral T-cell lymphoma are presented in Box 6. There are a number of distinctive clinical syndromes grouped together in the category of peripheral T-cell lymphoma. These include the angiocentric nasal NK-cell lymphoma that typically presents with necrotic nasal or facial lesions. Angioimmunoblastic T-cell lymphoma includes most patients who before would have been classed as having angioimmunoblastic lymphadenopathy with dysproteinaemia. These patients present with widespread disease, systemic system disease, skin rash, and polyclonal hypergammaglobulinaemia. Enteropathy-type intestinal T-cell lymphoma is a rare disorder that occurs in patients with gluten-sensitive enteropathy. Patients are frequently wasted and sometimes present with intestinal perforation. Hepatosplenic g,† T-cell lymphoma presents as a systemic illness with sinusoidal infiltration of the liver, spleen, and bone marrow by malignant T cells. Subcutaneous panniculitis-like T-cell lymphoma is a rare disorder that presents with subcutaneous nodules, which are often confused with panniculitis on biopsy. All subtypes of peripheral T-cell lymphoma have a poor prognosis.



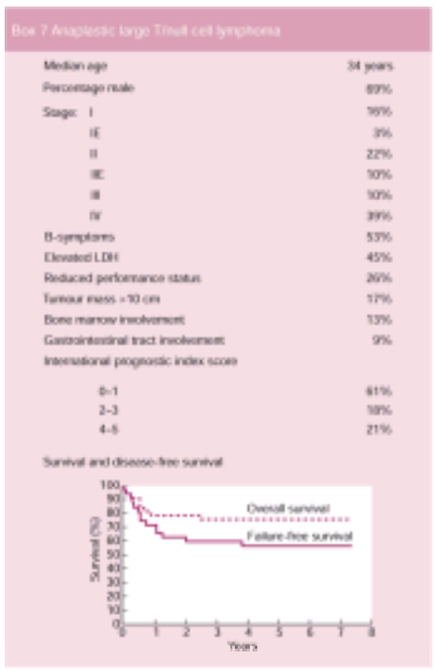
The treatment for patients with peripheral T-cell lymphoma involves the same regimens utilized for diffuse large B-cell lymphoma. Unfortunately, the overall 5-year survival is only 25 per cent and patients with a high International Prognostic Index score have a particularly poor outlook. Bone marrow transplantation can cure some patients who fail primary therapy, and this has been included in the initial treatment of patients with poor prognosis.

Anaplastic large T/null-cell lymphoma

Patients with this lymphoma were previously often diagnosed as having undifferentiated carcinoma, undifferentiated malignant neoplasm, or malignant histiocytosis. Discovery of the Ki-1 antigen (i.e. CD30) led to the recognition that some patients with anaplastic malignancies actually had non-Hodgkin's lymphoma. Subsequent

discovery of the t(2;5) and the resultant overexpression of the ALK protein led to the confirmation of anaplastic large T/null-cell lymphoma as a specific entity. In some patients, the B-cell lymphoma has an anaplastic appearance, but these patients have the same outcome as others with diffuse large B-cell lymphoma.

The clinical characteristics of patients with anaplastic large T/null-cell lymphoma are presented in Box 7. The diagnosis can be made confidently by an expert haematopathologist when facilities for immunophenotyping and staining for the ALK protein are available. The median age of patients with anaplastic T/null-cell lymphoma is approximately 30 years, and 70 per cent of the patients are male. Half the patients have localized (stage I/II) and half have disseminated (stage III/IV) disease. Systemic symptoms are present in 50 per cent of patients and a similar proportion have an elevated LDH level. Occasional patients present with localized disease in the skin and probably have a different and somewhat more indolent disorder.



Despite the anaplastic appearance of the lymphoma and frequent poor prognostic characteristics, patients with anaplastic large T/null-cell lymphoma respond well to therapy. The 5-year survival is approximately 75 per cent, and this lymphoma has one of the highest cure rates from combination chemotherapy of any non-Hodgkin's lymphoma. Patients relapsing can respond favourably to bone marrow transplantation.

Mycosis fungoides/Sezary syndrome

Mycosis fungoides or cutaneous T-cell lymphoma is an indolent lymphoma of mature T cells predominantly involving the skin. Patients who present with circulating, atypical (that is, Sezary) cells and erythroderma are said to have Sezary syndrome. The median age is approximately 50 years and the disease is more common in males and Blacks.

Mycosis fungoides often presents with eczematous or dermatitic skin lesions for many years before the diagnosis is firmly established. Frequently, patients will have several biopsies before the diagnosis is confirmed. Lymphoma first manifests itself as superficial lesions in the skin that thicken and eventually ulcerate. In the late stages of the illness, lymphoma can metastasize to lymph nodes and visceral organs.

Treatments utilized for mycosis fungoides include topical corticosteroids, topical nitrogen mustard, phototherapy, **PUVA** (psoralen ultraviolet A-range) therapy, electron-beam radiation, interferon, and systemic cytotoxic therapy. Some patients with localized mycosis fungoides can be cured with radiotherapy. However, the majority of patients will progress. In the end stages of this disease, management is difficult and the ulcerating cutaneous lesions present unpleasant problems for both the patient and the physician. The median survival from diagnosis averages over 10 years.

Adult T-cell lymphoma/leukaemia

The two major manifestations of infection by the human T-cell lymphoma/leukaemia virus-1 (HTLV-1) are tropical spastic paraparesis and adult T-cell lymphoma/leukaemia. Patients can be infected with HTLV-1 through sexual transmission, blood transmission, and transplacentally. The risk of developing lymphoma in a patient infected with HTLV-1 is between 1 and 7 per cent according to various studies. The latency between infection and the development of lymphoma averages approximately 20 years. The diagnosis is established by review of an adequate biopsy by an expert haematopathologist, demonstration of a T-cell immunophenotype, and demonstration of antibodies to HTLV-1. Most patients will have circulating tumour cells with a characteristic pleomorphic histology.

Adult T-cell lymphoma/leukaemia is most frequently seen in the southern islands of Japan and the Caribbean. Most patients seen in Europe and North America will be immigrants from those regions. Blood transfusion provides a possible source for infection, but screening for HTLV-1 has reduced the risk.

The clinical characteristics of patients with adult T-cell lymphoma/leukaemia vary considerably. Some patients present with an indolent disease manifested by lymphadenopathy and skin lesions and survive for extended times without specific therapy. Others present with progressive lymphadenopathy, hepatosplenomegaly, skin infiltration, hypercalcaemia, lytic bone lesions, and elevated LDH levels. Although patients sometimes respond to combination-chemotherapy regimens, complete remissions are unusual and survival is poor.

Lymphoma-like disorders (seeChapter 22.4.2)

Lymphadenopathy caused by infectious mononucleosis, drug reactions to diphenylhydantoin or carbamazepine, autoimmune disorders such as rheumatoid arthritis and lupus erythematosus, and bacterial infections such as cat-scratch disease can all be confused on biopsy with lymphoma. Castleman's disease is a specific condition that can present with localized or disseminated lymphadenopathy and systemic symptoms. The disease appears to be related to an overproduction of interleukin-6. The disseminated form of Castleman's disease is frequently accompanied by anaemia and polyclonal hypergammaglobulinaemia. Patients with localized disease can frequently be treated with local therapy, while systemic disease sometimes responds to systemic glucocorticoids. Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman's disease) typically presents with bulky lymphadenopathy in children or young adults. The disease is usually non-progressive and self-limited. Lymphomatoid papulosis is a cutaneous lymphoproliferative disorder that can be confused with T-cell lymphoma in the skin. The cells in lymphomatoid papulosis stain for CD30 and sometimes have a monoclonal T-cell receptor gene rearrangement. The condition is characterized by waxing and waning skin lesions that usually heal leaving small scars. Although these patients have an increased risk of developing lymphoma, aggressive therapy is inappropriate.

22.4.4 The spleen and its disorders

D. Swirsky

Since Hippocratic times the role of the spleen has been controversial. Galen called it an organ of mystery. Its structure was described during the seventeenth and early eighteenth centuries by Harvey, Glisson, Wharton, Malpighi, and van Leeuwenhoek. In 1777 William Hewson recognized an association with the lymphatic system, and in 1846 Virchow demonstrated that the Malpighian follicles are associated with the formation of white blood cells. In 1885 Ponfick showed that the spleen can remove particles from the blood and might be involved in the destruction of blood cells. Two years later Spencer Wells performed a laparotomy on a 27-year-old woman with a lifelong history of passing dark urine with attacks of jaundice and who had an abdominal tumour thought to be a fibroid. This turned out to be a large spleen and its removal was followed by a complete remission. The retrospective diagnosis of hereditary spherocytosis was made by Lord Dawson of Penn some 40 years later, by which time splenectomy was being performed quite frequently for the treatment of leukaemia, Hodgkin's disease, Banti's haemolytic jaundice, Gaucher's disease, polycythaemia, and thrombocytopenic purpura. The frequent success of the operation led Doan and Dameshek to engage in a lively argument on the mechanisms by which the spleen might destroy blood cells or suppress their formation, a process which Chauffard had earlier called 'hypersplenism'.

There is now a greater understanding of the splenic function in health and of the spleen's involvement in disease. Methods have been developed by which the various functions of the spleen can be defined and measured, sometimes with important clinical application.

Structure of the spleen

At birth the spleen has a mean weight of 11 g. By the age of 1 year the weight is 15 to 25 g; by 5 years it is 40 to 70 g, and by 10 years it is 80 to 100 g. It reaches a maximum weight of 200 to 300 g soon after puberty, and is slightly lighter throughout adult life until the age of about 65 years, when it decreases to 100 to 150 g or less. These figures have been derived from autopsy studies and are probably underestimates. This is mainly due to the splenic red cell pool which will be described later. Ultrasound, computed tomography (**CT**), magnetic resonance imaging (**MRI**) scans and scintigraphic radionuclide scans have shown that, *in vivo*, the normal adult spleen has a length of 8 to 13 cm, a width of 4.5 to 7 cm, a surface area of the order of 45 to 80 cm^2, and a volume less than 275 cm^3. A spleen greater than 14 cm long is usually palpable.

The spleen has a complicated structure (Fig. 1). It consists of a connective tissue framework, vascular channels, lymphatic tissue, lymph drainage channels, and cellular components of the haemopoietic and mononuclear phagocyte systems. There are two main components: (1) the red pulp; and (2) the white pulp. The red pulp consists of sinuses and pulp cords. The sinuses, 20 to 40 µm in diameter, are lined by endothelial macrophages. The white pulp consists of a periarteriolar lymphoid sheath and the adjoining lymphoid follicles (Malpighian bodies), which contain a germinal centre and are structurally similar to lymphoid follicles. From the capsule many lace-like trabeculae extend into the pulp, carrying blood vessels and autonomic nerve fibres. Within the spleen the trabeculae are in direct continuity with a mesh of reticular fibres that supports the pulp vessels and forms the basement membranes of arterial capillaries and the splenic sinuses. Along the reticular fibres lie adventitial reticular cells. These cells have an important role in regulating blood flow through the interendothelial slits of the vascular sinuses.

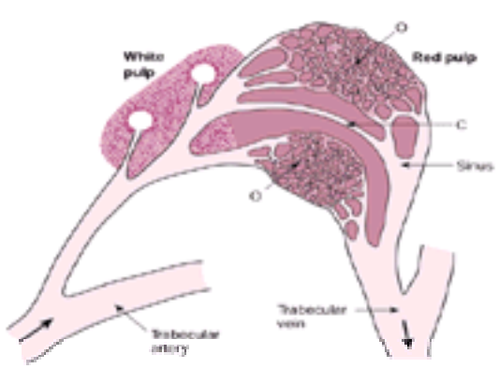

Fig. 1 Diagrammatic illustration of the spleen. The blood passes either directly into a sinus (C, closed system) or first into the cord space in the red pulp (O, open system).

Blood is supplied by the splenic artery and passes through the trabecular arteries, into the central arteries, which are sited in the white pulp. The central arteries run into the central axis of the periarteriolar lymphatic sheaths; they give off many arterioles and capillaries, some of which terminate in the white pulp whilst others go on to the red pulp. There they either connect directly with the sinuses and thence, via the collecting vein, to the trabecular vein (closed system), or they first pass into the cord spaces before joining up with the sinuses (open system).

Thus, as blood flows through the spleen it will come into contact with the reticular fibres, and also with endothelial macrophages, which line the interstices of the reticular mesh.

Blood flow in the spleen

Because the spleen has two vascular systems (open and closed) as described above, there are both rapid- and slow-transit components in the splenic circulation. The rapid transit (closed system) is of the order of 1 to 2 min and the slow transit (open system) about 30 to 60 min. In normal subjects the open system has a minor role and the blood flows through the spleen as rapidly as through organs possessing a conventional vasculature, at a rate of 5 to 10 per cent of the blood volume per

minute, so that each day the circulating blood has repeated passages through the spleen. When the spleen is enlarged, blood flow increases up to 20 per cent or more of the blood volume per minute. At the same time, a proportion of the blood may be pooled in the cord spaces (see below). As blood traverses the spleen, the plasma and leucocytes pass preferentially to the white pulp by a process of plasma skimming, and the plasma rapidly reaches the venous system, whilst blood with a relatively high packed-cell volume remains in the axial stream of the central artery. Some of this blood flows directly through the sinusoids to the venous system, while the remainder passes into the cords of the red pulp. The normally flexible red cells squeeze through the endothelial slits into the sinuses, whilst inflexible cells with fixed membranes or with inclusions remain in the cords where they either become conditioned for later transit or are destroyed.

Functions of the spleen

Haemopoiesis

In the fetus and compared with the liver, the spleen is a minor haemopoietic organ. There is, however, some erythropoiesis and granulopoiesis in the spleen from the 12th week of gestation; this continues until birth, after which there is normally no demonstrable haemopoiesis. However, the potential remains, and under severe haematological stress, in thalassaemia and in chronic haemolytic anaemias for example, extramedullary haemopoiesis may occur together with intense erythroid hyperplasia of the bone marrow. This must be distinguished from myeloid metaplasia occurring in myelofibrosis, chronic myeloid leukaemia, and occasionally other leukaemias and secondary carcinomas. In these conditions, foci of haemopoietic tissue become established in the spleen and elsewhere outside the bone marrow. They represent an abnormal proliferation which is distinct from compensatory haemopoiesis.

Cell sequestration, phagocytosis, and pooling

The spleen has a remarkable ability to 'cleanse' or 'recondition' red cells for recirculation and also to remove from the circulation effete or damaged cells as well as foreign matter. Of particular importance is the trapping of encapsulated bloodborne bacteria. It is important to distinguish between the three mechanisms involved. Sequestration is a temporary (reversible) process whereby cells are held in the spleen before returning to the circulation; phagocytosis represents the irreversible uptake of non-viable cells by macrophages, or the destruction of viable cells that have been damaged; pooling is the presence in the spleen of an increased amount of blood (or some of its component parts). In contrast to sequestration, pooled cells are in continuous exchange with the circulation.

As blood flows through the sinuses and cords, effete and damaged cells, and particulate foreign matter, are promptly phagocytosed by the endothelial macrophages. Intact red cells are held up temporarily, during which time siderotic granules, Howell–Jolly bodies, and Heinz bodies are removed. After the inclusions have been removed the red cells return to the circulation. Sequestration of reticulocytes also occurs, and they are retained in the splenic cords for part of their last 2 or 3 days of maturation while they lose their intracellular inclusions, alter their surface membrane composition, and become smaller. The spleen normally sequesters 30 to 45 per cent of the total circulating platelet content of the blood. This platelet pool is rapidly mobilized under conditions of stress, and normally there is a constant transit between the spleen and vascular pools.

As the blood becomes more viscous in the spleen, red cells are subjected to a further hazard. Because they are packed together in the presence of metabolically active macrophages, they are depleted of glucose and oxygen. This increases their membrane rigidity and reduces their deformability. Cells may become inflexible if: (1) they are metabolically abnormal (as in some congenital haemolytic anaemias) and thus unduly sensitive to the unfavourable environment of the spleen; (2) if they are held up in the spleen for a prolonged period and are thus rendered metabolically abnormal; and (3) if they are already spherical (as in hereditary spherocytosis), fragmented (as in microangiopathic haemolytic anaemia), or misshapen in some other way. This results in their being trapped in the cord spaces where they subsequently undergo phagocytosis.

Immune function

The spleen contains the largest single accumulation of lymphoid tissue in the body; about 25 per cent of the total T-lymphocyte pool and 10 to 15 per cent of the B-lymphocyte pool, with very marked exchange between circulating and splenic lymphocytes. Splenic macrophages are instrumental in antigen presentation to lymphocytes. The spleen is a major, but not unique, site for the conversion of naive circulating B cells into plasma cells which migrate to the bone marrow and into long-lived memory cells.

Micro-organisms or other antigens that find their way to the spleen are taken up and processed by cord macrophages and are presented to immunocompetent cells in the lymphoid tissue. This stimulates antibody production and an increase in size of the lymphoid germinal centres of the spleen. Secondary stimulation with the antigen enhances antibody production, usually IgG.

Antibody-coated red cells lose pieces of their membrane as they come in contact with the Fc receptors on macrophages, and become spherical and less flexible each time they pass through the sinus vasculature, until finally they become too rigid to traverse the endothelial pores and are trapped and destroyed. Red cells sensitized by IgG do not, as a rule, agglutinate in the peripheral blood, but the environment in the spleen promotes local agglutination with consequent sequestration and destruction (autoimmune haemolysis). Antibody-coated neutrophils and platelets are similarly destroyed by splenic macrophages.

Blood pool

The normal red cell content of the spleen is less than 80 ml of red cells, and always less than 5 per cent of the total red cell mass. There is no significant red cell pool in human spleens. However, enlarged spleens are capable of developing remarkably large pools with a relatively slow exchange of red cells with the general circulation. In the myeloproliferative disorders, as much as 40 per cent of the blood volume may be present in the spleen. Increased pools also occur in lymphoproliferative disorders, especially hairy-cell leukaemia and prolymphocytic leukaemia.

In health there is a good correlation between the amount of blood in the spleen and its size. In lymphomas, however, the splenomegaly is greater than can be accounted for by the pool alone; in such cases the increase in spleen size is due primarily to an expansion of the lymphoid components with replacement of splenic sinuses by tumour. In myelofibrosis there is an increase in the reticular element with expansion of the closed system in the red pulp. A similar effect occurs in hairy-cell leukaemia.

Not unexpectedly, the red cell content of the spleen increases with increasing body haematocrit. There is a disproportionately increased pool in primary proliferative polycythaemia compared with secondary polycythaemia, where the pool remains small irrespective of the haematocrit level. Increased pools are also found in patients with hepatic cirrhosis. Here it is the increased portal pressure that leads to an increased splenic blood flow: the splenic arteries are dilated and the splenic pulp becomes expanded with prominent dilated sinuses. Portal hypertension may result from myeloproliferative disorders associated with splenomegaly.

In myeloproliferative disorders and some other conditions an enlarged splenic blood pool may contribute significantly to anaemia. A low venous haematocrit can be present despite a normal red cell mass (pseudoanaemia). Direct measurement of the splenic red cell volume makes it possible to predict the extent to which splenectomy will improve anaemia and reduce transfusion requirements.

There is also a significant reservoir of platelets in the spleen, which is rapidly interchangeable with the circulation. In some cases of thrombocytopenia, destruction occurs mainly in the spleen and it is essential to distinguish this from pooling. As far as granulocytes are concerned, no pool is demonstrable in the normal spleen, but an abnormally large marginal pool has been found in cases of splenomegaly associated with neutropenia.

Plasma volume

Splenomegaly is frequently associated with an increased plasma volume, which may lead to an apparent anaemia (pseudoanaemia or dilutional anaemia), when a reduced venous haematocrit is the result of an expanded plasma volume in the presence of a normal or slightly reduced red cell mass.

Splenomegaly

A palpable spleen is usually enlarged. Occasionally a normal spleen is palpable if it is displaced downwards, by a pleural effusion for example. The spleen has to be

1.5 to 2 times its normal size to be palpable. Ultrasound, CT, and MRI provide reliable methods for measuring the actual spleen size.

Investigation of splenomegaly

The clinical history should include a relevant travel history (for example, to tropical areas) and family history (for example, Gaucher's disease, hereditary spherocytosis). Physical examination should specifically include assessment for hepatomegaly and lymphadenopathy. Laboratory investigations should include a full blood count, liver function tests and hepatitis serology, serum protein electrophoresis, total cholesterol, triglyceride and lipoprotein determinations, as well as immunoglobulin measurements. A bone marrow aspirate and trephine biopsy, and/or lymph node biopsy, with appropriate cytogenetic and immunophenotyping studies, should be done as indicated. These investigations will reveal the diagnosis in most haematological disorders and many chronic infections. CT or ultrasound scanning, with liver biopsy as required, will reveal hepatic or thrombotic causes of portal hypertension. HIV serology should always be done in puzzling cases of splenomegaly; in patients of Ashkenazi Jewish ancestry, Gaucher's disease or Niemann–Pick disease may be reasonably excluded by determining lysosomal hydrolase activity in leucocytes. If all investigations are negative, diagnostic splenectomy may be necessary, and in non-tropical areas the diagnosis will usually be non-Hodgkin's lymphoma or Hodgkin's disease.

Causes of splenomegaly

So many conditions are associated with splenomegaly that it is impossible to give a comprehensive list. It is even more difficult to list the 'common' causes as these depend on geographical pathology. In Western Europe and the United States viral infections and portal hypertension are the most common causes of splenomegaly, and these together with leukaemias, malignant lymphomas, myeloproliferative disorders, haemolytic anaemias, and other infections account for most cases. Isolated splenomegaly is a common manifestation of type I Gaucher's disease. Globally, however, the incidence of these haematological causes of splenomegaly is swamped by the great preponderance of splenic enlargement caused by parasitic infections, particularly malaria, leishmaniasis, and schistosomiasis. Human immunodeficiency virus (**HIV**) infection, particularly in the later stages of the disease, is an increasing cause of mild to moderate splenomegaly. Haemoglobinopathies head the list in some countries. Portal hypertension is an important cause of splenomegaly in most tropical countries but it is especially prevalent in north-eastern India and southern China. The 'tropical splenomegaly syndrome' associated with malaria is seen commonly in New Guinea and Central Africa.

Some of the causes of splenomegaly are listed in Table 1. The conditions which commonly give rise to massive splenomegaly are marked with an asterisk. The spleen sizes indicated are only a rough guide. Most of the conditions listed are described in other chapters.

Hypersplenism

Hypersplenism is a clinical syndrome of varied aetiology. It is characterized by:

1. Splenomegaly, although this may only be moderate.
2. Cytopenias: pancytopenia, single cytopenias, or any combination of anaemia, neutropenia, and thrombocytopenia.
3. A cellular or hypercellular bone marrow, sometimes showing a paucity of mature granulocytes.
4. A premature release of cells into the peripheral blood, resulting in a mild reticulocytosis with nucleated red cells and occasional immature granulocytes.

Other features are:

1. decreased red cell survival;
2. decreased platelet survival;
3. hypervolaemia (that is, increased plasma volume) if splenomegaly is marked.

The haematological features may be obscured or dominated by the primary disease, especially if it involves the marrow. The diagnosis of hypersplenism is ultimately confirmed by the response to treatment of the underlying cause or of splenectomy, although an immediate remission may be followed in the longer term by relapse with a return of cytopenia.

Tropical splenomegaly syndrome 'big spleen disease'

In areas where malaria is endemic, adults may present with moderate to massive splenomegaly, no obvious signs of active malaria, but all the features of hypersplenism including pancytopenia, expanded plasma volume, and haemolysis. The serum IgM level is usually high, and malarial antibody titres are raised. The spleen shows diffuse proliferation of macrophages. The relationship to malaria is evident by the response to long-term antimalarial treatment, which produces a sustained reduction in spleen size and reversal of the cytopenias. It is unclear why this effect is only seen in a proportion of individuals in areas of the world where malaria is endemic.

A similar degree of splenomegaly occurs in schistosomiasis (see Chapter 7.16.1). However, in this condition there is the further complication that the eggs (especially of *Schistosoma mansoni*) have a direct effect on the liver, resulting in hepatic fibrosis and leading to portal hypertension, which may be further exacerbated by splenic vein thrombosis.

Non-tropical idiopathic splenomegaly

Rare patients present with marked splenomegaly and the haematological features of hypersplenism but without exposure to malaria or other parasitic disorders. There may be a positive antiglobulin test and other evidence of autoantibody production. Some of these patients have a malignant lymphoma at the time of presentation, but in others the essential feature is non-neoplastic lymphoid hyperplasia, which probably represents an immunological reaction to as yet unidentified stimuli. The chances of long-term cure after splenectomy appear to be good. However, a lymphoma may appear from months to years after splenectomy. The disorder is diagnosed by the finding of massive splenomegaly in the absence of any other cause and by the non-specific histological appearances in the spleen.

Storage disease

The storage diseases are described in detail in Section 11.7. Some of them, notably Gaucher's disease and Niemann–Pick disease, may be complicated by marked splenomegaly. This may lead to hypersplenism, particularly in Gaucher's disease. The advent of specific enzyme therapy for Gaucher's disease has largely removed the need to consider splenectomy. The clinical picture of Niemann–Pick disease is dominated by hepatosplenomegaly and mental retardation. The disorder presents in infancy, and death often occurs between the second and third years of age, but, as with Gaucher's disease, it may present later in life. Hypersplenism becomes a feature in the older age groups, but anaemia and thrombocytopenia are uncommon in the childhood cases, and, if present, are mild. Several other lipid storage diseases may cause hypersplenism. They include Tangier's disease, in which cholesterol esters fill the histiocytes, and Wolman's disease, which is associated with an accumulation of triglycerides and cholesterol esters. Sea-blue histiocytosis is characterized by splenomegaly, hepatomegaly, thrombocytopenia, and, occasionally, neurological damage. The bone marrow and spleen contain cells that have an accumulation of glycosphingolipids, phospholipids, and mucopolysaccharides.

Rarely, Histiocytosis X (including Hand–Schuller–Christian disease, eosinophilic granuloma, Letterer–Siwe disease, and Langerhans' cell histiocytosis) cause splenomegaly. This is usually moderate, but occasionally it is more marked and may be associated with hypersplenism.

Space-occupying lesions and injury of the spleen

The most common causes of splenic masses are trauma leading to haematoma or rupture, abscesses, tumours, and cysts.

Splenic injury

The spleen is relatively unprotected and easily injured. Spontaneous rupture has been reported in a number of conditions in which the spleen is enlarged: these include typhoid, malaria, Epstein–Barr virus infection, leukaemia, Gaucher's disease, and polycythaemia. This may be restricted to a subcapsular haematoma or there

may be rupture into the peritoneal cavity.

The diagnosis is suggested by the symptoms of shock, left upper quadrant tenderness, guarding, pain referred to the left shoulder, and clinical and laboratory evidence of bleeding. Plain abdominal radiography is not, as a rule, helpful in diagnosis but CT scanning, ultrasound examination, and splenic arteriography are more useful.

Abscess

Although the spleen is frequently enlarged in association with systemic infection, splenic abscesses are rare. They result from direct or haematogenous spread, or when a haematoma becomes infected. Conditions associated with splenic infarction, such as sickle-cell disease, are particularly likely to give rise to splenic abscesses. Almost any organism can be involved.

Tumours

The spleen may be affected by benign tumours such as hamartomas. The very rare littoral-cell angioma is the only tumour confined to the spleen. Metastases in the spleen are uncommon by comparison to other organs, possibly because the spleen, unlike lymph nodes, lacks an afferent lymphatic system. They occur late in the course of carcinoma and are not found in the absence of metastases elsewhere. Metastases in the spleen are most frequently derived from malignant lymphomas, especially Hodgkin's disease. Lung, breast, prostate, colon, and stomach are the primary sites from which carcinoma is most likely to disseminate to the spleen. Melanoma is also a relatively frequent primary source.

Cysts

Splenic cysts are rare. The most frequent cause is *Echinococcus granulosum* (hydatid); other causes include haemangiomas, lymphangiomas, and dermoids. Cysts may also develop in areas of haemorrhage or infarction.

Loss of spleen function and splenic infarction

Splenic hypoplasia or atrophy

Congenital hypoplasia is rare; in some cases it is associated with extensive developmental abnormalities of the heart and gut. Splenic atrophy may occur in a number of conditions—sickle-cell disease, coeliac disease, dermatitis herpetiformis, ulcerative colitis, Crohn's disease, amyloidosis, selective IgA deficiency, and Fanconi's anaemia. There is evidence of reduced splenic reticuloendothelial function in alcoholics. The spleen shrinks in size in old age. Vascular blockade and repeated infarction is the basis for splenic atrophy in sickle-cell disease, and occurs in early childhood. The peripheral blood changes of hyposplenism, when present, are proportional to disease activity in gut diseases. In coeliac disease, withdrawal of gluten from the diet reverses the changes unless splenic atrophy has occurred. The mechanism of the splenic atrophy is unknown.

Splenic hypofunction and atrophy are characterized by changes in the blood film appearances; the main features are the presence of Howell–Jolly bodies and siderotic granules in some of the red cells. This is due to the loss of the spleen's macrophage 'pitting' function. Reduced sequestration (pooling) of red cells also occurs.

Splenic infarction

Splenic infarction occurs quite frequently in patients who have very large spleens from any cause. It is particularly common in association with myelosclerosis and chronic myeloid leukaemia. It also occurs in most patients with sickle-cell anaemia. In this disorder, splenic infarction occurs early in life and repeated episodes result in an autosplenectomy. Occasionally, when there is rapid growth of the spleen in association with an aggressive form of non-Hodgkin's lymphoma there may be multiple infarctions and spontaneous rupture of the spleen. Splenic infarcts are one of the presenting features of chronic myeloid leukaemia.

Splenic infarction causes pain in the left upper quadrant. If the diaphragmatic surface of the spleen is involved, the pain may be referred to the left shoulder tip. The physical signs include tenderness over the spleen, and sometimes a loud splenic rub is heard. Treatment is by rest and analgesia. The occurrence of repeated splenic infarction may be an indication for splenectomy, which may be complicated by adhesions between the spleen and the overlying peritoneum.

Specialized investigation of splenic function

Assessment of splenic function may be helpful, particularly in assessing the likely effect of splenectomy in haematological disorders. In many conditions it is sufficient to assess the spleen size, examine the peripheral blood for evidence of pancytopenia or a reduction in the number of neutrophils and platelets, and to examine the bone marrow to determine whether haemopoiesis is normal. Often this simple approach, combined with a knowledge of the likely effects of splenectomy for a particular haematological disorder, will be all that is necessary to make a decision about whether to proceed to surgery.

Studies with radionuclides provide information about the extent of splenic involvement in a disease process, the role of the spleen in producing anaemia, and the likely benefits of splenectomy. Details of the methods used and analysis of the results obtained in various conditions are to be found in specialized textbooks.

The following list summarizes the various *in vivo* tests useful for investigating splenic function:

- *Delineation of functional splenic tissue.* The spleen can be visualized and its size estimated by scintillation scanning following injection of isotope-labelled, autologous, heat-damaged red cells, which are selectively removed by functional splenic tissue. A gamma camera or rectilinear scanner visualizes splenic tissue (Fig. 2). The technique is most useful for identifying accessory spleens (splenunculi) associated with a postsplenectomy relapse of immune thrombocytopenia. The rate at which heat-damaged red cells are cleared from the circulation provides a rough guide to the competence of splenic function. A slow clearance may identify splenic hypofunction before the blood film shows Howell–Jolly bodies and other morphological changes.
- *Measurement of splenic red cell pool*. Quantitative scanning of the spleen after injection of undamaged, isotope-labelled, autologous red cells allows measurement of the splenic red cell pool. The size of the splenic red cell pool should be taken into account when assessing the significance of anaemia in the presence of splenomegaly. Measuring the pool is particularly useful for distinguishing polycythaemia vera (increased pool) from secondary polycythaemia (normal pool) and assessing the (useless) spleen pool in massive splenomegaly (Fig. 3).
- *Identification of sites of red cell destruction and quantification of splenic red cell destruction*. Surface counting over the spleen, heart, and liver following injection of autologous ^{51}Cr-labelled erythrocytes provides a qualitative indication of splenic red cell destruction in various haemolytic anaemias; quantitative scanning provides a more accurate measurement of the actual proportion of the cells that are destroyed in the spleen and elsewhere. These studies are moderately predictive of the outcome of splenectomy.
- *Identification and quantification of splenic extramedullary erythropoiesis*. Normally, transferrin-bound iron passes to the bone marrow, where the iron is released and enters erythroblasts for incorporation into the haemoglobin of developing erythrocytes. In the normal spleen, iron does not dissociate from transferrin. Hence, the uptake of iron demonstrable by surface counts shortly after administration of radioactive iron (^{59}Fe or ^{52}Fe), indicates that there is erythropoiesis in the spleen. Extramedullary erythropoiesis in the spleen occurs in the majority of patients with myelofibrosis (Fig. 4), and some patients with essential thrombocythaemia, but not in patients with polycythaemia vera. ^{52}Fe studies are useful for detecting early stages of transition from polycythaemia vera to myelofibrosis and for diagnosing the syndrome of transitional myeloproliferative disorder. Extramedullary haemopoiesis can be accurately identified in thalassaemia major or intermedia and sickle-cell disease by positron emission tomography (**PET**) after ^{52}Fe administration, for example paraspinal, mediastinal, or in lymph nodes.
- *Role of the spleen in platelet destruction*. About one-third of an injection of ^{51}Cr-labelled platelets disappears from the circulation during their lifespan, mainly in the spleen pool. Splenomegaly is associated with a marked increase in pooling: by contrast, in asplenia, nearly 100 per cent of the labelled platelets are recovered in the circulating blood. Surface counting and quantitative scanning have been used to assess the role of the spleen in thrombocytopenia, but are less reliable in predicting the response to splenectomy than in autoimmune haemolytic anaemia.

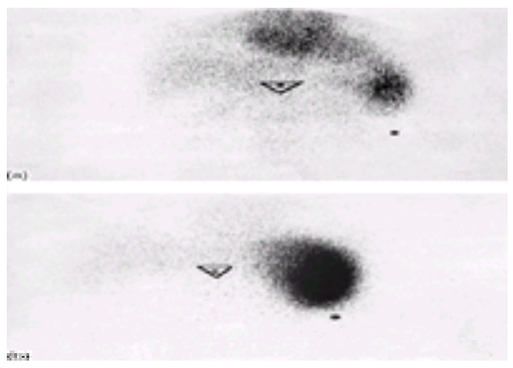

Fig. 2 Images obtained by scintillation camera following administration of (a) ^{99}Tc-labelled red cells and (b) ^{111}In-labelled, heat-damaged red cells.

Fig. 3 Splenic enlargement and increased red cell pool in a patient with myelofibrosis. Demonstrated by scanning after the administration of $^{113}In^{m}$-labelled red cells. The markings indicate the costal margin. The upper pole of the spleen merges with the image produced by labelled blood in the heart.

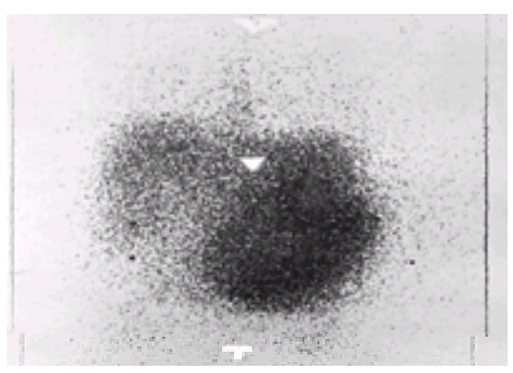

Fig. 4 ^{52}Fe scan in a patient with myelofibrosis showing the extent of splenic erythropoiesis. Vertebral erythropoiesis is markedly reduced.

The combinations of investigations used depends on the particular clinical problem. In many conditions associated with splenomegaly, it is important to distinguish increased macrophage activity causing cell destruction from increased red cell accumulation in a large pool, and to determine to what extent enlargement of the spleen is due to tumour infiltration. In myelofibrosis and hypersplenism, it may be helpful to ascertain the relative importance of the splenic red cell pool, red cell destruction, and extramedullary erythropoiesis, if present.

Indications for splenectomy

The main indications for splenectomy are summarized in (Table 2). Splenectomy should not be undertaken lightly. Where traumatic damage, usually from a blunt injury, has occurred, every effort should be made to preserve the spleen in whole or in part. Ultrasound and CT imaging are vital in assessing the damage as rupture and haematoma can be confused clinically. Surgical techniques for repairing or partially preserving the spleen have improved and should be encouraged. The use of diagnostic laparotomy and splenectomy in Hodgkin's disease has fallen into disuse, partly as a result of improved imaging in the CT and MRI scans, and partly because of the absence of therapeutic advantage, combined with the long-term dangers of splenectomy. In primary haematological disorders, splenectomy is indicated to alleviate complications—repeated infarction, massive red cell pooling, and hypersplenism for example. The decision is usually based on clinical assessment, but radioisotope studies to measure the splenic red cell pool, splenic erythropoiesis, and red cell survival may be helpful in difficult cases. Diagnostic splenectomy may still be required for splenic lymphomas where no other organ is affected. Increasingly, diagnostic splenectomy may be required in HIV-related diseases, particularly for a suspected lymphoma or opportunistic infection. The course of HIV disease is not influenced by splenectomy.

Clinical and haematological effects of splenectomy

Removal of the spleen is associated with certain immediate and delayed clinical complications, and with the presence of permanent changes in the eripheral blood picture.

Clinical complications

Early

In some splenectomies, particularly when the spleen is bound down by adhesions following a previous splenic infarction, there may be difficulty in achieving haemostasis, particularly if the preoperative platelet count is less than 50×10^{9}/l. Platelets should be infused as soon as the splenic pedicle has been ligated. Subphrenic abscess is a significant complication and may occasionally be fatal. Because the platelet count tends to rise immediately after the operation, there is an increased risk of thromboembolic disease in the first 2 or 3 weeks after splenectomy.

Subcutaneous heparin can be used if the preoperative platelet count is 50×10^{9}/l or greater. After wound healing, aspirin 75 mg daily should be given if the platelet count is elevated above 500×10^{9}/l, and continued until this normalizes. There is a small, long-term increase in myocardial infarction in splenectomized patients with persistently raised platelet counts, and in these patients aspirin should be given indefinitely.

Mortality depends on the clinical condition of the patient and the size of the spleen. Laparoscopic techniques for splenectomy are safer and reduce morbidity for small or moderately enlarged spleens. In patients with massive splenomegaly, usually myeloproliferative disorders, the mortality rate is up to 15 per cent in those patients thought fit for surgery.

Long term

All patients, whatever the reason for splenectomy, are at risk of overwhelming postsplenectomy infection (**OPSI**). Classically, OPSI presents with a vague general prodrome, followed by prostration, bacteraemic shock, and frequently disseminated intravascular coagulation. Death may occur within 6 h of the onset. The mortality rate in patients reaching hospital alive is in excess of 30 per cent. By far the most important causative organism is the pneumococcus (*Streptococcus pneumoniae*), but *Haemophilus influenzae*, *Neisseria meningitidis*, *Escherichia coli*, and *Pseudomonas* spp. have all been implicated. In endemic areas, plasmodium and babesia infections are of increased severity in non-immune individuals. Special warnings should be given to splenectomized patients travelling to malarial areas. Viral illnesses may also be of increased severity postsplenectomy.

The risk of OPSI does not decline significantly in the years after splenectomy. Children are at the greatest risk, followed by adults splenectomized for an underlying disorder that itself is immunosuppressive, or who require immunosuppressive treatment. Adults splenectomized for trauma are at least risk, but they still carry a lifelong susceptibility. OPSI has been recorded more than 40 years after splenectomy. The relative risk of severe infection compared with the non-splenectomized population is about 10-fold for traumatic splenectomy and as much as 100-fold for small children and patients with Hodgkin's disease.

Infections indistinguishable from OPSI also occur in non-splenectomized individuals who have hypofunctional spleens. It is well recognized as a cause of death in patients sickle-cell disease, particularly in children. Fatal overwhelming pneumococcal sepsis has been reported in patients with coeliac disease and primary amyloidosis affecting the spleen. Dermatitis herpetiformis and inflammatory bowel disease are also associated with splenic hypofunction. Bone marrow transplant recipients, particularly in the presence of chronic graft-versus-host disease are hyposplenic and have an increased risk of pneumococcal disease. Patients with lymphoproliferative disorders, particularly myeloma, are at increased risk of sepsis with encapsulated bacteria and should be considered for prophylaxis.

Strategies for preventing OPSI

All patients undergoing elective splenectomy should be immunized with polyvalent pneumococcal vaccine ('Pneumovax'), which currently gives variable protection against 23 strains of *S. pneumoniae*. Where possible, it should be given at least 1 month prior to splenectomy to allow IgG antibody production. Antibody responses may be suboptimal in patients with immunosuppressive diseases or in those receiving immunosuppressive treatment, or when it the vaccine is given perioperatively in an emergency. Patients should also be immunized against *H. influenzae* type b. Protection against *N. menigitidis* is of relatively short duration, and vaccination should be reserved for patients travelling to high incidence areas. Pneumovax is not fully protective, and a small proportion of patients fail to make detectable antibodies after vaccination. There are reports of OPSI occurring with strains of *S. pneumoniae* covered by the type of vaccine given, and therefore it should always be combined with life-long prophylactic antibiotics. Revaccination with Pneumovax every 5 to 10 years is recommended. Splenectomized individuals should always carry a card or wear a bracelet stating they have no spleen. At the onset of any febrile illness, particularly upper and lower respiratory infections, penicillin V should be stopped and therapeutic doses of a broad-spectrum antibiotic started. The penicillin V is resumed at the end of the course of antibiotics.

Prophylactic penicillin V, 250 mg twice daily, should be started postoperatively. Erythromycin can be substituted in penicillin-sensitive patients. The lifesaving value of prophylactic penicillin V in children with sickle-cell disease (that is to say, functional asplenia) has been proven beyond doubt, and there are only rare reports of OPSI in splenectomized patients regularly taking penicillin V. Surveys of patients dying of OPSI have identified the failure to follow the above guidelines as the greatest risk factor. While the penicillin does not prevent infection, it prevents the rapid onset of the OPSI syndrome. There is controversy as to the effectiveness of penicillin V in areas where resistant strains of pneumococci are common.

Following spleen rupture, splenic tissue may seed into the peritoneum, giving rise to nodules of recognizable splenic tissue (splenosis). These nodules have been shown to have some phagocytic function. This has led to the deliberate autotransplantation of splenic tissue at the time of splenectomy where partial splenic preservation has not been possible. Although such nodules of splenic tissue can phagocytose damaged red cells and reduce hyposplenic changes on the blood film, their protective capacity from infection is not established. The presence of demonstrable splenosis should not be relied upon to replace vaccination and penicillin prophylaxis.

The safest course is to immunize all patients, counsel them carefully about the dangers of infection, and impress upon them the need for lifelong penicillin prophylaxis. This should be reinforced at outpatient follow-up visits, and every effort should be made to maintain good compliance.

22.4.5 Myeloma and paraproteinaemias

Robert A. Kyle

The paraproteinaemias are a group of neoplastic, or potentially neoplastic, diseases associated with the proliferation of a single clone of immunoglobulin-secreting plasma cells. They include: multiple myeloma (**MM**); smouldering multiple myeloma (**SMM**); Waldenström's macroglobulinaemia (**WM**); heavy-chain diseases (**HCD**); solitary plasmacytoma of bone, extramedullary plasmacytoma, plasma-cell leukaemia, osteosclerotic myeloma (**POEMS** syndrome); monoclonal gammopathy of undetermined significance (**MGUS**); and primary systemic amyloidosis (**AL**).

The paraproteinaemias are characterized by the secretion of electrophoretically and immunologically homogeneous (monoclonal) (M) proteins (Table 1). Each M-protein consists of two heavy (H) polypeptide chains of the same class and subclass and two light (L) polypeptide chains of the same type. The heavy polypeptide chains are designated by Greek letters: g in IgG, a in IgA, μ in IgM, † in IgD, and e in IgE. The light-chain types are _ (kappa) and l (lambda).

Recognition of M-proteins

Agarose gel electrophoresis is preferred for the detection of M-proteins. Immunofixation should be used to confirm the presence of an M-protein and distinguish the immunoglobulin class and its light-chain type.

Serum protein electrophoresis should be done when MM, WM, or AL amyloidosis is suspected. A paraprotein is characterized by a narrow peak or spike in the densitometer tracing, or as a dense, discrete band on agarose gel (Fig. 1). In contrast, an excess of polyclonal immunoglobulins (having one or more heavy-chain types and both _ and l light chains) produces a broad-based peak or broad band. It is important to differentiate an M-protein from a polyclonal increase because the former is associated with a malignant process or a potentially neoplastic condition, whereas a polyclonal increase in immunoglobulins is associated with a reactive or inflammatory process. Immunofixation is the preferred technique for identifying an M-protein. Diseases associated with a paraprotein, as found in our practice in 2000, are shown in Fig. 2. Immunofixation of an adequately concentrated 24-hour urine specimen is best for detection of a monoclonal light chain (Bence Jones protein). The presence of a monoclonal light chain in nephrotic urine is strongly suggestive of AL or light-chain deposition disease.

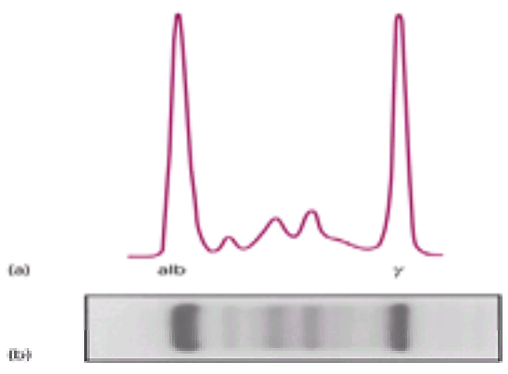

Fig. 1 (a) Monoclonal pattern of serum protein as traced by a densitometer after electrophoresis on agarose gel; tall, narrow-based peak of g mobility. (b) Monoclonal pattern from electrophoresis of serum on agarose gel (anode on left); dense, localized band representing monoclonal protein of g mobility. (From Kyle RA and Katzmann JA (1997). Immunochemical characterization of immunoglobulins. In: Rose NR, *et al*., eds. *Manual of clinical laboratory immunology*, 5th edn, pp 156–76. ASM Press, Washington, DC. By permission of the American Society for Microbiology.)

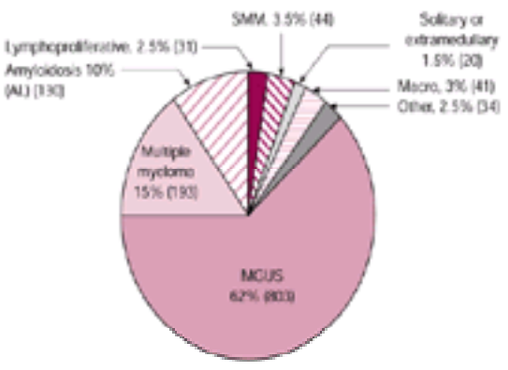

Fig. 2 Types of monoclonal gammopathies in 1296 Mayo Clinic cases in 2000.

Monoclonal gammopathy of undetermined significance (MGUS)

The term 'monoclonal gammopathy of undetermined significance' (MGUS) (benign monoclonal gammopathy) denotes the presence of a paraprotein in persons without evidence of MM, WM, AL, or related disorders. MGUS is characterized by a serum paraprotein concentration of less than 30 g/l; fewer than 5 per cent plasma cells in the bone marrow; no or only small amounts of paraprotein in the urine; absence of lytic bone lesions, anaemia, hypercalcaemia, and renal insufficiency; and, most important, the stability of the paraprotein and the failure of other abnormalities to develop. The prevalence of MGUS is 1 per cent in patients 50 years or older and 3 per cent in those over 70 years of age.

In a series of 241 patients with MGUS followed for 24 to 39 years, 26 per cent developed MM, WM, or AL. The median age at diagnosis was 64 years. Laboratory abnormalities such as anaemia or renal insufficiency were the result of unrelated disorders. The paraprotein concentration ranged from 3 to 30 g/l (median, 17 g/l). The paraproteins consisted of IgG (73 per cent), IgA (11 per cent), IgM (14 per cent), or biclonal (2 per cent). The bone marrow plasma cells ranged from 1 per cent to 10 per cent (median, 3.0 per cent).

After 24 to 39 years of follow-up, the 241 patients were classified into four groups (Table 2). Of these patients, 10 per cent have remained stable and could be classified as having 'benign' monoclonal gammopathy, but they must continue to be observed because serious disease may still develop. More than half of the patients died of unrelated causes without developing MM or a related disorder. In 26 per cent, MM (18 per cent), WM (3 per cent), AL (3 per cent), or related disorders (2 per cent) developed; the actuarial rate was 16 per cent at 10 years, 33 per cent at 20 years, and 40 per cent at 25 years. The interval from the time of recognition of the paraprotein to the diagnosis of serious disease ranged from 2 to 29 years (median, 10 years). In seven patients, MM was diagnosed more than 20 years after detection of the paraprotein.

Differential diagnosis of MGUS from MM and WM

The size of the paraprotein in the serum or urine is of some help. SMM is characterized by the presence of a paraprotein concentration of more than 30 g/l, more than 10 per cent plasma cells in the bone marrow, but no anaemia, renal insufficiency, or skeletal lesions. Affected patients must be recognized because they may remain stable for years and not require therapy. The presence of a urinary paraprotein suggests MM, but small amounts of _ or l paraprotein may persist in the urine and remain stable for years. Large numbers of plasma cells in the bone marrow suggest MM, but some patients may have a plasmacytosis of more than 10 per cent and remain stable. The presence of osteolytic lesions strongly suggests MM, but metastatic carcinoma must be excluded. The plasma-cell labelling index measures the synthesis of DNA, and when increased it is good evidence that the patient has MM. The presence of circulating plasma cells in the peripheral blood usually indicates MM rather than MGUS. No single test will distinguish the patient with MGUS who remains stable from those who develop MM or related disorders. The paraprotein level in the serum and urine should be serially measured, along with periodic re-evaluation of clinical and other features to determine whether MM or a similar disorder is present.

Multiple myeloma (MM)

MM (myelomatosis, Kahler's disease) is characterized by the neoplastic proliferation of a single clone of plasma cells producing a paraprotein. Proliferation of the plasma cells in the bone marrow produces skeletal destruction that leads to bone pain and pathological fractures. The paraprotein can lead to renal failure, recurrent bacterial infections, or hyperviscosity syndrome.

Epidemiology and aetiology

MM accounts for 1 per cent of all malignant diseases and slightly more than 10 per cent of haematological malignancies in the United States. The annual incidence is 4 to 5 per 100 000. The apparent increase during the past few decades is probably related to the increased availability and use of medical facilities, especially in older persons. The incidence in African–Americans is twice that in Caucasians, whereas rates are lower in Asian populations. The median age at diagnosis is about 65 years. Only 18 per cent of patients are younger than 50 years, and 3 per cent are younger than 40 years. The cause of multiple myeloma is unknown, but herbicides, insecticides, and organic solvents may play a role. Human herpesvirus-8 (HHV-8) has been reported in dendritic cells and may play a role in the pathogenesis of MM.

Biological aspects

The plasma cells are phenotypically CIg^{+}, CD38^{+}, PCA-1^{+}, CD56^{+}, with only a minority expressing CD10, CD20, and HLA-DR. Although still unknown, the clonogenic cell in MM appears to arise from the germinal centre, circulates in the peripheral blood, and may home to the bone marrow by means of adhesion molecules. Interleukin-6 (**IL-6**) is a potent plasma-cell growth factor and may be increased in MM, in contrast to MGUS. Overproduction of interleukin-1 (IL-1) and tumour necrosis factor, which have bone-resorbing activity, have been found in MM. Approximately 15 per cent of patients have point mutations of *p53*, a tumour suppressor gene.

Conventional cytogenetic studies reveal an abnormal karyotype in only 40 per cent of patients because of the low proliferative rate of plasma cells. Fluorescence *in situ* hybridization using chromosome-specific probes identifies abnormalities in more than 90 per cent of patients with MM, but no specific pattern has been identified.

Clinical manifestations

Bone pain, frequently in the back or chest, is present at diagnosis in more than two-thirds of patients. Loss of height from multiple vertebral collapses may occur. The most common symptoms are weakness and fatigue, which are often due to anaemia. Fever is rare and, when present, is usually due to an infection. An acute infection, renal failure, hypercalcaemia, or amyloidosis may be the presenting feature. The liver is palpable in about 20 per cent of patients, and the spleen in 5 per cent. Extramedullary plasmacytomas are uncommon and are usually observed late in the course of the disease as large, purplish, subcutaneous masses.

Laboratory findings

If MM is suspected, the laboratory tests listed in Table 3 should be performed. Anaemia is initially present in two-thirds of patients but eventually is found in almost all. The serum protein electrophoretic pattern shows a spike or localized band in 80 per cent of cases, hypogammaglobulinaemia is present in 10 per cent, and no apparent abnormality is found in the remainder. The paraprotein is IgG in about 50 per cent of patients, IgA in 20 per cent, and Bence Jones proteinaemia in almost 20 per cent. IgD occurs in 2 per cent, and biclonal paraproteinaemias are found in 1 per cent, whereas the remainder of the patients have no serum M-protein at diagnosis. Immunofixation of the urine shows a paraprotein in approximately 75 per cent of cases. The _/l ratio is 2:1. A paraprotein is found in the serum or urine at diagnosis in 98 per cent of cases. Hypercalcaemia is initially present in 15 per cent, about one-fifth of whom have a serum creatinine value of 20 mg/l or more.

The bone marrow usually contains more than 10 per cent plasma cells, but involvement may be focal, and repeat bone marrow examination may be necessary for diagnosis. The presence of monoclonal _ or l in the cytoplasm of plasma cells, identified by immunoperoxidase staining, is useful for differentiating monoclonal from reactive plasmacytosis (polyclonal) due to connective tissue disorders, metastatic carcinoma, liver disease, or chronic infections.

Conventional radiographs show abnormalities consisting of lytic lesions, osteoporosis, or fractures in almost 80 per cent of patients at diagnosis. The vertebrae, skull, thoracic cage, pelvis, and humeri and femurs are the most commonly involved sites. Osteoblastic lesions are rare. Technetium-99m bone scanning is inferior to conventional radiography and should not be used. Magnetic resonance imaging reveals abnormalities in 90 per cent of patients with MM. It is particularly helpful in patients who have back pain but no abnormalities on radiography, in whom spinal cord compression must be considered.

Organ involvement

Renal

The serum creatinine value is 20 mg/l or more in 20 per cent of patients at diagnosis. Bence Jones proteinuria is present in 75 per cent. The two major causes of renal failure are myeloma kidney and hypercalcaemia. Myeloma kidney is characterized by the presence of dense, waxy, laminated casts in the distal and collecting tubules. The casts consist mainly of monoclonal light chains. Dilatation and atrophy of the tubules occur, and the entire nephron becomes non-functional. Dehydration contributes to acute renal failure and must be avoided. Hypercalcaemia, present in 15 per cent of patients initially, is a major and treatable cause of renal insufficiency. Amyloidosis occurs in about 10 per cent of patients and may produce nephrotic syndrome and renal insufficiency. Hyperuricaemia, contrast media, antibiotics, and dehydration may contribute to renal failure.

Neurological

Radiculopathy is the most frequent neurological complication and usually involves the thoracic or lumbosacral areas. Compression of the spinal cord from extradural myeloma occurs in 5 per cent of patients. Leptomeningeal involvement is uncommon but is being recognized more frequently.

Other organ systems

The incidence of bacterial infection is increased in MM. Impairment of antibody response, neutropenia, treatment with glucocorticoids, and reduction of normal immunoglobulins increase the likelihood of infection. Coating of platelets by paraprotein may cause bleeding. Occasionally, a tendency to thrombosis is present.

Diagnosis

The diagnosis of MM depends on the presence of an increased number of plasma cells in the bone marrow (usually more than 10 per cent), a paraprotein in the serum (usually more than 30 g/l), Bence Jones proteinuria, and osteolytic lesions. The clinical features of MM must also be present for diagnosis. Metastatic carcinoma, connective tissue disorders, lymphoma, or chronic infections must be considered in the differential diagnosis.

Monoclonal gammopathy of undetermined significance (MGUS), smouldering multiple myeloma (SMM), primary systemic amyloidosis (AL), and metastatic carcinoma are the main conditions considered in the differential diagnosis. In MGUS, the paraprotein value is less than 30 g/l, and the bone marrow contains fewer than 10 per cent plasma cells. There are no osteolytic lesions, anaemia, hypercalcaemia, or renal insufficiency. SMM is characterized by the presence of a paraprotein value of 30 g/l or more and more than 10 per cent plasma cells in the bone marrow but no other findings or symptoms of MM. An increased plasma-cell labelling index strongly suggests that the patient has or soon will have symptomatic MM. However, it must be kept in mind that this value is normal in one-third of patients with symptomatic MM. Monoclonal plasma cells of the same isotype are present in the peripheral blood in 75 per cent of patients with active MM, but patients with MGUS or SMM have few or no circulating plasma cells.

The differentiation of AL and MM is arbitrary because both diseases are plasma-cell proliferative disorders with different manifestations. In AL, the bone marrow plasma-cell content is usually less than 20 per cent, there are no osteolytic lesions, and the amount of Bence Jones proteinuria is modest. Obviously, there is considerable overlap between AL and MM.

Prognostic features

The median duration of survival in MM is approximately 3 years, but there is a great deal of variability from one patient to another. In our experience, the plasma-cell labelling index and the b_2-microglobulin level are the two most powerful prognostic factors. The presence of a low index and a low b_2-microglobulin level is associated with a median survival of almost 6 years when treated with conventional chemotherapy. Cytogenetic abnormalities are an important prognostic factor. The deletion of chromosome 13 and the presence of translocations are predictors of poor outcome. The level of C-reactive protein correlates with the serum IL-6 level and is a useful prognostic factor. Plasmablastic morphology, circulating myeloma cells in the peripheral blood, and increased levels of IL-6 are all associated with more aggressive disease. The Durie–Salmon clinical staging system, in use for almost 25 years, has been superseded by these newer parameters.

Treatment

Although most patients with MM have symptomatic disease at diagnosis and require therapy, some are asymptomatic and should not be treated. All symptoms, physical findings, and laboratory data must be considered in making the decision to begin therapy. An increasing level of the paraprotein in the serum or urine, development of anaemia, hypercalcaemia, or renal insufficiency, and the occurrence of lytic lesions or extramedullary plasmacytomas are all indications for therapy. If there is doubt about beginning treatment, the most reasonable approach is to re-evaluate the patient in 2 months and to delay therapy until progressive disease is evident.

If the patient is younger than 70 years, the physician should discuss the possibility of autologous peripheral blood stem-cell transplantation. Haemopoietic stem cells should be collected before the patient is exposed to alkylating agents.

Chemotherapy is the preferred initial treatment for overt symptomatic MM in persons older than 70 years or in younger patients in whom transplantation is not feasible. Oral administration of melphalan and prednisone produces an objective response in 50 to 60 per cent of patients. A reasonable schedule is melphalan orally in a dosage of 8 to 10 mg/day for 7 days and prednisone 20 mg three times a day orally for the same 7 days. The melphalan should be given when the patient is fasting, because absorption is reduced after food is eaten. Leucocyte and platelet counts must be determined at 3-week intervals after the start of therapy, and the melphalan dosage should be altered until mid-cycle neutropenia or thrombocytopenia occurs. Melphalan and prednisone therapy should be repeated every 6 weeks and the dosage altered depending on the blood counts. Unless the disease progresses rapidly, at least three courses of melphalan and prednisone should be given before therapy is discontinued. An objective response may not be achieved for 6 to 12 months, or even longer in some patients.

Because of the obvious shortcomings of melphalan and prednisone, various combinations of therapeutic agents have been tried. In an overview of individual data in 4930 patients from 20 randomized trials comparing melphalan and prednisone with various combinations of therapeutic agents, the response rates were significantly higher with combination chemotherapy (60 per cent) than with melphalan and prednisone (53 per cent) (p <0.00001). There was no evidence that any subset of patients benefited from receiving combination therapy.

Chemotherapy should be continued until the patient is in a plateau state, or for at least 1 year. A plateau state is defined as stable serum and urine paraprotein levels and no other evidence of progression. Chemotherapy should be discontinued when a plateau state occurs, because continued therapy may lead to the development of a myelodysplastic syndrome or acute leukaemia.

Autologous transplantation

Autologous peripheral stem-cell transplantation has virtually replaced autologous bone marrow transplantation, because engraftment is more rapid and there is less contamination by myeloma cells. Autologous, peripheral stem-cell transplantation is applicable for more than half the patients with MM. The two major shortcomings are that: (1) the myeloma is not eradicated even with large doses of chemotherapy and total body radiation; and (2) autologous, peripheral stem cells are contaminated by myeloma cells and their precursors. Fortunately, the mortality from autologous transplantation is currently 1 per cent if patients are appropriately selected.

Most physicians initially treat the patient with vincristine (Oncovin), doxorubicin (Adriamycin), and dexamethasone (**VAD**) for 3 to 4 months to reduce the number of tumour cells in the bone marrow and peripheral blood. The peripheral stem cells are then collected after treatment of the patient with high-dose cyclophosphamide and granulocyte colony-stimulating factor (**G-CSF**). One can then proceed with the transplant, in which the patient is given high-dose chemotherapy followed by infusion of the peripheral blood stem cells. The other choice is to treat the patient with alkylating agents after stem-cell collection until a plateau state is reached, and then treat with a_2-interferon (**IFN-a**$_2$) or no therapy until early relapse. At that time the patient is given high-dose melphalan or total-body radiation, and the previously collected peripheral blood stem cells are infused. In a French study, 185 patients with primary resistant or relapsed disease were treated with three or four courses of VAD and then randomized to high-dose chemotherapy and autologous stem-cell transplantation or to conventional therapy with high-dose chemotherapy and

autologous transplantation given at relapse (early versus late transplantation); the two groups showed no difference in median overall survival (65 versus 64 months).

The largest single-institution experience with autologous transplantation in myeloma included 496 patients enrolled in a tandem transplant programme. Complete response was obtained in 36 per cent and the transplant-related mortality was 7 per cent. The overall survival from the time of the first transplant was 41 months. This series was heterogeneous and included patients with resistant disease and those with disease sensitive to conventional chemotherapy. In a recent report of 231 patients receiving tandem transplants, the overall median survival was 68 months.

A randomized trial performed by the French Myeloma Group compared high-dose chemotherapy and autologous bone marrow transplantation with conventional chemotherapy in 200 previously untreated patients under 65 years of age. The rates of response (81 per cent versus 57 per cent) and complete responses (20 per cent versus 5 per cent) were superior in the transplant group. The transplant group had a higher rate of 5-year, event-free survival (28 per cent versus 10 per cent) and overall survival (52 per cent versus 12 per cent).

It has been suggested that better results could be obtained with two (tandem) autologous peripheral stem-cell transplants. In a randomized trial of 400 patients from France, there was no difference in event-free or overall survival between double and single autologous stem-cell transplantation at 2 years. Longer follow-up analysis is necessary.

A major hurdle is improvement of the preparative regimen because residual myeloma is the likely source of relapse in most patients. In a comparison (non-randomized) of melphalan (140 mg/m^2) plus total-body radiation or melphalan (200 mg/m^2), no difference was found in remission status, event-free survival, or overall survival. The other major shortcoming of autologous stem-cell transplantation is the presence of myeloma cells and their precursors in the blood. Collection of CD34$^+$ cells produces a lower number of tumour cells, but it remains to be seen whether this results in better responses and survival. Because relapse occurs in nearly all patients, the use of dendritic cells and vaccines after autologous transplantation shows some promise.

Allogeneic bone marrow transplantation

This is advantageous because the graft contains no tumour cells that can lead to relapse. Unfortunately, the mortality rate is approximately 25 per cent within 3 months. Furthermore, more than 90 per cent of patients with MM are ineligible for an allogeneic transplant because of their age, lack of an HLA-matched sibling donor, or inadequate renal, pulmonary, or cardiac function.

The mortality rate for allogeneic transplantation must be reduced before it can assume a major role in the treatment of MM. A preparative regimen using fludarabine and melphalan ('mini-allotransplant') may result in a lower mortality. The use of T-cell-depleted peripheral allogeneic stem cells decreases the incidence of graft-versus-host disease and transplant mortality. The use of donor leucocyte infusions for relapses after allogeneic transplantation produces benefit in about half of patients. However, allogeneic transplantation is currently associated with a high mortality and cannot be recommended as a routine procedure.

Maintenance therapy

It would be desirable to keep the patient in a plateau state indefinitely, but this is not possible. An overview by the Myeloma Trialists' Group revealed relapse-free survival at 5 years in 23 per cent of patients receiving IFN-α_2 and 16 per cent without IFN-α_2 (p <0.001). The overall survival at 5 years was only modestly prolonged. Consequently, IFN-α_2 cannot be strongly recommended for maintenance therapy. Patients should be monitored closely during the plateau state, and the same therapy should be reinstituted if relapse occurs more than 6 months after the plateau state has begun.

Refractory multiple myeloma

The highest response rates have been reported with VAD given by continuous infusion for 4 days and dexamethasone (40 mg daily on days 1–4, 9–12, and 17–20). The response rate is approximately 60 per cent for patients who relapse while not receiving chemotherapy, but only 40 per cent for those who relapse while receiving alkylating agent therapy. Dexamethasone can be used as a single agent in the same dosage and schedule as VAD because the steroids probably account for 80 per cent of the benefit of VAD. Methylprednisolone (2 g three times weekly intravenously for 4 weeks) is helpful for refractory disease with pancytopenia. **VBAP** (vincristine (Oncovin), carmustine [BCNU], and doxorubicin [Adriamycin] on day 1 and prednisone daily for 5 days every 3 to 4 weeks) produces benefit in 30 per cent of patients and is easily administered. If the leucocyte and platelet levels are satisfactory, cyclophosphamide (600 mg/m^2 daily, intravenously, for 4 days) plus prednisone (50 mg twice daily for the same 4-day period) followed by G-CSF has been helpful for patients with refractory, advanced disease. The use of IFN-α_2 as a single agent benefits some patients, but the results have been disappointing.

Thalidomide has shown to be of benefit in approximately 30 per cent of patients with refractory disease. Resistance to chemotherapeutic agents is a major problem.

Supportive care

Skeletal complications

Skeletal involvement often leads to pathological fractures, spinal cord compression, pain, or hypercalcaemia. These complications result from increased osteoclastic bone resorption, which is inhibited by bisphosphonates. In a prospective placebo-controlled study, patients receiving pamidronate had fewer skeletal complications and experienced a reduction in bone pain as well as improved quality of life. Pamidronate in a dosage of 90 mg intravenously every 4 weeks is recommended for patients with MM who have lytic lesions or osteopenia. Its use should be continued indefinitely. Clodronate, an orally administered bisphosphonate, has also been reported to be beneficial.

Patients should be encouraged to be as active as possible, but they must avoid undue trauma. Fixation of fractures or pending fractures with an intramedullary rod and methyl methacrylate has produced good results. Bone pain should be treated with analgesics or narcotics as necessary.

Hypercalcaemia

This is present in 15 per cent of patients at diagnosis and should be suspected in the presence of anorexia, nausea, vomiting, polyuria, polydipsia, increased constipation, weakness, confusion, or stupor. If untreated, renal insufficiency develops. Hydration plus prednisone (25 mg four times a day until the serum calcium level decreases) is effective in most cases. If these measures fail, pamidronate or etidronate is effective.

Renal failure

Two major causes of renal insufficiency are 'myeloma kidney' and hypercalcaemia. Maintenance of a high urine output (3 litres/day) is important for preventing renal failure in patients with Bence Jones proteinuria. Haemodialysis or peritoneal dialysis is necessary in the event of symptomatic azotaemia. Plasmapheresis may be useful in acute renal failure, but patients with severe myeloma cast formation or other irreversible changes are unlikely to benefit. Allopurinol should be administered if hyperuricaemia is present. Patients with acute renal failure should be treated with VAD or dexamethasone to reduce the tumour mass as quickly as possible.

Infection

Appropriate therapy for bacterial infections is essential. Patients should receive pneumococcal and influenza vaccination despite their suboptimal antibody response. Prophylactic daily oral penicillin (500 mg daily indefinitely) often benefits patients with recurrent pneumococcal infections. Because many infections occur in the first 2 months after instituting therapy, trimethoprim–sulfamethoxazole is useful. Intravenously administered gammaglobulin can be used for recurrent infections, but it is very expensive.

Neurological

Spinal cord compression should be suspected in patients with severe back pain who develop weakness or paraesthesias of the lower extremities or bladder or bowel

dysfunction. Magnetic resonance imaging (**MRI**) or CT scans must be done immediately. Radiation therapy and dexamethasone are usually effective, and surgical decompression is rarely necessary.

Hyperviscosity

This is characterized by oral or nasal bleeding, blurred vision, paraesthesias, headache, reduced cerebration, or congestive heart failure. Serum viscosity levels do not correlate well with the symptoms or clinical findings. A decision to perform plasmapheresis depends on the symptoms and changes in the ocular fundus. Plasmapheresis promptly relieves the symptoms and should be done regardless of the viscosity level if the patient has signs or symptoms of hyperviscosity.

Anaemia

Anaemia occurs in almost all patients during the course of MM. Erythropoietin (150 U/kg 3 times weekly or 40 000-U weekly) will increase haemoglobin in 50 to 60 per cent of patients.

Emotional support

All patients with MM need substantial and continuing emotional support. The physician's approach must be positive and emphasize the potential benefits of therapy. It is reassuring for patients to know that some survive for 10 years or more. It is vital that the physician caring for patients with MM has the interest and capacity to deal with an incurable disease over the space of years with assurance, sympathy, and resourcefulness.

Variant forms of multiple myeloma

Smouldering multiple myeloma (SMM)

See above.

Plasma-cell leukaemia

Plasma-cell leukaemia is defined as the presence of more than 20 per cent plasma cells in the peripheral blood and an absolute plasma-cell count of more than 2×10^9/l. It is classified as primary when it presents *de novo* (60 per cent of cases) and as secondary when it is a leukaemia transformation of a previously recognized myeloma (40 per cent). Patients with primary plasma-cell leukaemia are younger and have a higher platelet count, fewer bone lesions, a smaller serum paraprotein, a greater incidence of hepatosplenomegaly and lymphadenopathy, and a longer duration of survival than patients with secondary plasma-cell leukaemia. Cytogenetic abnormalities are more common than in patients with MM. Autologous stem-cell transplantation after high-dose chemotherapy is beneficial for some patients. Those with secondary plasma-cell leukaemia rarely respond to chemotherapy because they already received treatment and are resistant.

Non-secretory myeloma

These patients have no paraprotein in either the serum or the urine and account for only 2 per cent of patients with myeloma at diagnosis. The diagnosis is established by identification of an M-protein in the cytoplasm of the plasma cells by immunoperoxidase or immunofluorescence staining.

Osteosclerotic myeloma (POEMS syndrome)

This is characterized by polyneuropathy (P), organomegaly (O), endocrinopathy (E), M-protein (M), and skin changes (S). The major clinical finding is a chronic inflammatory-demyelinating neuropathy with predominantly motor disability. Sclerotic bone lesions are found in most patients. The cranial nerves are not involved except for the presence of papilloedema. Hepatomegaly occurs in almost half of patients, but splenomegaly and lymphadenopathy occur in a minority. Hyperpigmentation and hypertrichosis are frequent but may be easily overlooked. Gynaecomastia and atrophic testes as well as clubbing of the fingers and toes may be present. Angiomatous lesions of the trunk are often prominent. Pulmonary hypertension has been recognized in several instances. Ascites, pleural effusion, and peripheral oedema may be present. In contrast to MM, the haemoglobin level is usually normal or increased, and thrombocytosis is common. The bone marrow usually contains fewer than 5 per cent plasma cells, and hypercalcaemia and renal insufficiency rarely occur. Most patients have a l light chain, and IgA is the most common heavy-chain type. Castleman's disease may be present. The diagnosis is confirmed by the identification of monoclonal plasma cells obtained from an osteosclerotic lesion. If the skeletal lesions are in a limited area, radiation almost always produces a substantial improvement of the neuropathy. If widespread osteosclerotic lesions exist, chemotherapy or an autologous stem cell transplant should be used for therapy.

Solitary plasmacytoma (solitary myeloma) of bone

The diagnosis depends on histological evidence of a plasma-cell tumour but no evidence of MM. Complete skeletal radiographs, bone marrow aspiration and biopsy, and immunofixation of the serum and urine should reveal no evidence of MM. Occasionally, a small paraprotein may be found in the serum or urine, but it usually disappears after radiation of a solitary lesion. Treatment consists of tumoricidal radiation (40–50 Gy). Overt MM develops in approximately 55 per cent of patients, and new solitary lesions or local recurrence develops in about 10 per cent. MRI scans may be helpful for identifying patients in whom MM will develop in the near future.

Extramedullary plasmacytoma

This is a plasma-cell tumour that arises outside the bone marrow. It is located in the upper respiratory tract in approximately 80 per cent of cases, and the nasal cavity and sinuses, nasopharynx, and larynx are most often involved. The gastrointestinal tract, central nervous system, urinary bladder, thyroid, breast, testes, parotid gland, and lymph nodes have all been reported as the initial site of an extramedullary plasmacytoma. There is a predominance of IgA M-protein in extramedullary plasmacytomas. The diagnosis depends on the finding of a plasma-cell tumour in an extramedullary location and the absence of MM on bone marrow examination, radiography, and appropriate studies of serum and urine. Treatment consists of tumoricidal radiation (40–50 Gy). Regional occurrences develop in approximately 25 per cent of patients, but the development of typical MM is uncommon.

Waldenström's macroglobulinaemia (WM)

This malignant plasma-cell proliferative disorder produces a high concentration of immunoglobulin M (IgM) paraprotein. It bears similarities to MM, lymphoma, and chronic lymphocytic leukaemia. The incidence rate is 0.5/100 000, and in our practice it is one-seventh as common as MM. The median age is approximately 65 years, and 60 per cent of patients are male.

Clinical findings

Weakness and fatigue are the most common features. Chronic nasal bleeding or oozing from the gums is characteristic, but postsurgical or gastrointestinal bleeding may occur. Blurring or loss of vision may be prominent. Dyspnoea and congestive heart failure may develop. Dizziness, headaches, vertigo, nystagmus, ataxia, and diplopia have been seen. Constitutional symptoms including fever, night sweats, and loss of weight may be present. Bone pain is rare. Hepatomegaly occurs in about 25 per cent of patients at diagnosis, and splenomegaly and lymphadenopathy are slightly less common. Retinal vein engorgement and flame-shaped haemorrhages are common and are a better measure of symptomatic hyperviscosity syndrome than is the measurement of serum viscosity.

Pulmonary involvement may be manifested by diffuse pulmonary infiltrates, isolated masses, or pleural effusion. Retroperitoneal and mesenteric lymphadenopathy are common, but they are usually asymptomatic. The most common neurological manifestation is sensorimotor peripheral neuropathy. It is often related to amyloid deposition.

Laboratory findings

Anaemia is found in most patients with symptomatic WM. Spuriously low haemoglobin and haematocrit levels may result from an increased plasma volume due to the

large amount of paraprotein.

Serum protein electrophoresis reveals a tall, narrow spike or dense band usually migrating in the g area. About 75 per cent of the IgM paraproteins are _. The IgM level obtained by nephelometry is often 1000 to 3000 mg/l more than that found with serum protein electrophoresis. A reduction of uninvolved IgG and IgA immunoglobulins is less striking than in MM. About 10 per cent of macroglobulins precipitate in the cold (cryoglobulin). A monoclonal light chain detected by immunofixation is present in the urine in 75 per cent of patients.

Fewer than 5 per cent of patients with WM have lytic bone lesions. The bone marrow aspirate is often hypocellular, but the biopsy specimen is usually hypercellular and extensively infiltrated with lymphoid or plasmacytoid cells.

Diagnosis

The diagnosis of WM depends on the presence of an IgM paraprotein and a lymphocyte–plasma cell infiltration of the bone marrow producing symptoms and physical findings consistent with WM. The differential diagnosis includes MM, MGUS of the IgM type, chronic lymphocytic leukaemia, lymphoma, and undifferentiated lymphoplasma-cell proliferative processes.

Treatment

Patients with WM should not be treated unless they are symptomatic. Symptoms and findings of hyperviscosity are quickly controlled by plasmapheresis with a cell separator. Therapy must be directed against the proliferating lymphocytes and plasma cells because symptoms will recur quickly.

Chlorambucil (Leukeran) is usually given orally in an initial dosage of 6 to 8 mg daily and is reduced when the leucocytes or platelets decrease. It also may be given intermittently at monthly intervals. Patients should be treated until the disease has reached a plateau state, which occurs in about 70 per cent of patients. Patients should be treated for at least 6 months before chlorambucil therapy is abandoned because of a slow response. Cyclophosphamide or combinations of alkylating agents such as the M2 protocol (vincristine, BCNU, melphalan, cyclophosphamide, and prednisone) have also been beneficial. Patients must be followed closely, and chemotherapy of the same type should be reinstituted when the disease relapses. Fludarabine and cladribine (2-chlorodeoxyadenosine) have been reported to produce responses in 80 per cent of patients. However, in a recent report, only one-third of patients with symptomatic WM responded to fludarabine. Rituximab (Rituxan) produces a response in approximately half of patients with refractory disease.

Packed red cells should be transfused into patients with symptomatic anaemia. Erythropoietin may be of help. The median duration of survival for patients with macroglobulinaemia is approximately 5 years.

Heavy-chain diseases

Gamma heavy-chain disease (g-HCD)

The paraprotein consists of a monoclonal g chain with significant amino-acid deletions. The median age of patients is approximately 60 years, but the disease has been recognized in persons under 20 years of age. The initial presentation is often a lymphoma-like illness, but the symptoms and clinical findings are diverse and range from an aggressive lymphoproliferative process to an asymptomatic state. Weakness, fatigue, and fever are the most common presenting symptoms. Hepatosplenomegaly and lymphadenopathy are found in about 60 per cent of patients. Anaemia is present in 80 per cent. The serum protein electrophoretic pattern usually shows a broad-based band more suggestive of a polyclonal than an M-protein. The urinary heavy-chain protein value is usually less than 1 g/24 h. Bence Jones proteinuria is not found. The bone marrow and lymph nodes contain an increased number of plasma cells, lymphocytes, and lymphoplasmacytoid cells.

Only symptomatic patients should be treated. Therapy with cyclophosphamide, vincristine, and prednisone is a reasonable choice. If there is no response, a doxorubicin-containing regimen should be used. The median duration of survival is approximately 1 year.

Alpha heavy-chain disease (a-HCD)

a-HCD is the most common type of heavy-chain disease, with more than 200 reported patients since its recognition. It usually occurs in the second or third decade of life, and about 60 per cent of patients are male. Most patients have been from the Mediterranean region and Middle East. Gastrointestinal tract involvement is most common and is manifested by malabsorption with loss of weight, diarrhoea, and steatorrhoea. It is similar to 'immunoproliferative small intestinal disease' (**IPSID**), but patients with IPSID do not synthesize a heavy chains. The serum protein electrophoretic pattern shows no spike. The diagnosis depends on recognition of a monoclonal a heavy chain in the serum or jejunal fluid. Bence-Jones proteinuria never appears. The bone marrow is not infiltrated with lymphocytes. a-HCD is progressive and fatal without therapy. Surprisingly, antibiotics may produce remission, particularly if given early in the course of the disease. Patients who have advanced disease or who do not respond to antibiotics should be treated with a combination of chemotherapy consisting of cyclophosphamide, doxorubicin (Adriamycin), vincristine, and prednisone.

Mu heavy-chain disease (µ-HCD)

µ-HCD is characterized by the presence of a monoclonal µ-chain fragment in the serum. Most patients have a chronic lymphoproliferative process resembling chronic lymphocytic leukaemia or lymphoma. The serum protein electrophoretic pattern contains a spike or localized band in about 40 per cent of patients. Bence Jones proteinuria, which is usually _, has been recognized in two-thirds of cases. Vacuolization of the plasma cells in the marrow is an important clue for the diagnosis of µ-HCD. There is an increase in lymphocytes, plasma cells, and lymphocytoid cells in the marrow. The course of µ-HCD is variable, with a median survival of approximately 2 years. Treatment with corticosteroids and alkylating agents has produced benefit.

Primary amyloidosis (AL)

Amyloid is a substance consisting of fibrils that appear homogeneous and amorphous under the light microscope and stain pink with haematoxylin–eosin. With polarized light, amyloid stained with Congo red produces an apple-green birefringence. Linear, non-branching, aggregated fibrils 7.5- to 10-nm wide and of indefinite length are seen with electron microscopy. These fibrils consist of various proteins such as monoclonal _ or l light chains in AL, protein A in secondary amyloidosis, transthyretin (prealbumin) in familial or senile systemic amyloidosis, and b $_2$-microglobulin in dialysis-associated amyloidosis. Because paraproteins are associated only with primary amyloidosis, the other types are not discussed here.

Aetiology and epidemiology

The annual incidence of AL is 0.9/100 000. The median age at diagnosis is 64 years, and only 1 per cent of patients are younger than 40 years. The cause of AL is unknown.

Clinical features

Weakness, fatigue, and weight loss are the most common initial symptoms. Light-headedness, syncope, change in the tongue or voice, jaw or hip claudication, paraesthesias, dyspnoea, and oedema are the most frequent symptoms. Macroglossia is present in 10 per cent of patients, and purpura, particularly in the periorbital and facial areas, is found in 15 per cent. The liver is palpable in 25 per cent of patients, but splenomegaly occurs in only 5 per cent. Nephrotic syndrome or renal failure is found in more than 25 per cent of patients at diagnosis (Fig. 3). Congestive heart failure, carpal tunnel syndrome, sensorimotor peripheral neuropathy, and orthostatic hypotension are other important features. The presence of one of these syndromes and a paraprotein in the serum or urine are strong indications of AL, for which appropriate biopsy specimens must be taken for diagnosis.

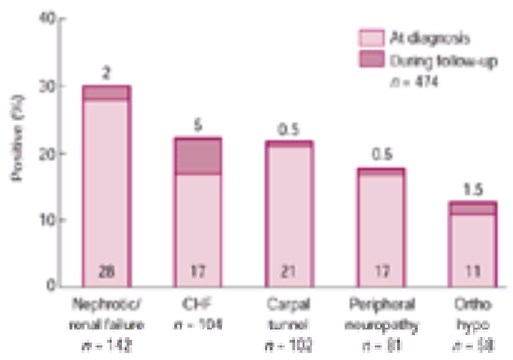

Fig. 3 Frequency of amyloid syndromes at diagnosis of primary systemic amyloidosis. CHF, congestive heart failure; Ortho hypo, orthostatic hypotension. (From Kyle RA and Gertz MA (1995). Primary systemic amyloidosis: clinical and laboratory features in 474 cases. *Seminars in Hematology* **32,** 45–59. By permission of WB Saunders Company.)

Laboratory findings

Anaemia is not a prominent feature of AL and, when present, is usually the result of MM, renal insufficiency, or gastrointestinal bleeding. Thrombocytosis (platelets >500 × 10^9/l) is present in about 10 per cent of cases. Renal insufficiency is present in almost half of patients at diagnosis; 20 per cent have a serum creatinine value of 20 mg/l or more. The serum protein electrophoretic pattern shows a modest localized band or spike in about half of the patients (median, 14 g/l). A paraprotein is found in the serum or urine in 90 per cent of patients, and l light chains are twice as common as _. The bone marrow contains 5 per cent or less plasma cells in almost half of patients. Only one-fifth of patients have more than 20 per cent plasma cells in the bone marrow, but they usually do not have the other features of MM.

An increased serum alkaline phosphatase level is not uncommon. Hyperbilirubinaemia is infrequent, but when present it is an ominous sign. The factor X level is decreased in more than 10 per cent of patients but is rarely the cause of bleeding.

Congestive heart failure is present in about 20 per cent of patients at diagnosis. Electrocardiography frequently reveals low voltage in the limb leads or characteristics consistent with anteroseptal infarction (loss of anterior forces). Arrhythmias, including atrial fibrillation or heart block, are common. Almost two-thirds of patients have an abnormal echocardiogram at diagnosis. Early cardiac involvement is characterized by abnormal relaxation followed by the features of constrictive cardiomyopathy. Amyloid heart disease may closely resemble constrictive pericarditis or hypertrophic obstructive cardiomyopathy. A sensorimotor peripheral neuropathy is present in about 15 per cent of patients at diagnosis. Autonomic dysfunction may be a prominent feature and is often manifested by orthostatic hypotension, diarrhoea, and impotence.

Diagnosis

The diagnosis depends on the demonstration of amyloid deposits. The possibility of AL must be considered in every patient who has a paraprotein in the serum or urine and who has a nephrotic syndrome, congestive heart failure, sensorimotor peripheral neuropathy, carpal tunnel syndrome, giant hepatomegaly, or idiopathic malabsorption syndrome. A paraprotein in the serum or urine or a monoclonal proliferation of plasma cells in the bone marrow occurs in 98 per cent of patients with AL.

The initial diagnostic procedure should be an abdominal fat aspiration, which is positive in about 80 per cent of patients (Fig. 4). A bone marrow aspiration and biopsy should be done to determine the degree of plasmacytosis, and amyloid stains will be positive in more than half of patients. The abdominal fat or bone marrow biopsy is positive in 90 per cent of cases; if negative, a rectal biopsy (including submucosa) or biopsy of a suspected involved organ such as the kidney, liver, heart, or sural nerve is indicated. Specific antisera to _, l, protein A, transthyretin, and b $_2$-microglobulin are useful for identifying the type of systemic amyloidosis. ^{123}I-labelled human serum amyloid-P component is helpful for detecting amyloid deposition.

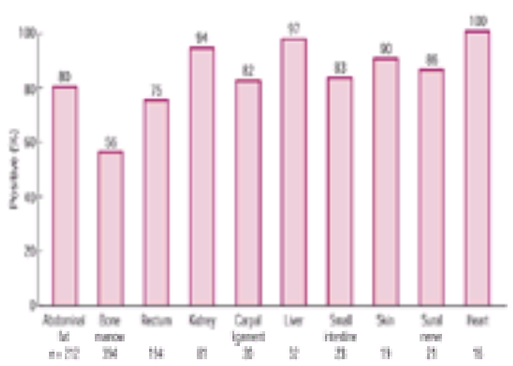

Fig. 4 Diagnosis of amyloidosis on the basis of deposits in tissues. (From Kyle RA and Gertz MA (1995). Primary systemic amyloidosis: clinical and laboratory features in 474 cases. *Seminars in Hematology* **32,** 45–59. By permission of WB Saunders Company.)

Prognosis

The median duration of survival for patients with AL is approximately 13 months. Survival varies greatly depending on the associated syndrome. It is 6 months after the onset of congestive heart failure but more than 2 years in patients presenting with peripheral neuropathy. Almost half of the deaths are due to cardiac involvement.

Treatment

Because amyloid fibrils consist of a monoclonal light chain, treatment with alkylating agents has been a common approach. In a randomized trial, survival of patients receiving the two melphalan–prednisone–containing regimens (17–18 months) was superior to that of patients receiving colchicine (8.5 months). Patients have had substantial clinical improvement after the administration of 4'-iodo-4'-deoxyrubicin (**I-DOX**). This agent appears to bind to the amyloid fibrils and contributes to the resolution of amyloid deposits. Encouraging results have been reported with high-dose intravenous melphalan (100 mg/m ^{2} for 2 days) followed by autologous peripheral blood stem-cell rescue. The impact of this treatment approach needs to be determined because of the short follow-up to date.

This was supported in part by CA 62242 from the National Cancer Institute.

Eosinophilia

Peter F. Weller

Eosinophilia is associated with distinct diseases that include helminth parasitic infections, allergic diseases, and varied diseases of often ill-defined aetiologies. This chapter considers the clinical disorders associated with eosinophilia, with additional information on these diseases available in other chapters and then discusses the idiopathic hypereosinophilic syndrome.

In comparison with other leucocytes, eosinophils are distinguished by their morphologies, constituents, products, and associations with specific diseases. The cytokine interleukin 5 (**IL-5**), specific in promoting the development, differentiation, and release of bone marrow-derived eosinophils, is principally responsible for increases in eosinophilopoiesis. Eosinophils are normally tissue-dwelling cells primarily distributed in those tissues with an epithelial interface with the environment, including the respiratory, gastrointestinal, and lower genitourinary tracts. Eosinophils are distinguished morphologically from neutrophils by their cytoplasmic granules which uniquely contain crystalloid cores visible by electron microscopy. Within these granules are four specific cationic proteins, major basic protein, eosinophil peroxidase, eosinophil cationic protein, and eosinophil-derived neurotoxin. The heavy content of these cationic granule proteins, which bind acidic dyes like eosin, are responsible both for the identifying tinctorial properties of eosinophils and for many of the functional properties of eosinophils. As recently established, eosinophils are sources of over two dozen cytokines; and many, if not all, of these are stored preformed within eosinophil granules. In addition to their content of preformed granule cationic and cytokine proteins, eosinophils also synthesize lipid mediators, including the 5-lipoxygenase pathway-derived eicosanoid, leukotriene C_4. The potential functional roles of eosinophils in parasite–host defence, in the pathogenesis of allergic diseases, and in other immunological responses remain uncertain, due to varied and at times conflicting experimental findings, but are subjects of active ongoing investigations.

Eosinophils normally number less than 450/μl in the blood with a mild diurnal variation, being higher in the morning and falling as endogenous glucocorticosteroid levels rise. Blood eosinophil numbers, however, do not always reflect the extent of eosinophil involvement in affected tissues in various diseases; and at times, as in eosinophilic pneumonias, eosinophils may be recruited into involved tissues without a concomitant increase in enumerable blood eosinophils. Eosinopenia, diminished blood eosinophil levels, occurs with corticosteroid administration and is frequent with active bacterial and viral infections. Thus, even normal blood eosinophil numbers in a febrile patient suggest that an illness is not simply due to a bacterial or viral infection.

Some, but not necessarily all, patients with sustained blood eosinophilia can develop organ damage, especially cardiac, as found in the idiopathic hypereosinophilic syndrome, and patients with sustained eosinophilia should be monitored for evidence of cardiac disease.

Diseases associated with eosinophilia Table 1)

Infectious diseases

Parasitic diseases

Eosinophilia is not elicited by infections with protozoan parasites (with the sole exceptions of the intestinal parasites, *Isospora belli* and *Dientamoeba fragilis*), but rather characteristically by multicellular helminth parasites. Magnitudes of eosinophilia tend to parallel the extent of tissue invasion, especially by helminth larvae. Eosinophilia may be absent in established infections which are well-contained within tissues or are solely intraluminal within the gastrointestinal tract (e.g. *Ascaris*, tapeworms). Even with helminth diseases, superimposed bacterial infections (e.g. in disseminated strongyloidiasis) can suppress expected eosinophilia. In patients with eosinophilia, geographical and dietary histories are pertinent in suggesting potential exposures to helminth parasites. Stool examinations for diagnostic ova and larvae should be obtained. In addition, for several helminth parasites that cause eosinophilia, diagnostic parasite stages are never present in faeces. Hence, negative stool specimens do not necessarily exclude a helminth aetiology for eosinophilia; and examination of appropriate blood or tissue biopsies, as guided by clinical findings and exposure histories, may be needed to diagnose specific tissue- or blood-dwelling infections, including trichinellosis and filarial infections.

Other infectious diseases

The characteristic response in acute bacterial and viral infections is eosinopenia. One fungal disease, coccidioidomycosis, either following primary infection, at times with progressive disseminated disease, or with central nervous system infection (with cerebrospinal fluid eosinophilia), may be associated with eosinophilia.

HIV and retroviral infections

Eosinophilia may be associated with HIV infections: (i) leukopenia may elevate the percentages, but not true numbers, of eosinophils; (ii) adverse reactions to medications may elicit eosinophilia; and (iii) eosinophilia may be due to adrenal insufficiency in patients with AIDS from cytomegalovirus and other infections. In addition, eosinophilia, often modest, is observed in some HIV-infected patients and may accompany eosinophilic folliculitis in HIV infection. Uncommonly, marked hypereosinophilia has developed with HIV infections, including those with a hyperimmunoglobulin E syndrome or exfoliative dermatitis. Eosinophilia frequently develops with HTLV-1 infections.

Allergic and immunological disorders

Common allergic diseases, including allergic rhinitis, asthma, and atopic dermatitis, are accompanied by tissue eosinophil infiltration and usually modest blood eosinophilia. The occurrence of marked blood eosinophilia suggests the presence of other diseases, such as Churg–Strauss vasculitis.

Medication-related eosinophilias

Therapeutic agents, including herbal or 'natural' therapies, can elicit eosinophilia. Eosinophilia may develop without other manifestations of adverse drug reactions, such as rashes or drug fevers. In the absence of organ involvement, blood eosinophilia by itself need not mandate cessation of drug therapy, if such is medically indicated. Drug-induced blood eosinophilia, however, should prompt an evaluation of whether organs, including the lungs, kidneys, and heart, are involved in the eosinophil-associated drug reaction. If organ involvement develops, cessation of drug administration is necessary.

Some cytokines are potential causes of eosinophilia. Granulocyte–macrophage colony-stimulating factor (GM-CSF), but not granulocyte colony-stimulating factor (G-CSF), stimulates eosinophilopoiesis and can cause prominent blood and tissue eosinophilia and, less commonly, eosinophil-associated diseases, including eosinophilic pneumonia and eosinophilic endomyocardial fibrosis. Administration of IL-2 or IL-2-stimulated lymphocytes frequently elicits eosinophilia, most likely due to production of IL-5. Eosinophilic myocarditis and endocardial thrombosis may complicate high-dose IL-2 therapy.

Diverse agents, including many antimicrobial agents and non-steroidal anti-inflammatory agents (**NSAIDs**), may elicit pulmonary eosinophilia. Blood eosinophilia is usually, but not always, present; and if blood eosinophilia is absent, sputum or bronchoalveolar lavage eosinophilia is necessary to help make the diagnosis.

In drug-induced acute interstitial nephritis, eosinophilia is common in the involved kidneys, urine, and at times, the blood. In addition to eosinophilia, fever, rash, and arthralgia support the diagnosis, but these are commonly absent in cases of drug-induced acute interstital nephritis. Agents that elicit acute interstitial nephritis include semisynthetic penicillins, NSAIDs, cimetidine, sulphonamides, ciprofloxacin, and aztreonam. Eosinophiluria is not uniformly present in all with drug-induced interstitial nephritis.

Acute necrotizing eosinophilic myocarditis is a serious but uncommon type of hypersensitivity myocarditis, with reactions to medications, such as ranitidine or penicillin, responsible in some cases. A syndrome of hepatitis with eosinophilia can be a manifestation of drug reactions, including to minocycline, ranitidine, sulpha antibiotics, and trovafloxicin. Other medication-related eosinophilic responses include drug-induced hypersensitivity vasculitis and forms of gastroenterocolitis elicited by medications, including clozapine and NSAIDs. Adverse reactions to contaminated L-tryptophan in 'natural' medications has previously caused a widespread development of the eosinophilia–myalgia syndrome.

Immunological disorders

The hyper-IgE syndrome is characterized by recurrent staphylococcal abscesses of the skin, lungs, and other sites, pruritic dermatitis, hyperimmunoglobulinaemia E, and blood, sputum, and tissue eosinophilia. Eosinophilia is characteristic of Omenn's syndrome, combined immuno-deficiency with hypereosinophilia.

Eosinophil infiltration accompanies rejection of lung, kidney, and liver allografts. Tissue and blood eosinophilia occur early in the rejection process, and eosinophil counts and granule protein levels have correlated with prognosis, severity, and response to rejection therapy.

Myeloproliferative and neoplastic diseases

The hypereosinophilic syndrome is considered below. Eosinophilia may accompany chronic myelogenous leukaemia and the M4Eo subtype of acute myelogenous leukaemia. Blood eosinophils may be elevated in the nodular sclerosing form of Hodgkin's disease. Some patients with carcinomas, especially of mucin-producing epithelial cell origins, have blood eosinophilia. Eosinophilia may accompany angio-immunoblastic lymphadenopathy, mycosis fungoides, Sézary's syndrome, lymphomatoid papulosis, and systemic mastocytosis.

Pulmonary syndromes

Diverse eosinophilic pulmonary syndromes are noted in Table 1.

Skin and subcutaneous diseases

Various cutaneous diseases can be associated with a heightened level of blood eosinophils (Table 1). In episodic angio-oedema with eosinophilia, recurrences are marked by prominent blood eosinophilia, significant angio-oedema, at times with excessive weight gain due to fluid retention, and less frequently by fever.

Gastrointestinal diseases

Eosinophilia is common with eosinophilic gastroenteritis, and tissue eosinophils are found in inflammatory bowel diseases and collagenous colitis.

Rheumatological diseases

The principal eosinophil-related vasculitis is the Churg–Strauss syndrome. Cutaneous necrotizing eosinophilic vasculitis with hypocomplementaemia and eosinophilia, a distinct vasculitis of small dermal vessels which are extensively infiltrated with eosinophils, may occur in patients with connective tissue diseases. Eosinophilia may uncommonly accompany rheumatoid arthritis itself but is more commonly due to adverse reactions to medications or concomitant vasculitis.

Endocrine diseases

Loss of normal adrenoglucocorticosteroid production causes increased blood eosinophilia.

Other disorders

The syndrome of atheromatous cholesterol embolization can be associated with eosinophilia and eosinophiluria. Uncommonly, kindreds with hereditary eosinophilia have been recognized. Irritation of serosal surfaces, as in eosinophilic pleural effusions and peritoneal, and at times blood, eosinophilia developing during chronic peritoneal dialysis, can be associated with eosinophilia.

Idiopathic hypereosinophilic syndrome

Eosinophilia may be associated with a variety of clinical disorders, including common allergic diseases, infections with helminthic parasites, and obvious neoplastic disease. However, in other patients eosinophilia that is pronounced, prolonged, and not associated with identifiable aetiologies has been classified as the idiopathic hypereosinophilic syndrome (HES), in which the heart is the most commonly affected organ due to the development of endomyocardial damage. With time, however, it has become clear that HES includes a clinically heterogeneous and aetiologically diverse group of eosinophilic disorders, with clonal abnormalities in T lymphocyte subsets or eosinophils themselves recognized in some HES patients. Thus, there is a range of syndromes that present with hypereosinophilia and may share some clinical features: as yet these are not fully delineated or differentiated.

Definition

HES is increasingly recognized not to be a single entity but rather a constellation of leucoproliferative disorders, each characterized by sustained overproduction of eosinophils. The three original defining criteria for this syndrome, identified by Chusid and colleagues, need to be expanded to encompass increasing clinical experience with varied eosinophilic syndromes. Contemporary criteria include:

1. Eosinophilia in excess of 1500/μl of blood, persisting for longer than 6 months.
2. Lack of an identifiable parasitic, allergic, or other aetiology for eosinophilia. Thus, varied eosinophil-associated diseases need to be sought and excluded. Amongst the potential parasitic aetiologies of eosinophilia it is especially important to exclude *Strongyloides stercoralis*, which may persist for decades and be difficult to diagnose solely by stool examinations, not only because of its capacity to cause marked eosinophilia mimicking HES, but also because it, unlike other helminthic causes of marked eosinophilia, can develop into a disseminated, often fatal, disease (hyperinfection syndrome) in patients given immunosuppressive corticosteroids.
3. Absence of other idiopathic eosinophilic syndromes clinically distinct from HES. This criterion was not included in the initial analysis of HES, but is needed to help exclude several other defined eosinophilic syndromes whose aetiologies remain unknown. These would include Churg-Strauss vasculitis (see Chapter 17.11.5) as well as syndromes that involve only limited organ systems (e.g., eosinophilic gastroenteritis, eosinophilic pneumonias) and do not have a propensity to cause eosinophil-associated damage to tissues outside their primary target organs. By this criterion, the syndrome of episodic angioedema with eosinophilia would be distinguished from HES.

4. Evidence by symptoms and signs of organ involvement. Not all patients with prolonged eosinophilia develop organ involvement and many have benign courses. These patients are often not reported or subjected to evaluation at referral centres due to the absence of eosinophil-associated disease. Blood eosinophilia *per se* does not warrant therapy in the absence of evidence of concomitant organ involvement.

Aetiology

The current diagnostic criteria for HES encompass a diversity of eosinophilic disorders of varying, and as yet often unknown aetiologies. Clonal abnormalities in the eosinophil lineage have been detected uncommonly: these are based on analyses of X-linked polymorphisms and hence applicable only to the minority of women with HES, but they do indicate that in some patients HES may be a manifestation of chronic eosinophilic leukaemia. Some patients with HES develop blast crises similar to those of chronic myelogenous leukaemia, or they evolve into chronic myelogenous leukaemia-like diseases. Included in the differential diagnosis of neoplastic causes of eosinophilia are chronic myelogenous leukemia with eosinophilia, the M4EO variant of acute myelogenous leukaemia, and acute lymphocytic leukaemia with eosinophilia. Some patients with the typical clinical and haematological features of HES have subsequently developed T cell lymphomas or acute lymphoblastic leukaemia. However, chromosome studies are normal in most patients with HES, with abnormal findings in only 1 of 18 in a British series and 8 of 33 patients at the National Institutes of Health.

Other potential aetiologies for HES might include dysregulated production of eosinophilopoietic cytokines, such as interleukin 5 (IL-5), IL-3, or granulocyte-macrophage colony stimulating factor (GM-CSF). In some patients with HES the disorder has been correlated with either clonal expansions of $CD3^{-}CD4^{-}$ or $CD4^{-}CD3^{+}CD8^{+}$ Th2-like lymphocytes, or other aberrant T cells or NK cells elaborating IL-5. A case with eosinophilia associated with polyclonal expansion of activated $CD3^{+}$ T cells expressing NK cell markers (CD16 and CD56), associated with IL-2 and IL-15 overproduction, has been reported. In other eosinophilic patients, however, it appears that overproduction of IL-5 is not solely responsible for the eosinophilia. In a kindred with autosomal dominant inheritance of eosinophilia, studies mapped the gene close to, but not involving the IL-3, IL-5, and GM-CSF genes, on chromosome 5q31-q33, suggesting an unidentified gene may regulate eosinophil production. However, for most patients with HES the aetiology of the eosinophilia is not currently understood.

Clinical features

HES is more common in men than women (9:1) and tends to occur between the ages of 20 and 50, although cases have developed in children. The initial manifestations may be due to sudden cardiac or neurological complications, but tend to be more insidious and present over months or longer. Eosinophilia may be detected only incidentally. Other frequent presenting symptoms include tiredness, cough, breathlessness, muscle pains, angioedema, rash, sweating, pruritus, or retinal lesions. Patients with HES do not exhibit a propensity to bacterial or other infections. Weight loss and cachexia are not usually seen. Some patients experience alcohol intolerance with abdominal pain, flushing, nausea, or diarrhoea.

Haematological manifestations

The defining haematological abnormality is sustained eosinophilia. Total leucocyte counts are usually less than 25 000/µl, with between 30 and 70 per cent eosinophils, but extremely high leucocyte counts (>90 000/µl) develop in some patients and are associated with a poor prognosis. Eosinophils in the blood may be mature or less commonly can include numbers of eosinophilic myeloid precursors. Eosinophils often exhibit morphological abnormalities including diminished granule numbers, cytoplasmic vacuolization, and nuclear hypersegmentation. At the ultrastructural level there may be loss of granule contents, either of the crystalline core or matrix of specific granules, fewer and smaller specific granules, increased tubulovesicular structures, and increases in cytoplasmic lipid bodies.

Although not often emphasized, many patients with HES will have an absolute neutrophilia along with their eosinophilia, further contributing to elevations in the white blood cell count. Band forms and less mature neutrophilic precursors may be present in the peripheral blood. Leucocyte alkaline phosphatase levels may be abnormally elevated or decreased. Serum vitamin B_{12} and vitamin B_{12} binding proteins may be normal or elevated. Anaemia is present in about 50 per cent of patients.

Bone marrow findings demonstrate increased numbers of eosinophils, often 30 to 60 per cent, with a shift to the left in eosinophil maturation. Increased numbers of myeloblasts are not usually seen. Myelofibrosis is encountered in a minority of patients. Splenomegaly is found in about 40 per cent of cases.

Cardiac manifestations

In HES, the heart is the most commonly affected organ due to the development of endomyocardial damage leading to a restrictive cardiomyopathy. This distinct form of cardiac involvement may also complicate other varied diseases marked by sustained eosinophilia, including Churg-Strauss vasculitis, eosinophilic leukaemia, eosinophilia with carcinomas or lymphomas, eosinophilia from GM-CSF or IL-2 administration or drug-reactions, and eosinophilia from helminthic infections such as trichinosis, visceral larva migrans, and filariasis. However, many patients with eosinophilia do not develop any evidence of endomyocardial damage; hence in addition to increased numbers of eosinophils, the pathogenesis of eosinophil-mediated cardiac damage probably involves some, as yet ill-defined, activating events that promote eosinophil-mediated endomyocardial damage. Patients with sustained eosinophilia should be monitored by echocardiography for evidence of cardiac disease.

Cardiac damage progresses through three stages, the first involving acute necrosis in the early weeks, the second involving the development of endocardial thrombi over many months, the final stage being the fibrotic stage after a couple of years of disease.

The risks of developing cardiac disease in two series of patients with HES were not related to the extent of eosinophilia or duration of disease. Those who developed evident cardiac disease were more likely to be male and to have splenomegaly, thrombocytopenia, elevated levels of vitamin B_{12}, hypogranular or vacuolated eosinophils, and abnormal early myeloid precursors in their blood. HES patients free of cardiac disease tended to be female and have angio-oedema, hypergammaglobulinaemia, and elevated serum levels of IgE.

Neurological manifestations

Neurological complications may be of three types. The first type is due to thromboemboli originating from the left ventricle, which may occur before cardiac disease is demonstrable by echocardiography and can be the presenting manifestation of HES. The second type of neurological disease is primary central nervous system dysfunction, presenting as an encephalopathy including changes in behaviour, confusion, ataxia, and memory loss, and exhibiting upper motor neurone signs with increased muscle tone, deep tendon reflexes, and a positive Babinski. Impaired cognitive abilities may persist for months. The pathological basis for this form of diffuse central nervous system disease remains unknown. Peripheral neuropathies constitute the third type of neurological dysfunction. Symmetric or asymmetric polyneuropathies manifest by sensory deficits, painful paraesthesiae, or mixed sensory and motor deficits are most common, but mononeuritis multiplex occurs with HES, as do radiculopathies and muscle atrophy due to denervation. Biopsies of affected nerves generally show an axonal neuropathy with varying degrees of axonal loss and no evidence of vasculitis or contiguous eosinophil infiltration.

Cutaneous manifestations

The skin is one of the most frequently involved organs, with cutaneous manifestations occurring in more than 50 per cent of patients. The most common skin manifestations are of two types, either angio-oedematous and urticarial lesions, or erythematous, pruritic papules and nodules. Patients who experience angio-oedema and urticaria are likely to have benign courses without cardiac or neurological complications and either do not require systemic therapy or respond to prednisone alone. Some patients with angio-oedema and eosinophilia are now recognized to have a syndrome, episodic angio-oedema and eosinophilia, that is distinct from HES. Particularly incapacitating mucocutaneous manifestations of HES are mucosal ulcers that may occur in the mouth, nose, pharynx, penis, oesophagus, stomach, and anus. Biopsies demonstrate only a non-specific mixed cellular infiltrate without a prominence of eosinophils and no evidence of vasculitis or microthrombi.

Pulmonary manifestations

Pulmonary involvement is reported in about 40 per cent of HES patients, the commonest respiratory symptom being a chronic, persistent, generally non-productive cough. The basis for this may be sequestration of eosinophils in pulmonary tissues, although most symptomatic individuals have clear chest radiographs. As noted by

Spry, asthma is rare in patients with HES.

Pulmonary involvement in HES may be secondary to congestive heart failure, pulmonary emboli originating from right ventricular thrombi, or primary infiltration of the lungs by eosinophils. Infiltrates may be diffuse or focal without a predilection for any region of the lungs, in contrast to the often peripheral infiltrates in chronic eosinophilic pneumonia (see Chapter 17.11.9). Pulmonary fibrosis may develop over time, especially in those with cardiac fibrosis.

Ocular manifestations

Patients with HES can experience visual symptoms, most commonly blurring. Even in those without visual symptoms, fluorescein angiography demonstrates that over 50 per cent of HES patients have choroidal abnormalities, including patchy and delayed filling, and retinal vessel abnormalities.

Rheumatological manifestations

Arthralgias, large joint effusions, cold-induced Raynaud's phenomenon, and digital necrosis of fingers or toes can occur with HES. Although myalgias are frequent, focal myositis or polymyositis occur only uncommonly.

Digestive system involvement

Gastrointestinal tract involvement can accompany HES, and 20 per cent of patients at some time may have diarrhoea. Eosinophilic gastritis, enterocolitis, or colitis may be present. Pancreatitis and sclerosing cholangitis occur rarely. Hepatic involvement with HES includes chronic active hepatitis and the Budd-Chiari syndrome from hepatic vein obstruction.

Diagnosis

There are no specific diagnostic tests for HES. Other diseases associated with eosinophilia need to be excluded. Bone marrow and chromosomal analyses should be performed, and phenotypic studies of blood lymphocyte subsets should be considered. IgE levels should be ascertained. Echocardiography is indicated to search for evidence of endocardial thrombi or fibrosis.

Treatment

For those eosinophilic patients without organ damage, no therapy need be administered. There is no clear threshold value of blood eosinophilia that predicts organ involvement or damage. For those requiring therapy, prednisolone is the initial agent, administered at 60 mg/day in adults. Those more likely to respond to this treatment alone are patients with angio-oedema, urticaria, or elevated serum IgE levels, and also those who experience prolonged eosinopenic responses to single doses of prednisolone. Patients less likely to respond include those with splenomegaly and those with cardiac or neurological dysfunction at the time of presentation. For those not responsive to prednisolone, daily hydroxyurea is one option, but increasing the currently preferred therapy for HES is interferon-a (1–10 million units/day or 3 times a week).

Medical management of cardiac complications, including arrhythmias and congestive heart failure, are important and effective measures in the longer-term management of HES, as is surgical replacement of damaged valves. Although early reports emphasized the mortality due to this disorder, many of the deaths were due to congestive heart failure and complications of endomyocardial damage. If the sequelae of organ damage, especially to the heart, can be managed, the hypereosinophilic syndrome can have a prolonged course in many patients.

Histiocytoses

D. K. H. Webb

Introduction

The histiocytoses are characterized by the infiltration of affected tissues with cells of monocyte/macrophage lineage. A classification subdividing the disorders into three classes has been proposed (Table 1). However, the boundaries between classes I and II may be blurred, and more than one class of disorder may be present in the same child.

Aetiology and epidemiology

Histiocytes are of bone marrow origin, derived by the migration and differentiation of blood monocytes, although local proliferation in the tissues may occur following contact with antigen, and in disease states. Growth and differentiation are controlled by haemopoietic growth factors produced by bone marrow stromal cells, fibroblasts, macrophages, and lymphocytes.

Normal histiocytes are divided into two subgroups: (1) dendritic cells (Langerhans' cells, dendritic reticulum cells, and interdigitating reticulum cells); and (2) macrophages. Langerhans' cells are normally found in the epidermis, the mucosa of the bronchial tree, in lymph nodes, and in thymus. Characteristic features include the expression of the CD1a surface antigen, and the presence of specific cytoplasmic organelles (Birbeck granules). These arise either by invagination of the surface membrane during endocytosis of antigen, or as secretory organelles derived from the Golgi apparatus. CD1a has considerable homology with HLA class I molecules and may have a role in antigen presentation to T cells. Following stimulation by antigen, Langerhans' cells migrate to lymph nodes, where they present antigen to T cells. Dendritic and interdigitating reticulum cells are localized to lymph nodes, where they present antigen to B and T cells, respectively.

Macrophages occur widely throughout the tissues where they have multiple functions in the immune response, wound healing, bone remodelling, haemopoiesis, haemostasis, the secretion of inflammatory cytokines, phagocytosis of particulate matter/antigens, and the release of proteases, antiproteases, and arachidonate metabolites.

Classification

Class I disorders

Langerhans' cell histiocytosis (LCH)

The term 'Langerhans' cell histiocytosis' has been widely adopted to replace the diagnosis 'histiocytosis X', following the recognition that the presence of Langerhans' cells is characteristic of lesions in the disorder. LCH is rare and can occur at any age, although there is a paucity of epidemiological data regarding the disease in adults. It affects 4 per million children each year, with a peak incidence between 1 and 3 years of age, and is considered to be a reactive disorder resulting from immune activation. Searches for potential triggers have been unsuccessful. There is no evidence for a viral aetiology. High levels of cytokines have been demonstrated both in lesions and in the serum of children with multisystem disease. Two studies of X-linked DNA polymorphisms have demonstrated clonality in lesional Langerhans' cells, but these data do not define LCH as a neoplastic disorder. Clonality has been demonstrated in a variety of non-neoplastic disorders. There is a recognized association between LCH and malignancy. A literature review revealed details of 87 LCH-associated malignancies—39 lymphomas, 22 acute leukaemias, and the remainder solid tumours, including secondary tumours arising within fields of previous irradiation. Amongst 341 children registered in two large international treatment trials, the incidence of secondary malignancy was 1 per cent.

Juvenile xanthogranuloma

Juvenile xanthogranuloma usually presents with single or multiple yellow–red skin lesions in newborns and infants—in one series, the median age at presentation in 36 children was 0.3 years (range from birth to 12 years). Histology shows a cutaneous accumulation of lipid-filled macrophages, Touton giant cells, and fibroblasts. Extracutaneous disease may occur in about 10 per cent of patients involving the CNS, liver, spleen, lung, eye, oropharynx, and muscles.

Class II disorders

Haemophagocytic lymphohistiocytosis (HLH)

This is a rare disorder with typical histology showing tissue infiltration by lymphocytes and macrophages, some manifesting haemophagocytosis (Fig. 1 and Plate 1). It appears likely that HLH is due to the abnormal function of T lymphocytes. Tissue infiltrates and haemophagocytosis is probably due to the dysregulated secretion of cytokines, rather than by a primary disorder of macrophages. The disorder occurs in primary and secondary forms. Primary HLH is an autosomal recessive disorder with an incidence of between 1 and 2 cases per million children each year in the United Kingdom and Sweden. Linkage studies indicate the involvement of at least three genes. In about 20 per cent of cases there is a history of previously affected siblings (familial HLH). Parental consanguinity or onset in early infancy are further supportive features.

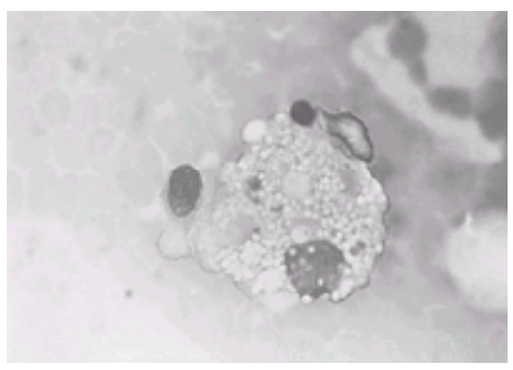

Fig. 1 Macrophage exhibiting haemophagocytosis in the bone marrow of a child with haemophagocytic lymphohistiocytosis. (See also Plate 1.)

Secondary HLH is at least as common as primary disease. Precipitants include viral, bacterial, fungal, or protozoan infections, often in an immunocompromised host. Other precipitants include malignancy, particularly T-cell lymphoproliferative states, autoimmune diseases, and lipid infusions.

Criteria for the diagnosis of HLH are shown in Table 2, although not all features are present in every case. The tissues which are most frequently sampled to substantiate the diagnosis are bone marrow, lymph node, and liver, although fine-needle aspiration of the spleen is reported to have a high diagnostic yield. Diagnostic changes may be difficult to demonstrate, and the bone marrow in particular is hypercellular and reactive in the early stages of the disease. Haemophagocytosis may not be a feature on liver biopsy, but there may be prominent sinusoidal Kupffer cells and lymphoid portal infiltrates similar to those seen in chronic persistent hepatitis.

Sinus histiocytosis with massive lymphadenopathy

This disease was described in 1969 by Rosai and Dorfman as a syndrome of cervical lymphadenopathy with typical histology showing preserved lymph node structure, dilated lymph node sinuses containing mixed inflammatory cells, with vacuolated macrophages manifesting haemophagocytosis and emperipolesis of lymphocytes (that is, a process whereby lymphocytes move straight through the cytoplasm of cells). Fibrosis may be marked. Although most cases are isolated, it has occurred in individuals with malignancy, autoimmune diseases, or other histiocyte disorders, especially LCH.

Class III disorders

Acute myelomonocytic and acute monocytic leukaemia account for 30 per cent of cases of acute myeloid leukaemia. Considerable controversy exists regarding other malignancies of the monocyte/macrophage system, due to difficulties in nosology. Malignant histiocytosis was described as a clinical picture of lymphadenopathy, hepatosplenomegaly, fever, wasting, and pancytopenia, with histology showing tissue infiltration by large cells with copious cytoplasm and irregular nuclei. However, recent studies of cell lineage in such cases indicate that the majority of these tumours are in fact of lymphoid origin, and reclassifiable as anaplastic large-cell (Ki 1-positive) lymphomas. Accordingly, true 'malignant histiocytosis' is an extremely rare entity, requiring careful pathological assessment to substantiate the diagnosis. Both localized and disseminated malignancies of dendritic cells occur, although these are extremely rare.

Clinical features

LCH

Some 60 per cent of children with LCH have single-system disease of skin or bone. The remaining 40 per cent have multisystem disease affecting two or more organ systems. There are inadequate data regarding the patterns of disease in adults, although lung involvement appears common, perhaps due to the association with smoking (see below). However, it is clear that adults may manifest a similar pattern of disease to that seen in childhood.

Skin

The skin rash comprises red or yellow-brown papules to the trunk, erythema in skin folds and behind the ears, and scaling, particularly affecting the scalp. Rarely, young infants manifest a vesicular rash, similar to varicella, which may be present at birth.

Ears

Ear discharge is a classic sign, and may be due either to skin involvement in the external auditory canal, or bone destruction around and in the middle ear, with polyp formation. Such destructive lesions may result in hearing loss, and formal ENT assessment is essential.

Bone

Bone lesions may be occult, but present clinically with pain and soft tissue swelling. They are best seen on plain radiographs as irregular lytic areas sometimes with marked periosteal reaction, most commonly affecting the skull and long bones (Fig. 2). There may be pathological fractures. Involvement of the axial skeleton may result in vertebral collapse and vertebral plana, although spinal cord compression is rare. Orbital disease may cause proptosis, a classical feature, but visual impairment is unusual.

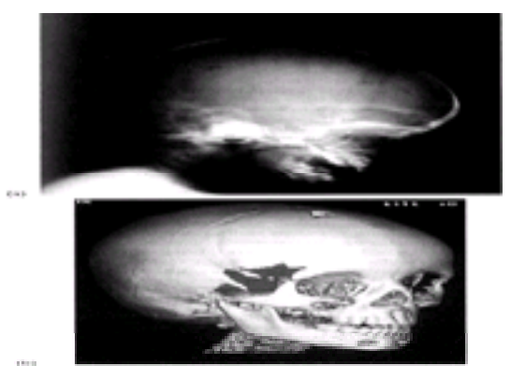

Fig. 2 Plain radiograph and 3D computed tomography scan showing bone lesions of Langerhans' cell histiocytosis in the skull.

Diabetes insipidus

Diabetes insipidus due to involvement of the hypothalamus and pituitary stalk is most common in multisystem disease, reaching 40 per cent in some series. Other risk factors include skull lesions, especially of the orbits or parietal bones. Magnetic resonance imaging (**MRI**) may demonstrate thickening of the pituitary stalk, a suprasellar mass, and/or loss of the posterior pituitary bright signal on *T*2-weighted images due to the absence of vasopressin. Once true diabetes insipidus is established it is irreversible.

Lungs

Lung disease occurs in one-third of children with multisystem disease but is very rare as a single site, it is characterized by cough, chest pain, and tachypnoea, with diffuse micronodular shadowing on chest radiograph. Progression to cyst formation and a honeycomb lung appearance occurs, and hypoxia, pleural effusions, and pneumothorax may occur in advanced disease. Amongst adults, tobacco smoking is a risk factor for pulmonary disease. There may be doubt as to the cause of pulmonary signs, but the diagnosis can be confirmed, and infection excluded, by bronchoalveolar lavage or lung biopsy. As Langerhans' cells are normally present in the bronchial tree, over 5 per cent CD1a-positive cells should be present in lavage fluid to support the diagnosis.

Liver

Hepatomegaly and elevated transaminases may occur without evidence of liver infiltration on biopsy. Jaundice may result from obstruction of the biliary tract by enlarged portal nodes, and therefore is not necessarily diagnostic of liver dysfunction. These provisos emphasize the need for careful assessment of the methods used for clinical findings and of the investigation results in the initial evaluation. Severe liver disease may result in fibrosis, sclerosing cholangitis, and hepatic failure.

Bone marrow and blood

A low haemoglobin due to anaemia of chronic disease is a common finding in active disease. Iron deficiency should be excluded in children with microcytosis and hypochromia. Pancytopenia due to secondary bone marrow infiltration by macrophages and haemophagocytosis may occur. CD1a-positive cells may be demonstrated with monoclonal antibodies by flow cytometry or by the alkaline phosphatase/antialkaline phosphatase technique on slides, but their significance is unclear. Pancytopenia associated with liver disease and splenomegaly carries a poor prognosis.

Gut

Gut involvement with vomiting, diarrhoea, malabsorption, and protein-losing enteropathy occurs in under 5 per cent of children, and requires full investigation, including adequate biopsy. Although infiltrates may be seen in the mucosa and submucosa, biopsy of the muscle wall may be required. Barium studies may reveal alternate dilated and stenotic segments throughout the intestine. Mandibular and maxillary disease may result in floating teeth, and there may be gingivitis and buccal ulceration.

Central nervous system

Disease in the central nervous system, excluding diabetes insipidus, occurs in around 4 per cent of cases, and typically affects the cerebellar and cerebral white matter, with ataxia, dysarthria, nystagmus, and cranial nerve palsies. CNS disease usually develops around 5 years from the original presentation. The mechanism of CNS disease is unknown. Most cases occur in individuals with multisystem disease, but also in the setting of single-system bone disease especially of the skull, and in children with diabetes insipidus. On imaging, several patterns are seen:

- poorly defined changes in the white matter of the cerebellum, cerebrum, and basal ganglia—biopsy in these cases shows perivascular and parenchymal infiltrates of macrophages and lymphocytes associated with oedema and demyelination;
- well-defined lesions in the white and grey matter;
- hypothalamic–pituitary involvement including suprasellar masses;
- extraparenchymal masses, generally not in continuity with skull lesions, which on biopsy comprise xanthomatous histiocytes, lymphocytes and Touton giant cells similar to those found in juvenile xanthogranuloma.

Lymph nodes

Lymphadenopathy occurs in both single- and multisystem disease, and may be gross. Local pressure effects may cause obstruction of the airways, vasculature, or biliary tree, and discharging sinuses may form to the overlying skin. Involvement of the thymus may be detected on chest radiography, and may be present on tissue examination even without enlargement of the organ.

HLH

Clinical manifestations include fever, splenomegaly, hepatomegaly, lymphadenopathy, pancytopenia, abnormal liver function, coagulopathy, and signs and symptoms referable to the central nervous system. Occasionally CNS involvement has been the only evidence of disease at presentation. Initial blood changes may show anaemia or thrombocytopenia, with the development of pancytopenia as the disease progresses. Other features include high fasting triglyceride levels, low fibrinogen, mononuclear pleocytosis and increased protein in the cerebrospinal fluid, high serum ferritin, and reduced or absent natural killer-cell function. Many of these changes result from immune activation with cytokine production. Involvement of the central nervous system varies from asymptomatic cerebrospinal fluid pleocytosis (usually to moderate levels comprising lymphocytes and macrophages) to symptomatic disease with encephalitis, abnormal head movements, fits, cranial nerve palsies, ataxia, regression of developmental milestones, and coma. In children who have died with CNS disease, histology of the brain shows oedema, softening and destruction of tissue, perivascular, parenchymal, and leptomeningeal infiltrates, with necrosis and destruction, especially of white matter.

Sinus histiocytosis with massive lymphadenopathy (SHML)

The lymphadenopathy may be gross. It is often painless, and may wax and wane with time. Involvement of cervical lymph nodes is present in most cases, but other groups are affected, either jointly or alone. Extranodal disease of the head and neck or a variety of other sites is present in almost half of cases, either alone or in association with lymphoid masses. Other features of SHML include: systemic ill health with fever and weight loss; destructive infiltrates in skin, bone, and other extranodal sites; hypergammaglobulinaemia; an elevated erythrocyte sedimentation rate; reactive leucocytosis; and immune dysfunction including autoimmune anaemia and neutropenia.

Management of histiocyte disorders

LCH

Initial work-up requires confirmatory biopsy and an accurate assessment of the extent of disease. Identification of Langerhans' cells within the lesional inflammatory cell infiltrate, with demonstration of either the CD1a surface antigen on immunohistochemistry or the presence of Birbeck granules on electron microscopy, is recommended. Thorough physical examination and investigations are required to determine the extent of disease, and investigations must include a full blood count, liver function tests, serum albumin, a coagulation screen, paired urine and plasma osmolalities, and skeletal survey by plain radiographs. Further investigations should be guided by the need to explain specific symptoms and signs. It is important to carefully assess the function of affected organs, as dysfunction carries prognostic significance (see below).

The majority of cases of LCH eventually resolve spontaneously. No therapy is uniformly effective. Approaches to treatment have varied, with particular controversy regarding the role of chemotherapy for children with multisystem disease. Deaths occur in 10 to 15 per cent of cases, and are largely restricted to children with organ dysfunction. For most cases the primary objectives are control of symptoms, and limitation of long-term disability, which affects 50 per cent of those with extensive disease. For children with skin disease requiring therapy, topical application of corticosteroids may prove beneficial. For those with more severe skin involvement, topical mustine has proved highly effective—in one study rapid improvement within 10 days occurred in each of 16 children, with complete healing in 14. Some children require systemic therapy. Oral corticosteroids result in improvement in over half of cases. Bone lesions may resolve following biopsy, but further local therapies include curettage or injected steroids. Radiotherapy is now uncommon due to concerns over late effects—in particular, secondary malignancies have been described within the radiation field. Systemic therapy is indicated for children with multifocal bone disease (30 per cent of all children with bone disease), or single, symptomatic lesions unsuitable for local therapy. Indomethacin may be effective, but it is unclear whether the drug provides more than symptomatic relief. Further lesions and reactivations of initially responding lesions develop in up to one-third of patients.

Children with multisystem disease may be managed conservatively with systemic therapy reserved for those who have organ dysfunction, pain, systemic upset, or failure to thrive. This issue is controversial. There are claims for better results if initial treatment employs relatively intensive chemotherapy, especially in regard to response rates and late effects. There is no evidence that a more-intensive therapy reduces the 40 per cent mortality rate in children with organ dysfunction. For children who require systemic treatment, the accepted agents are prednisolone, vinblastine, and etoposide in varying combinations. The uncertainty regarding the most effective and least toxic approach to treatment, together with the rarity of LCH, emphasizes the need for international collaborative randomized studies. Hepatic failure due to LCH has been successfully treated by orthoptic liver transplantation—80 per cent of children reported in the literature were alive at a median follow-up of 3 years. For children who fail first-line treatment, further options are limited. There is little evidence that immune modulation with cyclosporin or antilymphocyte globulin, or bone marrow transplantation are effective. Responses have been obtained with cladribine (2-chlorodeoxyadenosine). Further studies are underway.

LCH is associated with a wide range of potential late effects, particularly skeletal deformity and dysfunction, diabetes insipidus, growth hormone deficiency, ataxia,

intellectual impairment, and lung and liver fibrosis. These data stress the need for therapeutic trials to include standardized assessments for late effects which can be compared between treatments.

Juvenile xanthogranuloma

Spontaneous resolution is usual, and no treatment has been proven to be undoubtedly beneficial. Excision may be indicated for lesions resulting in complications.

Class II disorders

HLH

It can be difficult to determine whether a patient has primary or secondary disease, particularly in children with evidence of recent viral infection. Amongst 93 children with HLH reported to the Histiocyte Society registry, there was no difference in outcome between 40 children with and 53 children without evidence of viral infection. These data emphasize the overlap between these disorders, and the need for circumspection in determining the best approach to therapy in each case.

There are two standard approaches to treatment for primary HLH, one using etoposide and corticosteroids, and the other antithymocyte globulin, corticosteroids, and cyclosporin. Around 80 per cent of patients respond, but eventual disease recurrence is usual in primary HLH unless the child receives an allogeneic bone marrow transplant. Inadequate disease control, or reactivation, may also occur in some secondary cases. These children should then be treated in line with strategies for primary disease. Adequate control of CNS involvement is very important, but the role of routine intrathecal methotrexate in the control of CNS disease is controversial. Cranial radiation is no longer recommended. Experience with bone marrow transplantation is greatest using matched sibling donors, with around 80 per cent of children remaining disease-free. Increasing use of alternative donors, including matched and mismatched unrelated donors has demonstrated that similar results may be achieved by this approach. Full engraftment following transplantation is not a prerequisite for cure, as low levels of donor T cells may provide adequate disease control. A particular worry regarding the use of a sibling donor is that in familial disease there is a 25 per cent risk that the donor will also develop HLH. Continued improvement in the results of alternative donor procedures may make these the treatment of choice. It must also be remembered that some children, usually sporadic cases aged over 2 years at diagnosis, remain well following initial therapy. Bone marrow transplantation is not indicated for this group.

Case reports regarding the prognosis for secondary HLH are conflicting. The appropriate approach for these patients is treatment of the associated condition or removal of immunosuppression, with specific HLH therapy for individuals who fail to improve.

Sinus histiocytosis with massive lymphadenopathy

The natural history of the disorder is chronic with spontaneous resolution over months or years in many cases, although approximately 5 per cent of patients have died due to immune-mediated organ dysfunction, amyloidosis, or infection. Few individuals have died directly due to lymphohistiocytic infiltrates. Therapy with steroids, cytotoxic drugs, particularly vincristine and alkylating agents, or radiotherapy has been variably effective, and is unnecessary in most cases.

Class III disorders

The outlook for monocytic variants of AML has improved considerably over recent years, with around a 50 per cent survival at 5 years from diagnosis in children and young adults following standard chemotherapy regimens. The uncertainty over the pathology of reported cases of malignant histiocytosis clouds the issues regarding therapy. It appears appropriate to treat malignancies of macrophages with AML chemotherapy. Due to the rarity of dendritic-cell malignancies, treatment recommendations are anecdotal, but based on excision with or without adjuvant therapy.

22.5.1 Erythropoiesis and the normal red cell

Anna Rita Migliaccio and Thalia Papayannopoulou

Introduction

Mature circulating red cells are specialized cellular elements of the blood responsible for both the delivery of oxygen to and for the removal of carbon dioxide from all tissues of the body. In the adult, their number is constantly maintained by the balance of two ongoing processes: the destruction of old red cells, mainly in the spleen; and the generation of new red cells within the bone marrow by a process referred to as erythropoiesis.

The generation of new red cells, like other cellular elements, is accomplished through a complex interplay between haemopoietic cells, stromal cells, and the extracellular matrix within the bone marrow microenvironment. Unique to the erythropoietic process is its regulation not only by growth factors produced *in situ* in the bone marrow, but also by circulating erythropoietin (**EPO**), a true 'hormone' produced by the kidneys in the adult. Positive or negative alterations of erythropoietin production, whether acquired or congenital, and/or of its signalling pathway, result in quantitative changes in red cell production—that is to say, anaemia or erythrocytosis.

This chapter will summarize key biological features of normal human erythropoiesis, both in the adult and during embryonic/fetal life, and highlight pathogenetic mechanisms that can lead to perturbations of erythropoiesis.

The erythroid compartment

Erythropoiesis is a highly regulated, multistep process through which 10^{11} functional red cells are generated daily from very few haemopoietic stem cells (1:10^{4}–10^{5} marrow cells). Stem cells, after a series of amplification divisions, generate multipotential progenitor cells, then oligo- and finally unilineage erythroid progenitors, which give rise to morphologically recognizable erythroid precursors and mature red cells (Fig. 1).

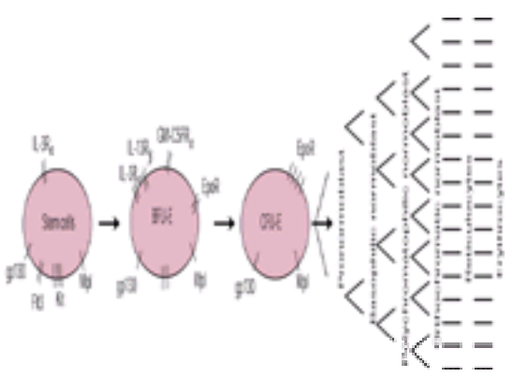

Fig. 1 Adult erythroid progenitor- and precursor-cell compartments. The number of bars on the cell surface is an estimate of the growth factor-receptor concentration/cell responsiveness during erythroid differentiation. A complex of interleukin-6 (**IL-6**) and its soluble receptor (or a fusion molecule called hyper IL-6) may induce growth of burst-forming units-erythroid (**BFU-e**) and erythroid maturation in the absence of exogenously added erythropoietin through activation of an autocrine erythropoietin loop.

Erythroid progenitors

Progenitor cells committed to a specific lineage are defined by their ability to generate colonies of differentiated cells *in vitro*. In these assays, multipotential progenitors generate colonies consisting of cells of several lineages, whereas unilineage cells give rise to colonies of only one lineage. The earliest erythroid progenitor is the burst-forming unit-erythroid (**BFU-e**), which generates colonies containing several thousand erythroid cells. The colony-forming unit-erythroid (**CFU-e**) generates smaller colonies that mature early in culture. Between these two extremes, there exist intermediate classes of BFU-e with less proliferative potential and shorter maturation time in culture. BFU-e tend to have an antigenic profile similar to progenitor cells of other lineages with few exceptions (that is, they are negative for CD45 RA, CD33, and AC133, but express higher levels, or possibly specific isoforms, of the transferrin receptor). CFU-e, in contrast, begin to express more of the markers found specifically in mature erythroid cells (that is, glycophorin A and blood group antigens). The first blood group antigen to be expressed at the BFU-e level is the glycoprotein (**gp**) Kell, followed by the orderly activation of the expression of Rh gp, Landersteiner–Wiener (**LW**) gp, glycophorin A, Band 3, Lutheran gp, and finally, at the erythroblast level, Duffy gp.

Progression of progenitor cells to terminal differentiation is marked not only by the acquisition of phenotypic markers, but also by the acquisition of specific responses to growth factors. The most active of these on early progenitors are stem-cell factor (**SCF**, or Steel factor, or kit ligand), interleukin-3 (**IL-3**), granulocyte/macrophage colony-stimulating factor (**GM-CSF**), and erythropoietin and thrombopoietin (**TPO**) on later progenitors.

The special importance of SCF in erythropoiesis is shown by genetic mutations of SCF (such as *Sl/Sl*^{d}), or of its receptor, kit (such as *W/W*^{v}), that result in mice with anaemia, the severity of which correlates with impairment in kit kinase activity. In humans, heterozygotes with c- *kit* mutations have been reported in individuals with piebaldism, but no homozygotes have been described. Furthermore, mice treated with anti-kit antibodies became anaemic, whereas human kit-antisense containing cultures did not expand the BFU-e compartment.

Erythroid precursors

Erythroid precursors, in contrast to progenitor cells, are morphologically recognizable and include cells at different maturation stages (Fig. 1). The earlier cell is the proerythroblast which, after around 7 days of proliferation and further maturation, gives rise to mature red cells. The maturation process includes haemoglobin synthesis, chromatin condensation (orthochromatic normoblast), and, finally, extrusion of the nucleus and a reduction in cell size (reticulocytes). These morphological changes are paralleled by the accumulation of haemoglobin and by several biochemical changes in the cytoskeleton, which guarantee maximum resistance to stress and flexibility during capillary passage. It has been estimated that about 64 reticulocytes are generated from each pronormoblast, 90 to 95 per cent of which egress

into the bloodstream. Within a day or two in the peripheral circulation, the reticulocytes mature further into red cells.

Ontogeny of erythropoiesis

The ontogenetic development of the erythroid system encompasses a series of well co-ordinated events during embryonic and early fetal life, the timing of which is distinct for each mammal. Erythroid cells are the first differentiated haemopoietic cells to appear during ontogeny, initially in the blood islands of the yolk sac, and later in the fetal liver. The recruitment of new erythropoietic sites during ontogeny (from yolk sac to fetal liver to bone marrow) is accompanied by profound differences in the stem-cell differentiation programme and the phenotypic/functional properties of the erythroid cells being developed in each site. Haemopoietic cytokines, specifically expressed and/or sequestered by each microenvironment, may probably mediate these changes in concert with cell intrinsic transcriptional factors. Furthermore, adhesion receptors on haemopoietic cells and their counter-receptors in the microenvironment ensure patterns of firm adherence, migration, and colonization of the successive haemopoietic sites.

Yolk sac erythropoiesis

In humans, the first erythroid cells (the primitive nucleated erythroblasts) are detected in the yolk sac at 3 to 4 weeks and are the only red cells circulating until week 8 of gestation. They synthesize mainly embryonic haemoglobins, such as Gower I (z_2e_2), Gower II (a_2e_2), and Portland (z_2g_2).

In addition to differentiated primitive erythroid cells, the yolk sac contains progenitor cells of definitive lineage that do not differentiate in the yolk sac but generate BFU-e-like colonies *in vitro*, which are composed of definitive erythroblasts. It is currently undecided whether primitive and definitive progenitor cells derive from the same stem cell.

Gene ablation studies indicate that yolk sac and fetal liver/bone marrow erythropoiesis have clearly distinct growth factor and molecular requirements. Primitive erythropoiesis is not affected by the ablation of several transcription factors (GATA1, AML-1, Rb, Myb, etc.) that affect definitive cells. Also, primitive erythropoiesis *in vivo* is SCF- and erythropoietin-independent, whereas thrombopoietin, but not erythropoietin, is produced *in situ* and may be important for cell survival and partial differentiation. Within the yolk sac, erythroid cells are found in close proximity to endothelial cells and macrophages. Therefore, they are most probably exposed to growth factors produced by these cells, including vascular endothelial growth factor (**VEGF**) and M-CSF. In this regard, yolk sac-derived endothelial cell lines *in vitro* produce leucocyte inhibiting factor (**LIF**), IL-6, flt-3 ligand, SCF, and M-CSF, but not G-CSF, GM-CSF, IL-3, IL-1, erythropoietin, and thrombopoietin. The exchange of trophic signals between endothelial and haemopoietic cells is also mutual at these early stages.

Fetal liver haemopoiesis

The major anatomical site of erythropoiesis in fetal life is the liver, in which newly formed definitive erythroblasts appear at 7 to 8 weeks' gestation within the sinusoidal walls of its parenchyma. Definitive erythroblasts are released into the blood after week 8 and remain the main circulating erythroid cells until birth.

The haemoglobin (Hb) patterns expressed by erythroid cells during ontogeny represent one of the best-studied developmental differences in gene expression. In contrast to primitive erythroblasts, the definitive cells synthesize mainly fetal haemoglobin (Hb F, a_2g_2), together with a small component (10–15 per cent) of adult haemoglobin (Hb A, a_2b_2). The fetal pattern of haemoglobin expression remains stable until 30 weeks' gestation, when a progressive increase in Hb A and a parallel slow decline in Hb F begins. At birth, approximately equal amounts of Hb A and Hb F are synthesized, with the final adult erythroid pattern (adult Hb with <1 per cent fetal Hb) being reached a few months after birth. The fetal to adult Hb switch is strictly related to gestational age and occurs within the same population of cells that undergo an intrinsic modification of its gene expression programme. Its molecular mechanism involves the formation and activation of specific transcriptional complexes within cells at specific stages of ontogeny, but details remain elusive.

Fetal erythroid progenitor cells display a unique phenotypic and functional profile, including higher cell-cycling rates (>30 per cent versus the adult rate of 10 per cent), a lower doubling time (20 h versus the 32 h for the adult cells), and faster kinetics of *in vitro* differentiation (10 days versus 16 days). The average telomeric length is also different (12.8 ± 0.35 kb versus 8.4 ± 0.3 kb). Human fetal BFU-e are exquisitely sensitive to erythropoietin, which is sufficient to sustain their maximal differentiation, whereas SCF complemented by IL-6 alone is sufficient for their maximal *ex vivo* expansion. Whether fetal progenitors do not truly require any other factors, or whether they, unlike adult cells, do not produce autocrine growth inhibitors (transforming growth factor-b (TGF-b)) or are insensitive to them, is unclear.

Unique to the fetal liver stage of haemopoiesis is its almost exclusive erythroid output, whereas its microenvironment is less conducive to myelomonocytic cell differentiation despite the abundant presence of their progenitors.

At the end of fetal development, liver erythropoiesis is suppressed and the organ enters the adult hepatic phase. Oncostatin-M, produced in the liver by haemopoietic CD45+ cells, may facilitate this transition by inhibiting the growth of haemopoietic progenitors while promoting the growth of the hepatocytes expressing its receptor. Increasing glucocorticoid concentrations in fetal liver near term may also contribute to the suppression of liver erythropoiesis.

Bone marrow erythropoiesis

The final site of erythroid cell production maintained throughout life is the bone marrow. Haemopoiesis in the marrow appears between 6.6 and 8.5 weeks after the establishment of a rudimental stroma of cartilagenous and endothelial cells, and is accomplished in four separate phases. Within the bone marrow, granulopoiesis predominates during all the stages of development (fetal and adult).

Erythropoietin and the regulation of erythropoiesis

Erythropoietin was the first haemopoietic growth factor to be identified. Its existence was hypothesized in 1906 by Carnot and Deflandre, but formal proof was obtained by Reissman in 1950 and by Stohlman *et al*. in 1954. Human erythropoietin, a 33- to 38-kDa sialoglycoprotein, was purified to homogeneity in 1977 and its gene, localized on chromosome 7q11, was cloned in 1984. Erythropoietin was also the first growth factor to be used in the treatment of patients because of the clear-cut relationship between its concentration in the blood and the numbers of red cells in the circulation.

Erythropoietin production

Erythropoietin has a short half-life (<5 h; 90 per cent of erythropoietin is rapidly degraded by the liver and 10 per cent secreted in urine), but its blood concentration (0.02 units/ml) is kept constant by continuous production. Erythropoietin levels are exquisitely regulated by changes in O_2 tension, and the kidney is in the ideal anatomical position for sensing these changes (Fig. 2). The kidney is the major producer of erythropoietin, although the liver, which is the main source of erythropoietin in the fetus, retains some capacity of low hypoxia-sensitivity in the adult. Low levels of erythropoietin are also produced in the marrow by the erythroid progenitors themselves.

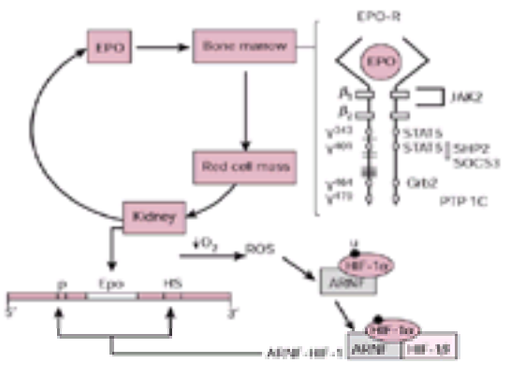

Fig. 2 The regulation of erythroid cell mass. The number of circulating red cells is regulated by the levels of erythropoietin (**EPO**) produced by the kidney under the exquisite control of the hypoxia-sensing machinery. Several pathways are involved in hypoxic recognition and respond by producing reactive O_2 species (**ROS**). The

purpose is to rescue (by ubiquitination) hypoxia-induced factor-1a (**HIF-1a**) from degradation, to facilitate its complex formation with aryl-hydrocarbon nuclear translocator (**ARNF**) and with the ubiquitously expressed b subunit of HIF-1. ARNF–HIF-1 activates the expression of several hypoxia-responsive genes such as *EPO*, glucose transporters, glycolytic enzymes, platelet-derived growth factor (**PDGF**), and vascular endothelial factor (VEFG). (ARNF ablation results in embryonic lethality attributed to the loss of induction of VEGF). ARNF–HIF-1 activates the expression of hypoxia-inducible genes by binding to specific cognate sequences, that, in the case of *EPO*, are present both in its promoter (indicated as p, a typical TATA less promoter) and in its DNA-hypersensitive site (**HS**), which has the function of a hypoxia-inducible enhancer. The enhancer is activated by the binding of a protein complex formed by HIF-1 itself, by the constitutively expressed hepatic nuclear factor-4 (**HNF-4**), and by the general transcriptional activator p300. Of note, the EPO promoter and enhancer also contain binding sites for the steroid hormone receptor, closing the bridge between activation of these receptors and control of the haematocrit level. Another link between a response to stress and EPO expression is provided by p38a, a member of the mitogen-activated protein (**MAP**) family that may be involved in cobalt-induced stabilization of HIF-1a and induction of EPO expression, at least in the fetal liver. EPO induces its effects in the marrow by binding to a specific receptor (**EPO-R**) present on erythroid cells. EPO/EPO-R binding induces tyrosine autophosphorylation and the activation of JAK2 (Janus kinase-2) which is physically associated to its cytoplasmic Box 1 (b1) domain. The activation of the JAK2 catalytic domain is responsible for the phosphorylation of several other proteins, including the EPO-R itself (phosphotyrosine residues involved in docking EPO-R with its transducer proteins are indicated as filled circle, not to scale), STAT5 (signal transducer and activator of transcription-5), and proteins involved in the Ras and PKC (protein kinase C) signal-transduction pathways. On the other hand, at least three other pathways are involved in bringing the receptor complex back to its resting configuration after activation: the phosphatase PTP-1C (protein tyrosine phosphatase-1C) /SHP2 (Src-homology-phosphatase 2), SOCS3 (suppressor of cytokine signalling-3) (overexpression of SOCS3 in transgenic mice results in embryonically lethal anaemia), and the proteasomes, which downregulate the number of activated receptors on the cell surface. PTP-1C becomes physically associated through its SH2 domains with Y479 after EPO stimulation, and SOCS3 becomes associated with the Y401 of EPO-R and with JAK2. The narrow bars on the left side of the EPO-R diagram indicate mutations identified in humans that result in familial erythrocytosis.

As the kidney is the primary site of erythropoietin production, it is not surprising that irreversible damage to this organ results in low or no erythropoietin production and consequently results in anaemia. Anaemia in chronic inflammatory states, such as rheumatoid arthritis, is due instead to the fact that proinflammatory cytokines, such as IL-1 and tumour necrosis factor (**TNF**), inhibit erythropoiesis both directly (by inhibiting the proliferation of the progenitor cells) and indirectly (by inhibiting erythropoietin synthesis by the kidney). At the other extreme, some kidney cancers, by increasing the number of erythropoietin-producing cells, also increase erythropoietin production and then lead to secondary erythrocytosis. Furthermore, disorders that impair O_2 delivery to the tissue are sensed as hypoxia and are also associated with secondary erythrocytosis, such as in chronic lung diseases and congenital heart anomalies. In haemoglobin mutations, because there is inefficient O_2 delivery to the tissues due to altered Hb/O_2 affinity, hypoxia is sensed and causes increased erythropoietin serum levels and secondary erythrocytosis. There are more than 50 different mutations in which changes in either the a- or b-globin gene result in increased Hb/O_2 affinity. Secondary autosomal recessive erythrocytosis (polycythaemias) can also be caused by abnormalities in enzymes such as 2,3-diphosphoglycerate (**2,3DPG**) mutase, involved in the regulation of tissue O_2 delivery (familial 2,3-bisphosphoglycerate deficiency). Secondary asymptomatic polycythaemias are also seen in methaemoglobinaemias. Methaemoglobin is a derivative of haemoglobin in which Fe^{2+}, which binds O_2 reversibly, is replaced by its oxidized form (Fe^{3+}), which binds O_2 irreversibly.

Genetic abnormalities in the O_2-sensing system (summarized briefly in Fig. 2) have not yet been described. Mice lacking hypoxia-inducible factor (HIF)-1a are viable, but are unable to increase their hematocrit levels in response to hypoxia, suggesting that mutations may eventually be found which are not likely to be lethal. In this regard, a congenital polycythaemia common in the Chuvashia region of Russia is characterized both by increased erythropoietin responsiveness of the erythroid cells and by increased erythropoietin concentration in serum. This polycythaemia is not associated with mutations in either *EPO* or *EPO-R* and represents a good candidate for a defective O_2-sensing apparatus such as mutations in the *HIF-1a* gene. Examples of acquired polycythaemias due to defects of the hypoxia-sensing mechanism are renal and neuronal cancers associated with mutations in the von Hippel-Lindau (*VHL*) gene. The product of this gene is a member of the protein complex responsible for the stabilization/degradation of HIF-1a. *VHL* mutations result in overexpression of VEGF and of other O_2-regulated genes.

Erythropoietin signalling pathway

Erythropoietin triggers its biological effect by binding to a specific 64- to 78-kDa (depending on its glycosylation degree) receptor, EPO-R, encoded by a gene on human chromosome 19p. This gene is expressed in erythroid, megakaryocytic, and endothelial cells. Also, marrow cells express high levels of soluble EPO-R species. These may be involved in the fine tuning of erythropoietin concentrations in specific marrow niches, thus allowing erythroid versus myeloid development. In addition to the full-length EPO-R (EPO-RF), immature erythroid cells express a truncated form of the receptor (EPO-RT) that acts as a dominant negative regulator of the EPO-RF mediated signals in mice.

The concentration of EPO-R on the surface of erythroid cells is roughly proportional to their erythropoietin responsiveness *in vitro* (Fig. 1). EPO-R is first detected on BFU-e (around 300 high-affinity erythropoietin binding sites per cell). Its expression increases as the cells progress to CFU-e and proerythroblasts (about 1100 high-affinity sites), but is virtually absent on late normoblasts and reticulocytes. The increase in EPO-R expression observed during erythroid differentiation is also accompanied by a decreased expression of receptors for early-acting growth factors, such as SCF and IL-3 (Fig. 1).

The rapid dimerization induced by erythropoietin binding to its receptor triggers a conformational change that results in autophosphorylation and activation of the kinase catalytic domain of JAK2, a member of the Janus kinase family (Fig. 2). JAK2 phosphorylates and activates several proteins, some of which are responsible for further transmitting the signal to the nucleus, while others, such as the protein tyrosine phosphatases (PTP)-1C (also called HCP or SHP) and -1D (or Syp), dephosphorylate the receptor complex, bringing it back to its resting configuration (Fig. 2). PTP-1C is physically associated with the carboxyterminal domain of EPO-R, a region that is deleted in all of the eight different mutations of *EPO-R* found to be associated with congenital erythrocytosis. 32D cells transfected with one such mutant receptor required erythropoietin to activate the JAK2/STAT5 pathway, but in these cells the activation lasted longer than in cells transfected with the normal receptor. This may explain why congenital polycythaemia/erythrocytosis is characterized by hyper-responsive, erythropoietin-dependent, CFU-e growth. Not all mutations of *EPO-R* cause polycythaemia, however. Two additionally described single-point *EPO-R* mutations are not accompanied by functional consequences or changes in hematocrit.

Signalling through EPO-R triggers several cellular responses, including inhibition of apoptosis, stimulation of cell proliferation, and the induction of expression of erythroid specific genes—that is, the globin genes. The best-studied effect of erythropoietin on erythroid cells is suppression of apoptosis. In fact, mice with targeted deletions of either *Epo*, of its receptor, or of its immediate signal-transduction protein JAK2, die prenatally because of profound anaemia. The livers of these fetuses contain normal numbers of BFU-e and CFU-e, but very few erythroblasts, all of which display signs of apoptosis. These results suggest that these defects impair the final stages of erythroid differentiation by interfering with the erythroblast's ability to survive. Erythropoietin/EPO-R signalling inhibits apoptosis through suppression of caspases (cysteine proteases with aspartate specificity). In erythroid cells, these degrade the erythroid-specific transcription factor GATA1, which is responsible not only for the activation of all the erythroid-specific genes analysed so far, but also of the antiapoptotic protein Bcl-xL. An indirect confirmation of the role of GATA1 in preventing apoptosis of erythroid cells is provided by a recent mutation described in the DNA-binding domain of *GATA1* causing anaemia and thrombocytopenia. As *GATA1* is on the X chromosome, it is possible that other X-linked anaemias or thalassaemia may be due to *GATA1* mutations yet to be identified.

Since survival is a cellular function which is dominant over proliferation, the phenotype of the deletion *Epo*/*Epo-R* mutant mice cannot exclude that erythropoietin may also play a role in the control of proliferation (or differentiation) at later stages of the erythroid differentiation. BFU-e are at least partially dependent on erythropoietin for proliferation and differentiation *in vitro*, but are insensitive to endogenous erythropoietin levels, and neither sustained anaemia nor hypertransfusion alters their frequency and cell-cycle characteristics. In contrast, both the number and cycling characteristics of CFU-e are increased three- to sixfold over the control value. Furthermore, fetal murine CFU-e which constitutively express either Bcl-2 or Bcl-xL survive but do not form colonies in the absence of erythropoietin.

Although the effects of erythropoietin on cell proliferation are not as well characterized as its effects on apoptosis, it can be expected that defects in the proliferation pathway may also result in altered red cell output. In this regard, polycythaemia vera is a human myeloproliferative disorder caused by an acquired presumed mutation at the stem-cell level that results in the formation of CFU-e-derived colonies in the absence of erythropoietin. A familiar autosomal dominant predisposition towards acquiring polycythaemia vera between the ages of 50 and 60 years of age has been described. Since, polycythaemia vera, in contrast to familial polycythaemia, may evolve into leukaemia, it is possible that its defect involves alterations in the proliferative control of erythroid cells.

Red cell homeostasis

Normal red cells have a finite lifespan of 120 ± 20 days. With red cell ageing, metabolic changes decrease their flexibility as they traverse through the microvasculature and promote their lysis or phagocytosis. Thus, the red cell's longevity and ability to carry out its proper function is critically dependent on cell-membrane structure and metabolism. The red cell membrane consists of a lipid bilayer and structural and integral membrane proteins which provide a lattice network under the bilayer and create the red cell cytoskeleton. Inherited defects in protein structure (hereditary spherocytosis, **HS**; hereditary elliptocytosis, **HE**; hereditary pyropoikilocytosis, **HPP**; etc.) lead to haemolytic anaemias. A number of specific receptors and enzymes are also associated with membrane proteins, several of which are important for the maintenance of its structural integrity or for nutrient and ion transport. Enzyme defects in metabolic pathways (pyruvate kinase, **PK**; hexokinase, **G6PD**), or haemoglobin defects (sickle-cell anaemia) can also increase the haemolytic potential of the red cell.

The character of the external red cell surface is defined by its antigenic structure. Over 300 antigens have been identified and many of these contribute to 15 genetic blood group systems. The latter are composed of oligosaccharide prosthetic groups of the integral membrane proteins and complex glycolipids. Nearly all (the Lewis system is an exception) are intrinsic components of the membrane and appear early in the differentiation process. Coating of red cell surface antigens with antibodies in cases of acquired autoimmunity interferes with the membrane functional integrity and allows rapid phagocytosis.

The transport of O_2 by red cells is dependent on their number, their haemoglobin content, and the ability to release O_2 or to increase 2,3DPG, according to tissue needs. However, O_2 transport by red cells is but one of the elements in a multicomponent highly integrated process that is responsible for appropriate O_2 supply to the tissues. A number of other physiological parameters, such as pulmonary function (sufficient O_2 loading in lungs), and haemodynamic factors (cardiac output, blood volume, and viscosity) must be incorporated in an integrated fashion. When anaemia is present, restoration of red cell number is dependent on the degree of erythropoietin stimulation, the ability to increase erythroid proliferation (adequate folic acid, vitamin B_{12} levels, etc.) within the bone marrow, and on the circulating levels and a normal erythroid cell response to iron. Several of these issues are addressed in more details in other chapters.

Finally, several hormones involved in the control of the cellular metabolism, such as corticosteroids, androgens, growth hormone, thyroxine, b-adrenergic agonists, and certain prostaglandins, stimulate erythroid differentiation *in vitro* in synergy with erythropoietin, or can alter hematocrit levels *in vivo*. A direct involvement of glucocorticoids in the control of the red cell mass has recently been provided by the observation that mice lacking the glucocorticoid receptor recover very poorly from haemolytic anaemia caused by phenylhydrazine treatment.

22.5.2 Anaemia: pathophysiology, classification, and clinical features

D. J. Weatherall

The main function of the red blood cells is oxygen transport. Hence a functional definition of anaemia is 'a state in which the circulating red-cell mass is insufficient to meet the oxygen requirements of the tissues'. However, many compensatory mechanisms can be brought into play to restore the oxygen supply to the vital centres, and therefore in clinical practice this definition is of limited value. For this reason anaemia is usually defined as 'a reduction of the haemoglobin concentration, red-cell count, or packed cell volume (**PCV**) to below normal levels'.

The definition of anaemia

It has been extremely difficult to establish a normal range of haematological values, and hence the definition of anaemia usually involves the adoption of rather arbitrary criteria. For example, the World Health Organization recommends that anaemia should be considered to exist in adults whose haemoglobin levels are lower than 13 g/dl (males) or 12 g/dl (females). Children aged 6 months to 6 years are considered anaemic at haemoglobin levels below 11 g/dl, and those aged 6 to 14 years below 12 g/dl. The disadvantage of such arbitrary criteria for defining anaemia is that there may be many apparently normal individuals whose haemoglobin concentration is below their optimal level. Furthermore, the published 'normal values' for adults (see Chapter 22.1) indicate that there is such a large standard deviation that many adult females must be considered 'normal' even though they have haemoglobin levels below 12 g/dl.

Prevalence of anaemia

Anaemia is a major world health problem and its distribution and prevalence in the developing world are considered in detail in the next chapter.

The prevalence of anaemia has been studied in many populations, but it is difficult to compare data from different sources because of variations in methodology and criteria. Certain patterns emerge, however. An early survey carried out in Great Britain established that haemoglobin levels were low in a significant proportion of the population, particularly susceptible groups being children under the age of 5 years, pregnant women, and those in social classes IV and V. A later random population study in the United Kingdom reported a prevalence of anaemia of 14 per cent for women aged 55 to 64 years and 3 per cent for men aged 35 to 64 years. These and similar studies have shown that anaemia is most common in women between the ages of 15 and 44 years and that it then becomes relatively less frequent, although the prevalence increases again in the 75-and-over age group. Interestingly, it is only in the last group that the prevalence in males and females is almost the same. Where the cause of the anaemia has been analysed in these surveys, the majority of cases have been due to iron deficiency. No doubt these prevalence data vary considerably between the developed countries, but it is clear that nutritional anaemia is relatively common in most populations at certain periods during development and late in life.

Adaptation to anaemia

The function of the red cell is to carry oxygen between the lungs and the tissues. However, tissue oxygenation is the result of a complex series of interactions of different organ systems, of which the red cell is only one (Table 1). Obviously the cardiac output, ventilatory function, and state of the capillaries are of great importance as well. Each of these oxygen supply systems is regulated differently. Ventilation responds to changes in pH, CO_2, and hypoxia. Cardiac output responds to the amount of blood entering the heart, and this is regulated mainly by the effects of tissue metabolism as it modifies the resistance to blood flow in the microvasculature. The erythron itself responds to changes in haemoglobin concentration, arterial oxygen saturation, and to the oxygen affinity of the circulating haemoglobin. Thus a decreased capacity of any of these components may be compensated for by increased activity of the others in an attempt to maintain tissue oxygenation.

Oxygen diffuses across the alveolar membrane and into the blood, which equilibrates with the alveolar gas; the approximate oxygen tension is 100 mmHg, at which the blood is fully saturated with an oxygen content of 20 vol per cent. As blood is pumped through the tissue capillaries oxygen diffuses out. Although the venous oxygen tension varies between organs, the oxygen tension of the pooled venous blood in the pulmonary artery, the 'mixed venous oxygen tension', is remarkably constant at 40 mmHg. At this oxygen tension the oxygen content is 15 vol per cent. Hence, oxygen delivery, as measured by the arteriovenous oxygen difference, is normally 5 vol per cent. By reducing the oxygen-carrying capacity of blood, anaemia tends to reduce the arteriovenous oxygen difference, and this may be compensated for by the following mechanisms: (1) modulation of oxygen affinity; (2) redistribution of flow between different organs; (3) increase in cardiac output; and (4) reduction of mixed venous oxygen tension to increase the arteriovenous oxygen difference.

Intrinsic red-cell adaptation

The consequences of anaemia on the normal oxygen-binding curve of blood are shown in Fig. 1. Anaemia, by lowering the haemoglobin concentration, proportionately reduces the oxygen-carrying capacity of the blood. As a response to this there is an increase in the 2,3-biphosphoglycerate (**2,3-BPG**) concentration in the red cell, shifting the dissociation curve to the right, so significantly enhancing tissue oxygen delivery (Fig. 1).

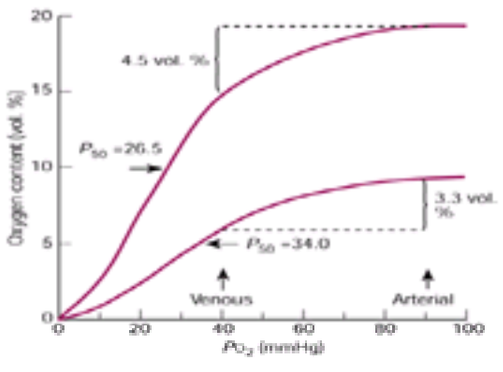

Fig. 1 Enhancement of oxygen loading by decreased red-cell oxygen affinity in a patient with anaemia. An anaemic patient with a 50 per cent reduction in haemoglobin concentration has only a 27 per cent reduction in oxygen unloading. (Based on Klocke RA (1972). *Chest*, **69**, 795.)

With increasing severity of anaemia there is a progressive increase in 2,3-DPG, which may increase oxygen delivery by as much as 40 per cent for the same haemoglobin concentration. It should be noted, however, that a consequence of this adaptation is a lower venous oxygen content and hence a lower reserve of oxygen available for a further increase in oxygen demand, as might occur on exercise for example. Hence the increase in 2,3-BPG in anaemia tends to ameliorate the effects of the diminished oxygen-carrying capacity of the blood, so reducing the adaptation required by other steps involved in tissue oxygen delivery (Fig. 2). 2,3-BPG levels vary in a variety of other clinical conditions, some of which are summarized in Table 2.

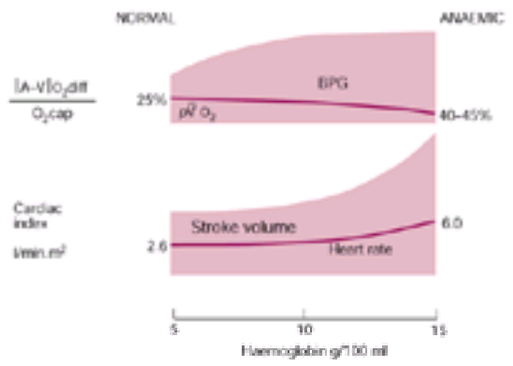

Fig. 2 The changes in factors involved in oxygen delivery with progressive anaemia. As anaemia becomes more severe, cardiac compensation becomes more significant ($P(V)O_2$, mixed venous oxygen tension). (From Bellingham, 1974.)

Local changes in tissue perfusion

The total blood volume does not change greatly in anaemia and therefore increased tissue perfusion has to be achieved by shunting blood from less to more vital organs. There is vasoconstriction of the vessels of the skin and kidney; this mechanism has little effect on renal function. The organs that gain from the redistribution seem to be mainly the myocardium, brain, and muscle.

Cardiovascular changes

It seems likely that mild anaemia is compensated for by shifts in the oxygen dissociation curve. Overall, oxygen consumption is unchanged in anaemia. However, when the haemoglobin level falls below 7 to 8 g/dl, there is an increase in cardiac output, both at rest and after exercise (Fig. 2). The stroke rate increases and a hyperkinetic circulation develops, characterized by tachycardia, arterial and capillary pulsation, a wide pulse pressure, and haemic murmurs. The circulation time is shortened, left ventricular stroke work is increased, and coronary flow increased in proportion to the increased cardiac output. It has been found that there is an acute reversal of the high-output state of chronic anaemia in response to orthostatic stress or pressor amines. This suggests that redistribution of blood volume and vasodilatation with reduced afterload play a dominant role in the hyperkinetic circulatory responses to chronic anaemia. The mechanism of the vasodilatation is not known; it may be a direct result of tissue hypoxia. An additional factor that may be of some importance in increasing cardiac output is the reduction in blood viscosity produced by a relatively low red-cell mass.

While the normal myocardium may tolerate sustained hyperactivity of this type indefinitely, patients with coronary artery disease or those with extreme anaemia may have impaired oxygenation of the myocardium. In such cases, cardiomegaly, pulmonary oedema, ascites, and peripheral oedema may occur, and a state of high-output cardiac failure is established. At this stage the plasma volume is almost always increased.

Pulmonary function

As blood, regardless of its oxygen-carrying capacity, is almost completely oxygenated in the lungs, the oxygen pressure of arterial blood in an anaemic patient should be the same as that in a normal individual, and hence an increase in respiratory rate should not improve the oxygenation of the tissues. Curiously, however, severe anaemia is associated with dyspnoea. Although in some patients this may be related to incipient cardiac failure, in most cases it appears to be an inappropriate response to hypoxia which is centrally mediated.

Clinical manifestations and classification of anaemia

Clinical effects of anaemia

Because anaemia reduces tissue oxygenation it is not surprising that it is associated with widespread organ dysfunction and hence an extremely varied clinical picture. The picture depends, of course, on whether the anaemia is of rapid or more insidious onset.

After acute blood loss the red-cell mass and plasma volume are reduced proportionately and the symptoms are mainly of volume depletion. Depending on the amount of fluid replacement there may be a small fall in the PCV during the first 10 h; volume replacement by the influx of albumin from the extravascular compartment takes between 60 and 90 h. Hence the picture of rapid blood loss is characterized by the typical syndrome of shock, with collapse, dyspnoea, tachycardia, a poor volume pulse, reduced blood pressure, and marked peripheral vasoconstriction.

With anaemia of a more insidious onset, the compensatory mechanisms outlined above have time to come into play. In mild anaemia there may be no symptoms or simply increased fatigue and a slight pallor. As the anaemia becomes more marked the symptoms and signs gradually appear. Pallor is best discerned in the mucous membranes; the nailbeds and palmar creases, although often said to be useful sites for detecting anaemia, are relatively insensitive for this purpose. Cardiorespiratory symptoms and signs include exertional dyspnoea, tachycardia, palpitations, angina or claudication, night cramps, increased arterial pulsation, capillary pulsation, a variety of cardiac bruits, reversible cardiac enlargement, and, if cardiac failure occurs, basal crepitations, peripheral oedema, and ascites. Neuromuscular involvement is reflected by headache, vertigo, light-headedness, faintness, tinnitus, roaring in the ears, cramps, increased cold sensitivity, and haemorrhages in the retina. Acute anaemia may occasionally give rise to papilloedema. Gastrointestinal symptoms include loss of appetite, nausea, constipation, and diarrhoea. Genitourinary involvement causes menstrual irregularities, urinary frequency, and loss of libido. There may be a low-grade fever.

In the elderly, in whom associated degenerative arterial disease is common, anaemia may present with the onset of cardiac failure. Alternatively, previously undiagnosed coronary narrowing may be unmasked by the onset of angina. Other symptoms of arterial degenerative disease may be also exacerbated or unmasked; intermittent claudication and a variety of neurological pictures associated with cerebral arteriosclerosis for example. It is important that anaemia is recognized as a contributing factor to the symptoms of these degenerative diseases as its correction may frequently bring about considerable symptomatic improvement.

Causes and classification of anaemia

A reduction in the red-cell mass can result from either the defective production of red cells or an increased rate of loss of cells, either by premature destruction or bleeding. Decreased production of red cells may result from a reduced rate of proliferation of precursors in the bone marrow or from failure of maturation leading to their intramedullary destruction: that is to say, ineffective erythropoiesis. Based on this approach we can derive a very simple pathophysiological classification of anaemia, as shown in Table 3, in which the causes are divided into failure of red-cell proliferation, defective maturation, haemolysis, and blood loss.

Anaemia due to defective proliferation of red-cell precursors

The major causes of this group of anaemias are an inadequate supply of iron, primary diseases of the bone marrow that involve stem cells or later erythroid

precursors, and a reduction in the amount of erythropoietin reaching the red-cell precursors (Table 4).

Iron deficiency results in defective erythroid proliferation and also in abnormal maturation of the red-cell precursors due to defective haemoglobin synthesis. Red-cell precursors require adequate iron supplies for normal proliferation, and the anaemia of iron deficiency tends to be hypoproliferative as well as dyserythropoietic. Chronic inflammatory disorders and related conditions also interfere with the iron supply to precursors, probably by blocking the release of catabolized red-cell iron from reticuloendothelial cells. The basic defect in iron-deficiency anaemia and that due to inflammation is similar, therefore, in that the supply of iron is inadequate to meet the requirements for erythropoiesis.

Defective proliferation of red-cell precursors can result from any of the causes of bone marrow failure, including infiltration with leukaemic or other neoplastic cells, damage due to ionizing radiation, drugs, or infection, and various intrinsic lesions of the stem cells or red-cell precursors. The intrinsic disorders include the congenital hypoplastic anaemias, involving either all the formed elements or the red-cell precursors alone.

Finally, decreased proliferation of the red-cell precursors may result from erythropoietin deficiency. The most common cause is chronic renal failure. A similar mechanism may be involved in conditions in which the tissue requirement for oxygen is reduced. These include various endocrine disorders such as hypothyroidism and hypopituitarism. It may also explain the mild anaemia associated with haemoglobin variants with decreased oxygen affinity.

As a group, the hypoproliferative anaemias are associated with a low reticulocyte count and defective proliferation of the bone marrow precursors. The red cells are usually normochromic and normocytic, although there may be a mild macrocytosis. If the anaemia is due to iron deficiency, the cells are hypochromic. If granulopoiesis is normal, the defect in red-cell proliferation is reflected by an increase in the myeloid:erythroid (**M/E**) ratio.

Defective red-cell maturation

Defects of red-cell maturation may involve primarily nuclear or cytoplasmic maturation (Table 4). Those involving nuclear maturation include vitamin B_{12} and folic acid deficiency and other causes of megaloblastic anaemia, and some of the primary marrow disorders including erythroleukaemia. The important causes of defective cytoplasmic maturation include the inherited disorders of globin synthesis, the thalassaemia syndromes, and the genetic and acquired defects of iron metabolism that characterize the sideroblastic anaemias. There are other genetic defects of red-cell maturation, the congenital dyserythropoietic anaemias, in which the aetiology is unknown. Furthermore, agents such as drugs, chemicals, and infections may interfere with erythroid maturation.

The main pathological mechanism common to all the anaemias that result from maturation abnormalities is ineffective erythropoiesis. In other words, there is marked erythroid proliferation but many of the precursors are destroyed in the bone marrow before they enter the circulation. Hence, the characteristic finding is marked erythroid hyperplasia with a reduction in the M/E ratio, associated with a low reticulocyte count. Because of the significant intramedullary destruction of precursors there is usually an elevated level of bilirubin and lactate dehydrogenase. Furthermore, there are nearly always morphological abnormalities of the red-cell precursors. The anaemias that are associated with abnormal nuclear maturation, such as those due to vitamin B_{12} and folic acid deficiency, are characterized by megaloblastic erythropoiesis and macrocytic red cells, while those caused by abnormal cytoplasmic maturation are characterized by normoblastic hyperplasia and hypochromic and microcytic red cells. However, even in the last conditions, there is marked anisocytosis and there may be a proportion of macrocytes in the peripheral circulation.

Blood loss

As mentioned earlier, the clinical picture associated with an acute loss of a large volume of blood is that of hypovolaemic shock.

Anaemias due to chronic blood loss may develop very insidiously and cause considerable diagnostic problems. Chronic blood loss from the gastrointestinal tract or uterus of more than 15 to 20 ml per day produces a state of negative iron balance. Assuming that the patient starts with a normal body store of iron, which is usually in the region of 1 g, the bone marrow will be able to maintain a normal haemoglobin level until the iron stores are totally depleted. At this stage there is no demonstrable iron in the bone marrow and the plasma iron level starts to fall but the patient is not anaemic. With a further fall in the plasma iron level, the haemoglobin level starts to fall, although at this stage the erythrocyte morphology may be relatively normal, as are the red-cell indices. It is only when iron-deficiency anaemia is well established that the typical morphological appearances of the red cells develop, and only after extreme periods of iron depletion that the tissue changes of iron deficiency become manifest.

From these considerations it is apparent that there may be prolonged blood loss before a patient presents with the symptoms and signs of anaemia. During the earlier stages the peripheral blood film may not be helpful in diagnosis, even though the serum iron level may be extremely low. Indeed, sometimes a dimorphic blood picture with normochromic and hypochromic cell populations may be seen. With chronic blood loss there is quite often a persistent thrombocytosis, and a hypochromic blood picture with thrombocytosis should always raise the possibility of chronic bleeding. In practice, the most common sites of such bleeding are a hiatus hernia, peptic ulcer, and tumour of the large bowel or the uterus.

Haemolytic anaemia (Table 5)

When the lifespan of red cells is shortened there is a reduction in the circulating red-cell mass, which leads to relative tissue hypoxia. This causes an increased output of erythropoietin with stimulation of the bone marrow and an increased rate of red-cell production. This is reflected by a raised reticulocyte count and a macrocytosis due to the presence of young cells in the peripheral circulation. Because of the increased rate of red-cell destruction, there is an increased production of bilirubin, which leads to mild icterus and the presence of increased amounts of urobilinogen in the urine and stool. Thus the haemolytic anaemias are characterized by a variable degree of anaemia, a reticulocytosis, and hyperbilirubinaemia. Their pathophysiology is considered in detail elsewhere.

Red cells are prematurely destroyed either because of an intrinsic lesion or as a result of the action of an extrinsic agent. The intrinsic abnormalities of the red cells that lead to their premature removal are nearly all genetic defects of either the membrane, haemoglobin, or metabolic pathways. The extrinsic agents that may cause premature destruction of the cells include a variety of antibodies, chemicals, drugs, and toxins, or bacteria and parasites. In addition, red cells may be damaged by direct trauma in the microcirculation or on body surfaces.

Premature destruction of red cells may take place either intravascularly or extravascularly, or, as occurs more commonly, in both sites. The site of destruction depends on the type and degree of damage to the red cell. For example, complement-damaged cells develop large holes in the membrane and are destroyed in the circulation, whereas IgG-coated cells are removed mainly in the reticuloendothelial system.

Clearly, there are numerous causes of premature destruction of red cells. These will be considered in detail later in this section. Usually it is easy to recognize that a particular anaemia has a haemolytic basis, by virtue of the reticulocytosis and macrocytosis associated with erythroid hyperplasia of the bone marrow, hyperbilirubinaemia, and increased urinary urobilinogen. However, it should be remembered that many anaemias associated with the abnormal proliferation or maturation of red cells have a haemolytic component. For example, there may be a slightly shortened red-cell survival in patients with pernicious anaemia or thalassaemia and yet there may be a very poor reticulocyte response. Similarly, there is a haemolytic component in the anaemia due to inflammation or malignancy but again the marrow response is poor. In such cases it may be necessary to measure the lifespan of the red cells directly in order to determine the magnitude of the haemolytic component as compared with defective proliferation or maturation.

General approach to the anaemic patient

Clinical assessment

The clinical assessment of patients with anaemia has two main objectives. First, it is essential to determine the degree of disability caused by the anaemia and hence how quickly treatment must be started. Second, as much information as possible about the likely cause of the anaemia must be obtained from a detailed clinical history and physical examination. There is no place for the 'blind' treatment of anaemia without first establishing the cause.

In assessing the severity of the anaemia and how urgently treatment should be instituted, a detailed history of the patient's exercise tolerance must be obtained. This should include a specific enquiry of symptoms suggestive of cardiac complications including angina, dysrhythmias, positional dyspnoea, cough, or ankle swelling. The clinical examination should include a careful assessment of the degree of pallor, the position of the neck veins, whether there are warm extremities and a bounding

pulse with a large pulse pressure, the presence of ankle or sacral oedema, and whether there are basal crepitations. The finding of profound anaemia with signs of cardiac failure indicates that urgent treatment is required. If the anaemia is associated with marked splenomegaly there will almost certainly be an increased blood volume and, particularly if there are already signs of cardiac failure, the patient may well go into acute left ventricular failure if transfused. Severely ill patients with profound anaemia require immediate treatment in an environment where they can be under constant observation, have regular measurements of their central venous pressure, and where they can be managed by experienced clinical and nursing staff.

An account of history taking and clinical examination in patients with haematological disorders was given earlier in this section (Chapter 22.1). It cannot be emphasized too strongly that in many cases the anaemia is a symptom of a non-haematological disorder. A detailed history and clinical examination will often provide a clue as to the likely cause of the anaemia, and which laboratory investigations are likely to be most productive for confirming the diagnosis.

Haematological investigation

A preliminary blood count and blood film examination should classify anaemia into hypochromic-microcytic, and macrocytic or normochromic, normocytic varieties (Table 6). In middle-aged women with a history of several pregnancies or heavy menstrual loss it is reasonable to assume that a hypochromic anaemia is due to iron deficiency, and to treat them with iron without further investigation. However, hypochromic anaemia in males or young or postmenopausal women always suggests blood loss and should be investigated accordingly. If there is any doubt about a hypochromic anaemia being due to iron deficiency, the serum iron level and total iron-binding capacity should be established. Hypochromic anaemia with a normal serum iron suggests a genetic or acquired defect in haemoglobin synthesis, common causes being thalassaemia and sideroblastic anaemia. The diagnosis of a macrocytic anaemia always requires further investigation and should be followed up with a bone marrow examination. A macrocytosis with a normoblastic bone marrow may result from alcohol abuse, haemolysis, or, occasionally, one of the refractory anaemias with hyperplastic bone marrow (see Chapter 22.5.8). Macrocytic anaemias with megaloblastic bone marrows are usually due to vitamin B_{12} or folate deficiency and should be investigated accordingly. If there is macrocytosis with a reticulocytosis, hyperbilirubinaemia, and a normoblastic marrow, a haemolytic anaemia is likely; an approach to the further investigation of haemolysis is described in Chapter 22.5.9.

The normochromic, normocytic anaemias often cause more diagnostic difficulty. Some help can be gained from a determination of whether the white-cell and platelet counts are normal. If there is associated neutropenia and thrombocytopenia, a primary disease of the bone marrow is likely; hence, bone marrow examination should be made to determine whether there is hypoplasia of the various precursor forms, hypoplastic or aplastic anaemia, or whether the pancytopenia results from infiltration of the bone marrow as occurs in the various forms of leukaemia. If there are nucleated red cells or young white cells on the peripheral film (that is, a leucoerythroblastic picture), a bone marrow examination is essential, as this type of reaction usually indicates infiltration of the bone marrow with abnormal cells, either as part of a primary marrow disease such as leukaemia, or metastatic carcinoma. In the normochromic, normocytic anaemias in which the white-cell count and platelet count are normal, it is also helpful to make a bone marrow analysis. The most common cause is anaemia of chronic disorders, the diagnosis of which is described in detail below. Another particularly common cause is chronic renal failure. After these conditions have been excluded, there remain the chronic anaemias associated with endocrine deficiencies (see Chapter 22.7) or the primary red-cell hypoplasias (Chapter 22.3.11).

The management of anaemia

The management of specific forms of anaemia is described in detail in subsequent chapters. However, a few principles can be outlined here. In general, a cause should always be sought before treatment is instituted. There is no place whatever for treating anaemia 'blind' with multihaematinic preparations. As mentioned above, most cases of iron-deficiency anaemia require further investigation for a source of blood loss. If there is a clear-cut history of poor diet, multiple pregnancies, or obvious uterine bleeding, it is reasonable to start iron therapy and observe the haemoglobin level both during the period of treatment and for some months after iron therapy has been stopped. A rise in the haemoglobin level of approximately 1 g/dl per week indicates a full haematological response. For the megaloblastic anaemias it is quite reasonable to start treatment with vitamin B_{12} and folic acid once a diagnosis has been established and blood samples have been obtained for serum folate and vitamin B_{12} levels. The precise cause of the megaloblastic anaemia can be established at leisure once these samples have been obtained. A brisk reticulocyte response 5 to 7 days after initiating therapy suggests that there will be a full restoration of the haemoglobin level to normal. Failure of response of a hypochromic anaemia to adequate iron therapy should be managed by first finding out whether the iron is being taken by the patient and, if so, by determining the serum iron level. If it is normal, causes of hypochromic anaemia that are not associated with iron deficiency—thalassaemia and sideroblastic anaemia for example—should be sought. Similarly, refractory macrocytic anaemias require detailed analysis of the bone marrow morphology as there may be an underlying preleukaemic state.

Blood transfusion should always be avoided unless the haemoglobin level is dangerously low, in which case it is reasonable to transfuse the patient up to a safe level and then allow the haemoglobin to return to normal following appropriate treatment of the underlying cause. The decision whether to transfuse an anaemic patient depends mainly on the severity of the anaemia and its cause. For example, a young patient with a haemoglobin of 5 g/dl who is shown to have an active duodenal ulcer should probably be transfused because they would be at severe risk from a further brisk bleed from the ulcer. On the other hand, a patient of similar age with a similar haemoglobin level due to chronic nutritional iron deficiency might well be allowed to restore their haemoglobin level by oral iron therapy.

Occasionally, patients present in gross congestive cardiac failure with profound anaemia. This picture is usually seen in elderly patients with long-standing pernicious anaemia or iron deficiency. This type of condition still carries a high mortality and requires urgent treatment. Such profoundly anaemic patients require transfusing up to a safe level, that is a haemoglobin value of 6 to 8 g/dl. This can usually be achieved by the slow transfusion of two or three units of red cells with the intravenous administration of a potent diuretic such as furosemide (frusemide) with each unit; the diuretic should never be mixed directly with the blood. A very careful check on the neck veins and lung bases should be made throughout the period of transfusion. Ideally, a central venous-pressure line should be inserted before the transfusion is started. Occasionally, patients are encountered in such gross heart failure that the administration of packed cells and diuretics worsens the failure. In this situation it is possible to raise the circulating red-cell mass by infusing packed cells or whole blood through one arm while removing an equal volume of blood from the other. By carrying out a two-to-three unit exchange transfusion of this type it may be possible to tide the patient over while treating the heart failure by conventional means.

22.5.3 Anaemia as a world health problem

D. J. Weatherall

Despite improvements in nutrition and hygiene, which have reduced childhood mortality in many emerging countries, anaemia continues to be a major world health problem. It is not, of course, a disease in its own right but simply a by-product of a wide variety of different disorders, most of which are described in detail elsewhere in this book. However, because of its importance as a source of chronic ill health in many populations, the global aspects of the aetiology and manifestations of anaemia are summarized briefly in this chapter. Readers who wish to learn more of the complex literature on this important topic are referred to the extensive reviews cited at the end of the chapter.

Definition and prevalence

It has been very difficult to produce an adequate definition of anaemia. 'Normal' haematological values vary with age, between sexes, at different altitudes, and, possibly, between races. On the other hand, it is helpful to have a standard set of haemoglobin levels at different ages below which 'anaemia' is defined. The World Health Organization (WHO) have attempted to set out criteria of these kind, summarized in Table 1. Despite their many shortcomings, including methodological vagaries, they at least provide a way of obtaining an approximate comparison of the distribution and frequency of anaemia among the different countries of the world.

The global prevalence of anaemia, based on WHO criteria, was estimated in the 1980s. A review of the epidemiological data available at this time suggested that about 1.3 billion people were affected by anaemia, particularly in the developing countries. Infants, young children, menstruating, and, especially, pregnant women were the most severely affected groups (Table 2). The highest prevalence of anaemia was found in southern Asia and Africa. More recent work suggests that while there has been some improvement, anaemia is still a major public health problem in many developing countries. Though found most frequently in poorer countries, anaemia is still an important problem in richer societies, particularly in infancy, pregnancy, and old age.

The complex and multiple aetiology of anaemia in the Third World

The major causes of anaemia in the developing countries are summarized in Table 3. It is very difficult to determine their relative importance, particularly in tropical countries. Most surveys have focused on one particular mechanism, iron or folate deficiency for example. To obtain a true picture of the cause of anaemia in a particular population it is essential to obtain consecutive data over a long period. For example work in the Gambia has shown that the haemoglobin levels in children vary significantly at different times of the year; anaemia is much more common in the wet season when malaria transmission is at its highest. To complicate matters, this is also the time when diarrhoea and malnutrition are most common. Heavy rains after many dry months have profound effects on the community; sanitation measures are disrupted and food stores are at the lowest level in the annual cycle (Fig. 1).

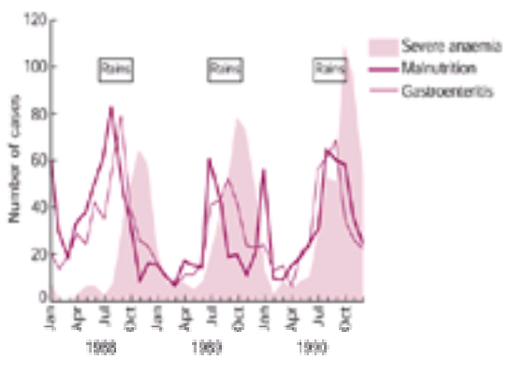

Fig. 1 Admissions to the children's ward in a hospital in The Gambia over dry and rainy seasons. (Data from Brewster DR and Greenwood BM (1993). Season variation of paediatric disease in The Gambia, West Africa. *Annals of Tropical Paediatrics* **13**, 133.)

These observations underline the multifactorial aetiology of anaemia in the developing world. Nonetheless it is clear that iron deficiency, which probably affects at least 20 per cent of the world's population, is the most important factor; the many other diseases that can exacerbate anaemia are often operating in the background of low body-iron stores.

Iron deficiency

It was estimated in the 1980s that some 600 to 700 million individuals suffer from anaemia due to iron deficiency. Surveys using more sensitive indicators of iron status showed that iron depletion is even more prevalent than frank anaemia. The causes of iron deficiency anaemia are extremely complex and vary widely among different populations. The absorption of non-haem iron, except from breast milk, is comparatively restricted, and the content of iron in breast milk is very low. Iron deficiency is particularly common in communities in which food is predominantly of vegetable origin. The three great staples in these populations are rice, wheat, and maize. Sorghum and millet are also important in parts of Africa and Asia. Soy and similar legumes are a major source of protein in many countries. The iron content of these diets is generally low, and, furthermore, absorption is inhibited by fibre, phytates, phosphates, and polyphenols, all of which occur in high levels in vegetarian diets. Populations who have remained as hunter-gatherers, and pastoralists who eat blood and meat, appear to have a lower frequency of iron deficiency anaemia.

Against this background of deficient or borderline dietary iron intake, there are a number of other factors which may exacerbate iron deficiency. Iron requirements are greatly increased during pregnancy because of the expansion of the maternal red cell mass (approximately 500 mg), iron transport to the fetus (approximately 300 mg), and the constitution of the placenta (approximately 25 mg), together with any blood loss at birth. Although there is some compensation by the cessation of iron loss due to menstruation (approximately 200 mg), the total requirements for a single pregnancy are greater than 1000 mg. Iron is also excreted in breast milk and although the concentration is low this loss, particularly with prolonged breast feeding, places a further burden on maternal iron stores.

In many tropical countries, there are important sources of pathological iron loss due to parasitic infection. Hookworm infestation affects millions of people world-wide. These parasites attach themselves to the mucosa of the intestinal tract. With a worm-load of 1000 eggs per gram of faeces, the intestinal blood loss averages about 2.5 ml/day, representing 1 mg of iron. Although some of this is reabsorbed, perhaps up to 40 percent, hookworm infestation is an important source of iron imbalance. Infection with *Schistosoma mansoni* results in intestinal blood loss, while *S. haematobium* results in chronic haematuria. In Kenyan children, for example, mean iron losses in those infected with *S. haematobium* varied from 149 to 652 µg/day, according to the magnitude of the egg counts.

Finally, it should be remembered that chronic ill health due to protein–calorie malnutrition or chronic infection may, by its effect on a patient's appetite, result in further depletion of iron intake.

It must be emphasized that many surveys for assessing body iron stores have used methods which are confounded by associated inflammatory disease or other disorders. These problems are particularly germane to surveys which have been based on serum iron or ferritin levels. More recently, screening methods based on estimation of transferrin receptor levels have been developed but their application to large populations is, as yet, limited.

Folate deficiency

Folate deficiency is thought to be the second commonest cause of nutritional anaemia in the world population. The mechanisms are complex and differ widely between different populations depending in the way in which food is prepared, in particular the temperature at which it is cooked. It is also clear that dietary folate deficiency is not the whole story. Research in Africa suggests that the continuous anorexia which accompanied recurrent infections, such as malaria or tuberculosis, is a major cause of folate deficiency in children. Postinfective malabsorption and the tropical sprue syndrome are also important causes of folate deficiency, particularly in the Indian subcontinent. Folate requirements may be increased in patients with erythroid hyperplasia secondary to chronic haemolytic anaemia, sickle cell anaemia for example, or chronic malarial infection. They also increase markedly during pregnancy. In women with low baseline folate stores, megaloblastic anaemia in pregnancy or the puerperium is particularly common.

Vitamin B_{12} deficiency

Nutritional vitamin B_{12} deficiency is uncommon, although it is observed in true vegans, particularly in the Indian subcontinent. Infants born of mothers with sprue or postinfective malabsorption who are fed on breast or goats milk containing insufficient vitamin B_{12} may develop megaloblastic anaemia with locomotor complications during the early months of life.

Infection

Almost any chronic infection may produce anaemia. Globally, the most important are the parasitic disorders, malaria, visceral leishmaniasis (kala-azar), schistosomiasis, and some forms of trypanosomiasis. The anaemias due to chronic hookworm infestation were considered in Chapter 22.5.2

Malaria is still the most important parasitic illness of humans. Currently it is estimated that it has a global incidence of about 200 million cases per year, with over one million deaths. Its transmission and clinical manifestations are considered in Section 7. Profound anaemia is a major cause of mortality and morbidity during acute attacks of *P. falciparum* malaria in non-immune persons but, from the perspective of health in the developing world, chronic infection with this organism in childhood is an extremely common cause of anaemia. This is most commonly seen in areas of high malarial transmission and is a growing problem in regions of lower transmission because the rise in antimalarial drug resistance prolongs the average duration of infection. The anaemia of chronic malaria has a complex basis involving haemolysis, hypersplenism, and a suboptimal bone marrow response, often set against a background of iron or folate deficiency. In some populations, notably those of Africa, India, and parts of Southeast Asia, chronic malarial infection may be complicated by the hyper-reactive malarial splenomegaly syndrome, in which hypersplenism plays a major role in the generation of chronic anaemia.

The haematological manifestations of the other common parasitic illnesses in the tropics are considered elsewhere.

Malabsorption

A large proportion of people in tropical climates, both indigenous populations and expatriates who have worked in rural areas, have abnormalities of the intestinal mucosa, often associated with impairment of absorption. These structural and functional alterations of the gut have been called 'tropical enteropathies'. It is likely that they result from adaptation to life in the contaminated environment of the tropics, with frequent gastrointestinal infections and differences of diet.

More severe malabsorption syndromes, called sprue and postinfective malabsorption, are associated with chronic diarrhoea, wasting, and a variable degree of anaemia. The pathophysiology and world distribution of these syndromes are considered in Section 14. They are nearly all associated with anaemia which has a complex aetiology including folate deficiency and, in some cases, iron deficiency.

It should also be remembered that in a tropical setting malabsorption can also result from colonization of the small bowel by specific parasites, including *Giardia lamblia*, *Strongyloides stercralais*, *Cryptosporidium*, and others. Abdominal tuberculosis with malabsorption is also common. In Africa, HIV infection is now an important cause of malabsorption.

Inherited anaemias

The inherited haemoglobin disorders are becoming an increasingly common cause of anaemia, particularly in tropical countries. They are described in detail elsewhere.

Because of heterozygote advantage against *P. falciparum* malaria, the important inherited haemoglobin disorders, notably sickle cell anaemia and the thalassaemias, have a high frequency throughout tropical populations of the Old World. Sickle cell anaemia and its variants are particularly common in Africa, some Mediterranean populations, and throughout the Middle East and parts of India. They also occur at a high frequency in the Caribbean and in other regions with large African populations. The thalassaemias occur at a high frequency in parts of Africa, the Mediterranean, the Middle East, the Indian subcontinent, and throughout Southeast Asia. There is now clear evidence that these conditions will produce a major public health problem in these countries in the future. As poorer countries go through the demographic transition, resulting from better hygiene and control of infectious illness, infants with these genetic anaemias are now surviving long enough to present for diagnosis and treatment. Some estimated figures for the annual numbers of new births of babies with sickle cell anaemia or b thalassaemia are shown in Fig. 2.

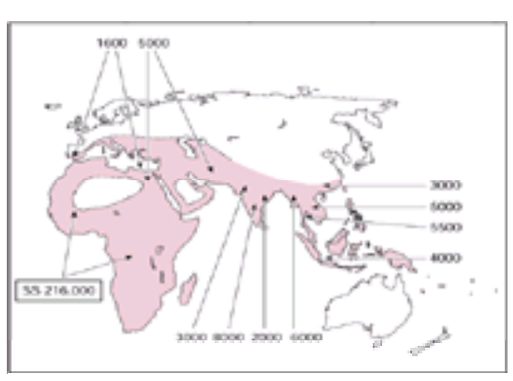

Fig. 2 Estimated annual numbers of births of babies with b thalassaemia and sickle cell anaemia (SS). (Original data in Weatherall and Clegg (2001). *The thalassaemic syndromes*, 4th edn, p.599. Blackwell, Oxford.)

The effect that a high frequency of a disease such as thalassaemia can have on the health economy of an emerging country was shown graphically in the case of Cyprus after is passed through the demographic transition in the 1950s. It was estimated that if every patient with this disease was treated with regular blood transfusion and appropriate medication, within 15 years the management of this one condition would consume up to 40 per cent of the island's health budget. Recent studies in Indonesia indicate that, at a minimum estimate, approximately 1.25 million units of blood will be required each year to treat a proportion of the thalassaemic

population in future years.

In many populations, there are hundreds of thousands of carriers for b thalassaemia or the more common severe forms of a thalassaemia. Although they are asymptomatic they have haemoglobin values which, on average, are 1 to 1.5 g/dl below normal. During pregnancy they retain this difference so that in the midtrimester they have haemoglobin values of approximately 8 g/dl or less. They have increased folate requirements and, in some populations, there appears to be an increased frequency of folate deficiency in pregnancy.

It should be remembered that the inherited anaemias may be exacerbated by other illnesses which are widespread in tropical countries. Folate requirements are increased in all these conditions and secondary folate deficiency is extremely common. They may also be exacerbated by malaria; children may develop malarial infection from infected blood donors. There is also a high frequency of other blood-borne infections, particularly hepatitis C and, in some populations, HIV. Furthermore, there is clear evidence that sickle cell anaemia and thalassaemia can render children more prone to infection. In short, like all forms of anaemia in the tropical world, the inherited disorders of haemoglobin may present with a complex series of complications due to a background of nutritional deficiency and a wide variety of infections.

These complex interactions have a major effect on the prognosis for the important inherited haemoglobin disorders. Early studies in Africa reported a marked paucity of patients with sickle cell anaemia despite a very high carrier frequency, indicating that very few patients with this disorder were surviving beyond early childhood. This may still be the case in parts of rural Africa. On the other hand, in more advanced countries, and with a high quality of medical care, patients with this disease are regularly surviving into adult life; the mean survival time in the United States is now approximately 42 years, with many patients surviving to old age. A similar situation exists for b thalassaemia. In poorer countries, supplies of blood may be limited, there may be difficulties in screening blood for agents such as hepatitis C and HIV, and the prohibitive cost of iron chelating agents means that even children who do receive transfusion die from iron loading before they reach the age of 20 years.

There are other inherited anaemias which are particularly common on tropical countries due to heterozygote advantage against malaria. Glucose-6-phosphate dehydrogenase deficiency is estimated to occur in some 100 million individuals world-wide. Its clinical and haematological manifestations are discussed in Chapter 22.5.12. They include haemolytic reactions to a wide variety of drugs, and, of particular public health significance, to certain foods (favism). There is a form of ovalocytosis which is particularly common in Melanesia which is associated with a mild and well compensated haemolytic anaemia. Recent studies have shown that carriers of Melanesian ovalocytosis are completely protected against cerebral malaria.

Consequences of anaemia

The results of many studies directed at determining the functional consequences of anaemia are still controversial. It is often difficult to distinguish between the effects of anaemia *per se* and the consequences of iron or folate deficiency on other physiological functions. Whatever the mechanism, chronic anaemia is associated with diminished function.

Many studies have suggested that even mild anaemia may reduce near-maximal work capacity. There is some evidence that both in iron-deficient animals and children it reduces mental performance and immune function. There is no doubt that anaemia increases maternal mortality and morbidity. There is a very large literature on the effect of iron deficiency on resistance to infection, as mediated through either immune function or the bacteriostatic and bacteriocidal roles of iron-containing proteins such as transferrin and lactoferrin. The entire complex relationship between iron status and susceptibility of infection requires further work. It is clear that folate deficiency is associated with an increased prevalence of obstetric complications and fetal malformation, although its effect on intellectual and immune function is less clear.

In short, because of the remarkable ability of otherwise healthy individuals to adapt to moderate anaemia it seems likely that many of the associated manifestations which have been observed result from the effects of different deficiency states on other physiological functions rather than the anaemia *per se*. On the other hand, chronic severe anaemia, particularly in childhood, results in a wide variety of complications including failure of growth and development and, possibly, proneness to infection.

Prevention

It is beyond the scope of this brief review to discuss the protean aspects of the prevention of anaemia, particularly in poorer countries. Its high prevalence is a reflection of gross poverty, particularly as manifested by nutritional deficiency, infection, and malabsorption. Its control requires action on many different fronts, including improvements in diet, fortification of commonly eaten foods with iron, the use of modified milk formulae for infants, malaria and hookworm control, iron and folate supplementation in pregnancy, and all round improvements in hygiene. The problem of the population control of sickle cell anaemia and thalassaemia is discussed in Chapter 22.5.7. Good antenatal care helps to prevent anaemia in childhood by reducing prematurity, increasing average birth weight, and improving the nutritional status of the newborn.

Summary

The extremely high prevalence of anaemia in the poorer countries is a reflection of the abject poverty of many of their populations. The anaemia of the developing world, particularly in childhood, seems to reflect a series of vicious circles. Maternal anaemia due to iron or folate deficiency and chronic malaria is associated with the birth of underweight infants who frequently have low iron stores and may also be folate depleted. Anaemia is usually present from about 6 months of age. Such infants are prone to infection, particularly gastrointestinal, and may be further depleted of iron or folate by inappropriately prolonged breast feeding or weaning onto an inadequate diet. They are exposed to hookworm infection as soon as they start to crawl, malaria becomes a major problem after 6 months, and in many populations the increasingly common haemoglobinopathies are a further cause of anaemia after the first few months of life.

22.5.4 Iron metabolism and its disorders

T. M. Cox

Homeostasis, transport, and storage of iron

Iron is a critically important micronutrient. As a component of metalloenzymes and complexed to form haem, it participates in the transport of oxygen by haemoglobin and myoglobin and in the harnessing of metabolic energy by cytochromes of the electron transport chain.

Iron is abundant in the environment and is the fourth most common element in the earth's crust but iron chemistry poses exceptional problems for living organisms. The metal exists in two readily interconvertible redox states (divalent ferrous and trivalent ferric iron) which are very reactive. In the environment, most iron is oxidized to the trivalent state which, under neutral conditions, is then rapidly hydrolysed to insoluble polyhydroxide complexes that are metabolically inaccessible. High-affinity iron-binding proteins that complex ferric iron have evolved to ensure its transport in the body and delivery to sites of utilization and haem biosynthesis. In bacteria and archaebacteria, a family of compounds termed siderophores have evolved that are secreted into the environment to complex ferric iron competitively for uptake. The availability of iron is limiting for growth for many microbes and for algal growth in the oceans.

In humans, iron deficiency is probably the most frequent organic illness. It affects infants, children, young adults, and the elderly in many populations. Iron deficiency is associated with anaemia and non-haematopoietic disturbances that impair work efficiency and contribute to chronic ill health as well as loss of mucosal integrity; iron-deficiency anaemia is frequently associated with pica, which has important environmental and behavioural associations with hookworm infection. In any event, the prevalence of iron deficiency worldwide provides strong evidence of the critical availability of iron in available nutrients.

Iron may be toxic and excess iron in the tissues is associated with structural injury and functional impairment. The harmful effects of iron are a consequence of its electrochemical properties and potential for the formation of reactive oxygen and nitrogen species which injure cell structures including DNA. There are many causes of excess iron in the tissues but all represent disturbances of iron homeostasis that overwhelm the mechanisms which the body uses to acquire, transport, and store iron safely.

Body iron composition

The total amount of iron in the adult body is between 3 and 4 g—most of which is co-ordinated in protoporphyrin IX as haem (Fig. 1). Haem is found principally as haemoglobin and myoglobin, although appreciable quantities are found in the viscera, especially the liver, kidney, and intestine. Cytochromes of the electron transport chain and of the P-450 system for the metabolism of xenobiotics are abundant in these organs and remarkably selective regions of the brain. In an adult, about 2.5 g of iron is complexed in haemoglobin with an additional 0.5 g as myoglobin in the muscles. In the plasma compartment, very small amounts of iron circulate, bound in the ferric form to the glycoprotein transferrin—this protein is normally only one-third saturated with iron, so that with a mean concentration of 3 g/l for a protein of molecular weight 80 000, it represents less than 2 mg of elemental iron. The normal level of serum ferritin is up to about 250 µg/l, which does not represent an appreciable amount of iron; however, the concentration of ferritin in the serum faithfully reflects the stores of iron in the body. Iron is stored in the mononuclear phagocyte (previously reticuloendothelial) system principally as intracellular ferritin and its proteolytic degradation product, haemosiderin. Body iron stores do not exceed 1.5 g in men and are usually 0.5 g or less in adult women. Non-haem deposits of iron that serve as stores in the iron-rich tissues may be visualized by staining with Perls's reagent (acid potassium ferrocyanide) with which they give a strong Prussian-blue reaction. Faint staining with Perls's reagent may be observed in normal parenchymal liver cells, but in health the principal deposits of storage iron are observed in bone marrow and spleen macrophages as well as in Kupffer cells of the liver.

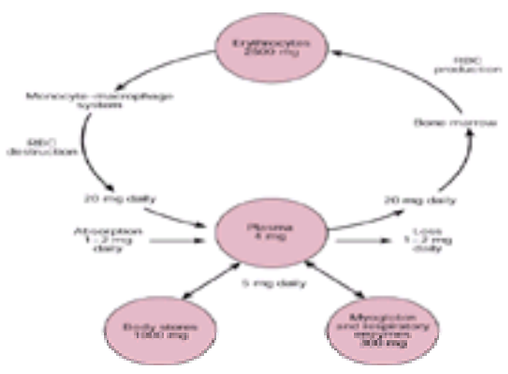

Fig. 1 Daily flux of iron through storage and transport compartments.

Erythropoiesis and iron balance

The mean lifespan of the red cell is 120 days and thus approximately 1 per cent of the steady-state haemoglobin pool is resynthesized each day—this requires *de novo* synthesis of approximately 6 g of haemoglobin into which 20 mg of iron is incorporated. The principal fraction of the iron required for daily haemoglobin production in the basal state is recycled from senescent red cells after their destruction by macrophages; the iron is delivered to the erythron in the plasma by transferrin that binds to cell surface receptors and erythroid precursors (Fig. 1). The transferrin–receptor complex is internalized and, after acidification in endosomes, the iron is released leaving the apotransferrin to be recycled to the surface and re-utilized. Transferrin is the normal mediator of iron delivery and transport in the body.

Under circumstances in which erythropoiesis is stimulated, for example under conditions of reduced oxygen saturation, after bleeding and haemolysis, as well as in dyserythropoietic conditions (including thalassaemia and megaloblastic anaemia), uptake and delivery of iron are greatly increased. Increased delivery of iron occurs in association with an expansion in the number of erythroid precursors that express cell surface transferrin receptors under the influence of the hepatorenal hormone, erythro-poietin.

Iron homeostasis

Iron, an essential nutrient, is fastidiously conserved by the body and only a fraction of that which is utilized in the bone marrow is subject to obligatory daily losses through the exfoliation of epithelia and intercurrent blood loss, such as that incurred in trauma or menstruation. The requirements for iron are met from the diet by the specific absorption of iron in the upper small intestine. The amount of iron available in the diet varies greatly and even under optimal circumstances only a fraction is normally absorbed: in adult men the daily requirement is on average 0.8 mg, whereas in adult women of the reproductive age group, the requirement is usually more than 2 mg daily—the recommended daily allowance in the diet is 10 to 20 mg depending on the bioavailability of food iron components. Inorganic and haem iron complexes are released by digestion; there is a belief that haem iron may be more readily absorbed than inorganic iron in the human intestine and, depending principally on the content in meat, may constitute an important source of iron. Dietary phytates and medication including antacids and tetracyclines, as well as proton pump inhibitors, H_2 antagonists, and prior upper gastrointestinal surgery, all greatly influence the absorption of food iron. The requirement for iron is clearly increased in patients with recurrent bleeding, or in those who are blood donors; iron requirements are also increased during periods of growth in childhood and adolescence. In pregnancy, the daily requirement may be as much as 5 mg and the maternal investment of iron, depending in part on peripartum blood losses, may be as much as 1.5 g—this greatly exceeds the savings due to the cessation of menstruation. Given its iron content, the exsanguination of 1 ml of blood constitutes a loss of approximately 0.5 mg of iron; this relationship facilitates estimates of iron requirements as a result of blood losses, for example those incurred by menorrhagia (more than 80 ml/month) or from other sources.

Iron absorption

In health, iron absorption in the duodenum and upper jejunum is a scrupulously regulated process that matches the acquisition of iron from the diet to body requirements for erythropoiesis and to meet obligatory losses. Under conditions of iron deficiency or on depletion of body iron stores, a greater proportion of bioavailable iron is taken up by the intestine. For reasons that are not fully understood, certain anaemias, particularly those associated with ineffective erythropoiesis and dyserythropoiesis, are also associated with enhanced absorption of iron in the intestine. Where the anaemia is longstanding, for example congenital or acquired sideroblastic anaemia, or in haemoglobinopathies such as b-thalassaemia, intestinal absorption of iron may be such as to cause iron overload leading to tissue injury—secondary haemochromatosis.

The regulation of iron balance by the intestine normally protects the body from iron-rich diets; only under exceptional circumstances, such as the ingestion of alcoholic beverages containing abundant iron as a result of toxic manufacturing processes (for example the kaffir beers that are fermented in iron pots by the South African Bantu), does excess dietary iron lead to iron storage disease. It seems probable that those individuals who develop iron storage disease because of longstanding excessive oral intake do so as a result of the operation of genetic cofactors such as mutant alleles of the adult haemochromatosis gene product, *HFE*, or because of an underlying haematological disorder such as a- or b-thalassaemia trait.

Evaluation of body iron status

Clinical features

The most useful clinical measures of iron status include the detection of pallor and non-erythropoietic manifestations of disease including angular cheilosis, atrophic glossitis, and dystrophy of the nails with longitudinal ridging and koilionychia. Iron deficiency has been associated with behavioural changes in experimental animals. In humans, unusual syndromes of food craving (pica) have been recorded and appear to respond to iron supplementation: this includes craving for soils and the ingestion of silica-rich earths as a cult practice in black populations of the Southern United States—geophagia. Pagophagia (ice-craving) combined with the abnormal taste preferences of pregnancy may account for the bizarre food craving that constitutes part of the folklore of pregnancy. Severe iron deficiency may occasionally be associated with splenomegaly and the signs of underlying disease include peripheral oedema (hypoalbuminaemia associated with massive hookworm infection) and oronasal telangiectasia associated with Osler–Rendu–Weber disease (hereditary haemorrhagic telangiectasia).

Laboratory findings

The most useful measurements apart from those identifying the hypochromic microcytic anaemia associated with abnormal blood cell indices and confirmed by microscopy of the blood film involve surrogate measures of body iron stores. A raised platelet count would suggest a haemorrhagic component associated with iron deficiency anaemia. Iron-deficient erythropoiesis is associated with an elevation of free protoporphyrin in red cell precursors which is reflected in a raised free erythrocyte protoporphyrin in the peripheral blood; this may be easily identified in small samples of blood, taken for example as part of population screening, by the use of portable fluorimeters.

In iron-deficiency anaemia, the absolute concentration of transferrin is raised, with an increase in transferrin iron-binding capacity (**TIBC**). This is reflected by a decrease in serum iron and serum iron transferrin saturation. Such measurements may often serve to discriminate the hypochromic microcytic anaemias of thalassaemia and sideroblastic anaemia from true iron-deficiency anaemia. Such discrimination is necessary before a commitment to iron therapy is ever undertaken.

Measurement of the serum ferritin is often helpful in iron deficiency; serum ferritin concentrations are low, reflecting reduced or absent body iron stores. Neither the serum transferrin saturation nor serum ferritin, however, are absolutely infallible measures of iron deficiency: serum transferrin iron saturation may be artificially elevated with a low transferrin and low serum iron in chronic inflammatory states associated with the anaemias of chronic disorders. Likewise, serum ferritin serves as an acute-phase reactant and may be elevated in malignant disease (especially lymphomas including Hodgkin's disease), or released from the liver in hepatitis and in chronic inflammatory states. Recently there are advocates for the measurement of free circulating transferrin receptors which may be determined by immunoassay. Expression of soluble transferrin receptor protein is enhanced under conditions of iron deficiency and plasma concentrations are elevated in the presence of functionally iron-deficient erythropoiesis; however, greatly increased serum transferrin receptor concentrations are found under conditions of erythroid hyperplasia in the bone marrow and especially when ineffective erythropoiesis occurs (megaloblastic anaemia, haemoglobinopathies, sideroblastic anaemia).

Staining of iron stores in the bone marrow with Perls's reagent is a robust and relatively simple method for resolving difficulties that arise in the investigation of patients with suspected iron-deficiency anaemia. Although an examination of the amount of iron (usually graded semiquantitatively on a scale from 0 to 4, reflecting the strength of Prussian-blue staining) does not provide any information as to the availability of the iron for haemoglobin formation, it does provide useful information as to the appropriateness of iron therapy for hypochromic anaemia. Bone marrow examination, moreover, may be diagnostic in patients suffering from hypochromic anaemias due to primary or sideroblastic change in the marrow, since the characteristic ring sideroblasts with or without other myeloblastic changes will be apparent.

In summary, the laboratory evaluation of patients with suspected iron deficiency should include a full examination of haematological parameters including microscopy of the blood film. Quantification of serum iron, serum transferrin, and transferrin saturation (TIBC) may be valuable in establishing the cause of the hypochromic or microcytic anaemia. Serum ferritin measurements are often confirmatory in the absence of malignant, hepatitic, or other inflammatory diseases—as may fluorimetric red-cell protoporphyrin assays. Determinations of serum transferrin receptor concentration may provide evidence of increased demands for iron by the marrow or indeed expansion of the erythron but this test is not readily available. Microscopic examination of a bone marrow aspirate, including staining with Perls's reagent, may

provide valuable information about iron stores in macrophages and the need for iron supplementation.

Disturbances of iron metabolism

Disorders of iron metabolism are common contributory factors in disease: iron deficiency is rife, particularly amongst the poor and others whose access to meat is limited and those in whom hookworm infestation occurs. At the same time, the prevalence of haemoglobinopathies and other anaemias such as myelodysplasia and sideroblastic syndromes that require transfusion and cause hyperabsorption of iron associated with ineffective erythropoiesis mean that iron storage disease also represents a major world health problem. In addition, as discussed in Chapter 11.7.1, hereditary haemochromatosis occurs at a high gene frequency in certain populations: this includes peoples of North European descent (adult haemochromatosis, due to mutations in *HFE*) and those of sub-Saharan African origin (African iron overload), in whom the nature of the predisposing gene is unknown.

Iron deficiency

About 30 per cent of the world's population, nearly two billion individuals, are anaemic and at least half of this group are believed to have iron-deficiency anaemia. Up to 20 per cent of menstruating females even in rich countries, such as the United States and in Europe, have signs of iron deficiency. In children and young adults, there is a frequency of between 5 and 10 per cent of iron-deficiency anaemia—particularly in deprived socio-economic groups.

Many population studies have in the past been based on erroneous attribution of anaemia solely to iron deficiency: there are many conditions, including the anaemia of chronic disorders and haemoglobinopathies such as b-thalassaemia trait, that lead to hypochromic or microcytic red-cell indices. Population surveys based on the detection of iron-deficient erythropoiesis, especially those using determination of free red-cell zinc protoporphyrin concentrations by fluorimetry, may enhance the detection of true iron-deficiency anaemia; determinations of serum ferritin concentrations also facilitate discrimination between the anaemia of chronic disease and true iron deficiency.

Causative factors

Iron-deficiency anaemia in populations is often attributed solely to an iron-poor diet, but in the absence of significant blood loss or intestinal parasites including hookworm, even the most iron-poor diets rarely cause iron-deficiency anaemia, except in growing children. The amount of iron required to repair obligatory losses is very small so that at least 90 per cent of the iron required for *de novo* haemoglobin formation in erythropoiesis is retrieved from senescent erythrocytes broken down by the mononuclear phagocyte system. Furthermore, once iron deficiency develops, striking adaptive changes occur in the absorptive mechanism for iron in the upper small intestine. In experimental animals with iron deficiency, mucosal expression of the divalent metal transporter 1 (**DMT 1**), on the brush border membrane of the intestinal epithelium, is induced. Iron-deficiency anaemia is also associated with enhanced intestinal expression of mucosal ferrireductase activity.

These changes may not represent the portfolio of adaptive changes that occur. There is evidence that iron deficiency is associated with the recruitment of a greater length of mucosal surface in the upper small intestine for participation in the absorption of luminal iron. Iron deficiency, and the response to the removal of a unit of blood, may increase the overall absorptive efficiency of the intestine for iron up to 10-fold—thus greatly enhancing the bioavailability of dietary iron.

Alcoholic beverages may provide a source of iron and the absorption of haem iron present in red meat, poultry, and fish is usually between 15 and 35 per cent. Between 2 and 20 per cent of non-haem iron present in fruit and vegetable sources is absorbed. Natural enhancers of iron absorption such as ascorbic acid, which maintains ferrous iron in its reduced form in the intestinal lumen, promote direct uptake by DMT 1. Fructose and other organic compounds of low molecular weight also form soluble and reduced complexes with iron released from non-haem sources in food. In the West, normal individuals ingest between about 10 and 15 mg of iron daily. Adult men with normal iron stores absorb approximately 2 per cent of the non-haem iron ingested, whereas men with iron deficiency absorb more than 20 per cent of iron from this source in the diet; the comparable figures for haem iron are 26 and 47 per cent, respectively.

Many compounds present in the diet also inhibit or impede the absorption of iron released by digestion in the lumen. These compounds include tannin, especially present in tea, phytates present in bran and nuts, dietary fibre, and other inhibitory factors such as drugs, including tetracycline and alkalis. Some vegetarians of Asian origin ingest large amounts of phosphate and phytates which inhibit the absorption of iron provided in diets that may contain up to 30 mg of assayable total iron each day. A typical example is spinach which, although rich in iron, leads to the appearance of black stools when consumed in small or moderate amounts; these stools are black because of the passage of iron through the small intestine and its delivery to the colon where it forms insoluble ferrous sulphide complexes through the action of colonic sulphur-reducing bacteria.

Malabsorption of iron

The inability to release and absorb adequate amounts of iron from the diet is an important but unusual cause of iron deficiency. Disease of the stomach, duodenum, and upper jejunum may be responsible for the malabsorption of food iron, which may not be readily detected by studies involving the use of simple radioactive tracer measurements. On the other hand, properly conducted radioactive food labelling studies show that after gastric bypass surgery and after intestinal resection, malabsorption of non-haem and haem food iron sources is the rule. Rarely, iron deficiency may result from inflammatory disease of the upper intestine that causes malabsorption: coeliac disease in infants and adults may be responsible, and the iron deficiency may be combined with deficiency of folic acid. Sometimes large pharmacological doses of iron with or without folic acid may overcome the anaemia caused by coeliac disease but unless a strict gluten-free diet is instituted, the anaemia recurs rapidly after iron therapy is stopped. Although malabsorption of food iron is an important aspect of the iron deficiency associated with coeliac disease, loss of iron exacerbates the effects of malabsorption. In coeliac disease this results from increased exfoliation of the epithelium in association with crypt hyperplasia and bleeding due to ulceration. The abnormal motility and maldigestion associated with upper gastrointestinal surgery compounded by anacidity caused by gastritis or acid-suppressing drugs, also impair the absorption of food iron.

Loss of iron

Women in the reproductive age group lose iron regularly at menstruation. An increased recommended daily allowance for women is higher than in all other groups: the average requirement for healthy menstruating women is approximately 1.4 mg of iron daily to replace losses, compared with normal men who lose about 0.8 to 0.9 mg of iron per day. Pregnancy is often associated with iron deficiency when growth of the fetus is rapid. Twin pregnancies and frequent childbirth, especially in women of low socio-economic groups, are associated with iron-deficiency anaemia. Although anaemia is important, a very large study has been conducted that shows no reliable association between maternal anaemia and the complications of pregnancy, including preterm labour. Pregnancy itself is associated with the development of adaptive responses in the intestine and iron transport proteins that enhance the avidity of the gastrointestinal tract for bioavailable food iron. Clearly socio-economic and sociopolitical considerations are likely to influence the population occurrence of iron deficiency in women of the reproductive age group, particularly since the investment of about 1 to 1.5 g of iron occurs with each pregnancy carried to term. This estimate includes blood loss associated with the birth and the investment of iron placed in human milk, which contains up to 0.5 mg/l of iron bound to the whey protein, lactoferrin.

Other sources of iron loss

Intestinal parasites

Several hundred million people are heavily infested with hookworms. The two common hookworms of humans are *Anclyostoma duodenale* and *Necator americanus*. These helminths attach themselves to the lining of the small intestine by their buccal capsules and cause chronic blood loss by sucking blood from the intestinal villi. Hookworm infestation may be light, so that iron loss is not sufficient to cause iron deficiency. In hookworm disease, involving Old World and New World hookworms, heavy infestation occurs as a result of repeated exposure of the skin to contaminated soil. Mucosal immunity may also be reduced in the susceptible host. Although it is not known exactly what hookworms abstract from human blood, microscopic preparations show red cells expelled from the worm: each *Anclyostoma* induces the loss of up to 300 µl of blood daily, whereas each *Necator* causes the loss of up to 50 µl of blood. Clearly the occurrence of anaemia is dependent on the iron content of the diet, the extent of tissue iron stores, and the duration and intensity of the mucosal helminth infestation itself.

Since up to two-thirds of the haemoglobin iron released by the worms can be reabsorbed in the intestine, significant anaemia requires a very heavy parasite load; none the less, extremely severe anaemia may develop in patients with hookworm disease with all the attendant symptoms of fatigue, dyspnoea, palpitations, and mental changes—including pica. Non-specific abdominal pain may occur and radiographic examination of the intestine or endosccopy may reveal duodenitis with a punctate inflammation associated with partial villus atrophy of the duodenojejunal mucosa. Oedema may result from cardiac failure in severe cases and also in

association with hypoalbuminaemia, since heavy infestation may lead to significant protein-losing enteropathy. Hookworm disease may be associated with other helminth infections such as strongyloidiasis and ascariasis and itself may contribute to poor socio-economic circumstances as a result of incapacity for work due to illness.

Major hookworm parasites are widely distributed in Southern Europe, Africa, the Middle and Far East, and the New World, including the Southern United States. The heaviest infections usually affect rural workers in agricultural communities where repeated exposure occurs in isolated locations and where crops are harvested under conditions of poor sanitation. The iron-deficiency anaemia of hookworm disease may present difficulties for diagnosis when the mucosal inflammation that accompanies heavy infestation is associated with reduction in serum proteins such as albumin and transferrin; this, combined with an acute-phase response, may at first lead to a mistaken diagnosis of the anaemia of chronic disorders.

Other sources of blood loss

The gastrointestinal tract represents an important source of blood loss which should always be considered in patients with iron-deficiency anaemia. Ulcerating lesions of the small and large intestine, including cancers, are frequent causes of iron-deficiency anaemia. However, chronic intermittent bleeding can arise from unusual sources such as Meckel's diverticula, angiodysplastic lesions, hamartomas, and other benign ulcerating tumours such as leiomyomas. Gastric ulcers may be associated with chronic intermittent bleeding, but duodenal ulcers rarely cause chronic gastrointestinal blood loss.

Oesophageal ulceration and inflammatory lesions can cause iron-deficiency anaemia, but precaution is needed in attributing blood loss sufficient to cause iron deficiency to such a source unless other potential sites of bleeding have been excluded. Other unusual sources of gastrointestinal bleeding include multiple telangiectatic lesions of Osler–Rendu–Weber disease (hereditary haemorrhagic telangiectasia)—in which bleeding may occur anywhere from the nasal or oropharynx down to the stomach and upper intestine. The blue bleb naevus syndrome, the Peutz–Jeghers syndrome, and other hereditary gut polyposes are rare causes of chronic gastrointestinal bleeding. Inflammatory disease of the lower small intestine and colon such as Crohn's disease and ulcerative colitis, usually associated with chronic intestinal blood loss, may present with an abdominal history in which iron-deficiency anaemia is prominent. Very occasionally, artefactual iron-deficiency anaemia due to self-bleeding may occur; blood may be removed from any source but bizarre methods may be adopted to conceal it, thus requiring considerable ingenuity, and often detective work, to identify the cause. Because of the striking appearance of expectorated blood, iron-deficiency anaemia associated with frank haemoptosis requires little diagnostic skill, but occasionally recurrent intra-alveolar lung haemorrhage causes unexplained illness and anaemia. Occasionally, iron may be lost in the urine through the kidney in conditions where chronic intravascular haemolysis occurs. Losses may be sufficient to induce iron deficiency in the absence of marked changes in urine colour. Patients with haemolysis due to prosthetic or paraprosthetic cardiac valve malfunction may be revealed by the presence of characteristic red-cell changes; likewise in paroxysmal nocturnal haemoglobinuria, chronic intravascular haemolysis causes chronic urinary iron loss with or without visible haemoglobinuria. In these circumstances, free haemoglobin is released which quickly saturates the capacity of the plasma protein, haemopexin to bind it; free haemoglobin spills into the glomerular filtrate where it is taken up by the proximal tubular cells and degraded. After degradation to haemosiderin, iron is lost in the urine when the iron-loaded epithelial cells are exfoliated.

Clinical and laboratory features of iron deficiency

Symptoms of iron deficiency include fatigue, pallor, palpitations, irritability, and little-recognized mental changes, such as pica. The patient may complain of a sore tongue, deleterious changes in the appearance of hair or hair loss, and angular cheilosis. Examination of the nails may reveal longitudinal ridging and, most often in elderly women with chronic iron deficiency for many years, koilionychia. There may be a complaint of dysphagia associated with the development of an oesophageal web (Patterson–Brown–Kelly or Plummer–Vinson syndrome). This again usually occurs in elderly or middle-aged women with chronic iron deficiency. A small proportion of patients with iron-deficiency anaemia have detectable but modest splenomegaly.

Diagnosis

Blood parameters will reveal microcytic anaemia usually in association with an unequivocal reduction in serum transferrin saturation (below 16 per cent) and a reduced serum ferritin concentration (below 12 µg/l). The absence of these features and of an acute-phase reactive response may suggest dyserythropoietic or sideroblastic anaemia or b-thalassaemia trait. Lead poisoning may be associated with iron deficient indices with or without full-blown sideroblastic changes. A bone marrow aspirate stained with Perls's reagent for iron in marrow macrophages will rapidly confirm reduced or absent stainable iron in the storage compartment and may also be revealing about other aspects of the anaemia, such as the presence of ring sideroblasts, dyserythropoietic features, and/or megaloblastic change.

The presence of immunoreactive serum transferrin receptors may provide additional evidence in favour of iron-deficiency anaemia but because increased serum concentration of these receptors may be observed in several disorders of the bone marrow and the ELISA tests are relatively expensive, the role of this determination in the routine diagnosis of iron deficiency is as yet unestablished. Red-cell zinc protoporphyrin concentrations greater than 35 µg/dl of whole blood are usually observed in patients with iron deficiency; values in excess of 100 µg/dl are generally associated with lead toxicity. Extremely high levels may indicate the presence of erythropoietic protoporphyria or lead poisoning. Modest elevations in erythrocyte protoporphyrin can be observed in patients with haemolytic anaemias, sideroblastic anaemia, and occasionally, the anaemia of chronic disorders.

Investigations and management

The identification of iron-deficiency anaemia should be regarded in a sense as a symptom rather than a diagnosis of a patient's malady: the management of those affected should always include an attempt to determine the cause. Common errors occur when, in elderly patients, iron deficiency is cynically ascribed to the presence of mild oesophagitis or gastritis observed at endoscopy, when the underlying cause is bleeding due to a coincidental but sinister gastrointestinal cancer elsewhere—and for which a diligent search is often required.

A full evaluation of the patient with iron deficiency should include an adequate dietary history including the consumption of drugs, such as aspirin and non-steroidal anti-inflammatory drugs, that may be responsible for gastrointestinal bleeding. An enquiry should be made about additional gastrointestinal symptoms and other signs of blood loss; reasonable attempts should be made to evaluate the extent of menstrual loss, if the bleeding is to be ascribed to menorrhagia in women of the reproductive age group. Attention should be placed on the family and a travel history to exclude causes such as hereditary haemorrhagic telangiectasia or hookworm disease.

Clinical examination should extend from an enquiry about previous gastrointestinal disease or surgery to an examination for visceral enlargement, abdominal lymphadenopathy, splenomegaly, and other features suggestive of intra-abdominal pathology such as portal hypertension and abdominal cancer. Hereditary haemorrhagic telangiectasia may be detected by the presence of the most subtle oronasal lesions.

In patients in which the cause of the iron deficiency is not apparent, further studies may be needed to search for gastrointestinal bleeding, including detection of occult faecal blood on several samples taken consecutively. Endoscopic and radiographic studies of the gastrointestinal tract, and serological studies for the presence of coeliac disease may be required and occasionally there is a need to quantify the amount of blood loss daily in the faeces or during menstrual flow by using radiolabelled chromium red-cell studies. In difficult cases, percutaneous visceral angiography of the coeliac and mesenteric arteries has proved invaluable for detecting sites of active gastrointestinal bleeding that are beyond the reach of conventional endoscopic procedures. In those patients who are actively bleeding, such a procedure can identify local sites of blood loss greater than 0.5 to 1.0 ml/min. Meckel's diverticulum is a potential cause of obscure gastrointestinal bleeding in young adults and children. Some Meckel's diverticula can be diagnosed by scintigraphic studies using technetium-99m labelled pertechnetate which may be concentrated in the ectopic gastric mucosa. Meckel's diverticulum and intestinal strictures, particularly in the ileum, may be occasionally revealed by retrograde colonic contrast radiographic studies. Other diagnostic tests include searching for endomysial antibodies, with confirmatory duodenojejunal biopsy to detect coeliac disease. Examination of the urine and sometimes sputum may be required to detect occult iron loss in exfoliated macrophages or proximal tubular cells, respectively, where intrapulmonary haemorrhage or renal iron loss is suspected.

Sometimes extensive diagnostic procedures fail to identify the cause of iron deficiency when occult gastrointestinal bleeding is responsible. Under these circumstances, it remains appropriate to conduct a diagnostic laparotomy, after consultation with an experienced surgeon, to identify the bleeding lesion. In adults of any age, an appreciable number of obscure gastrointestinal malignancies or treatable benign tumours can be identified by such a procedure which, when combined with angiography with or without enteroscopy, may permit identification of angiodysplastic lesions at remote sites. In younger adults and children, diagnostic laparotomy may be indicated to identify Meckel's diverticula, intestinal stricture, and congenital abnormalities such as duplications that serve as occult sources of

blood loss.

It is not unusual for the patient with recurrent chronic iron-deficiency anaemia to present a challenge for diagnosis. Even the most experienced physician would be well advised to consult widely with colleagues with expertise in radiology, nuclear medicine, and surgery before either prematurely abandoning the search of the causal lesion or requesting an ill-considered laparotomy without a thorough appreciation of the further difficulties it may pose.

Replenishing iron stores is but one aspect of the treatment of iron-deficiency anaemia. Iron should be replaced not only to restore the normal haemoglobin concentration but to replenish body iron stores. It is necessary to replace iron depleted in systemic tissues such as the muscles, where it is an essential component of cytochromes and other enzymes critical for optimal aerobic metabolism. Occasionally a therapeutic trial of oral iron for a defined period may be used to verify the suspected diagnosis of iron-deficiency anaemia. Adequate replacement of iron should be monitored for its effects: a reticulocyte response should be observed in peripheral blood maximally between the 7th and 10th days after initiating treatment and significant increases in blood haemoglobin concentration should be apparent within 2 to 4 weeks. If there is no evidence of continued blood loss, the haemoglobin concentration should come within the normal range within 2 months. Failure to meet these expectations suggests either that the anaemia is not caused by iron deficiency or that there is continued depression of bone marrow function—or that there is bleeding for which further investigation is needed.

Therapeutic preparations of iron

Iron salts should be administered by mouth unless there are overwhelming reasons for using the parenteral route—parenteral preparations of iron are associated with a greatly increased risk of toxicity and hypersensitivity reactions including anaphylaxis. Ferrous salts are better absorbed than ferric salts and show little difference amongst preparations in terms of rate of repair of anaemia at a given dosage of elemental iron.

It is usual to treat iron-deficiency anaemia with at least 100 to 200 mg of elemental iron daily. For full-blown iron-deficiency anaemia, ferrous sulphate is administered three times daily (equivalent to 3 × 65 mg of elemental iron). Some patients are unable to tolerate such a dose of iron because of constipation, diarrhoea, or abdominal pain; the presence of tarry, black stools may interfere with personal hygiene and thus lead to ultimate rejection of iron therapy by the patient. Under these circumstances the dose of iron may be reduced and this, rather than a change of iron salt preparation, usually improves tolerability. The frequency of unwanted effects with ferrous sulphate is the same as that of other iron salts when compared with the amount of elemental iron ingested. Once established, the optimal therapeutic response to oral iron increases the blood haemoglobin concentration by 0.1 to 0.2 g/dl per day. Replenishment of iron has a slow effect on the epithelial changes of iron deficiency and the atrophic glossitis may take several months to improve as iron stores are replenished.

Slow-release oral preparations of iron are available, which the manufacturers often claim release sufficient iron over a 24-h period for optimal haematological responses after once daily dosages. However, these preparations are likely to distribute the iron beyond the upper jejunum and thereby bypass those regions of the intestine in which iron absorption is most avid. Compound preparations of iron including B vitamins and folic acid are available but there is little justification for prescribing these except for prophylactic use in pregnancy (see below). In infants and children, sugar-free preparations of iron complexes are available in the form of polysaccharide iron or iron–sodium EDTA (sodium ironedetate) complexes, which can be used as recommended by the manufacturer. In premature infants, up to 2.5 ml of a syrup containing approximately 5 mg/ml may be used twice daily; up to 5 ml three times daily may be given to children aged 6 to 12 years.

Pregnancy

Prophylactic iron preparations are recommended in pregnant women who have risk factors for iron deficiency such as poor diet, prior menorrhagia, or those in whom gastric surgery has been carried out. Prophylactic iron may also be used in the management of infants of low birth weight including premature babies, twins, and infants delivered by caesarian section. Compound preparations of iron with folic acid may be used for the treatment of iron and folic acid deficiencies in pregnancy. For the prevention of neural tube defects in women planning a pregnancy, the United Kingdom Department of Health advises that a medicinal or food supplement of 400 µg of folic acid daily be taken before conception and during the first 12 weeks of pregnancy. Lone or combined iron compound preparations are not routinely indicated for prophylaxis in patients with chronic haemolysis or in renal dialysis since they may lead, in the circumstances of dyserythropoiesis, to chronic iron overload and secondary haemochromatosis.

Parenteral preparations of therapeutic iron

Given its potential toxicity, the only justification for the use of parenteral iron is in patients who are unable to co-operate with or tolerate oral iron therapy, or those with severe gastrointestinal disease that causes malabsorption or continuing severe blood loss. Provision of iron by the parenteral route does not normally lead to more rapid repair of anaemia than when adequate oral iron preparations are administered. Some patients with renal failure who receive haemodialysis have obligatory blood losses which cannot be treated adequately with oral iron preparations. These patients, and occasional patients receiving peritoneal dialysis, may require intravenous iron regularly. Two parenteral preparations of iron are now available in the United Kingdom: a ferric hydroxide–sucrose complex containing 20 mg/ml of iron (2 per cent) and iron sorbitol citrate that consists of a colloidal stabilized preparation of iron containing 50 mg/ml. Severe sensitivity reactions to these agents may occur and facilities for cardiopulmonary resuscitation should be at hand with the use of iron–sucrose complex. Moreover, administration of these preparations should not be followed by oral iron therapy until at least 5 days after the last injection.

Unwanted and toxic effects of parenteral iron preparations

A history of allergic disorders including asthma, eczema, and prior anaphylaxis are regarded as contraindications to the use of parenteral iron, as is liver disease and concurrent infection. Moreover, these drugs are not recommended for children. Side-effects include nausea, vomiting, taste disturbances, hypotension, parasthesias, abdominal disorders, fever, flushing, anaphylactoid reactions, and the reactivation of inflammatory arthropathies. Injection site reactions, including phlebitis, have been reported. Iron sorbitol is contraindicated in patients with untreated urinary tract infections and early pregnancy as well as liver disease and kidney disease. Parenteral iron should probably be avoided in patients with pre-existing cardiac disease including arrythmias or angina.

Administration

Iron sorbitol is given only by deep intramuscular injection, whereas iron–sucrose complex may be given slowly intravenously or by intravenous infusion. In both instances the total dose is calculated according to body weight and the presumed iron deficit set out in the manufacturer's product literature.

General aspects of iron therapy

Treatment of causes of anaemia, including bleeding, is clearly a critical aspect of the management of iron-deficiency anaemia and its diagnosis. Coeliac disease should be treated with a gluten-free diet; bleeding lesions in the gastrointestinal tract may require definitive surgery directed to their healing. Occasionally, patients with a chronic bleeding disorder for which surgery is not indicated, such as hereditary haemorrhagic telangiectasia, may require long-term iron supplementation at doses less than that required to treat the acute iron-deficiency state. Periodic monitoring is required to ensure that the level of iron replacement is adequate to meet the demands of the bone marrow for *de novo* haem synthesis and that iron overload is not occurring. It should be recognized that relief of iron deficiency will improve many symptoms suffered by a patient even though they may suffer from an incurable underlying disease.

Treatment with iron should be continued until iron stores are replenished: there is no excuse for inadequate therapy—especially in those patients who are likely to suffer recurrent bleeding. Particular attention is needed for iron-deficient patients who have had episodes of acute bleeding treated by blood transfusion and who at the time of therapy are not anaemic. These patients require appropriate iron replacement to replenish iron stores for their long-term restitution of health. Because iron therapy leads to a reduction in the avidity of the transport system of the intestine for iron, it should be continued for several months after the anaemia has been corrected to re-establish appropriate iron stores, ideally as reflected by a serum ferritin determination within the normal range.

Unusual syndromes with iron-deficient erythropoiesis

Congenital deficiency of serum transferrin

There are a few reports of deficiency or virtual absence of serum transferrin in infants with disturbed growth, marked hypochromic anaemia, and disordered iron

metabolism associated with systemic iron storage leading to tissue injury. This disease is extremely rare but holds great fascination for those investigators with an interest in the pathophysiology of iron metabolism. Profound deficiency of serum transferrin disturbs the normal ligand–receptor signalling mechanisms indicated in the overall control of body iron balance and absorption in the intestine. Hypo- or atransferrinaemia in humans appears to be inherited as an autosomal recessive trait; the gene encoding human serum transferrin maps to chromosome 3.

Studies of a naturally occurring mutant mouse, the *hpx* mouse, that also has deficiency of serum transferrin associated with runting and hypochromic anaemia due to iron-deficient erythropoiesis indicate that the disorder responds to infusions of serum transferrin or plasma. These infusions restore normal growth and improve the abnormalities of iron homeostasis; iron-deficient erythropoiesis is also corrected, with resolution of the anaemia. The half-life of transferrin in the plasma is 5 to 10 days and so infusions of plasma or purified preparations enriched with transferrin can be administered at intervals. Since most individuals with transferrin deficiency do express limited amounts of the protein antigen, immune reactions to exogenous human transferrin appear to be either mild or rare. Absolute deficiency of transferrin receptors, for example as occurs in mouse embryos generated as a result of gene disruption technology in embryonic stem cells, is incompatible with normal development beyond the late embryo stage.

Other causes of refractory iron-deficient erythropoiesis

There are sporadic reports of iron deficiency occurring in children and adults for which no cause can be established after intensive investigation. In some instances the expected parameters of iron deficiency associated with iron-deficient erythropoiesis can be demonstrated in individuals who fail to respond to generous oral supplementation with iron salts; administration of parenteral iron, however, leads to an improvement in reticulocytosis with resolution of iron-deficient red-cell indices. Although at the time of writing no molecular lesions have been identified in any of the implicated iron and transport proteins, it is not impossible that disturbed function of DMT 1, ferroportin, haephastin, or as yet uncharacterized moieties involved in the transport of iron across the intestine will be found in these disorders.

Occurrence of iron-deficient erythropoiesis in both females and males that responds only to parenteral iron supplementation is unlikely to be caused by hephastin mutations since this gene maps to the long arm of the X chromosome in humans. It is possible that acquired defects of the intestinal mucosa other than inflammatory disorders may contribute to malabsorption of therapeutic iron. Several young children have been reported with iron-deficiency anaemia refractory to oral therapy but which was corrected by parenteral supplementation. Careful investigation revealed an absorptive defect for iron which was corrected itself by systemic iron supplementation and raises the possibility that severe iron deficiency itself prejudices the ability of the mucosal epithelium in the upper small intestine to carry out its normal absorptive function. However, no further investigations to identify the nature of this acquired metabolic defect have been provided. There is at least one well-documented instance of an acquired defect of iron delivery associated with signs of iron-deficient erythropoiesis caused by loss of human transferrin receptor function. This condition was associated with the development of antinuclear factor and other autoantibodies as part of an autoimmune illness in an adult woman with hypochromic anaemia. Autoantibodies directed against the transferrin receptor were identified in the serum of the patient, but the anaemia with its attendant sideropenia ultimately responded to a combination of steroids and azathioprine therapy; the titre of transferrin receptor autoantibodies of peripheral blood cells diminished. The extent to which this phenomenon occurs generally during the course of autoimmune disorders associated with anaemia is unknown.

Secondary iron storage disease (secondary haemochromatosis)

This is a worldwide problem. It occurs when excess iron is absorbed from the intestine or obtained by the breakdown of transfused red cells in the mononuclear phagocyte system. Each transfused unit of blood contains 200 to 225 mg of iron as haemoglobin. There are instances of iron storage disease occurring in patients who have received oral iron therapy over many years as medicinal tonics or as treatment for refractory anaemia. However, it is unknown if this would occur in the absence of another disorder, such as homozygosity for mutant alleles of the *HFE* gene that predisposes to iron storage disease or underlying bone marrow disease. Conversely, iron excess may develop spontaneously in patients with haemolytic (and especially dyserythropoietic) anaemias alone, although it most commonly results from transfusion with or without underlying bone marrow disease (Table 1).

Each millilitre of human blood contains the equivalent of 0.5 mg of elemental iron complexed with protoporphyrin. Iron present in transfused red cells is eventually retrieved after their breakdown in the macrophage system as a result of the actions of haem oxygenase, which releases bilirubin, carbon monoxide, and one atom of iron per haem molecule; thus each molecule of haemoglobin A yields four iron atoms. Although it is the mononuclear phagocyte system in which significant iron storage is first detected in transfused individuals, continued delivery of iron by its route leads to the excess of iron-loaded ferritin and its breakdown product, haemosiderin, in parenchymal cells throughout the body, with ensuing tissue injury and functional impairment. After the transfusion of 15 to 20 units of blood (representing around 5 g of elemental iron), iron toxicity occurs.

In dyserythropoietic anaemias such as thalassaemia and sideroblastic anaemia, symptoms and signs of iron storage disease may develop early in life and are related to increased dietary iron absorption by the intestine. Although some patients with b-thalassaemia intermedia are treated by occasional transfusion, much of the excess iron stored in the body originates from ingested rather than transfused iron. Iron absorption in healthy adults amounts to 1 to 2 mg/day, but in b-thalassaemia intermedia this may be increased more than fivefold. In regularly transfused patients with b-thalassaemia major, the massive expansion of the erythropoietic marrow may be suppressed to render absorption of iron normal or near normal. However, in patients with thalassaemia who are transfused only intermittently, erythroid hyperplasia persists and excessive absorption of iron from the diet contributes significantly to the iron storage derived from transfused cells; several grams of additional iron may thus be acquired each year.

Patients with hypochromic anaemias due to sideroblastic change in the marrow are particularly at risk because they may be misdiagnosed as suffering from chronic or recurrent iron-deficiency anaemia; they thus receive long-term supplementation with oral iron that serves merely to exacerbate the iron-loading state. It is noteworthy, however, that patients with haemolytic anaemia due to sickle-cell haemoglobin C disease do not commonly develop iron overload as a result of enhanced iron absorption: iron storage disease is thus generally restricted to transfused patients with chronic anaemias. Particular difficulties arise in refractory anaemias in which there is a hyperplastic bone marrow with ineffective erythropoiesis which appears to drive the inappropriate absorption of iron by the intestine.

In the South African Bantu people, the excess iron is ingested in an unusually bioavailable form in beers and other alcoholic drinks prepared by fermentation in iron pots (kaffir beers). Soluble complexes of readily bioavailable iron in these drinks contribute to secondary haemochromatosis, which is common in men in this population and other related sub-Saharan African populations. Although much of the iron is at first detected in the mononuclear phagocyte system (and is seen particularly in Kupffer cells on liver biopsy), associated hypogonadism and vitamin C deficiency later induce scurvy and osteoporosis. Dietary adjustment and iron chelation therapy may relieve the disorder, which is becoming less common after its recognition in the early 1950s. It is of interest that family studies point to a genetic component which predisposes individuals to this secondary iron storage disease within given pedigrees.

The nature of the stimulus leading from the excess iron turnover that accompanies hyperplastic bone marrow to the intestinal disturbance is unknown. The degree of excess iron absorption is however related to the extent of expansion of the red-cell precursor population: blood transfusions, which suppress the marrow, decrease the absorption of food iron. The toxic properties of iron appear to be related to its capacity to participate in free radical-generating reactions that form reactive oxygen and nitrogen intermediates implicated in tissue injury.

Clinical features

The clinical features of secondary iron storage disease in children with chronic anaemias closely resemble hereditary forms of juvenile haemochromatosis (see Chapter 11.7.1). Iron accumulates rapidly in the liver and in the endocrine glands. The several hundred gonadotrophs present within the anterior pituitary gland appear to be particularly susceptible to iron toxicity and hypogonadotrophic hypogonadism results. Iron also accumulates in the b-cells of pancreatic islets, leading to diabetes; in the zona glomerulosa of the adrenal glands, leading to early-onset adrenocortical failure; and in the parathyroid glands, ultimately causing hypoparathyroidism. Secondary iron storage disease also has a predilection for the myocardium. This causes sudden death as a result of tachyarrythmias and injury to cardiac conducting tissue or cardiomyopathy which causes intractable cardiac failure. Secondary iron storage disease in b-thalassaemia and congenital dyserythropoietic anaemias is thus characterized by progressive myocardial disease, endocrine failure, and infantilism.

Untreated iron storage disease is the most common cause of death in these disorders. Similar manifestations of iron toxicity are observed in other patients with secondary iron storage in which the accumulation of iron is less rapid. A picture resembling full-blown adult haemochromatosis ultimately supervenes with complications of diabetes and cirrhosis (sometimes complicated by transfusion-related viral hepatitis and the formation of hepatocellular carcinomas) in the presence of deep skin pigmentation. Secondary iron storage disease represents a significant threat to well-being and prognosis in the chronic anaemias. Once cardiac arrythmias have developed, the outlook is usually bleak and urgent chelation therapy with parenteral desferrioxamine is indicated.

Diagnosis

Secondary iron storage disease should be suspected when the saturation of serum transferrin is greater than 60 per cent. In established secondary iron storage disease, there is a raised non-transferrin iron-binding fraction which may contribute to the tissue injury, since the amount of circulating iron may exceed the binding capacity of circulating transferrin. Under these circumstances, transferrin saturation is usually measured at greater than 90 to 95 per cent and is accompanied by an elevation of serum ferritin which, in the absence of active liver disease, faithfully reflects the extent of iron storage disease and the risks of iron-mediated damage.

Iron chelation therapy should probably be introduced at serum ferritin concentrations greater than 1000 µg/l or if there is biopsy evidence of excess iron storage or a transfusion load of more than 15 units of exogenous red blood cells. Diagnostic evidence of iron storage may be obtained from biopsies of the liver or myocardium; skin biopsy shows excess iron in the sweat gland acini and perifollicular apocrine glands together with increased melanin deposition. In biopsy samples of the liver and heart, histochemical iron storage can be quantified by chemical iron estimations: often the liver iron content exceeds 2 per cent of tissue dry weight (normally less than 0.14 per cent or 7 mg of iron per gram dry weight). Iron concentrations may exceed 5 per cent in affected tissues such as endocrine glands and the pancreas. Liver biopsy may facilitate staging of the disease, particularly in relation to coincidental viral hepatitis where the presence of fibrosis and cirrhosis combined with iron deposits in the parenchymal cell may contribute useful prognostic information. In patients in whom tissue biopsy determinations are not possible, an estimate of body iron overload may be gained by injection of a single dose of 500 mg of desferrioxamine intramuscularly and collection of urine for 24 h in an iron-free plastic container; the daily excretion of more than 2 mg of the coloured ferrioxamine–iron complex indicates iron excess.

Although serum ferritin concentrations generally reflect the amount of iron stored in the tissues, there is a poor correlation between the levels of ferritin in iron-overloaded subjects and clinical outcome. Ferritin concentrations in serum are subject to wide variations; as a result of infection or inflammation (when as an acute reaction it is spuriously elevated), and ferritin concentrations may be reduced when vitamin C is deficient. In contrast, since the liver is the principal site of the iron storage, hepatic iron concentrations provide useful guidance as to prognosis overall, including outcomes from iron-induced cardiac injury, fatal complications of which are usually observed in patients when tissue iron exceeeds 1.5 per cent of dry liver weight. In specialized centres, non-invasive methods have been developed to measure liver iron concentrations, including whole-body magnetic susceptibility techniques but neither this nor sophisticated T_2-weighted magnetic resonance imaging of the heart or liver has been generally accepted in practice. Conventional T_2-weighted imaging may provide a crude assurance that iron storage is either present or under control but is too insensitive to contribute to serial monitoring of secondary iron storage disease—except for the investigation of potential complications such as hepatocellular carcinoma.

Treatment

Patients with homozygous b-thalassaemia and related conditions who are transfusion dependent require adequate blood transfusion to maintain a normal or near normal haemoglobin concentration combined with desferrioxamine as an iron-chelating agent. Long-term studies provide compelling evidence that survival in iron-loaded b-thalassaemic subjects is greatly enhanced by treatment with subcutaneous desferrioxamine, which prevents and reverses the cardiac manifestations of iron storage disease. It must be noted, however, that full compliance with this demanding treatment is required for benefit to accrue, which requires equal commitment from the patient and attending medical and nursing personnel alike. Splenectomy or bone marrow transplantation may be considered in certain cases but is beyond the scope of this article (see Chapter 22.5.7). The overall outcome and prognosis for b-thalassaemia has also been improved by screening donor blood for HIV and hepatitis B and C viruses, as well as other pathogens. These factors are ancillary but may potentiate the development of secondary iron storage disease.

The preferred route for desferrioxamine administration is by slow subcutaneous infusion over 12 to 16 h for up to 7 days per week; this is usually done on an ambulatory basis in adults but nocturnal administration is used particularly in children. Nocturnal administration relies on the use of slow clockwork or battery-operated infusion devices. Although electrical syringe pumps are in common use (such as the Graseby driver device), smaller quieter infusion devices (such as the Cronoject) are now available. Light precharged balloon pumps manufactured by Baxter, though expensive, are also in use. The total daily dose of desferrioxamine is usually set at 20 to 30 mg/kg of body weight with the maximum usually determined by the extent to which near-saturated solutions of the drug can be tolerated by the patient. In patients without cardiac disease it has been shown that the daily oral administration of ascorbic acid at 2 to 3 mg/kg increases the amount of iron that can be chelated by desferrioxamine. Serial determinations of serum ferritin concentrations, combined with regular clinical monitoring and assessment of cardiac, hepatic, and endocrine function assist in the assessment of iron storage disease and the efficacy of iron chelation therapy. Periodic echocardiograms and electrocardiography, with 24-h ECG monitoring, are desirable aspects of management. Urinary excretion of the coloured ferrioxamine complex can be easily measured by light spectroscopy. Desferrioxamine promotes not only urinary excretion of iron but also chelates iron from the body stores, which is excreted into the faeces via the biliary system.

Several studies show that patients with b-thalassaemia maintained on adequate transfusion regimes who are able to tolerate their infusions of subcutaneous desferrioxamine, grow and develop normally and have a better prognosis than those who either default from or do not comply fully with the chelation regimen. When treatment is initiated, careful monitoring is needed using 24-h urine collections for iron measurements to judge the excretion of iron as the dose of desferrioxamine is escalated. Daily doses of desferrioxamine may be increased to about 50 mg/kg of body weight; this usually represents the maximum that can be tolerated. In infants and growing children, unless severe cardiac disease or iron overload is present, the dose should not exceed 35 mg/kg per day over 5 nights each week. Thereafter, most well-transfused patients with b-thalassaemia can be maintained in negative iron balance by the use of not more than 40 mg/kg. For patients who receive blood transfusions, a single intravenous infusion of desferrioxamine given separately from but at the same time as each blood transfusion, at a dose of approximately 150 mg/kg of body weight, also contributes to the control of iron storage disease. In patients who develop endocrine failure, prompt replacement of deficient hormones should be introduced. Sex-steroid hormone replacement may relieve infantilism and improve self-esteem in developmentally arrested adolescents and children.

Desferrioxamine is usually well tolerated and, apart from minor skin reactions, is remarkably non-toxic. These reactions can usually be controlled by lowering the concentration of the drug in the infusion and by alternating sites of infusion; hydrocortisone in doses of up to 10 mg has been reported to reduce severe cutaneous reactions. Very high doses of desferrioxamine, particularly those used for treatment of life-threatening cardiac iron overload and given by intravenous rather than subcutaneous infusion (see below), have been associated with retinal injury and lens opacities as well as hearing loss. Since high-tone hearing loss may occur also, it may be prudent to monitor visual acuity and auditory function at intervals during treatment over the years for which desferrioxamine is required. Minor gastroenterological disturbances, myalgia, and very rarely anaphylaxis may occur; rapid administration of desferrioxamine may be associated with hypotension, especially when given intravenously. Desferrioxamine interacts unfavourably with phenothiazines and coma may result from its use in patients receiving these agents. Some patients receiving desferrioxamine develop infections with micro-organisms such as *Yersinia* and fungi such as *Mucor* that have fastidious requirements for iron. Iron-overloaded patients may also develop other systemic microbial infections and are particularly susceptible to infections with the marine vibrio, *V. vulnificus*. It seems likely that under these circumstances the desferrioxamine may serve, as nature intended, as a source of iron for uptake by microbial siderophore systems.

In patients with acute or subacute cardiac manifestations of iron overload, there are encouraging reports of the effects of high-dose intravenous desferrioxamine: desferrioxamine may reverse cardiac failure and life-threatening tachyarrythmias. An oral iron chelator of a different chemical class from the naturally occurring bacterial agent desferrioxamine has recently been licensed for treatment of iron overload in patients unable to tolerate desferrioxamine or in whom it is contraindicated. This drug, of the hydroxpyridone class, Deferiprone, is used at a dose of 25 to 100 mg/kg of body weight daily in three divided doses; the agent is not recommended for children under the age of 6 years.

Deferiprone appears to induce overall negative body iron balance in patients with severe homozygous b-thalassaemia with attendant reductions in serum ferritin concentrations and clearly represents the first newly licensed oral drug with this important indication. In a proportion of patients, however, negative iron balance does not appear to be maintained and the drug may cause serious toxicity including neutropenia and the occasional incidence of agranulocytosis which appears to be mediated by an immune mechanism. The use of Deferiprone appears to be somewhat controversial following a recent report that its continued administration may be associated with progressive hepatic fibrosis. Conversely, despite the inconvenience of its use, long-term studies of patients receiving desferrioxamine for iron storage disease in homozygous b-thalassaemia show that it is largely safe; moreover desferrioxamine improves cardiac function and life expectancy and arrests hepatic fibrosis in secondary haemochromatosis. Safety information and a side-effect profile on the use of Deferiprone at a daily dose of 75 mg/kg is available.

Other aspects of care

The single most important aspect of care is compliance with iron chelation therapy and monitoring—especially for infants and other young patients with iron-loading anaemias such as thalassaemia. Regular attendance of special clinics is advisable so that wide-ranging professional support from familiar personnel can be given to reinforce medical care delivered with attention to continuity and the nurturing of independence.

Patients with secondary iron overload should be monitored not only for the progression of their iron storage as determined by parameters of iron metabolism but also clinically for the presence of iron-mediated tissue injury. Regular echocardiography, electrocardiography, hormone measurements, and physical examinations are required to search for the presence of endocrine failure, including hypoparathyroidism and adrenocortical failure, both of which may be very difficult to detect. Patients with evidence of hypogonadism should be treated with hormone supplementation to ensure normal sexual characteristics and vigilance should be maintained for the development of diabetes mellitus. Psychological difficulties are prevalent in children and adolescents receiving iron-chelation therapy and transfusion for chronic anaemias and appropriate counselling is often needed over long periods to build up trust with them and their families and to maintain compliance with treatment. Patients with established infantilism and stunted growth frequently develop skeletal disease in addition to that related to their marrow disorder and investigations should be carried out to search for osteopenia and osteoporosis for which additional therapy will be needed. Bone disease and growth arrest may be caused by the overenthusiastic use of desferrioxamine in young infants, and in these patients the daily dose of desferrioxamine should be reduced to below 40 mg/kg, which usually restores growth velocity to normal.

Finally, patients with secondary iron storage disease should be advised to moderate their dietary intake of iron-rich foods such as meat: some investigators advocate the drinking of strong tea at meal times, especially in patients with thalassaemia intermedia. This tannin-rich drink has been shown to decrease bioavailability of dietary iron and should improve overall iron balance in this at-risk group. As far as possible, the blood haemoglobin concentration should be maintained in the normal range to ensure growth and responsiveness to hormone supplements; patients with significant transfusion requirements should be considered for splenectomy when they reach an age of over 5 years. As with patients who are not iron overloaded, splenectomized individuals should be treated appropriately by immunization and antimicrobial prophylactic therapy as far as possible to reduce the risk of intercurrent bacterial infection. This risk is potentiated by systemic iron storage.

Treatment of severe cardiac manifestations of iron storage disease

Continuous intravenous infusions of desferrioxamine not exceeding 50 to 60 mg/kg daily are now recommended for life-threatening heart disease. High-dose intravenous infusions may cause unacceptable toxic injury, especially in the retina and inner ear. Desferrioxamine given continuously through a permanent indwelling portable catheter within the superior vena cava, with careful attention to sepsis, is a satisfactory method for securing reversal of cardiac disease in high-risk patients with serum ferritin concentrations that persist at greater than 2500 µg/l or who have hepatic iron concentrations that exceed 1.5 per cent of dry liver weight. Improved outcomes have been reported with the use of anticoagulation induced by warfarin, and scrupulous attention to cutaneous needle re-siting and skin care to reduce the risk of thrombosis and complicating infections.

Pregnancy

Desferrioxamine therapy is not recommended by the manufacturer during pregnancy but despite this, many successful pregnancies have been reported without fetal injury. The drug should probably be avoided during the middle trimester and should almost certainly be avoided, because of unknown teratogenicity, in early pregnancy or at the time of any planned conception. None the less, it may be reasonable to restart desferrioxamine therapy in the final trimester of pregnancy if the risks to the mother from iron storage disease are high. No information is available on Deferiprone in pregnancy and it should probably not be used until more experience with the drug is forthcoming.

Prognosis and outcome

The principal causes of death in secondary iron storage disease include cardiac failure and arrythmias, endocrine failure and the consequences of diabetes mellitus, infection, and hepatocellular carcinoma. Unless treated, secondary haemochromatosis is a rapidly fatal disease when associated with transfusion therapy and intestinal hyperabsorption of iron in the chronic anaemias. Less than one-third of those unable to comply with iron chelation therapy survive with b-thalassaemia major to the age of 25 years. However, the outcome of iron storage disease in patients with chronic anaemia is now greatly improving, with enhanced life quality and duration. One study has indicated that 95 per cent of patients with b-thalassaemia who administer desferrioxamine subcutaneously more than 250 times each year will survive to 30 years; whereas only 12 per cent of those who do not will survive to this age. In the United Kingdom the overall survival is 50 per cent at 35 years, but at one specialist centre the actuarial survival in more than 100 patients was 80 per cent at 40 years. This again emphasizes the benefits of care administered at a dedicated treatment centre. Several reports also show that the frequency of hypogonadism, diabetes, and growth retardation is significantly reduced by effective iron chelation. Continuous intravenous desferrioxamine can be claimed to reverse life-threatening arrythmias in cardiac iron overload and also improve or reverse left ventricular or biventrical heart failure in a majority of cases. One report describes the actuarial survival of more than 60 per cent at 13 years of patients with life-threatening disease and b-thalassaemia so treated; this outcome appears to be accompanied by improved cardiac tissue iron signals on magnetic resonance imaging.

22.5.5 Normochromic, normocytic anaemia

D. J. Weatherall

A mild normochromic anaemia is one of the commonest findings in every branch of clinical practice. It is important to decide whether the anaemia is of significance and how far it should be investigated.

The first decision to be made is whether the blood findings represent 'anaemia' for the particular patient. The haemoglobin level varies considerably at different ages and there is a wide range of 'normal' values for any particular age. Knowledge of any previous blood count is particularly useful since a haemoglobin value in the lower range of normal may represent anaemia in a patient previously known to have a higher haemoglobin when in good health.

Most of the normochromic, normocytic anaemias are secondary to other diseases; a minority reflect a primary disorder of the blood. The most common causes are summarized in Table 1.

Anaemia of chronic disorders (ACD)

This is the rather unsatisfactory phrase used to cover the most common of the normochromic, normocytic anaemias, namely, those found in association with chronic infection, all forms of inflammatory diseases, and in malignant disease. It is very important for clinicians to be able to identify the main features of this type of anaemia. Although it may be extremely mild and asymptomatic, the presence of this blood picture should always alert the clinician to the possibility of there being a serious underlying disease.

Pathogenesis

The precise mechanism of the anaemia of chronic disorders is still not understood. Several different pathological processes that occur in response to inflammation conspire to cause a defective proliferation of red cell progenitors. In addition, at least in some cases, there may be a mild haemolytic component.

The most constant feature of ACD is a low serum iron level despite adequate iron stores in the reticuloendothelial elements of the bone marrow. This abnormal accumulation of iron in the storage cells, together with a low serum iron level in the blood, suggests that there is a block in the release of iron to the developing red cell precursors. This phenomenon may be observed within 24 h after major surgery, for example. There is also a reduced concentration of transferrin, and turnover studies suggest that this reflects a decreased rate of production.

Several studies have found a mild shortening of the red cell life span in ACD, which appears to be due to an extra corpuscular factor and not to an intrinsic abnormality of the red cells. The red cell survival is not grossly shortened; if marrow function were normal it should be able to compensate for the reduced red cell survival. However, there is a defect in the proliferation of red cell progenitors in ACD. This may reflect inadequate iron delivery or the effect of cytokines produced as a response to infection, or both. There also seems to be a subnormal erythropoietin response for the degree of anaemia, possibly arising from the action of various cytokines.

Recent studies have identified a number of cytokines that inhibit haemopoiesis in bone marrow culture and reduce the output of erythropoietin in hepatoma cell lines. The relevance of these *in vitro* studies to the generation of ACD in patients with such a diversity of associated disorders is uncertain. It is very unlikely that one mechanism will be found to account for such diverse abnormalities. Rather, it appears that ACD is a by-product of the acute phase reaction, probably augmented by a variety of different cytokine responses.

Clinical and laboratory findings

The anaemia of chronic disorders is usually mild. In patients with severe inflammation the haematocrit may fall to levels at which symptoms are experienced. Although the anaemia is usually normocytic and normochromic there may be mild hypochromia with a slight reduction in the MCH and MCV, particularly in children. Occasionally there may be marked microcytosis. Microcytosis should prompt consideration of concomitant iron deficiency, especially in patients who might have gastrointestinal bleeding, for example individuals with inflammatory bowel disease or rheumatoid arthritis on aspirin. The reticulocyte count is in the normal range.

The most important finding is a reduction in the serum iron concentration. Because there is a concurrent reduction in the level of transferrin, the per cent saturation of the iron binding capacity is usually normal or only slightly reduced. This observation clearly distinguishes ACD from true iron deficiency anaemia (Table 2). This distinction can also be confirmed by measuring the serum ferritin level, which is usually in the normal range or slightly elevated in patients with ACD while it is low in those who are iron deficient.

The bone marrow appearance is unremarkable. There may be a slight deficiency of red cell progenitors. Iron staining shows a paucity of iron in the red cell precursors and an accumulation of iron in the storage elements of the marrow. Again, this distinguishes ACD from true iron deficiency in which there is an absence of both sideroblasts and storage iron. The abnormal distribution of iron in an adequately stained sample, together with the low serum iron level, is the true hallmark of ACD and a finding that should always be followed up by a search for an underlying inflammatory or neoplastic condition.

Other forms of normochromic, normocytic anaemia

Other causes of this type of blood picture are summarized in Table 1.

Renal failure

Normochromic, normocytic anaemia is a common presenting feature of renal disease. The features of the anaemia of renal failure are discussed in more detail in the section on blood changes in systemic disease.

Endocrine disease

The hypometabolism observed in hypopituitary and hypothyroid states reduces demand for oxygen in the tissues and, therefore, output of erythropoietin. This is probably the major factor in the development of the mild normochromic, normocytic anaemia which is observed in some patients with these conditions.

Bone marrow failure

Non-specific anaemia is a common feature of bone marrow failure. It may occur in the pure red cell aplasias or as part of aplastic anaemia.

Acute blood loss and early iron deficiency

Blood loss from the gastrointestinal or genitourinary tract may be sufficient to cause anaemia but as long as the iron stores are sufficient to maintain an output of normal red cells the anaemia is normochromic and normocytic. This picture is seen in early cases of bleeding or intermittent bleeding. There is usually a slight increase in the reticulocyte count, reflecting an increased rate of proliferation of red cell progenitors.

Polymyalgia rheumatica and giant cell arteritis

Polymyalgia rheumatica (see Chapter 18.10.4) is nearly always associated with a moderate normochromic, normocytic anaemia together with a marked increase in the erythrocyte sedimentation rate. However, particularly in elderly patients, anaemia may be the presenting feature. The symptoms of polymyalgia or cranial arteritis may be minimal or even absent. This common variant of the polymyalgia syndrome should always be considered in old people with anaemia and a very high sedimentation rate who do not have paraprotein in the blood. The anaemia responds quite dramatically to corticosteroids.

Management

Mild, non-specific anaemias should always be investigated because they may be the first indication of a serious underlying disease. It is important to try to distinguish ACD from iron deficiency or other non-specific normochromic, normocytic anaemias. In ACD, the serum iron level is low and there is a normal saturation of the iron binding capacity. It is worth carrying out a bone marrow examination to study the distribution of iron between the red cell precursors and the storage cells. If the pattern of ACD is observed, it is important to carry out a careful search for chronic inflammation or neoplastic disease. The commonest causes of ACD which give rise to diagnostic problems are low-grade urinary infections, chronic sinus infection, and occult malignancy.

The treatment of anaemias of this type is essentially that of the underlying disease. In the subgroup of elderly patients presenting with this type of anaemia in association with a very high sedimentation rate, in whom underlying blood dyscrasias and paraproteinaemias have been ruled out, it is justifiable to give a therapeutic trial of corticosteroids; and to proceed to further investigations only if there is no immediate and dramatic response characteristic of the polymyalgia syndromes. Early recognition of the true diagnosis may save weeks of fruitless investigation for a non-existent neoplasm.

The major problem for the management of this condition is encountered in those case in which it is impossible to correct the underlying disorder, patients with advanced malignant disease or intractable rheumatoid arthritis, for example. It has been found that the quality of life is undoubtedly improved for many patients of this type if the haemoglobin level is raised. This may be achieved by instituting a regular blood transfusion regimen. As an alternative approach, a number of disorders of this type have been treated with erythropoietin at varying doses. A limited number of trials, some of which were placebo-controlled, have suggested that at least some patients with malignant disease, rheumatoid arthritis, or AIDS experience a useful rise in the haemoglobin level using this approach. In view of the cost of this treatment, further studies of its efficacy are required.

22.5.6 Megaloblastic anaemia and miscellaneous deficiency anaemias

A. V. Hoffbrand

Introduction

The megaloblastic anaemias are a group of disorders characterized by a macrocytic anaemia and distinctive morphological abnormalities of the developing haemopoietic cells in the bone marrow. In severe cases, the anaemia may be associated with leucopenia and thrombocytopenia. Megaloblastic anaemia arises because of inhibition of DNA synthesis in the bone marrow, usually due to deficiency of one or other of two water-soluble B vitamins, vitamin B_{12} (B_{12}, cobalamin) or folate. B_{12} deficiency may also cause a severe neuropathy but whether this occurs with folate deficiency is controversial. In a minority of cases, megaloblastic anaemia arises because of a disturbance of DNA synthesis due to a drug or a congenital or acquired biochemical defect that causes a disturbance of B_{12} or folate metabolism or affects DNA synthesis independent of B_{12} or folate. B_{12} and folate are discussed first and the other rare megaloblastic anaemias are mentioned at the end of this chapter.

Biochemical and nutritional aspects of vitamin B_{12} and folate

Vitamin B_{12}

Biochemistry

Four major forms of the vitamin exist in man, all with the same cobalamin nucleus, which consists of a planar corrin ring (hence the term 'corrinoids' for B_{12} compounds) attached at right-angles to a nucleotide portion, 5,6-dimethylbenzimidazole joined to ribose-phosphate (Fig. 1; Table 1). 5'-deoxyadenosyclobalamin (ado-B_{12}) accounts for about 80 per cent of B_{12} inside human and other mammalian cells and is mainly in mitochondria; methyl-cobalamin (methyl-B_{12}) is a minor component in cells but the main form in plasma. Both are extremely light-sensitive and are photolysed to hydroxocobalamin (hydroxo-B_{12}) within 10 s of exposure to daylight; hydroxo-B_{12} is present in small amounts in tissues and plasma and is available commercially for therapeutic use. The fourth form, cyanocobalamin (cyano-B_{12}), is present only in traces in nature, but is stable and is used radioactively labelled with cobalt-57 or cobalt-58 for *in vitro* and *in vivo* studies of B_{12} metabolism. Hydroxo- and cyano-B_{12} are converted, after two reduction steps in cells of the body, to the two biochemically active forms. The fully reduced compounds are termed Cob(I)alamins, and the oxidized compounds Cob(III)alamins. Analogues of B_{12} (pseudo-B_{12}s) exist in nature and have a different sugar (cobamides) or no nucleotide portion (cobinamides), or alterations in the corrin ring. The source and identity of analogues in human serum is unclear. Endogenous production is suggested by their presence in all sera (including fetal serum) and their fall in parallel with physiologically active B_{12} in B_{12} deficiency.

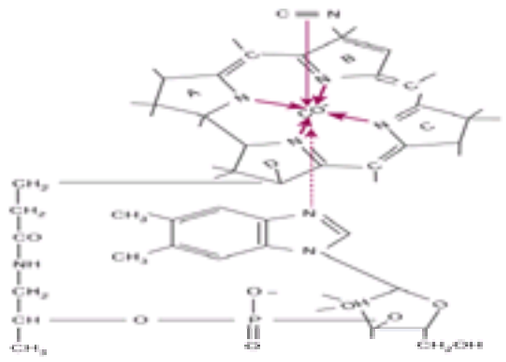

Fig. 1 The structure of cyanocobalamin.

B_{12} is known to be involved in only three reactions in human tissues: as ado-B_{12} in the isomerization of methylmalonyl CoA to succinyl CoA and of a-leucine to b-leucine, and as methyl-B_{12} in the methylation of homocysteine to methionine, a reaction that also requires methyltetrahydrofolate (Fig. 2). In some bacteria, but not

in man, B_{12} has a direct role in DNA synthesis by virtue of its involvement in ribonucleotide reductase.

Fig. 2 Biochemical reactions of vitamin B_{12} in human tissues.

Nutrition

Vitamin B_{12} is synthesized by micro-organisms; animals obtain it by eating parts of other animals or animal produce (milk, cheese, eggs, etc.), or vegetable foods contaminated by bacteria. Clean vegetables, fruit, nuts, and cereals do not contain B_{12}; cooking has little effect on it. A normal mixed diet contains between 5 and 30 µg daily, the amount increasing with the quality. In some species, but not in man, B_{12} is absorbed after synthesis by bacteria in the large intestine. Total B_{12} in man is about 3 to 5 mg, which is mainly stored in the liver (about 0.7–1.1 µg/g). Adult daily losses are related to body stores; to maintain normal body stores, daily requirements are of the order of 2 µg. It takes 3 to 4 years, on average, for deficiency to develop if supplies are totally cut off by malabsorption. There is an enterohepatic circulation for B_{12}, variously estimated at 3 to 9 µg daily, that is intact in vegans, which may partly account for their tendency to maintain low body stores without progressing to severe deficiency. The body is unable to degrade B_{12} and deficiency has not been shown to be due to excess utilization or loss.

Absorption

About 15 per cent of food B_{12} is available for absorption. It is released from protein binding in food by proteolytic enzymes, heat, and acid, and combines one molecule to one molecule with a glycoprotein 'R' B_{12}-binding protein (also called 'haptocorrin') in gastric juice. This protein is related to plasma transcobalamin I. It binds food B_{12} but does not facilitate its absorption. Pancreatic trypsin is needed to degrade this protein and so release B_{12} for attachment to intrinsic factor (IF) and subsequent absorption. The 'R' binder, unlike IF, also binds B_{12} analogues in food. IF is a glycoprotein produced by the parietal, and possibly other, cells of the stomach (Table 2). The IF gene has been localized to chromosome II. Glycosylation of IF is not required for its B_{12} or ileal receptor binding but may play a part in protecting it from digestion by pancreatic proteases in the intestinal lumen. The normal stomach produces a vast excess of IF, measured in units (1 unit binds 1 ng B_{12}). B_{12} in bile is also attached to IF and reabsorbed through the ileum. At neutral pH, in the presence of calcium ions, the B_{12}–IF complex attaches passively to a specific IF receptor, cubulin, on the brush border of the mucosal cells of the terminal ileum. Cubulin is a 460-kDa, 3597 amino acid, peripheral membrane protein present in the epithelium of intestine and kidney. It shows high-affinity, calcium- and cobalamin-dependent binding of IF–cobalamin. The cDNA encodes a precursor protein that undergoes proteolytic processing due to cleavage at a recognition site (Arg ^{7}-Gen^{8}-Lys^{9}-Arg^{10}) for the trans-Golgi proteinase furin. The gene is on the short arm of chromosome 10.

After cubilin-mediated endocytosis, IF undergoes lysosomal degradation. After a delay of 3 to 5 h, B_{12} appears in portal blood, with a peak level 8 h after ingestion, complexed with transcobalamin (TC)II secreted into the circulation from the basolateral side of the intestinal cells. IF itself is digested by the cell and is not absorbed. Ileal absorption of B_{12} is limited, by the number of ileal receptors, to a few micrograms daily and although 80 per cent of a single dose of 1 to 2 µg may be absorbed, the proportion diminishes steeply at higher doses. A small (less than 1 per cent) trace of a large (1 mg or more) dose of B_{12} can be absorbed passively and rapidly through the buccal, gastric, and duodenal mucosae without IF participating.

Transport

Vitamin B_{12} in plasma is 70 to 90 per cent attached to a glycoprotein, TC I, which does not enhance cell uptake of B_{12} (see Table 2). It is one of a group of glycoproteins, the 'R' binders or haptocorrins (see above), that are present in many tissues and fluids (e.g. gastric juice, saliva, tears, milk, and colostrum) and have the same amino acid composition but differ in the composition of the carbohydrate moiety. The haptocorrins may have the role of binding analogues of B_{12} derived from food or intestinal organisms and transporting them to the liver for excretion in the bile. A closely related haptocorrin, TC III, also occurs in human plasma and is probably derived from specific granules of neutrophils. It normally carries only 0 to 10 per cent of plasma B_{12}.

The most important plasma B_{12}-binding protein, TC II, is synthesized in macrophages, liver, the ileum and possibly endothelium. TC II gains B_{12} from the ileum and by release of free B_{12} from the liver and other organs. It is normally almost completely unsaturated; however, it actively enhances uptake of B_{12} by bone marrow, placenta, and other tissues of the body that contain receptors for it. The receptor is a dimer of molecular weight 124 000. TC II–B_{12} is internalized by endocytotosis; B_{12} is split off in lysosomes but TC II is not reutilized (Table 1). TC II accounts for most of cell B_{12} uptake; it has 20 per cent amino acid homology and greater than 50 per cent nucleotide homology with human TC I and with rat IF. The regions of homology common to all three proteins are located in seven domains and it is likely that one or more of these are involved in cobalamin binding. Presumably three-dimensional differences at the ligand-binding site of the proteins exist to explain the different affinities of these proteins (TC I < TC II < IF) for cobalamin analogues. At least five genetic variants of TC II exist, distinguished by their electrophoretic mobility, probably reflecting autosomal polymorphism with many codominant alleles at one locus. Serum TC II is normally higher in women than men and in blacks than whites. The concentration of B_{12} in cerebrospinal fluid is low, with a mean of 10 ng/l in normal subjects. Most of this is attached to TC II. There is virtually no B_{12} in normal urine.

Folate

Biochemistry

This vitamin exists in nature in over 100 forms, all of which are derivatives of folic acid (pteroylglutamic acid), which consists of a pteridine, a *para*-aminobenzoic acid moiety and L-glutamic acid (Fig. 3). Natural folates may differ from folic acid by:

1. being reduced in the pteridine ring to di- or tetrahydo- forms;
2. having a single carbon moiety attached at positions N_5 or N_{10} (e.g. methyl, formyl, etc.); and
3. having a chain of glutamate moieties attached by g-peptide bonds to the L-glutamate moiety.

In human and other mammalian cells, the number of glutamates is mainly four, five, or six. Metabolism of pteroylmonoglutamates to polyglutamates by the enzyme folylpoly-g-glutamate synthetase allows tissues to concentrate folates. In addition, folypolyglutamates are the active coenzyme forms with increased affinity or lowered K_m values for most of the enzymes of one-carbon metabolism. In body fluids (plasma, cerebrospinal fluid, bile, milk, etc.), however, folates are invariably monoglutamate derivatives. In plasma, 5-methyltetrahydrofolate (methyl-THF) predominates.

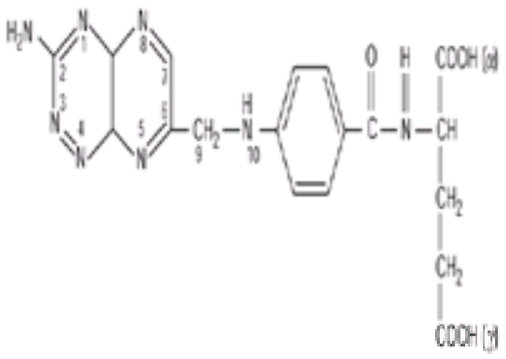

Fig. 3 The structure of pteroylglutamic (folic) acid.

The biochemical reactions of folates are shown in Table 3. In each there is transfer of a single carbon group, methyl ($-CH_3$), formyl (–CHOH), methenyl (ºCH), methylene ($=CH_2$), or formimino (=CHNH), from one compound to another. Three of the reactions are concerned with synthesis of DNA precursors (two in purine and one in pyrimidine synthesis). During thymidylate synthesis, oxidation of folate to the dihydro state occurs; the enzyme dihydrofolate reductase, the major target for the antifolates methotrexate and pyrimethamine, returns folate to the active tetrahydro state (Fig. 4). During its reactions, folate is not completely reutilized, some degradation at the C_9–N_{10} bond occurs to non-folate compounds. Thus, folate ultilization is increased and folate deficiency likely when cell turnover and DNA synthesis are increased.

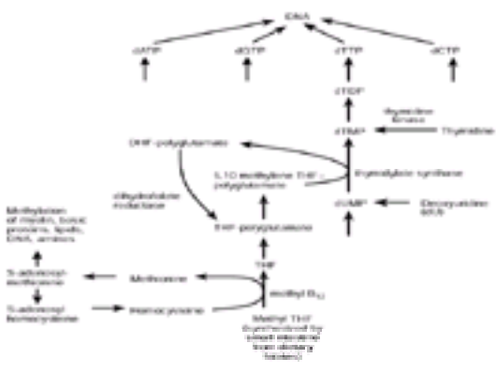

Fig. 4 Suggested mechanisms by which B_{12} deficiency affects folate metabolism and interferes with DNA synthesis. Indirect involvement of B_{12}, as methyl-B_{12}, in DNA synthesis is suggested by the 'methylfolate' trap ('tetrahydrofolate starvation') hypothesis. Methyl-B_{12} is involved in formation of intracellular THF from plasma methyl-THF. THF and/or its formyl derivative, but not methyl-THF, are the 'ground substances' from which all folate coenzymes are made by glutamate addition and single carbon unit transfer (see text). 5,10-Methylene-THF polyglutamate is involved in thymidylate synthesis. D, deoxyribose; A, adenine; G, guanine; T, thymine; C, cytosine; TP, triphosphate; DP, diphosphate; U, uridine; THF = tetrahydrofolate.

Nutrition

Folate occurs in most foods, the highest concentrations (more than 30 µg/100 g wet weight) being found in liver (where, like B_{12}, its is easily destroyed by cooking, particularly if large volumes of water and high temperatures are used); vitamin C protects it from oxidative destruction so reheating of food is particularly likely to reduce the folate content. Recent studies of a Western diet suggest an average normal daily intake of 250 µg, with 50 per cent or more in the polyglutamate form. Body stores are about 10 to 12 mg, with a mean liver concentration of about 7 µg/g. Primitive or rapidly growing tissues have higher folate concentrations than corresponding mature tissues. Normal adult requirements are about 100 µg daily, although estimates as low as 50 µg and as high as 200 µg have been made.

Absorption

Folates are absorbed rapidly, mainly through the duodenum and jejunum. Polyglutamates are deconjugated to the monoglutamate in the intestinal lumen, at the brush border, and possibly in lysosomes of intestinal cells by the enzyme, 'folate conjugase' (g-glutamylcarboxypeptidase, pteroylpolyglutamate hydrolase). They are then completely reduced to the tetrahydro state and methylated at the N_5 position so that methyl-THF enters portal plasma whatever food folate is ingested (Table 1). Folic acid itself, which is not present in food, but is used therapeutically, enters the portal blood largely unchanged at doses of more than 100 to 200 µg, as it is a poor substrate for reduction by dihydrofolate reductase. It does, however, share a specific folate uptake process through the intestine, as in the rare disorder, specific malabsorption of folate, there is failure of absorption of all folates including folic acid. The small intestine has a large capacity to absorb folate; on average 50 per cent of natural folate is absorbed whatever the dose. If excessive amounts are fed, the excess is largely excreted in urine as folates or their breakdown products after cleavage of the C_9–N_{10} bond. There is a substantial enterohepatic circulation for folate, estimated to contain up to 90 µg folate daily. If this is broken, plasma folate falls to about a third within 24 h.

Transport

Folate is transported in plasma, two-thirds unbound and about one-third loosely bound to albumin and possible other proteins. An active transport mechanism exists, however, for getting folates into cells. This is closely linked to the rate of folate polyglutamate synthesis and occurs by a carrier-mediated process, that is saturable, pH and energy dependent, with a greater preference for reduced than oxidized folates. In most cells, the folates then remain until the cells die but the liver can release folate from intact cells. Folate-binding proteins are present in human placenta, brush-border membranes of kidney tubular cells, and other cells. They are linked to membranes by a glycosyl-phosphatidyl anchor and play a part in cell uptake of folates and antifolates. Their level is regulated by extracellular and intracellular folate concentration. Milk protein, however, may enhance intestinal folate uptake. In plasma, the binding protein may take oxidized folates and breakdown products of folates to the liver for excretion or reconversion back to functional folates. Plasma folate is filtered by the glomerulus and mostly reabsorbed unless the renal tubular maximum is exceeded. Normal urine folate is 0 to 13 µg in 24 h. Folate is secreted into cerebrospinal fluid (which has a mean concentration of 24 µg/l) and is present in bile. Human milk has a concentration of 50 µg/l. Prostate-specific membrane antigen is a folate hydrolase carboxypeptidase which can release glutamates in either a or g linkages. The physiological significance of this is unknown.

Biochemical basis of megaloblastic anaemia

All known causes of megaloblastic anaemia, whether drugs, deficiencies, or inborn errors of metabolism, inhibit DNA synthesis by reducing the activity of one of the many enzymes concerned in purine or pyrimidine synthesis or by inhibiting DNA poymerization from its precursors. Folate deficiency, by reducing supply of the coenzyme 5,10-methylene-THF inhibits thymidylate synthesis, a rate-limiting reaction in DNA synthesis. B_{12} does not have a direct role in this or any other reaction in mammalian DNA synthesis. B_{12} deficiency inhibits DNA synthesis indirectly by its effect on folate metabolism.

Clinical, laboratory, and biochemical observations have all shown that B_{12} deficiency disturbs folate metabolism. Patients with severe B_{12} deficiency may show a haemaotological response to folic acid in large doses. Cell folate tends to be low, formiminoglutamic acid (FIGLU) and 5-amino-4-imidazole carboxamide excretion raised, and serine–glycine interconversion reduced in B_{12} deficiency, as in folate deficiency. The deoxyuridine blocking test suggests a defect in thymidylate synthesis in B_{12} deficiency that can be corrected *in vitro* by THF as well as by B_{12}. On the other hand, cell uptake of methyl-THF is reduced and serum folate raised in B_{12} deficiency. The most anaemic patients with B_{12} deficiency, as in folate deficiency, show the lowest levels of serum and red-cell folate, and the greatest disturbance of

folate biochemical reactions.

An explanation for these effects of B_{12} deficiency on folate metabolism is provided by the 'methylfolate trap' or tetrahydrofolate starvation hypothesis. This suggests that in B_{12} deficiency, folate is 'trapped' as methyl-THF, the form circulating in plasma, because of the need for methyl-B_{12} in the conversion of methyl-THF to THF. The 'trap' is supposed to lower the intracellular supply of THF, the most active of the folate compounds from which the other folate coenzymes are made. The natural folate coenzymes are the reduced derivatives of the folate polyglutamates rather than monoglutamates. Methyl-THF cannot act as a substrate for synthesis of these folate polyglutamates in human cells whereas THF (and formyl-THF) can.

The result is that B_{12} deficiency or inactivation puts a block between methyl-THF entering cells from plasma and the formation of intracellular folate polyglutamate coenzymes (Fig. 4). This causes the rise in plasma folate, a low level of intracellular folates, and reduced activity of all reactions requiring folate coenzymes, including those involved in DNA synthesis. The DNA defect has been ascribed to thymidine starvation. Thymidine corrects *in vitro* apoptosis of folate-deficient cells. Misincorporation of uracil, because of the pile up of deoxyuridine monophosphate and hence of deoxyuridine triphosphate, has been proposed to contribute to the cell abnormality.

Clinical features and causes of megaloblastic anaemia

Although pernicious anaemia is only one of the many causes of megaloblastic anaemia (Table 4, Table 5, and Table 6), it is convenient to describe the general clinical features of the anaemia under this heading because it is the most frequent cause of megaloblastic anaemia in Western countries. The laboratory findings and treatment of pernicious anaemia and other megaloblastic anaemias are discussed later.

Acquired pernicious anaemia (addisonian pernicious anaemia, Biermer's anaemia)

Definition

A disease of unknown origin in which there is atrophy of the stomach leading to severely reduced or absent IF secretion with consequent severe malabsorption of B_{12} and B_{12} deficiency.

Aetiology and associated diseases

Although a disease of the stomach, pernicious anaemia is considered with blood diseases because it usually presents with anaemia; it is indeed the most common cause of megaloblastic anaemia in many countries. It is a disease of older persons, less than 10 per cent of patients are under 40 years, with an incidence of 127/100 000 in Caucasians. There is a female:male ratio in most (but not all) series of about 1.6:1. There is a higher incidence (about 44 per cent compared to 40 per cent) of blood group A compared with controls in Britain. No overall association between pernicious anaemia and HLA type has been found, but those with an endocrine disease also have a greater incidence of HLA-B8, -B12, and -BW15. There are regional differences in incidence in the United Kingdom, with over 200 cases per 100 000 in Scotland but less than 60 per 100 000 in south-east England. It occurs in all races including African, Indian, Native American, and Chinese, as well as Caucasians. There is an association with early greying and blue eyes and a higher incidence in close relatives, of either sex, of an affected person. Family history is positive in about 30 per cent of cases. Those with a positive family history exhibit a younger mean age at presentation (55 years) than those without (66 years), but the type of inheritance is not clear.

Carcinoma of the stomach occurs in about 4 per cent of patients with pernicious anaemia, about three times the control rate. Pernicious anaemia may also be associated with other 'autoimmune' diseases, particularly primary myxoedema, thyrotoxicosis, Hashimoto's disease, Addison's disease, and vitiligo. About 55 per cent of patients show thyroid antibodies and 33 per cent with primary myxoedema have parietal-cell antibody. Close relatives also may show these diseases or their associated antibodies. There is probably no significant association with diabetes mellitus. Other evidence for an immune aetiology of the gastritis of pernicious anaemia is the improvement in mucosal appearance and function with corticosteroid therapy, the presence of antibodies in serum and gastric juice directed against parietal cells and IF, and of cell-mediated immunity to IF (see Chapter 5.2). Parietal-cell antibody is present in the serum of 85 to 90 per cent of patients. The autoantigens are the a- and b-subunit of the gastrin proton pump (H^+, K^+ATPase). Two antibodies to IF exist in serum. Type I ('blocking') occurs in about 50 per cent and is directed against the B_{12}-binding site. Type II (to the ileal binding site) occurs in 30 to 35 per cent but only if type I antibody is also present. Antibodies to IF exist in gastric juice and here they may neutralize the action of remaining IF. The incidence of parietal-cell and IF antibodies in serum in pernicious anaemia may be different in different groups of patients, younger patients having a lower incidence of parietal-cell antibody while Blacks and Hispanics may have a higher incidence of IF antibodies.

The antibodies to IF are virtually specific for pernicious anaemia but parietal-cell antibody occurs in many subjects with atrophic gastritis without pernicious anaemia. Cell-mediated immunity to IF can be demonstrated in all cases of pernicious anaemia. Lymphocyte populations in IF antibody-positive patients show a CD4 to CD8 ratio higher than in controls of those negative for IF antibody. Antibody to IF may cross the placenta and cause temporary deficiency of the factor in the newborn infant. An autoantibody to the gastrin receptor may also occur in serum in pernicious anaemia.

The anaemia may also be associated with hypgogammaglobulinaemia or with selective IgA deficiency when it tends to present at an early age, and antibodies to parietal cell and IF may then be absent. The gastric lesion then includes atrophy of the antrum in contrast to classical pernicious anaemia without hypogammaglobulinaemia. Serum gastrin concentrations are normal whereas these are raised above 200 µg/l in 90 per cent of patients with pernicious anaemia and serum pepsinogen (PG) concentrations are below 30 µg/l in 92 per cent of such patients with a low PGI/PGII ratio.

The relationship of pernicious anaemia to simple gastric atrophy, which occurs in about 15 per cent of people between 40 and 60 years and in 20 to 30 per cent of the older population, is not clear. In many cases, simple gastric atrophy does not progress to the anaemia after 10 or more years of follow-up. In a minority, however, deficiency of IF severe enough to cause malabsorption of B_{12} and megaloblastic anaemia, glossitis, or B_{12} neuropathy occurs. In these people, the development of antibody to IF in the gastric juice may be important.

Pathology

There is a gastritis in which all layers of the body and fundus of the stomach are atrophied with loss of normal gastric glands, mucosal architecture, and absence of parietal and chief cells, but mucous cells lining the gastric pits are well preserved. An infiltrate of plasma cells and lymphocytes with an excess of CD8 cells occurs and intestinal metaplasia may be present. The antral mucosa is remarkably well preserved except in hypogammaglobulinaemia, and, like the fundus, shows an increased number of gastrin-secreting cells.

Clinical features

The general features of megaloblastic anaemia are similar, whatever the underlying cause. Particular clinical features may point to the underlying disease, whether pernicious anaemia or some other cause. In pernicious anaemia, the anaemia usually develops gradually, perhaps over several years, and symptoms may not occur until it is severe. The most common complaints are due to the anaemia, while loss of mental and physical drive, numbness, or difficulty in walking suggest neuropathy. Psychiatric disturbances are common and range from mild neurosis to severe organic dementia. They may occur in the absence of anaemia or macrocytosis. Mild jaundice is frequent. Loss of appetite and weight, indigestion, and episodic diarrhoea are frequent. An intercurrent infection may precipitate severe anaemia and thus symptoms. Older patients may present with congestive heart failure. In a few patients, bruising due to thrombocytopenia is marked. On the other hand, many patients are diagnosed because a routine blood test is made.

The typical patient with pernicious anaemia has fair hair (prematurely grey), with blue eyes, and wide cheekbones. Physical signs, if present, are those of anaemia, perhaps with mild jaundice, giving the patient a so-called lemon-yellow tint. A few patients with either B_{12} or folate deficiency develop a widespread brown pigmentation, affecting nail beds and skin creases particularly, but not mucous membranes, which is reversible with the appropriate therapy. The biochemical basis for this is not clear, nor for the depigmentation that also occurs rarely. The tongue may be red, smooth, and shiny, occasionally with ulcers. A mild pyrexia up to 38°C is common in patients with moderate to severe anaemia. The liver may be enlarged while the cardiovascular system shows changes due to anaemia. Patients with pernicious anaemia may also have features of an associated disorder on presentation, most commonly myxoedema. Other thyroid disorders, vitiligo, carcinoma of the

stomach, Addison's disease, and hypoparathyroidism, may precede, occur simultaneously with, or follow the onset of the anaemia.

Vitamin B_{12} neuropathy

B_{12} deficiency may cause a symmetrical neuropathy affecting the lower limbs more than the upper (Section 24), which usually presents with paraesthesiae or with ataxia, particularly in the dark. In some cases, loss of cutaneous sensation, muscle weakness, urinary or faecal incontinence, an optic neuropathy, or psychiatric disturbance dominates. The neuropathy is due to severe B_{12} deficiency judged by serum B_{12} levels or methylmalonic acid excretion, but may occur with mild or no anaemia. It may be due to any cause of severe B_{12} deficiency, most commonly pernicious anaemia. A similar neuropathy has been described in dentists and others repeatedly exposed to nitrous oxide (N_2O) which inactivates methionine synthase. The biochemical explanation for the neuropathy is not clear. A defect in fatty acid metabolism in myelin tissue has been suggested. Studies in N_2O-treated monkeys have also suggested that the neuropathy results from accumulation of *S*-adenosyl homocysteine (caused by the block in conversion of homocysteine to methionine) with inhibition of transmethylation reactions in the brain. Methionine has been shown to prevent the neuropathy caused by N_2O in experimental animals. Defective methylation has yet to be shown in B_{12} neuropathy occurring clinically in man, however, or induced experimentally by dietary deficiency in fruit bats or by N_2O exposure of monkeys or rats. The role of B_{12} and folate in brain metabolism has been extensively reviewed (see Further reading list).

General tissue effects of B_{12} and folate deficiencies

Both deficiencies cause macrocytosis and other abnormal features of proliferating epithelial cells throughout the body (e.g. bronchial, bladder, buccal, and uterine cervix), with glossitis and angular cheilosis, a mild malabsorption syndrome, and reduced regeneration of damaged liver cells. In both sexes, sterility (reversible with B_{12} or folate therapy) may result from effects on the gonads. It is possible that the deficiencies in children affect overall body growth. Nutritional B_{12} deficiency in infants long term causes failure to thrive and poor brain growth with poor intellectual outcome. There does seem to be a real association of maternal folate deficiency with prematurity.

Generalized, reversible melanin pigmentation occurs in a few patients with B_{12} or folate deficiency, the cause of which is uncertain. Defective bactericidal activity of phagocytes due to impaired intracellular killing has been described in B_{12} deficiency but not in folate deficiency. B_{12} deficiency reduces serum levels of the osteoblast-related proteins alkaline phosphatase and osteocalcin but whether clinically important bone disease occurs is unknown.

Neural tube defects (NTD)

Studies by Hibbard and Smithells and coworkers in the 1960s suggested that NTD was associated with reduced maternal folate status and their early studies showed an apparent prevention of NTD by periconceptional vitamin supplementation. It is now established that folic acid supplements at the time of conception and in the early (first weeks) stage of pregnancy reduce the incidence of NTDs (anencephaly, encephalocele and spina bifida) in the first pregnancy and in subsequent pregnancies where such a malformation has occurred previously. The prophylactic daily dose used in a Medical Research Council (MRC) study was 4 mg and this reduced recurrence from 21 to six among 1195 randomized women studied; in a Hungarian first-pregnancy study, 0.8 mg daily preconception reduced the incidence from six to zero among 5000 women.

The explanation for the effect of folic acid on NTD is not certain. Women carrying NTD fetuses have lower serum folate and B_{12} levels and higher serum homocysteine levels than matched controls. There is a linear relationship when plotted on logarithmic scales between prevalence of NTD births and maternal red-cell folate, indicating that an increase in red-cell folate of a given amount is associated with a constant, proportional decrease in the birth prevalence of NTD from any given point on the red-cell folate distribution even within the accepted normal range. Folic acid prevention of NTD despite normal serum and red cell folate levels suggests that folic acid is overcoming a metabolic abnormality in folate metabolism. Only one such defect, a mutated tetrahydofolate reductase, has been identified so far.

Mutated 5,10 methylene tetrahydrofolate reductase (MHTFR)

A common thermolabile variant (677C ® T) (Ala 225 Val) of the enzyme MHTFR is associated with lower serum and red-cell folate levels and with higher plasma homocysteine levels than in controls in the general population. The incidence of the homozygous state in the population is approximately 5 per cent; the incidence in the parents and fetuses with NTD is approximately 13 per cent. The presence of this mutation can therefore account for only a small proportion of NTDs.

Cardiovascular disease

McCully (1969) first implicated homocysteine as a cause of atherosclerosis. This was based on pathological studies of children or young adults with congenital homocystinuria, whether due to a defect of cystathionine synthase, methionine synthase, or MHTFR (Fig. 5). In these children, plasma homocysteine levels are raised to 10 to 100 times normal. It is now apparent that even mild rises in plasma homocysteine are associated with coronary or peripheral arterial disease, with stroke and deep vein thrombosis. Determinants of plasma homocysteine include age, sex, renal function, protein intake, vitamin B_6, folate, and vitamin B_{12} status, the presence of the thermolabile variant MHTFR, smoking, and alcohol consumption, as well as intake of various drugs. Folate deficiency assessed by serum or red cell folate or by dietary folate intake is also associated with coronary vascular disease, myocardial infarct, or peripheral vascular disease. Meta-analysis, however, does not confirm an association of the presence of the thermolabile variant of MHTFR with coronary artery disease.

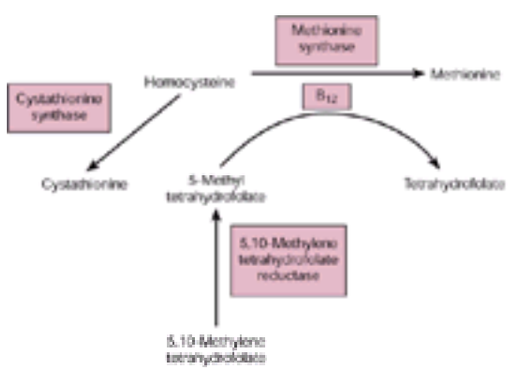

Fig. 5 The role of three enzymes (cysathione synthase, methionine synthase, and MHTFR) and three vitamins (B_{12}, B_6, and folate) in homocysteine metabolism.

It seems likely that homocysteine is a cause of vascular disease rather than an associated abnormality. Folic acid fortification of the diet reduces plasma homocysteine levels. It has been estimated that fortification of the British diet with folic acid will result in 10 000 fewer annual deaths from myocardial infarct. Trials of folic acid therapy aimed at reducing the incidence of myocardial infarct are now in progress. Preliminary results of electrocardiographic studies and of coronary restenosis after coronary angioplasty in patients with coronary arterial disease receiving folic acid are encouraging.

Other causes of vitamin B_{12} deficiency

Juvenile pernicious anaemia

A few cases of pernicious anaemia with gastric atrophy, achlorhydria, and IF antibodies have occurred in children. They may show associated ('autoimmune') conditions, for example myxoedema, hypoparathyroidism, Addison's disease, or chronic mucocutaneous candidiasis.

Congenital deficiency or structural abnormality of intrinsic factor

About 40 cases have been reported of a child being born with absent or non-functioning IF but an otherwise normal stomach on biopsy and normal secretion studies (e.g. of acid). Inheritance is autosomal recessive. In some cases, IF is present in the gastric juice that is susceptible to acid degradation, cannot bind B_{12}, or that binds B_{12} but cannot attach it to ileal receptors. These children tend to present with irritability, vomiting, diarrhoea, and loss of weight, and are found to have megaloblastic anaemia. The usual age of diagnosis is about 2 years, although a few have been diagnosed as early as 4 months and others only in their teens.

Total gastrectomy

All patients who have this operation will develop B_{12} deficiency, which usually presents between 2 and 6 years postoperatively. They should be treated with prophylactic B_{12} injections from the time of the operation.

Partial gastrectomy

Iron deficiency usually accounts for the anaemia that occurs in up to half of subjects after this operation. Subnormal serum B_{12} levels develop in about 18 per cent of patients from about 2 years postoperatively. About 6 per cent develop megaloblastic anaemia due to the deficiency. In most of these patients, malabsorption of B_{12} is due to an abnormal jejunal flora. The exact incidence of B_{12} deficiency depends mainly on the size of the remnant, which tends to be smaller if the operation is subtotal and the peptic ulcer gastric rather than duodenal. Vagotomy and pyloroplasty is not a cause of B_{12} deficiency.

Small-intestinal lesions

Colonization of the upper small intestine with colonic bacteria, if sufficiently heavy as in the stagnant-loop syndrome, leads to malabsorption of B_{12}. The most common causes are listed in Table 4. It appears that the bacteria destroy IF. Infestation with the fish tapeworm (*Diphyllobothrium latum*) has a similar effect but is now almost completely eradicated; infestation is only sufficiently marked in Finland and around the lakes of Russia to frequently cause megaloblastic anaemia.

Human immunodeficiency virus (HIV) infection

Serum B_{12} levels fall progressively in HIV-infected patients and subnormal serum levels occur in 10 to 35 per cent of patients with the acquired immune deficiency syndrome. Increased levels of TC II are usual and malabsorption of B_{12}, normally not corrected by IF, has been found in some of these patients. An abnormal small-intestinal flora is the most likely cause of B_{12} malabsorption. Megaloblastic anaemia due to B_{12} deficiency is, however, rare.

Resection of a metre or more of terminal ileum

This causes severe malabsorption of B_{12}. Other diseases that may affect ileal structure and function include: tropical sprue, in which severe B_{12} deficiency with anaemia or, rarely, neuropathy is a manifestation only in the chronic phase; gluten-induced enteropathy in which megaloblastic anaemia, if it occurs, is always due to folate deficiency (and B_{12} deficiency, if it occurs, is mild); in Crohn's disease malabsorption of B_{12} is frequent but severe B_{12} deficiency is unusual unless an ileal resection, fistula, or stagnant loop occurs.

Selective malabsorption of vitamin B_{12} with proteinuria (Imerslund's disease, Imerslund–Gräsbeck syndrome, recessive megaloblastic anaemia, MGA1)

This congenital disorder with autosomal recessive inheritance is the most common cause of megaloblastic anaemia due to B_{12} deficiency in non-vegan children. The child secretes IF normally but is unable to transport B_{12} across the ileum to portal blood. Most Finnish patients with MGA1 carry the disease specific mutation P1297L (FM1) in cublin. This mutation increases the K_d for IF–B_{12} binding several fold, so that is there is substantial loss of affinity of the FM1 mutant for B_{12}. A second less frequent mutation (FM2) activates a cryptic splice site with insertion of multiple stop codons in the CUB6 domain. The proteinuria, present in over 90 per cent of cases, is benign, non-specific, and persists after B_{12} therapy. The clinical presentation of the disease is identical to that of congenital IF deficiency. The disease may be heterogeneous, encompassing defects of the ileal IF receptor or subsequent steps in transfer of B_{12} to TC II.

Other causes of malabsorption of vitamin B_{12}

A number of other conditions and drugs may cause malabsorption of B_{12} but rarely cause B_{12} deficiency of clinical severity. *p*-Aminosalicylate, colchicine, neomycin, 'slow' potassium tablets, metformin, and phenformin have all been reported to cause malabsorption of B_{12}. In chronic pancreatitis and the Zollinger–Ellison syndrome, there is failure to release B_{12} from R protein due to absence of or inactivation of pancreatic trypsin. Malabsorption of B_{12} also occurs in inherited TC II deficiency.

Malabsorption of B_{12} occurs temporarily after total-body irradiation before bone marrow transplantation. If chronic graft-versus-host disease affecting the gut develops, malabsorption of B_{12} is usual, due to the abnormal gut flora as well as any ileal defect. Irradiation to the ileum during radiotherapy treatment for carcinoma of the cervix has also been reported to cause B_{12} malabsorption.

Dietary vitamin B_{12} deficiency

This occurs most commonly in Hindus who omit all animal produce from their diet. The incidence of overt megaloblastic anaemia is much lower than the incidence of subclinical deficiency assessed by the serum B_{12} assay. These individuals have low B_{12} stores. In India, babies have been born B_{12} deficient with megaloblastic anaemia caused by severe B_{12} deficiency (due to poor diet or sprue) in the mother. Dietary deficiency of B_{12} also occurs in non-Hindu vegans, and rarely in non-vegetarian people living on inadequate diets because of poverty.

Folate deficiency

Clinical features

The main clinical features of megaloblastic anaemia due to folate deficiency are similar to those when the anaemia is due to B_{12} deficiency, except that a severe neuropathy does not occur and the underlying aetiology tends to be different. Folate deficiency may develop rapidly, and although many mildly deficient patients do not progress for months or years, in some patients the deficiency may lead to a severe pancytopenia ('arrest of haemopoiesis') over a short period, particularly if an infection supervenes.

Folate deficiency is less well established as a cause of an organic neuropathy than B_{12} deficiency but in some studies a mild peripheral neuropathy has been found in as many as 20 per cent of patients, with spinal cord dysfunction less frequently. Neurological abnormalities do occur with inborn errors of folate metabolism and may be precipitated by antifolate drugs. The suggestion that folate therapy may precipitate fits in epileptics has not been confirmed by double-blind trials. Methyl-THF donates a methyl group to homocysteine to form methionine, which passes it on to *S*-adenosyl-methionine involved in methylation of biogenic amines (e.g. dopamine), proteins, phospholipids, and neurotransmitters in the brain. This may explain some of the psychiatric disturbances, such as depression, that seem to be equally common in folate as B_{12} deficiency.

Nutritional folate deficiency

Minor degrees of nutritional folate deficiency are frequent in most countries, but severe folate deficiency may account for about 17 per cent of all cases of megaloblastic anaemia in Britain. It occurs mainly in the old and poor and psychiatrically disturbed living alone on an inadequate diet from which liver, fruit, and fresh

vegetables are omitted; in many, barbiturate or alcohol consumption or a physical abnormality—partial gastrectomy, rheumatoid arthritis, or tuberculosis for example—may aggravate the effect of a poor diet. A few cases have developed because a special diet is taken, such as for pheonylkentonuria or for slimming. Scurvy is usually accompanied by severe folate deficiency while goat's milk anaemia is a nutritional folate deficiency due to the low (6 µg/l) folate content of goat's milk. In some countries, nutritional folate deficiency may be the main cause of megaloblastic anaemia, often presenting in pregnancy (e.g. in Burma, Malaysia, Africa, or India). Among Hindus, nutritional B_{12} deficiency is also common, however, and in many countries—Caribbean islands, Sri Lanka, and South-East Asia for example—tropical sprue (see Section 14.9) is an important cause of both deficiencies and is difficult to distinguish from 'pure' nutritional deficiency.

Malabsorption (see Section 14.9)

Gluten-induced enteropathy

Folate deficiency occurs in virtually all untreated patients, the serum folate being subnormal whether or not megaloblastic anaemia is present; red-cell folate is subnormal in 80 per cent or more. Anaemia occurs in about 90 per cent of adult cases, due to folate deficiency alone in 30 to 50 per cent and to mixed iron and folate deficiency in the remainder. Mild B_{12} deficiency may also occur but it is not a cause of anaemia in uncomplicated cases. Spontaneous atrophy of the spleen occurs in most of the patients; in about 10 to 15 per cent of cases, the blood film shows the presence of Howell–Jolly bodies, siderotic granules, and target and crenated cells that do not disappear with either folic acid or a gluten-free diet. Malabsorption of folic acid and of folate polyglutamates has been demonstrated in almost all untreated patients. A gluten-free diet produces a spontaneous rise in serum and red-cell folate and improved folate absorption in those patients who respond.

Malabsorption of folate also occurs in children with gluten-induced enteropathy and virtually all show subnormal serum and red-cell folate levels; anaemia is most often due to combined iron and folate deficiency but 'pure' megaloblastic anaemia also occurs.

Patients with dermatitis herpetiformis almost all show some degree of gluten-induced duodenal and jejunal abnormality; the severity of folate malabsorption and deficiency correlates with the severity of the intestinal lesion.

Tropical sprue (see Section 14.9)

Malabsorption of folate occurs in all severe, untreated patients in the acute phase and megaloblastic anaemia due to folate deficiency may develop within a few months. Not only does the anaemia respond to folate therapy but in many patients all the clinical features, and malabsorption of xylose, fat, B_{12}, and other substances, improve on folate therapy alone. Favourable responses to folic acid are most frequent in the first year of the disease, when about 60 per cent of patients appear to be cured by folic acid alone. Long-standing cases are more likely to be B_{12} deficient and thus to require B_{12} as well as folate and antibiotic therapy.

Congenital specific malabsorption of folate

This is a rare, autosomal recessive abnormality. Affected children all showed features of damage to the central nervous system (mental retardation, fits, athetotic movements) and present with megaloblastic anaemia responding to physiological doses of folic acid given parenterally but not orally. All forms of folate are poorly absorbed. Low levels of folate in cerebrospinal fluid also suggest a defect of folate transport through the choroid plexus.

Other causes

Absorption of folate is impaired by systemic infections. Mild degrees of folate malabsorption have also been reported after jejunal resection or partial gastrectomy, with Crohn's disease, and with lymphoma. In the intestinal stagnant-loop syndrome, folate levels tend to be high due to absorption of bacterially produced folate. Alcohol, anticonvulsants, oral contraceptives, antituberculous drugs, nitrofurantoin, sulphasalazine, bile-salt metabolites, and sodium bromosulphapthalein have been suggested, on variable evidence, to cause malabsorption of folate in some subjects but none is definitely established except sulphasalazine.

Increased folate utilization

A general mechanism of increased folate utilization in conditions of increased cell turnover has emerged. This consists of partial degradation of folate at the C_9–N_{10} band rather than complete recycling of the folate coenzymes required in DNA synthesis.

Pregnancy (see also Section 13)

This, associated with poor nutrition, is probably the most common cause of megaloblastic anaemia world-wide, unless folic acid supplements are taken. The frequency of the anaemia was about 0.5 per cent in most Western cities and up to 50 per cent in some areas of Asia and Africa until the introduction of prophylactic folic acid. The incidence increases with parity, is higher in twin pregnancies, and in some but not all series has been highest at the end of the winter. Folate requirements in a normal pregnancy are thought to be increased to about 300 to 400 µg daily, some 200 to 300 µg above normal. Serum and red-cell folate tend to fall as pregnancy progresses, and to rise spontaneously about 6 weeks after delivery. Lactation may prove an additional cause of folate deficiency, however, which may precipitate megaloblastic anaemia post partum.

The cause of the deficiency in pregnancy is increased degradation of folate due to hydrolysis at the C_9–N_{10} bond. Folate transfer to the fetus may play a minor part. Malabsorption of folate and increased urine folate excretion may be minor factors in some patients; in a few, megaloblastic anaemia of pregnancy is the first sign of adult coeliac disease. The statistical association of iron and folate deficiencies in pregnancy is probably due to a poor quality of the diet in certain women.

Prophylactic folic acid should now be given routinely in pregnancy; 400 µg daily is recommended (see earlier) and intake in women who may become pregnant should be at least this amount daily from food or supplements. Larger doses (4–5 mg daily) should be used if there has been a previous infant with a neural-tube defect. Conventional doses of 5 mg daily are satisfactory generally but have the theoretical drawback of being more likely to mask anaemia in the rare pregnant subject with untreated pernicious anaemia and thus might allow B_{12} neuropathy to develop.

Prematurity

Newborn infants have higher serum and red-cell folate concentrations than adults. These fall to a lowest value at about 6 weeks of age because utilization (and possibly excessive urinary loss) exceed intake. In premature infants, the fall in folate levels after birth is particularly steep and a number of such infants have developed megaloblastic anaemia, particularly if infections, feeding difficulties, or haemolytic disease with exchange transfusion have occurred. Prophylactic folic acid (e.g. 1 mg weekly for the first 3–4 weeks of life) may be given, particularly to those babies weighing less than 1.5 to 1.8 kg at birth.

Malignant diseases

Mild folate deficiency is frequent in patients with cancer (Table 5). In general, the severity correlates with the extent and degree of dissemination of the underlying disease. Patients with megaloblastic anaemia due to folate deficiency are unusual and folic acid might 'feed the tumour'; it should be withheld unless there is a real indication for its use, for example gross megaloblastosis causing severe anaemia, leucopenia, or thrombocytopenia.

Blood disorders

Chronic haemolytic anaemia

Requirements for folate are increased in patients with increased erythropoiesis, particularly when there is ineffective erythropoiesis with a high turnover of primitive cells. Occasional patients, presumably those with a poor folate intake, develop megaloblastic anaemia, particularly in sickle-cell anaemia, thalassaemia major, hereditary spherocytosis, and warm-type autoimmune haemolytic anaemia, Prophylactic folic acid is usually given in these disorders.

Chronic myelofibrosis

Megaloblastic haemopoiesis was reported in as many as one-third of patients in a series in London (England) with this disease but a lower incidence occurred in a large series in the United States. Circulating megaloblasts, increased transfusion requirements, severe thrombocytopenia, or pancytopenia may be the first indication that folate deficiency has developed. Polycythaemia vera is not a cause of folate deficiency.

Sideroblastic anaemia

Folate deficiency, usually mild, may occur in about half of acquired cases. Megaloblastosis, refractory to folate or B_{12}, also occurs in the acquired form as in other myelodysplastic diseases.

Inflammatory diseases

Folate deficiency has been described in patients with tuberculosis, malaria, Crohn's disease, psoriasis, widespread eczema, and rheumatoid arthritis. The degree of deficiency is related to the extent and severity of the underlying disorder. Increased demand for folate probably is a factor but reduced appetite is also important in those who develop megaloblastic anaemia.

Metabolic

Homocystinuria (see Section 11)

Patients with the most common form of this disorder, due to cystathionase deficiency, may show folate deficiency, possibly due to excess conversion of homocysteine to methionine and thus excess utilization of the folate coenzyme concerned.

Excess urinary loss of folate

Urine folate excretion of 100 µg a day or more occurs in some patients with congestive cardiac failure or active liver disease causing necrosis of liver cells. It is presumed that losses are due to release of folate from damaged liver cells. Haemodialysis and peritoneal dialysis remove folate from plasma. Folic acid (e.g. 5 mg weekly) is now usually given prophylactically to patients with renal failure who require long-term dialysis.

Drugs

Dihydrofolate reductase (DHFR) inhibitors

Methotrexate, aminopterin, pyrimethamine, and trimethoprim all inhibit DHFR but have different relative activities against the human, malarial, and bacterial enzymes. Methotrexate is converted to polyglutamate forms, which increases its activity against DHFR and also increases its retention in cells. They cause varying degrees of impairment of folate metabolism in man. Trimethoprim, used as an antibacterial agent, may aggravate pre-existing folate or B_{12} deficiency but does not of itself cause megaloblastic anaemia.

Alcohol

Folate deficiency may occur in spirit-drinking alcoholics. The main factor is poor nutrition and it is likely that alcohol interrupts the enterohepatic circulation for folate. It also has a direct effect on haemopoiesis, causing vacuolation of normoblasts, impaired iron utilization, sideroblastic changes, macrocytosis, megaloblastosis, and thrombocytopenia, even in the absence of folate deficiency. Beer drinkers seem relatively immune to folate deficiency because of the high folate content of beer. The usual macrocytosis in less severe, non-anaemic alcoholics is not related to folate deficiency.

Anticonvulsants, barbiturates

Diphenylhydantoin, primidone, and barbiturate therapy may be associated with some degree of folate deficiency. The more severe deficiency is associated with poor dietary intake of folate and usually prolonged drug therapy at high doses. The mechanism for the deficiency is undetermined. Malabsorption of folate, excess utilization due to induction of folate-requiring enzymes, displacement of folate from its binding protein, or competition for folate-requiring enzymes have all been suggested but not proven.

Other drugs

Nitrofurantoin, triamterene, proguanil, and pentamidine have been suggested to cause folate deficiency. Homofolates and carboxypeptidase G are two folate antagonists that have not been used in man.

Liver disease

Folate deficiency occurs most commonly in alcoholic cirrhosis where alcohol, poor nutrition, poor storage, and excess urine losses may all be important. The deficiency is less frequent in other types of liver disease.

Laboratory investigation of megaloblastic anaemia

This consists of three stages: (i) recognition that megaloblastic anaemia is present; (ii) distinction between B_{12} or folate deficiency (or rarely some other factor) as the cause of the anaemia; (iii) diagnosis of the underlying disease causing the deficiency (Table 7).

Recognition of megaloblastic anaemia

The peripheral blood

There is a raised mean corpuscle volume (MCV) to between 100 fl and 140 fl. Oval macrocytes are seen in the blood film. In mild cases, macrocytosis is present before anaemia has developed. Poikilocytosis and anisocytosis are marked in severe cases. Cabot rings (composed of arginine-rich histone and non-haemoglobin iron) and occasional Howell–Jolly bodies (DNA fragments) may occur due to extramedullary haemopoiesis in the liver and spleen. The MCV may be normal if there is associated iron deficiency, when the blood film appears dimorphic, or if the anaemia (usually due to folate deficiency or antimetabolite drug therapy) develops acutely over the course of a few weeks. The MCV is also normal in some severely anaemic cases involving excess red-cell fragmentation. The reticulocyte count is low for the degree of anaemia, usually of the order of 1 to 3 per cent.

The peripheral blood also shows hypersegmented neutrophils (which have nuclei with more than five lobes) (Plate 1) and the leucocyte count is often moderately reduced in both neutrophils and lymphocytes, although the total leucocyte count rarely falls to less than 1.5×10^{9}/l. The lymphocyte CD4/CD8 ratio is reduced. The platelet count may be moderately reduced but rarely falls below 40×10^{9}/l.

Biochemical changes

These are confined to the anaemic patient and include a slight rise in serum bilirubin (up to 50 µmol/l), mainly unconjugated, a rise in serum lactic dehydrogenase of up to 10 000 IU/l, with less marked rises in serum lysosyme and serum transaminases. The serum iron is also raised and falls within 12 to 24 h of effective treatment;

the serum ferritin is mildly raised and falls over the first few days of therapy. The serum cholesterol is low and alkaline phosphatase mildly reduced. Absence of haptoglobins is usual. In severe cases, free haemoglobin may be present in plasma, Schumm's test for methaemalbumin in serum is positive, and haemosiderin and fibrin degradation products are present in urine. The direct Coombs' test is weakly positive in some patients, due to complement.

Bone marrow

The bone marrow is hypercellular in moderate or severely anaemic cases and expanded along the lengths of the long bones. The myeloid–erythroid ratio is often reduced or reversed. The erythroblasts are larger than normal and show a number of morphological abnormalities; there is asynchronous maturation of nucleus and cytoplasm, nuclear chromatin remaining primitive with an open, lacy, fine granular pattern despite normal maturation and haemoglobinization of the cytoplasm. Fully haemoglobinized cells with incompletely condensed nuclei may be seen. Excessive numbers of dying cells, and nuclear remnants including Howell–Jolly bodies, mitoses, and multinucleate cells may be present. Because of death (by apoptosis) of later cells, there is a disproportionate accumulation of early cells. Giant and abnormally shaped metamyelocytes and megakaryocytes with hypersegmented nuclear lobes are also usually present (Plate 2). Studies with labelled thymidine have shown an increase of cells in G_2 and mitosis, and of cells with intermediate amounts of DNA between 2C and 4C but not synthesizing DNA, and presumably destined to die.

The severity of these changes tend to parallel the degree of anaemia. In milder cases, changes, described as 'intermediate', 'transitional', or 'moderate', are principally in the size and nuclear chromatin pattern of the individual developing erythroid cells, with giant metamyelocytes present; hypercellularity and gross dyserythropoiesis may be absent. In very mild cases, megaloblastic changes are difficult to recognize. In patients with severe anaemia but only mild megaloblastic changes, some additional cause for the anaemia should be sought.

Deoxyuridine suppression test

This is an *in vitro* biochemical test for B_{12} or folate deficiency based on the presence of a block in thymidylate synthesis (see Fig. 2). Deoxyuridine added to normoblastic cells reduces the incorporation of radioactive thymidine into DNA. The deoxyuridine is converted into deoxyuridine monophosphate (dUMP) and hence to mono-, di-, and tri-thymidine phosphates, which inhibit thymidine kinase and so reduce uptake of the labelled thymidine. Uptake of labelled thymidine into DNA is not blocked as much by deoxyuridine in cells from patients with B_{12} or folate deficiency as in normoblastic cells because of the block in conversion of dUMP to dTMP (thymidine monophosphate) in megaloblasts. Correction of the test *in vitro* with B_{12} or methyl-THF can be used to differentiate the two deficiencies as B_{12} will correct in B_{12} deficiency whereas methyl-THF does not; the reverse occurs in folate deficiency. The test is normal in cells from patients with megaloblastosis due to a block in DNA synthesis other than at thymidylate synthetase.

Chromosomes

Changes found in marrow and other proliferating cells include: (a) random chromatin breaks; (b) exaggeration of centromere constriction; and (c) thin, elongated, uncoiled chromosomes.

Ineffective haemopoiesis

The increased cellularity of the marrow with degenerate forms, and the low reticulocyte count, account for the degree of anaemia and suggest that many developing cells are dying in the marrow. This occurs by apoptosis, especially of late erythroblasts. Red-cell survival is moderately shortened, and radio-iron studies show rapid clearance, with increased plasma iron turnover but poor red-cell iron utilization. The raised uncongugated serum bilirubin, lactic dehydrogenase, and lysosyme are all due to ineffective haemopoiesis.

Differential diagnosis

Other causes of macrocytosis include a high reticulocytosis (e.g. haemolytic anaemia or regeneration of blood after haemorrhage), aplastic anaemia, red-cell aplasia, liver disease, alcoholism and myxoedema, the myelodyplastic syndromes, myeloid leukaemias, cytotoxic drug therapy, chronic respiratory failure, myelomatosis, and other causes of a leucoerythroblastic anaemia. Once a bone marrow biopsy has been done, the principal differentiation is from other causes of megaloblastosis, particularly myelodysplasia. Other causes of megaloblastic anaemia not due to B_{12} or folate deficiency are listed in Table 6.

Some patients with rapidly developing megaloblastic anaemia, particularly due to folate deficiency, may develop almost complete aplasia of the red-cell series, and the peripheral blood and bone marrow may resemble that of acute myeloid leukaemia.

Diagnosis of vitamin B_{12} or folate deficiency

The peripheral blood and bone marrow appearances are identical in folate or B_{12} deficiency. Special tests are, therefore, needed to distinguish between the two deficiencies. The deoxyuridine suppression test has been described already (see above), and is used for reliable and rapid diagnosis in some laboratories but it is not widely available.

Vitamin B_{12} deficiency

The assay of the B_{12} content of serum is now usually done by immunoassay. The normal ranges have been reported to be higher with the immunoassays (e.g. 200–1200 ng/l) than the previously used microbiological assays (e.g. 160–900 ng/l). Subnormal levels are found in cases of megaloblastic anaemia due to B_{12} deficiency, being extremely low in B_{12} neuropathy. Subnormal serum B_{12} concentrations in the absence of tissue B_{12} deficiency have been reported in pregnancy, in severe nutritional folate deficiency, in subjects taking large doses of vitamin C, and occasionally in iron deficiency.

Raised serum B_{12} levels, if not due to therapy or a contaminated serum, are most commonly caused by a raised B_{12}-binding capacity due to a rise in TC I as in a leucocytosis due to a myeloproliferative disease—chronic myeloid leukaemia, polycythaemia rubra vera, or in eosinophilic leukaemia for example. Raised levels of 'R' binder also occur in association with some tumours, especially hepatoma and fibrolamellar tumour of the liver. In benign leucocytosis, the rise is mainly of TC III and this is often not accompanied by a high serum B_{12}. Raised levels of TC II occur in conditions where macrophages are stimulated; for example autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, in Gaucher's disease and in some monocytic or monoblastic leukaemias, in histiocytic lymphomas, and inflammatory bowel disease. In active liver diseases, serum B_{12} leaks from the liver with saturation of the serum B_{12} binders.

A third and less widely used test for B_{12} deficiency is the measurement of the serum concentration of methylmalonic acid (MMA) or 24-h urine excretion of MMA. Serum MMA levels and excretion of MMA are raised in B_{12} deficiency but not in folate deficiency but raised levels may occur in renal failure. Rare cases of congenital methylmalonic aciduria have been described, owing to a variety of enzyme defects.

A sensitive method of measuring MMA in serum has been introduced and combined with serum homocysteine assay for the diagnosis of B_{12} or folate deficiency. Savage, Lindenbaum, Stabler, Allen, and others have used the serum MMA concentration to diagnose B_{12} deficiency in the absence of macrocytes or anaemia in patients with neuropathy and serum B_{12} concentration of more than 200 ng/l. Most find that patients with B_{12} neuropathy show haematological changes of B_{12} deficiency and there are not substantial numbers of patients with undiagnosed pernicious anaemia with normal haematological findings and borderline or even normal serum B_{12} levels.

Folate deficiency

Direct tests include the serum and red-cell folate assay. In most laboratories immunoassays are now used. The serum folate is always low in folate deficiency (and is normal or raised in B_{12} deficiency unless folate deficiency is also present). The serum folate does not accurately measure the severity of folate deficiency. Raised levels occur after folate therapy and also in B_{12} deficiency and in the stagnant-loop syndrome. Red-cell folate is a better guide than the serum folate to tissue folate

stores but is also low in a proportion of patients with megaloblastic anaemia solely due to B_{12} deficiency. Serum homocysteine levels are usually raised in folate deficiency, but also in B_{12} deficiency and many other situations.

Diagnosis of the cause of vitamin B_{12} deficiency

Although the clinical and family history and the clinical findings may point to pernicious anaemia or some other cause of B_{12} deficiency, it is important to establish this for certain. A brief dietary history will rapidly establish whether or not the patient is a vegan or takes a very inadequate diet. Radioactive B_{12} absorption tests are valuable to demonstrate malabsorption of B_{12} and to differentiate gastric from small-intestinal lesions as the cause. The patient, after an overnight fast, is fed an oral radioactively labelled dose of cyanocobalamin, usually 1 µg cobalt-57 B_{12}. Absorption can be measured by whole-body counting or by 24-h urinary excretion after a non-radioactive, parenteral flushing dose of 1 mg B_{12} (Schilling test). Hydroxo-cobalamin, instead of cyanocobalamin as originally described, can be used to flush absorbed, labelled B_{12} into urine.

Normal subjects absorb more than 30 per cent of the 1-µg dose. In patients with a gastric cause, malabsorption is corrected when the labelled B_{12} is given with IF, whereas if the lesion is small intestinal, the absorption does not improve with IF. Treatment with broad-spectrum antibiotics may improve the absorption in the stagnant-loop syndrome. In some patients with pernicious anaemia, the absorption with IF only improves substantially after weeks of B_{12} therapy, possibly due to slow recovery of ileal function from the effects of B_{12} deficiency. A combined test 'Dicopac' was available in which B_{12} labelled with cobalt-57 is given simultaneously with cobalt-58 B_{12} attached to IF. This has been withdrawn because human IF cannot be guaranteed to be virus or prion free. A double isotope test has also been developed in which cobalt-58 B_{12} is incorporated *in vitro* in egg yolk; cobalt-58 B_{12} is given in crystalline form. It is aimed to give a more accurate guide to food B_{12} absorption. Some patients with atrophic gastritis, or after partial gastrectomy and low serum B_{12} levels, may show normal absorption of crystalline B_{12} but reduced absorption of food B_{12}. Patients with pernicious anaemia show malabsorption of both forms.

Gastric secretion studies after pentagastrin stimulation in pernicious anaemia reveal achlorhydria (resting pH 7.0 and not falling by more than 1.0 unit on stimulation) and grossly reduced or absent IF in gastric juice.

Endoscopy and gastric biopsy will show features of gastric atrophy and help to exclude gastric carcinoma. Follow-through radiographic examination of the small intestine will help to exclude a small-intestinal lesion, duodenal or jejunal diverticulosis for example.

The serum gastrin level is raised in most patients with gastric atrophy and the serum is tested for antibodies to IF, parietal cells, and thyroid; serum immunoglobulins are measured in view of the association with hypogammaglobulinaemia.

Diagnosis of the cause of folate deficiency

An inadequate diet is usually at least partly implicated, but an exact estimate of dietary intake from the clinical history is impossible because of variation in folate content of foods, losses in cooking, and size of portions. Often it is the general social circumstances that suggest a poor intake. Drug intake, particularly of barbiturates, is important. Many underlying inflammatory or malignant diseases may exaggerate the tendency to folate deficiency in patients with inadequate diets. The main cause of malabsorption of folate is gluten-induced enteropathy; in patients with severe folate deficiency, tests for antiendomysial and antigliadin antibodies and a duodenal biopsy are usually necessary. In certain tropical countries, sprue may cause a generalized malabsorption syndrome in which folate deficiency commonly occurs. Tests of folate absorption have been devised, either by measuring the rise in serum folate after an oral dose of folic acid or of more natural folate derivatives (e.g. folate polyglutamates), or by measuring urinary or faecal excretion of radioactivity after feeding one or other labelled folate compound. None of these tests has achieved routine use.

Treatment of megaloblastic anaemia

Therapy is aimed at correcting the anaemia, completely replenishing the body of whichever vitamin is deficient, treatment of the underlying disorder, and prevention of relapse. In most cases, it is possible to diagnose which deficiency is present before starting therapy.

Vitamin B_{12} deficiency

Hydroxocobalamin 1000 µg intramuscularly given six times at several days' interval over the first few weeks will restore normal B_{12} stores. There is no evidence that patients with B_{12} neuropathy derive greater benefit from more frequent doses, although many physicians use these for 6 months or so.

Response to therapy

The patient feels better within 24 to 48 h, and the mild fever, if not due to infection, falls to normal. A painful tongue and unco-operative, disorientated state may also be improved in 48 h. The reticulocyte count begins to rise on the second day with a peak after 5 to 7 days. The white-cell count becomes normal by the third to seventh day and the platelet count rises and may reach levels of 500 to 1000 × 10^9/l before falling to normal at about 10 to 14 days. The bone marrow reverts to normoblastic by 36 to 48 h, although giant metamyelocytes persist for 10 to 12 days. The serum iron falls within 24 h, usually to subnormal levels, while the serum lactic dehydrogenase falls more slowly during the first 14 days of therapy.

The neuropathy always improves with therapy but residual deficits remain in some patients, particularly those with the longest histories and the most severe manifestations.

Maintenance

Hydroxocobalamin, 1000 µg intramuscularly, is given once every 3 months for life in pernicious anaemia and most other causes of B_{12} deficiency to prevent relapse. The life expectancy in pernicious anaemia once treated, is as good as that in the general population in women, and slightly lower in men, probably due to the increased incidence of carcinoma of the stomach. In a few patients with B_{12} deficiency, the underlying cause can be reversed; for example expulsion of the fish tapeworm, improvement of vegan diet, surgical correction of an intestinal stagnant loop. A few micrograms of B_{12} can be absorbed each day in pernicious anaemia from oral doses of 1000 µg or more by passive diffusion, but this maintenance therapy is usually reserved for those who cannot have injections—for example those with a bleeding disorder, or who refuse them—and for the extremely rare individual who is allergic to all injectable forms of B_{12}. Vegans may be maintained on much smaller oral doses of B_{12} each day, such as 50 µg as a tablet or syrup.

Prophylactic maintenance

B_{12} therapy should be given from the time of operation after total gastrectomy or after ileal resection if a B_{12} absorption test postoperatively reveals malabsorption of the vitamin. Patients with pernicious anaemia tend to develop iron-deficiency anaemia and they may also develop thyroid disorders or carcinoma of the stomach. It is advisable that a regular blood count be made once a year. Routine, regular endoscopy is not warranted but these diseases must be particularly borne in mind if relevant symptoms or signs develop.

Folate deficiency

This is corrected by giving 5 mg folic acid by mouth daily. It is essential to exclude B_{12} deficiency so that precipitation of a neuropathy is avoided. It is usual to continue for at least 4 months until there is a completely new set of red cells, although body stores will theoretically be normal within a few days of therapy. In patients with severe malabsorption of folate, larger oral doses of folic acid (e.g. 5 mg three times daily) may be used but it is not necessary to give parenteral folate except for those unable to swallow tablets. The response to therapy is as described for B_{12}. The decision whether or not to continue folic acid beyond 4 months depends on whether or not the cause can be corrected. In practice, long-term folic acid is usually needed only in patients with severe haemolytic anaemias (e.g. sickle-cell

anaemia and thalassaemia major), myelofibrosis, and in gluten-induced enteropathy when a gluten-free diet is either unsuccessful or not feasible. In patients on a gluten-free diet, assessment of folate status is one simple way of following the improvement in absorption.

Prophylactic folic acid

This should be given to all pregnant women (doses of 300 to 400 µg daily are used, often combined with an iron preparation) and, if the diet is poor, to all women likely to become pregnant. Larger doses are given if there has been a previous neural tube-deficit infant. Folic acid is given to patients undergoing regular haemodialysis or peritoneal dialysis, to premature infants weighing less than 1.5 kg at birth, and to selected patients in intensive care units or receiving parenteral nutrition.

Folate therapy has been shown to improve chromosomal stability in the fragile X syndrome, even though these patients do not have folate deficiency or a demonstrable defect of folate metabolism.

Food fortification

Fortification of cereals and grains with folic acid (140 µg/100 g cereal grain) began in the United States in 1996. Median serum folate in clinical specimens in United States rose from 12.6 to 18.7 µg/l between 1997 and 1998. There was also a reduction of plasma homocysteine in patients with coronary heart disease by consumption of a breakfast cereal fortified with folic acid. These results are consistent with those of the Framingham study which found a rise in serum folate and fall in serum homocysteine in the subjects taking a fortified diet from 1997 to 1998. In one study, addition of 400 µg folic acid daily over a 6-month period resulted in a rise in mean red-cell folate in young adult females from 295 to 571 µg/l, sufficient to reduce the incidence of NTD by 58 per cent. It is also hoped that there will be a significant reduction of deaths from cardiovascular disease by food fortification with folic acid. The theoretical side-effects of fortification are largely in patients with unsuspected B_{12} deficiency who theoretically might present with neuropathy if the extra folate consumed prevents the development of anaemia due to B_{12} deficiency. There is, however, no definite evidence for this at the supplemental doses given in the United States and proposed in Britain. In Britain fortification of flour with folic acid 240 µg per 100 g flour has been recommended but not yet implemented.

Folinic acid (5-formyl-THF)

This reduced folate is used to prevent or treat toxicity due to methotrexate or other dihydrofolate reductase inhibitors.

Severely ill patients

Some patients, usually elderly, are admitted to hospital severely ill with megaloblastic anaemia, perhaps in congestive heart failure or with pneumonia. In this case, it is necessary to commence therapy immediately after obtaining blood for B_{12} and folate assay and aspirating bone marrow, before it is known which deficiency is present. Both vitamins should be given simultaneously in large doses. Heart failure and infection should be treated in conventional fashion but blood transfusion should be avoided, except in cases of extreme anaemia, when 1 to 2 units of packed cells may be given slowly, accompanied by removal of a similar volume of blood from the other arm, and diuretic therapy.

Other therapy

Hypokalaemia may occur during the response to therapy and oral potassium supplements should be given to those with initial heart failure or if severe hypokalaemia is demonstrated, but are not needed routinely. An attack of gout has been reported on the sixth to seventh day of therapy. Most patients develop hyperuricaemia at this stage but the clinical disease probably only occurs in those with a strong gouty tendency. Iron deficiency commonly develops in the first few weeks of therapy and this should be treated initially with oral ferrous sulphate in the usual way.

Megaloblastic anaemia due to inborn errors of folate or vitamin B_{12} metabolism

Folate

A number of babies have been described with congenital deficiency of one or other enzyme concerned in folate metabolism: 5-methyltetrahydro-folate, methylene THF-reductase, FIGLU-transferase, methenyl-THF cyclohydrolase. Some of the babies had multiple congenital defects including the heart and cerebral ventricles and nearly all showed impaired mental development. In the methylfolate transferase deficiency, megaloblastic anaemia was present.

Vitamin B_{12}

Congenital deficiency of TC II was first reported in 1971 in two siblings who developed megaloblastic anaemia requiring therapy with large daily doses of B_{12} at 3 and 5 weeks of age. Similarly affected families have been described in which neuropathy developed in the absence of adequate therapy. A spectrum of loss of TC II occurs and functionally inactive TC II has been detected in some cases, often presenting later in life. The serum B_{12} level is usually normal, B_{12} being bound to TC I. Absorption of B_{12} is impaired. Treatment is with massive doses of B_{12} (e.g. 1000 µg intramuscularly three times each week). In contrast, in subjects with rare, inherited, low levels of TC I, low serum B_{12} levels occur, but haemopoiesis is normal.

Children with one form of congenital methylmalonic aciduria, which responds to B_{12} therapy in large doses, have been shown to have a defect in conversion of hydroxocobalamin to ado-B_{12}. They do not show megaloblastic anaemia. In a few, this defect has been associated with a defect of formation of methyl-B_{12} and with homocystinuria, but some of the children have also surprisingly not shown megaloblastic anaemia. Neurological abnormalities are usual. Homocystinuria and megaloblastic anaemia without methymalonic aciduria have also been reported. In some cases, the defect appears to be in maintaining B_{12} bound to methionine synthase in the reduced state.

Megaloblastic anaemia due to acquired disturbances of folate or vitamin B_{12} metabolism

Folate

Therapy with dihydrofolate reductase inhibitors may cause megaloblastic anaemia. This is usual with methotrexate and less likely with pyrimethamine unless high doses are used or the patient is already folate deficient. Trimethoprim and triamterene are very weak folate antagonists in man, but may precipitate megaloblastic anaemia in patients already B_{12} or folate deficient (see earlier).

Vitamin B_{12}

Nitrous oxide (N_2O)

This anaesthetic gas oxidizes B_{12} from the active fully reduce cob(I)alamin form to the inactive cob(II)alamin and cob(III)alamin forms, inactivating methyl-B_{12} and hence methionine synthase. Megaloblastosis develops within several hours in man and a fault in thymidylate synthase can be demonstrated by the deoxyuridine suppression test in human marrow exposed to N_2O. This recovers over several days when exposure to N_2O is discontinued. After many weeks exposure to N_2O, monkeys develop a neuropathy resembling B_{12} neuropathy in man; peripheral neuropathies have also been described in humans (e.g. dentists and anaesthetists) repeatedly exposed to the gas. When N_2O is used as anaesthetic for patients with low B_{12} stores, megaloblastic anaemia or neuropathy may be precipitated months later, due to failure to replenish B_{12} stores by absorption. Recovery from N_2O exposure needs new cobalamin and also synthesis of new apoenzyme (methionine synthase) because this protein is also damaged by active oxygen derived from the N_2O–cobalamin reaction. Methylmalonic aciduria has not been found in animals or

humans exposed for short periods to N_2O, as methylmalonic CoA mutase does not need reduced B_{12}.

Megaloblastic anaemia not due to folate or vitamin B_{12} deficiency or metabolic defect

Congenital

Orotic aciduria

This is a rare, recessive disorder involving two consecutive enzymes (orotidylic pyrophosphatase and orotidylic decarboxylase) in pyrimidine synthesis and presents with megaloblastic anaemia in the first few months of life. The diagnosis is made if needle-shaped, colourless crystals of orotic acid are found in the urine, daily excretion ranging from 0.5 to 1.5 g. Heterozygotes excrete slightly raised amounts of orotic acid but show no haematological disorder. Treatment with uridine (1–1.5 g daily) leads to a haematological response, restoration of normal haemopoiesis and growth, and reduction in orotic acid excretion.

Lesch–Nyhan syndrome

A few patients with this rare disorder of purine synthesis have shown megaloblastic change but whether this was due to associated folate deficiency or a direct result of reduced purine synthesis is not certain (see Section 11).

Vitamin E deficiency

This has been reported to cause megaloblastosis in a group of children with kwashiorkor. However, many were also folate deficient.

Vitamin C deficiency

Megaloblastic appears to be due to associated folate deficiency.

Thiamine responsive

About 12 cases have been well documented. They have also shown sideroblastic change and a defect in phosphorylation of thiamines has been implicated. Diabetes mellitus and semineural deafness are additional features.

Responding to large doses of vitamin B_{12} and folate

A single patient has been reported who needed both vitamins in large doses but the site of the defect was not elucidated.

Congenital dyserythropoietic anaemia

Some cases of congenital dyserythropoietic anaemia show megaloblastic changes not due to B_{12} or folate deficiency.

Acquired

Megaloblastic changes are often marked in acute myeloid leukaemia/M6 and less commonly in other forms of acute myeloid leukaemia. They also occur in about 50 per cent of patients with primary acquired sideroblastic anaemia and in other myelodysplastic syndromes. The exact site of block in DNA synthesis in these syndromes is unknown.

Drugs that directly inhibit purine or pyrimidine synthesis (e.g. cytosine arabinoside, 5-fluorouracil, hydroxyurea, 6-mercaptopurine, or azathioprine) may cause megaloblastic anaemia. Alcohol has also been found to have a direct effect on the bone marrow, causing megaloblastosis in some cases even in the absence of B_{12} or folate deficiency. On the other hand, drugs that inhibit mitosis (e.g. colchicine or daunorubicin) or alkylate preformed DNA (e.g. cyclophosphamide, chlorambucil, or busulfan) do not cause megaloblastosis.

Other deficiency anaemias

Vitamin C

Anaemia is usual in scurvy but the pathogenesis is complicated. It is likely that vitamin C has a direct effect on erythropoiesis but folate and iron deficiencies, haemorrhage, or haemolysis often complicate the picture.

Biochemical and nutritional aspects

Vitamin C is needed for collagen synthesis by its involvement in the hydroxylation of protein and for maintenance of intercellular substance of skin, cartilage, periosteum, and bone. It may also have a general role in oxidative–reduction systems, for example glutathione, cytochromes, pyridine, and flavin nucleotides. Although vitamin C is also thought to be needed for maintaining body folates in the reduced active state, the exact reactions involved are unclear. Vitamin C has a particular role in iron metabolism, iron excess causing increased utilization of vitamin C and in extreme cases clinical scurvy, whereas iron deficiency is associated with a raised leucocyte ascorbate concentration. Vitamin C is needed for incorporation of iron from transferrin into ferritin and for iron mobilization from ferritin. Vitamin C therapy increases iron excretion in patients receiving subcutaneous desferrioxamine infusions and also, at least in experimental animals, affects iron distribution by increasing parenchymal relative to reticuloendothelial iron. Minimum adult daily requirements for vitamin C are about 10 mg but 30 to 70 mg is recommended; utilization, and therefore requirement, are relatively higher in infants, children, and pregnant and lactating women. Vitamin C may be excreted as such but is also broken down to oxalate.

Vitamin C is present in food as its reduced (ascorbic acid) and oxidized (dehydroascorbic acid) forms, the highest concentrations occurring in greens, fruits, tomatoes, liver, and kidney. Potatoes are not a rich source but provide a substantial proportion of normal dietary intake. Cooking, particularly in alkaline conditions with large volumes of water, destroys the vitamin, which is also lost on storage with exposure to the air. Absorption occurs through the length of the small intestine and deficiency is never solely due to malabsorption.

The anaemia of scurvy is typically normochromic, normocytic with a slightly raised reticulocyte count to 5 to 10 per cent and a normoblastic marrow with erythroid hyperplasia. This suggests a direct role for vitamin C in erythropoiesis but not all patients with clinical scurvy are anaemic. Extravascular haemolysis with mild jaundice and increased urobilinogen excretion occurs in many of the patients. Moreover, in many the anaemia is complicated by folate deficiency (due to inadequate folate intake) with a megaloblastic marrow, or in a few by iron deficiency due to external haemorrhage, reduced diet intake, and possibly reduced iron absorption. In a few patients placed on a low folate diet, response of megaloblastic haemopoiesis to vitamin C alone has been described. In others, response of the megaloblastic anaemia to folic acid alone on a low vitamin C diet has occurred but in most such cases, both vitamin C and folic acid have been found necessary.

Vitamin B_6

This, as its coenzyme form pyridoxal-5-phosphate, is involved in many reactions of the body, especially transaminases and decarboxylases. It is also a cofactor in the important rate-limiting reaction in haem synthesis, †-aminolaevulinic acid (ALA)-synthetase (see Section 11). It occurs in natural tissues in three major forms: pyridoxine, pyridoxamine, and pyridoxal phosphate. Red cells are capable of interconverting them. Anaemia due purely to vitamin B_6 deficiency has been produced in animals. It is hypochromic and microcytic with a raised serum iron and increased iron in erythroblasts, with some partial or complete ring sideroblasts. A similar anaemia has occurred in humans with malabsorption, pregnancy, or haemolysis but has not been fully documented to respond to physiological doses of vitamin B_6

alone. Vitamin B_6-responsive anaemia is, however, well documented among patients with sideroblastic anaemia of all types. Pyridoxine responses occur particularly in the inherited form (when it is assumed that a fault in one or other enzyme of haem synthesis, for example ALA-synthetase, increases the need for pyridoxal phosphate as cofactor) and when sideroblastic anaemia occurs in patients receiving pyridoxine antagonists, such as antituberculous drugs. The value of pyridoxine dietary supplements in lowering serum homocysteine and reducing the incidence of cardiovascular disease has yet to be explored.

Riboflavin

On the basis of studies in experimental animals and humans fed a deficient diet together with a riboflavin antagonist, deficiency of this vitamin is known to cause a normochromic, normocytic anaemia associated with a low reticulocyte count and red-cell aplasia in the marrow, sometimes with vacuolated normoblasts. The exact biochemical basis is undecided. Clinically, a similar anaemia may occur in pure form but is usually associated with the anaemia due to protein deficiency, as in kwashiorkor or marasmus. Other clinical features of riboflavin deficiency—dermatitis, angular cheilosis, and glossitis for example—may be present.

Thiamine

For discussion, see under megaloblastic anaemia not due to folate or B_{12} deficiency or metabolic defect.

Nicotinic acid, pantothenic acid, and niacin

Deficiencies of these vitamins cause anaemia in experimental animals but anaemia purely due to one or other of these deficiencies has not been established to occur in man.

Vitamin E

This vitamin is needed for preventing peroxidation of cell membranes. A haemolytic anaemia responding to vitamin E has been reported in premature infants. Less well documented is a macrocytic anaemia due to vitamin E deficiency in protein-calorie-deficient infants and aggravation of anaemia in patients with thalassaemia major because of vitamin E deficiency.

Protein deficiency (see Section 10)

Anaemia is usual in both 'pure' protein deficiency, kwashiorkor, and in protein-calorie malnutrition (marasmus). It has been reported in many parts of the world where malnutrition, especially in children and pregnant women, is common. The anaemia also occurs in patients with gastrointestinal disease and severe malabsorption. The anaemia is typically normochromic, normocytic, and of the order of 8.0 to 9.0 g/dl. The reticulocyte count is usually reduced and the marrow may show a selective reduction in erythropoiesis. Experimental studies in animals suggest that the anaemia is largely due to reduced serum erythropoietin levels consequent on a lack of stimulus for erythropoietin secretion. Lack of amino acids for synthesis of erythropoietin or globin is not the cause. In many patients, the anaemia is complicated by infection, folate or iron deficiency, and possibly other vitamin deficiencies (e.g. riboflavin, vitamin E) and then it may be more severe and show additional morphological abnormalities in the blood and marrow.

22.5.7 Disorders of the synthesis or function of haemoglobin

D. J. Weatherall

Disorders of the synthesis or structure of haemoglobin may be either inherited or acquired. The inherited disorders of haemoglobin are the commonest single gene disorders in the world population. Figures compiled by the World Health Organization suggest that there are hundreds of millions of carriers. Each year 200 000 to 300 000 severely affected homozygotes or compound heterozygotes are born. In many of the developing countries, the very high mortality from infection and malnutrition in the first year of life causes these conditions to be under-appreciated as an important public health problem. However, once economic conditions improve and infant and childhood death rates fall, the genetic disorders of haemoglobin start to place a major burden on the health services. This phenomenon has already been observed in parts of the Mediterranean region and Southeast Asia.

As a result of mass migrations of populations from high incidence areas for the haemoglobin disorders these conditions are being seen with increasing frequency in parts of the world where they have not been recognized previously. Some of them, particularly sickle cell anaemia and the more severe forms of thalassaemia, can produce life-threatening medical emergencies. It is thus important for clinicians to have a working knowledge of their clinical features, management, and prevention.

Haemoglobin disorders have also become of particular interest in recent years because they were the first group of diseases to be analysed by the methods of recombinant DNA technology. More is known about their molecular pathology than any other genetic disorders. Their study has given us a good idea of the repertoire of mutations that underlie inherited diseases in man.

Before describing the haemoglobin disorders it is necessary to discuss briefly the structure, function, and synthesis of haemoglobin and the way that it is genetically determined.

The structure, function, genetic control, and synthesis of haemoglobin

Structure

Human haemoglobin is heterogeneous at all stages of development; different haemoglobins are synthesized in the embryo, fetus, and adult, each adapted to the particular oxygen requirements.

Each human haemoglobin has a tetrameric structure made up of two different pairs of globin chains, each attached to one haem molecule (Fig. 1). Adult and fetal haemoglobins have a chains combined with b chains (Hb A, a_2b_2), † chains (Hb A_2, $a_2†_2$), or g chains (Hb F, a_2g_2). In embryos, a-like chains, called z chains, combine with g chains to produce Hb Portland (z_2g_2), or with e chains to make Hb Gower 1 (z_2e_2), and a and e chains combine to form Hb Gower 2 (a_2e_2). Fetal haemoglobin is itself heterogeneous; there are two kinds of g chains which differ in their amino acid composition at position 136, where they have either glycine (^{G}g) or alanine (^{A}g). The ^{G}g and ^{A}g chains are the products of separate (^{G}g and ^{A}g) loci.

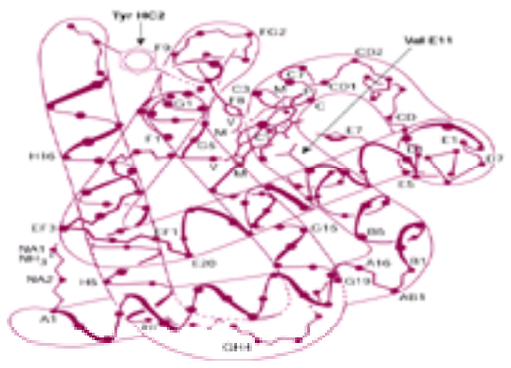

Fig. 1 The a-chain subunit of human haemoglobin showing the position of the haem molecule in a cleft formed by the globin chain. The helical parts of the chain are given letters of the alphabet and each amino acid residue in each helical region has a specific number, for example val E11 is the eleventh amino acid in the E helical region. The non-helical regions of the amino- and carboxyl-terminal ends of the chains are labelled NA and HC respectively. (Reproduced by permission of Dr MF Perutz and the editors of the Cold Spring Harbor Symposia for Quantitative Biology.)

Function

The well-known sigmoid shape of the oxygen dissociation curve, which reflects the allosteric properties of haemoglobin, ensures that oxygen is rapidly taken up at high oxygen tensions in the lungs, and that it is released readily at the lower tensions encountered in the tissues. The shape of the curve is due to co-operativity between the four haem molecules. When one takes on oxygen, the affinity for oxygen of the remaining haems of the tetramer increased dramatically. This is because haemoglobin can exist in two configurations, deoxy (T) and oxy (R) (T and R stand for tight and relaxed states, respectively). The T form has a lower affinity than the R form for ligands such as oxygen. During the sequential addition of oxygen to the four haems, transition from the T to R configuration occurs and the oxygen affinity of the partially liganded molecule increases rapidly.

The position of the oxygen dissociation curve can be modified in many ways. First, oxygen affinity is decreased with increasing CO_2 tensions, the Bohr effect. This facilitates oxygen delivery to the tissues, where a drop in pH due to CO_2 influx lowers oxygen affinity. The opposite effect occurs in the lungs. Oxygen affinity is also modified by the level of 2,3-diphos-phoglycerate (2,3-DPG) in the red cell. Increasing concentrations move the curve to the right, reducing oxygen affinity. Diminishing concentrations have the opposite effect. The 2,3-DPG mechanism plays an important role in response to hypoxia. Increased levels of DPG, with an associated decrease in P_{50} (partial pressure at which haemoglobin is 50 per cent saturated), occur in anaemia, alkalosis, hyperphosphataemia, hypoxic states, and in association with a number of red cell enzyme deficiencies.

Genetic control

The arrangement of the two main families of globin genes is illustrated in Fig. 2. The b-like globin genes form a linked cluster on chromosome 11, that spans about 60 kb (kb = kilobase or 1000 nucleotide bases); they are arranged in the order 5'-e- ^{G}g-^{A}g-yb-†-b-3'. The a-like globin genes form a linked cluster on chromosome 16, in the order 5'-z-yz-ya-a2-a1–3'. The yb, yz, and ya genes are pseudogenes; their sequences resemble the b, z, or a genes but contain mutations which prevent them from functioning as structural genes. They may be 'burnt out' remnants of genes which were functional at an earlier stage of evolution.

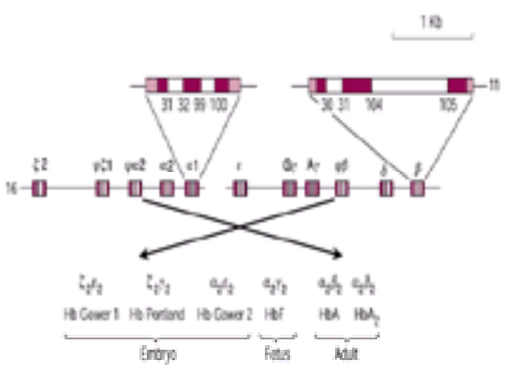

Fig. 2 The genetic control of human haemoglobin. Two of the genes are enlarged to show the introns (unshaded) and exons (dark staining). 1 kb = 1000 nucleotide bases.

Some of the important structural aspects of the globin genes and their flanking sequences are illustrated in Fig. 2 and Fig. 3. Like most mammalian genes, the globin genes are interrupted by one or more non-coding regions called intervening sequences (IVS) or introns. The non-a globin genes contain two introns of 122 to 130 and 850 to 900 base pairs between codons 30 and 31 and 104 and 105, respectively. Similar though smaller introns are found in the a and z globin genes. In the 5' flanking regions of the globin genes there are blocks of nucleotide homology which are found in analagous positions in many species. The first, the ATA box, is about 30 bases upstream (to the left) of the initiation codon. The second, called the CCAAT box, is found about 70 base pairs upstream from the 5' end of the genes. There is a third region of this kind, about 100 base pairs upstream. These regions, called promoters, are involved in the initiation of transcription and hence play an important role in the regulation of the structural genes. As we shall see later, mutations which involve them can reduce the output of the related genes. In the 3' non-coding regions of all the globin genes there is a sequence AATAAA (Fig. 3) which is the signal for polyA addition to RNA transcripts; we shall discuss the significance of this when we consider the disorders of globin chain synthesis.

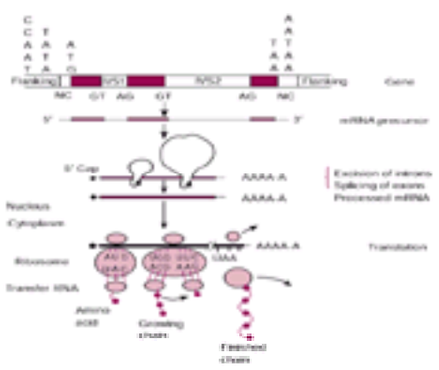

Fig. 3 Globin gene structure, mRNA processing, and globin synthesis. Each of the structures and steps illustrated is described in the text and in Section 5.

The globin gene clusters also contain other types of regulatory elements that interact to promote erythroid-specific gene expression and to co-ordinate changes in globin gene activity during development. They include enhancers, regulatory elements that increase gene expression despite being located at a variable distance from the genes, and master sequences upstream from the clusters which render them transcriptionally active. All these regulatory regions contain sequences to which an array of regulatory molecules called transcription factors are able to bind, some of which are specific for erythropoiesis, while others are ubiquitous in their tissue distribution.

Synthesis

When a globin gene is transcribed a messenger RNA molecule is synthesized from one of its strands by the action of an enzyme called RNA polymerase. The primary transcript of the globin genes is the large messenger RNA precursor molecule which contains both introns and the coding regions or exons. While in the nucleus, this molecule undergoes a number of modifications (Fig. 3). First, the introns are removed and the exons are joined together, a process called splicing. The exon/intron junctions always have the sequence GT at their 5' end, and AG at their 3' end. This appears to be essential for accurate splicing and if there is a mutation in these sites normal splicing cannot occur. The messenger RNAs are chemically modified (capped) at their 5' end, and at their 3' end a string of adenylic acid residues (polyA) is added. The processed messenger RNA now moves into the cytoplasm to act as a template for globin chain production.

Globin mRNA is transported from the nucleus to the cytoplasm where it associates with ribosomes, tRNA, and proteinaceous translation factors. These complexes, called polyribosomes, translate the information encoded in the globin mRNA into the primary amino acid sequence of each globin chain. Individual globin chains combine with haem, which is synthesized through a separate pathway, and with themselves, to form definitive haemoglobin molecules.

Classification of the disorders of haemoglobin

The main groups of disorders of haemoglobin are shown in Table 1. The genetic disorders are divided into those in which there is a reduced rate of production of one or more of the globin chains, the thalassaemias, and those in which a structural change in a globin chain leads to instability or to abnormal oxygen transport. In addition, there is a harmless group of mutations, known collectively as hereditary persistence of fetal haemoglobin, that interfere with the normal switching of fetal to adult haemoglobin production. The acquired disorders of haemoglobin can also be subdivided into those characterized by defective synthesis of the globin chains and those in which the structure of the haem molecules is altered, leading to inefficient oxygen transport.

Like all biological classifications, this way of splitting up the haemoglobin disorders is not entirely satisfactory. For example some structural variants are synthesized in reduced amounts and hence produce the clinical picture of thalassaemia.

The thalassaemias

Historical introduction

The thalassaemias are the commonest of the inherited haematological disorders and, indeed, are the commonest single gene disorders in the world population. The condition was first recognized in 1925 by a Detroit physician called Thomas B. Cooley who described a series of infants who became profoundly anaemic and developed splenomegaly over the first year of life. A milder form was described independently in the same year by an Italian physician, Fernando Rietti. Subsequently, further cases were identified and the disorder was variously called von Jaksch's anaemia, splenic anaemia, erythroblastosis, Mediterranean anaemia, or Cooley's anaemia. In 1936, George Whipple and Lesley Bradford recognized that many of their patients came from the Mediterranean region and hence they invented the word 'thalassaemia' from the Greek qalassa, meaning 'the sea'. Although it was realized later that the disorder occurs throughout the world and is not localized to the Mediterranean region, the name has stuck.

Thalassaemia is extremely heterogeneous. Its clinical picture can result from the interaction of many different genetic defects. This chapter concentrates mainly on the clinical and haematological aspects; readers who wish to learn more about the molecular pathology and population genetics of thalassaemia are referred to several reviews and monographs which are cited at the end of this chapter.

Definition and classification

The thalassaemias are a heterogeneous group of genetic disorders of haemoglobin synthesis, all of which result from a reduced rate of production of one or more of the globin chains of haemoglobin. They are divided into the a, b, †b, or eg†b thalassaemias, according to which globin chain is produced in reduced amounts (Table 2). In some thalassaemias, no globin chain is synthesized at all, they are called a° or b° thalassaemias. In others, the a $^{+}$ or b^{+} thalassaemias, globin chain is produced but at a reduced rate. Thalassaemia occurs in populations in which structural haemoglobin variants are common. It is not at all unusual for an individual to inherit a thalassaemia gene from one parent and a gene for a structural haemoglobin variant from the other. Both a and b thalassaemia occur commonly in some countries and hence individuals may receive genes for both types. These different interactions produce an extremely complex and clinically diverse series of genetic disorders which range in severity from death *in utero* to extremely mild, symptomless hypochromic anaemias.

The thalassaemias are inherited in a simple mendelian fashion. Heterozygotes are usually symptomless, although they can be easily recognized by simple haematological analysis. More severely affected patients are either homozygotes for a or b thalassaemia, compound heterozygotes for different molecular forms of a or b thalassaemia, or compound heterozygotes for thalassaemia and a structural haemoglobin variant. Clinically, the thalassaemias are classified according to their severity in major, intermediate and minor forms. Thalassaemia major is a severe transfusion-dependent disorder. Thalassaemia intermedia is characterized by anaemia and splenomegaly though not of such severity as to require regular transfusion. Thalassaemia minor is the symptomless carrier state. While these descriptive terms do not have a precise genetic meaning, they remain useful in clinical practice.

The b thalassaemias

The b thalassaemias are the most important types of thalassaemia because they are very common and produce severe anaemia in their homozygous and compound heterozygous states (Table 3).

Distribution

The b thalassaemias occur widely in a broad belt ranging from the Mediterranean and parts of north and west Africa through the Middle East and Indian subcontinent to Southeast Asia (Fig. 4). The high incidence zone stretches north through Yugoslavia and Romania and the southern parts of the former USSR and includes the southern regions of the People's Republic of China. The disease is particularly common in Southeast Asia where it occurs in a line starting in southern China and stretching down through Thailand and the Malay peninsula through Indonesia to some of the Pacific islands. In these populations, and in some of the Mediterranean island and mainland countries, gene frequencies for the various forms of b thalassaemia range between two and 20 per cent. It should be remembered that b thalassaemia is not entirely confined to these high incidence regions; it occurs sporadically in every racial group.

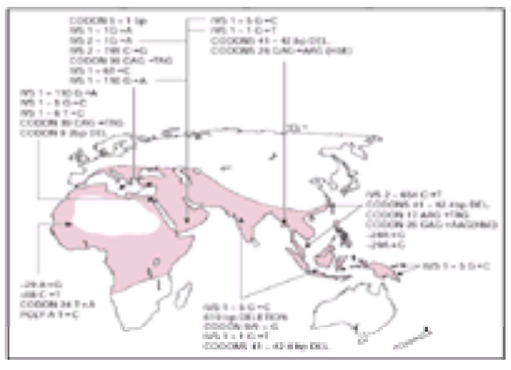

Fig. 4 World map showing the distribution of the different b thalassaemia mutations.

Molecular pathology

The precise molecular lesions responsible for the defective synthesis of the b globin chains have been determined for many patients with b thalassaemia. The disease is extremely heterogeneous. About 200 different mutations can produce the clinical phenotype of b thalassaemia. Some completely inactivate the b globin genes leading to b° thalassaemia; others cause a reduced output from the genes and hence the picture of b $^{+}$ thalassaemia.

The main classes of mutations that cause b thalassaemia are summarized in Fig. 5. With the exception of a deletion of about 600 bases at the 3' end of the b globin gene, which is only found in certain populations of northern India, deletions are an uncommon cause of b thalassaemia. Most of the mutations are single base changes or small deletions and insertions of one or two bases. As shown in Fig. 5, they occur in both introns and exons, and also outside the coding regions.

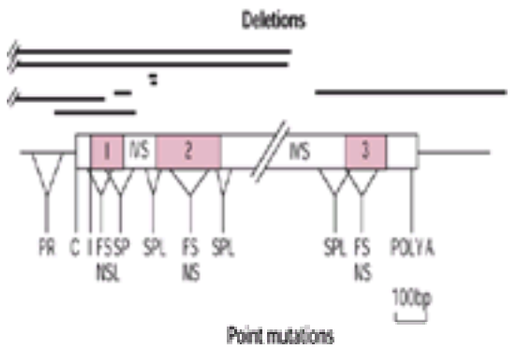

Fig. 5 Some of the mutations that produce b thalassaemia. The b globin gene is divided into three exons (hatched) and two introns (IVS; unshaded). The different deletions are shown at the top of the figure while below the general position of the different point mutations is represented. PR, promoter; C, CAP site; I, initiation site; FS, frameshift; NS, nonsense; SPL, splice-site mutation; polyA, RNA cleavage and polyA addition site.

Many of the exon mutations are nonsense mutations, that is the substitution of a single base in a codon produces a stop codon in the middle of the coding part of the messenger RNA (Fig. 6). Some mutations result in frame shifts; because the information carried by messenger RNA is in the form of a triplet code, the loss of one, two, or four bases throws the reading frame out of phase (Fig. 6). Another important class interfere with splicing. They may alter the invariate GC/AG dinucleotides at the intron/exon junctions, in which case they usually cause b° thalassaemia. Alternatively, they may activate so-called cryptic splice sites, providing an alternate splice site so that both normal and abnormal messenger RNA species are produced (Fig. 7). These lesions cause a b^+ thalassaemia, the severity of which depends on the relative usage of the normal and abnormal splice site and hence the quantity of normal and abnormal b globin messenger RNA that is produced.

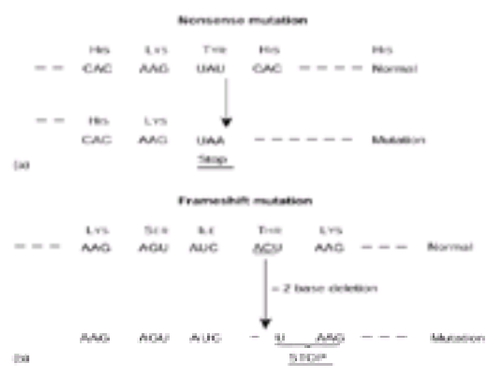

Fig. 6 Point mutations that cause b° thalassaemia: (a) premature stop codon (nonsense mutation); (b) frameshift mutation. See text for further details.

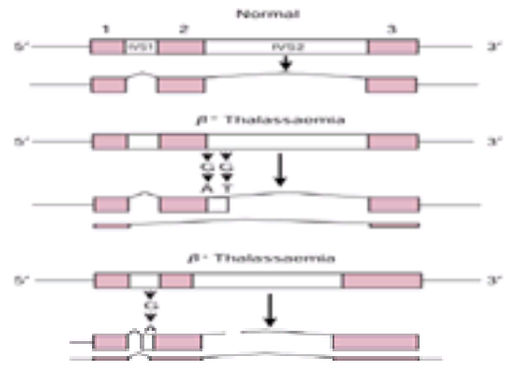

Fig. 7 A representation of the consequences of different splice-site mutations. In b° thalassaemia two different mutations are shown, one that inactivates the normal splice site, and another that produces a new splice site. Two abnormal mRNA molecules are produced. In the b^+ thalassaemia case a new splice site is produced in the first intron. Both normal and abnormal mRNAs are produced, the latter in greater amounts.

Many single base substitutions have also been found in the flanking regions of the b globin genes. They alter either the proximal promoter regions or adjacent sequences, causing down regulation of b globin gene transcription to a varying degree. They are usually associated with milder forms of b^+ thalassaemia.

Because there are so many different b thalassaemia mutations it follows that many patients who are apparently homozygous for b thalassaemia are, in fact, compound heterozygotes for two different molecular lesions.

Pathophysiology

The mutations that cause b thalasaemia result in absent or reduced b chain production. Alpha chain synthesis proceeds at a normal rate and hence there is imbalanced globin chain synthesis (Fig. 8). In the absence of their partner chains the excess a chains are unstable and precipitate in the red cell precursors, forming large intracellular inclusions. These interfere with red cell maturation, and hence there is a variable degree of intramedullary destruction of red cell precursors, that is ineffective erythropoiesis. Those red cells which mature and enter the circulation contain a chain inclusions which interfere with their passage through the microcirculation, particularly in the spleen. These cells are prematurely destroyed. Thus the anaemia of b thalassaemia results from both ineffective erythropoiesis and a shortened red cell survival. The mechanisms of the destruction of red cell precursors and their progeny are extremely complex and are not simply a reflection of mechanical damage to the red cells. Free a chains and their degradation products, particularly haem and iron, cause severe oxidative damage to the red cell membrane proteins. The end result is a dehydrated, rigid erythrocyte with a markedly shortened survival.

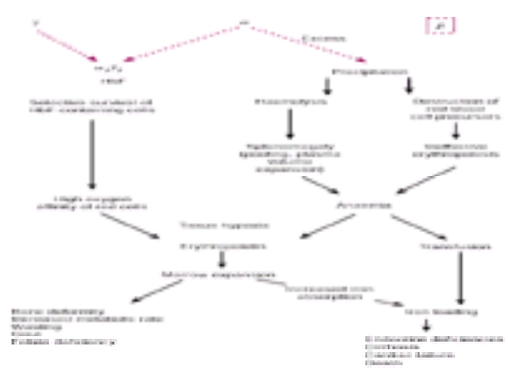

Fig. 8 The pathophysiology of b thalassaemia.

The anaemia acts as a stimulus to increased erythropoietin production, causing massive expansion of the bone marrow which may lead to serious deformities of the skull and long bones. Because the spleen is being constantly bombarded with abnormal red cells, it hypertrophies. The resulting splenomegaly and bone marrow expansion gives rise to an increase in the plasma volume which, together with pooling of the red cells in the enlarged spleen, causes an exacerbation of an already severe degree of anaemia.

As mentioned previously, fetal haemoglobin production largely ceases after birth. However, some adult red cell precursors (F cells) retain the ability to produce a small number of g chains. Because the latter can combine with excess a chains to form haemoglobin F, cells which make relatively more g chains in the bone marrow of b thalassaemics are partly protected against the deleterious effect of a chain precipitation. Red cell precursors which produce haemoglobin F are selected in the marrow and peripheral blood of these patients. Thus, they have relatively large amounts of haemoglobin F in their red cells. Furthermore, because † chain synthesis is unaffected, the disorder is characterized by a relative or absolute increase in haemoglobin A $_2$ ($a_2†_2$) production. These interactions are summarized in Fig. 7.

If the anaemia is corrected with blood transfusion the erythropoietic drive is reduced, growth and development are improved, and bone deformities do not occur. On the other hand, each unit of blood contains 200 mg of iron; with regular transfusion there is steady accumulation of iron in the liver, endocrine glands, and myocardium. Even though well-transfused thalassaemic children grow and develop normally, they die of iron overload unless steps are taken to remove iron.

The severe homozygous or compound heterozygous forms of b thalassaemia

These are the commonest and most important forms of thalassaemia and give rise to a major public health problem in many parts of the world.

Clinical features

Most severe forms of b thalassaemia present within the first year of life, as fetal haemoglobin declines, with failure to thrive, poor feeding, intermittent bouts of fever, or failure to improve after an intercurrent infection. At this stage the affected infant looks pale. In many cases splenomegaly is already present. There are no other specific clinical signs. Diagnosis depends on the haematological changes outlined below. If the infant is established on a regular transfusion regimen at this stage, early development is normal. Further symptoms do not occur until puberty, when the effects of iron loading start to appear. If, on the other hand, the infant is not adequately transfused, the typical clinical picture of homozygous b thalassaemia develops. Thus the clinical manifestations of the severe forms of b thalassaemia have to be described in two contexts, that is the well-transfused child and the child with chronic anaemia throughout early life.

In the well-transfused thalassaemic child, early growth and development is normal. Splenomegaly is minimal. However, there is a gradual accumulation of iron. The effects of tissue siderosis start to appear by the end of the first decade. The normal adolescent growth spurt fails to occur. Hepatic, endocrine, and cardiac complications of iron overloading produce a variety of problems including diabetes, hyopoparathyroidism, adrenal insufficiency, and progressive liver failure. Secondary sexual development is delayed or does not occur at all. Short stature and lack of sexual development may lead to serious psychological problems. By far the commonest cause of death, which usually occurs toward the end of the second or early in the third decade, is progressive cardiac damage. Ultimately these patients die due to either protracted cardiac failure or suddenly due to an acute arrhythmia.

There is now good evidence that children who have been both adequately transfused and chelated may grow and develop normally, pass through a normal puberty, and survive to adult life in excellent condition. However, it is becoming apparent that even children who have been well managed in this way still tend to suffer from complications as they get older, particularly delayed sexual maturation, growth disturbances, and osteoporosis. It seems likely that many of these problems are due to subtle damage to the hypothalamic/pituitary axis with secondary hypogonadism. In addition, some of the growth disturbances may reflect toxicity of the chelating agents used to remove iron (see below).

The clinical picture in children who are inadequately transfused is quite different. Early childhood is interspersed with a series of distressing complications. The overall rates of growth and development are markedly retarded. There is progressive splenomegaly; hypersplenism may cause a worsening of the anaemia, sometimes associated with thrombocytopenia and a bleeding tendency. Because of the bone marrow expansion there may be deformities of the skull with marked bossing and overgrowth of the zygomata giving rise to the classical mongoloid facial appearance of b thalassaemia (Fig. 9(a) and (b)). These findings are reflected by radiological changes which include a lacy, trabecular pattern of the long bones and phalanges and a typical 'hair on end' appearance of the skull (Fig. 10). These bone changes may be associated with recurrent fractures. There is increased susceptibility to infection which may cause a catastrophic drop in the haemoglobin level. Because of the massive marrow expansion, these children are hypermetabolic, run intermittent fevers, lose weight (Fig. 8(b)), have increased requirements for folic acid, and may become acutely folate depleted with worsening of their anaemia. Increased turnover of red cell precursors occasionally gives rise to hyperuricaemia and secondary gout. There is a bleeding tendency which, partly due to thrombocytopenia secondary to hypersplenism, may be exacerbated by liver damage associated with iron loading and extramedullary haemopoiesis. There is also an increased risk of thrombotic complications, possibly reflecting procoagulant properties of the abnormal red cell membranes. The bone deformities of the skull can cause distressing dental complications with poorly formed teeth and malocclusion, and inadequate drainage of the sinuses and middle ear which may lead to chronic sinus infection and deafness. If these unfortunate children survive to puberty, they develop the same complications of iron loading as the well-transfused patients. In this case, some of the iron accumulation results from an increased rate of gastrointestinal absorption as well as that derived from the inadequate transfusion regimen.

Fig. 9 Homozygous b thalassaemia: (a) skull and facial deformity due to bone marrow expansion; (b) gross wasting of the limbs and hepatomegaly in an undertransfused child.

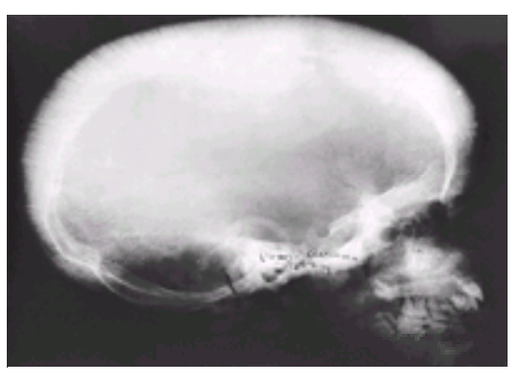

Fig. 10 Radiological changes of the skull in homozygous b thalassaemia.

Haematological changes

There is always a severe anaemia. The haemoglobin values on presentation range from 2 to 8 g/dl. The appearance of the stained peripheral blood film is grossly abnormal (Fig. 11). The red cells show marked hypochromia and variation in shape and size. There are many hypochromic macrocytes and misshapen microcytes, some of which are mere fragments of cells. There is a moderate degree of anisochromia and basophilic stippling. There are always some nucleated red cells in the peripheral blood. After splenectomy, these are found in large numbers. In the postsplenectomy film, many of the nucleated cells and mature erythrocytes show ragged inclusions after incubation of the blood with methyl violet. There is usually a slight elevation in the reticulocyte count. The white cell and platelet counts are normal unless there is hypersplenism in which case they are reduced. The bone marrow shows marked erythroid hyperplasia, with a myeloid/erythroid (M/E) ratio of unity or less. Many of the red cell precursors show ragged inclusions after incubation with methyl violet.

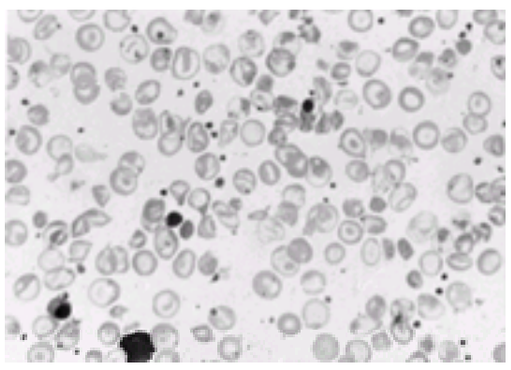

Fig. 11 Peripheral blood film in homozygous b thalassaemia (×630, Leishman stain).

There are biochemical changes of increased haemolysis and progressive iron loading. The bilirubin level is usually elevated and haptoglobins are absent. The ^{51}Cr red cell survival is shortened. The serum iron rises progressively. Most transfusion-dependent children have a totally saturated iron binding capacity. This change is mirrored by a high plasma ferritin level. Liver biopsies show a marked increase in hepatic iron, which may be distributed both in the reticuloendothelial and parenchymal cells (Fig. 12).

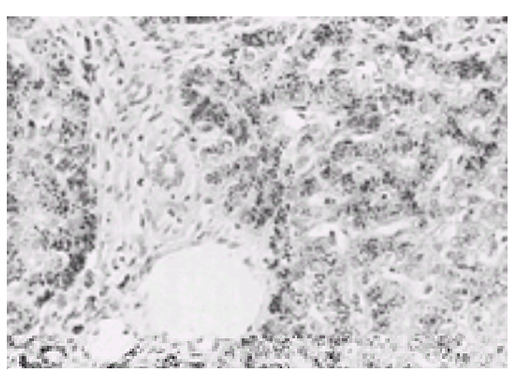

Fig. 12 Histological appearances of the liver in homozygous b thalassaemia showing gross iron deposition (×270, iron stain).

Other biochemical changes

Many thalassaemic children are vitamin E and ascorbate depleted. Folic acid deficiency has already been mentioned. Frank diabetes may develop and endocrine function tests may reveal parathyroid or adrenal insufficiency, or inappropriate response by the pituitary to various release hormones; growth hormone levels are usually normal.

Haemoglobin changes (Table 3)

The haemoglobin F level is always elevated. In b° thalassaemia there is no haemoglobin A and the haemoglobin consists of F and A_2 only. In b^+ thalassaemia the level of haemoglobin F ranges from 30 to 90 per cent of the total haemoglobin. The haemoglobin A_2 level is usually normal and is of no diagnostic value.

Heterozygous b thalassaemia

Carriers for b thalassaemia are usually symptom free except in periods of stress such as pregnancy, when they may become more anaemic than normal women. Splenomegaly is rarely present.

Haematological changes

There is a mild degree of anaemia with haemoglobin values in the 9 to 11 g/dl range. The red cells show hypochromia and microcytosis with characteristically low MCH and MCV values. The reticulocyte count is usually normal. The bone marrow shows moderate erythroid hyperplasia.

Haemoglobin changes

The characteristic finding is an elevated haemoglobin A_2 level in the 4 to 6 per cent range. There is a slight elevation of haemoglobin F in the 1 to 3 per cent range in about 50 per cent of cases. A less common form occurs in which the haemoglobin A_2 is not elevated.

b thalassaemia in association with haemoglobin variants

In many populations where there is a high incidence of both b thalassaemia and various haemoglobin variants it is common for an individual to inherit a b thalassaemia gene from one parent and a gene for a structural haemoglobin variant from the other. Although numerous interactions of this type have been described, in clinical practice only three are of importance, that is sickle cell b thalassaemia, haemoglobin C b thalassaemia, and haemoglobin E b thalassaemia.

Sickle cell b thalassaemia

The clinical manifestations which result from the interaction of the b thalassaemia and sickle cell genes vary considerably from race to race. In African populations, there are mild forms of b^+ thalassaemia which, when they interact with the sickle cell gene, produce a condition characterized by mild anaemia and few sickling crises. This condition is compatible with normal survival and is often ascertained by chance haematological examination. On the other hand, in Mediterranean populations it is quite common for an individual to inherit a b° or severe b $^+$thalassaemia determinant from one parent and a sickle cell gene from the other. These interactions are

often associated with a clinical picture which is indistinguishable from sickle cell anaemia.

The diagnosis of sickle cell thalassaemia rests on the clinical features of a sickling disorder found in association with a peripheral blood picture with typical thalassaemic red cell changes, that is a low MCH and MCV. In the more severe forms of sickle cell b° thalassaemia, there may be an elevated reticulocyte count and sickled red cells are found on the peripheral blood film. The diagnosis can be confirmed by haemoglobin electrophoresis, which in sickle cell b^+ thalassaemia shows haemoglobin S together with 10 to 30 per cent haemoglobin A and an elevated haemoglobin A_2 value. In sickle cell b° thalassaemia, the haemoglobin consists mainly of haemoglobin S with an elevated level of haemoglobins F and A_2. To confirm the diagnosis it is necessary to examine the parents; one should have the sickle cell trait and the other the b thalassaemia trait.

Haemoglobin C thalassaemia

This disorder is restricted to West Africans and some North African and southern Mediterranean populations. It is characterized by a mild haemolytic anaemia associated with splenomegaly. The peripheral blood film shows numerous target cells and thalassaemic red cell changes with a moderately elevated reticulocyte count. Haemoglobin electrophoresis shows a preponderance of haemoglobin C. The diagnosis is confirmed by finding the haemoglobin C trait in one parent and the b thalassaemia trait in the other.

Haemoglobin E b thalassaemia

This is a very common form of thalassaemia in Southeast Asia and throughout the Indian subcontinent. Haemoglobin E is inefficiently synthesized. Thus, when a haemoglobin E gene is inherited together with a b° or severe b^+ thalassaemia determinant, that are the commonest types of b thalassaemia in Southeast Asia, there is a marked deficiency of b chain production. The resulting clinical picture can closely resemble thalassaemia major.

The clinical and haematological changes in haemoglobin E thalassaemia are variable. There is usually a marked degree of anaemia and splenomegaly with typical thalassaemic bone changes (Fig. 13). Although not always transfusion dependent, patients with this disorder usually have low haemoglobin values in the 4 to 9 g/dl range with an average of 5 to 7 g/dl. The blood film shows typical thalassaemic red cell changes and the bone marrow shows marked erythroid hyperplasia with a chain inclusions in many of the red cell precursors. Although very little is known about the natural history of this disorder, it seems likely that in many parts of Southeast Asia and India it causes a very high mortality in the early years of life. Complications include a marked susceptibility to infection, secondary hypersplenism, progressive iron loading, a variety of neurological lesions (due to tumours caused by extramedullary erythropoiesis extending in from the inner tables of the skull or vertebrae), folate deficiency, and recurrent pathological fractures. On the other hand, some patients with haemoglobin E thalassaemia grow and develop normally with few complications and there are many recorded cases of pregnancy in women with this disorder.

Fig. 13 Bossing of the skull in haemoglobin E thalassaemia.

The diagnosis of haemoglobin E thalassaemia is confirmed by finding haemoglobins E and F and little or no haemoglobin A on haemoglobin electrophoresis and by demonstrating the haemoglobin E trait in one parent and the b thalassaemia trait in the other.

Other b thalassaemia variants

It is not uncommon to encounter patients with the clinical and haematological features of heterozygous b thalassaemia who do not have an elevated haemoglobin A_2 level. Many of these individuals are heterozygotes for both b and † thalassaemia. It is important to recognize this interaction because, if it is inherited together with a typical b thalassaemia gene, it can produce a severe transfusion-dependent disorder. Hence this variant is important in antenatal screening programmes. It can only be identified for certain by globin chain synthesis or gene analysis in a specialized laboratory. Families are encountered occasionally in which there is a more severe form of heterozygous b thalassaemia associated with anaemia, jaundice, and splenomegaly. In some of these families it is apparent that the affected individuals are in fact compound heterozygotes for b thalassaemia and the so-called 'silent' b thalassaemia gene, that is a determinant which cannot be identified haematologically in heterozygotes. In other families, a severe form of b thalassaemia behaves as a single gene disorder with full expression in heterozygotes, that is it follows a dominant form of inheritance. In most of these families, the disorder results from the synthesis of a highly unstable b globin chain.

The †b thalassaemias (Table 3)

Molecular genetics and classification

Disorders due to reduced b and † chain synthesis are much less common than those due to defective b chain production. They are remarkably heterogeneous at the molecular level. In some cases they result from deletions of the b and † globin genes, while in others there appears to have been mispaired synapsis and unequal crossing over between the † and b globin gene loci with the production of †b fusion genes. The latter produce †b fusion chains which combine with a chains to form haemoglobin variants called the Lepore haemoglobins (Lepore was the family name of the first patient to be recognized with this disorder). Hence it is usual to classify this group of conditions into the (†b)° thalassaemias and the haemoglobin Lepore or $(†b)^+$ thalassaemias.

Clinical and haematological changes

The (†b)° thalassaemias have been reported in many populations although there are no high frequency areas. In the homozygous state there is a mild degree of anaemia with haemoglobin values of 8 to 10 g/dl. There is often a moderate degree of splenomegaly but these patients are usually symptomless except during periods of stress such as infection or pregnancy. Haemoglobin analysis shows 100 per cent haemoglobin F. Heterozygous carriers have thalassaemic blood pictures, elevated levels of haemoglobin F of 5 to 20 per cent, and normal levels of haemoglobin A_2.The homozygous state for haemoglobin Lepore is characterized by a clinical picture which is usually similar to that of homozygous b thalassaemia although in some cases it may be milder and non-transfusion dependent. The haematological findings are similar to those of b thalassaemia. The haemoglobin consists of F and Lepore only. Heterozygous carriers have thalassaemic blood pictures associated with about 5 to 15 per cent haemoglobin Lepore.

The (eg†b)° thalassaemias

There are several rare forms of thalassaemia which result from long deletions of the b globin gene cluster which, as well as removing or inactivating the b genes, involve the †, g, and embryonic e genes. They also involve the main regulatory sequence upstream of the b globin gene cluster, the locus control region. This means that there is no output of globin chains from this gene cluster at all. Clearly, the homozygous state for these disorders would not be compatible with survival. Heterozygotes often have severe haemolytic disease of the newborn with anaemia and hyperbilirubinaemia. If they survive the neonatal period they grow and develop normally; in adult life they have the haematological picture of heterozygous b thalassaemia with mild anaemia, hypochromic microcytic red cells, and a haemoglobin

pattern consisting of haemoglobin A, no elevation of haemoglobin F, and a normal level of haemoglobin A_2.

Hereditary persistence of fetal haemoglobin

There is a complex family of conditions characterized by persistent fetal haemoglobin synthesis into adult life associated with no major haematological abnormalities. In some cases they result from long deletions of the b globin gene cluster, similar to those which cause †b thalassaemia. Indeed, they form a continuum with this condition; homozygotes have 100 per cent fetal haemoglobin, elevated haemoglobin levels and no clinical findings. Other forms result from point mutations in the promoter regions of the g globin genes. In this case there is increased g chain production together with reduced b chain production on the affected chromosome. Hence, homozygotes have markedly elevated levels of haemoglobin F but also produce some haemoglobin A. Finally, there is a group in which persistent low levels of haemoglobin F, in the 3 to 10 per cent range, are observed. There is increasing evidence that they may result from mutations either within the b globin gene cluster or on other chromosomes.

The only clinical importance of this complex group of conditions is that they may interact with the thalassaemias or structural haemoglobin variants and reduce the severity of different phenotypes by increasing the amount of haemoglobin F that is produced.

The a thalassaemias

Although the a thalassaemias are commoner on a global basis than the b thalassaemias they pose less of a public health problem. This is because the severe, homozygous forms cause death *in utero* or in the neonatal period and the milder forms do not produce major clinical problems.

Distribution

The a thalassaemias occur widely through the Mediterranean region, parts of West Africa, the Middle East, parts of the Indian subcontinent, and throughout Southeast Asia in a line stretching from southern China through Thailand, the Malay peninsula, and Indonesia to the Pacific island populations (Fig. 14). For reasons which will become apparent when we consider the molecular pathology of these disorders, the serious forms of a thalassaemia are restricted to some of the Mediterranean island populations and Southeast Asia.

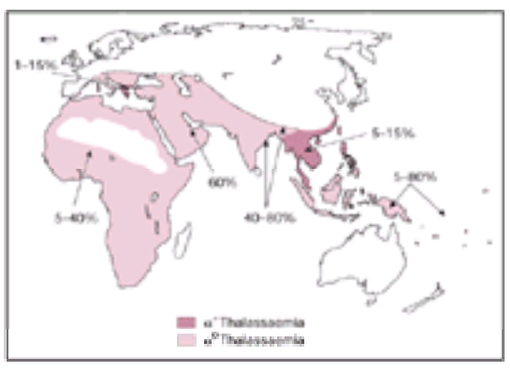

Fig. 14 World map showing the distribution of the a thalassaemias.

Inheritance and molecular pathology

The genetics of a thalassaemia is complicated, and has generated a confusing nomenclature over the years.

Because both haemoglobins A and F have a chains, genetic disorders of a chain synthesis result in defective fetal and adult haemoglobin production. In the fetus, deficiency of a chains leads to the production of excess g chains which form g_4 tetramers, or haemoglobin Bart's (Fig. 15). In adults, a deficiency of a chains leads to an excess of b chains which form b_4 tetramers, or haemoglobin H, the adult counterpart of haemoglobin Bart's. Thus, the presence of haemoglobins Bart's or H in red cells is the hallmark of a thalassaemia. For reasons which are not yet clear, a critical level of globin chain imbalance is required before detectable amounts of haemoglobins Bart's or H appear in the red cells. Unfortunately for clinicians, in persons with mild forms of a thalassaemia this level is not reached; significant amounts of these variants only occur in the red cells of patients who have a severe degree of a chain deficiency. This means that the carrier states for different forms of a thalassaemia are difficult to diagnose.

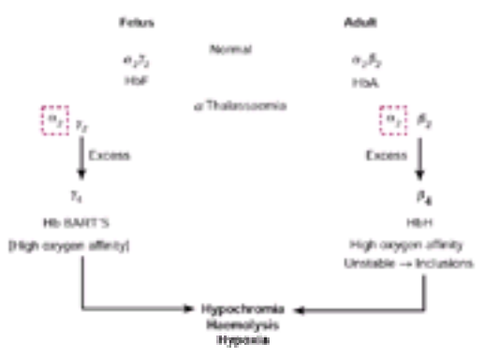

Fig. 15 The pathophysiology of a thalassaemia.

Because normal individuals receive two a globin genes from each of their parents, aa/aa, the genetics of the a thalassaemias is more complicated than that of the b thalassaemia. It is useful to define these conditions in heterozygotes. First, there is a more severe form which is called a° thalassaemia, which results from loss of both of the linked a globin genes, – –/aa. The second type is almost completely silent in carriers; their red cells are normal or are only slightly hypochromic. This condition is due to the deletion, –a/aa, or reduced activity due to a mutation, a ^{T}a/aa, of one of the linked a globin genes. Because there is still some output of a globin from the affected chromosome this is called a^+ thalassaemia. To put it in another way, the terms a° and a^+ thalassaemia describe haplotypes, that is the products of two linked a globin genes on one of a pair of homologous chromosomes 16.

In clinical practice we encounter two symptomatic types of a thalassaemia, the haemoglobin Bart's hydrops syndrome and haemoglobin H disease (Table 4). The former results from the homozygous inheritance of a° thalassaemia. On the other hand, haemoglobin H disease usually results from the coinheritance of both a° and a^+ thalassaemia. We now know that there are many different molecular types of both a° and a^+ thalassaemia. These genetic interactions are summarized in Fig. 16.

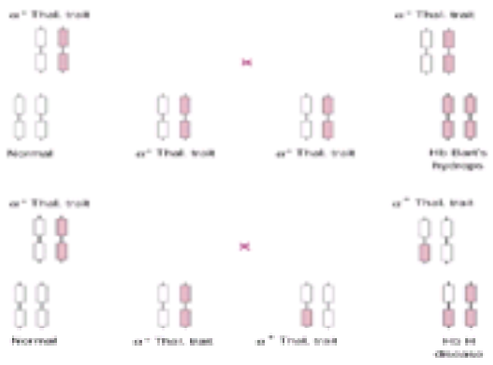

Fig. 16 The genetics of a thalassaemia. The black a genes represent gene deletions or otherwise inactivated genes. The open a genes represent normal genes. a° Thalassaemia and a^+ thalassaemia are defined in the text.

Like the b thalassaemias, the a thalassaemias are extremely heterogeneous at the molecular level. Many different sized deletions can remove either both the a globin genes or the main regulatory regions of the a globin gene cluster and cause a° thalassaemia, but there are only two which are common. One is found in Southeast Asia. The other occurs mainly in Mediterranean populations (Fig. 17). Similarly, there are several different sized deletions that remove a single a globin gene to produce the deletion forms of a^+ thalassaemia; the commonest are those that remove either 3.7 kb or 4.2 kb of the a gene cluster. There are also many different mutations that can produce the non-deletion forms of a^+ thalassaemia. Many of them are similar to those which produce b thalassaemia. A particularly common form of non-deletion a^+ thalassaemia, found in up to 5 per cent or more of some Southeast Asian populations, results from a single base change in the a globin chain termination codon UAA, which changes to CAA. The latter is the code word for the amino acid glutamine. When the ribosomes reach this point, instead of the chain terminating, they read through messenger RNA that is not normally translated until another stop codon is reached. An elongated a chain variant is synthesized, but the messenger RNA is destabilized by read through of sequences which are not normally translated and so the variant is also produced at a reduced rate. It is called haemoglobin Constant Spring after the name of the town in Jamaica in which it was first discovered. Several other chain termination mutations of this type occur, with different base changes in the terminating codon and hence different amino acids at the beginning of the extension of the a globin chain.

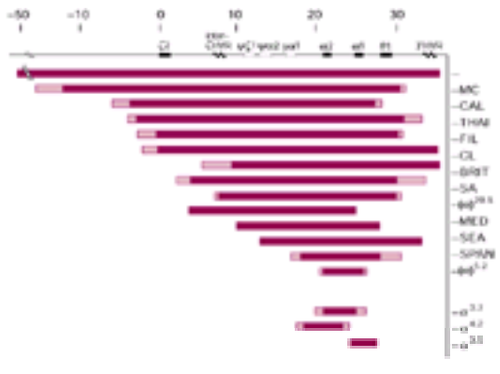

Fig. 17 The different-sized deletions responsible for some forms of a° or a^+ thalassaemia. The a globin gene cluster is shown at the top of the figure. Two highly variable regions (HVR) are shown. The abbreviations on the right-hand side indicate the source of origin of patients with the deletions: MED, Mediterranean; SEA, Southeast Asia. The three smaller deletions at the bottom of the figure show some of the main classes of a^+ thalassaemia. The superscripts 3.7, 4.2, and 3.5 indicate the size of the deletions.

Genotype/phenotype relationships

Molecular studies explain much of the clinical variability of a thalassaemia in different populations. Since the haemoglobin Bart's hydrops syndrome requires the homozygous inheritance of a° thalassaemia (– –/– –), this condition only occurs in populations in which a° thalassaemia is common. It is mainly confined to Southeast Asia and the Mediterranean islands, populations in which the haemoglobin Bart's hydrops syndrome causes a public health problem. Most forms of haemoglobin H disease are due to the inheritance of a° thalassaemia from one parent and a^+ thalassaemia from the other (–a/– – or $–a^T/– –$). Thus, haemoglobin H disease is also restricted mainly to Mediterranean and Oriental populations. On the other hand, a^+ thalassaemia occurs very commonly throughout parts of West Africa, the Indian subcontinent, and the Pacific island populations. a° Thalassaemia does not occur in these regions so that the haemoglobin Bart's hydrops syndrome and haemoglobin H disease are not seen. The homozygous state for a^+ thalassaemia (–a/–a) is characterized by a mild hypochromic anaemia, very similar to the heterozygous state for a° thalassaemia; the results of having only two out of the normal four a genes seem to be the same whether the two genes are missing from the same chromosome or opposite pairs of homologous chromosomes. To complicate matters, sometimes the homozygous state for the non-deletion forms of a^+ thalassaemia, a^Ta/a^Ta, are more severe and cause haemoglobin H disease.

Pathophysiology

The pathophysiology of a thalassaemia is different to that of b thalassaemia. A deficiency of a chains leads to the production of excess g chains or b chains which form haemoglobins Bart's and H respectively (Fig. 15). These more soluble tetramers do not precipitate to any great extent in the bone marrow. Erythropoiesis is thus more effective than in b thalassaemia, that is there is less intramedullary destruction of red cell precursors. However, haemoglobin H is unstable and precipitates in red cells as they age. The large inclusion bodies produced in this way are trapped in the spleen and other parts of the microcirculation leading to a shortened red cell survival. Furthermore, both haemoglobins Bart's and H have a very high oxygen affinity; because they have no a chains there is no haem/haem interaction and their oxygen dissociation curves resemble myoglobin. Thus the pathophysiology of severe forms of a thalassaemia is based on defective haemoglobin production, the synthesis of homotetramers which are physio-logically useless, and a haemolytic component due to their precipitation in older red cells. Furthermore, excess b chains cause a different pattern of damage to red cell membrane proteins than free a chains; the red cells tend to be overhydrated in a thalassaemia.

The haemoglobin Bart's hydrops syndrome

This condition is a common cause of fetal loss throughout Southeast Asia and in Greece and Cyprus. Affected infants produce no a chains and hence can make neither fetal nor adult haemoglobin.

The clinical picture is very characteristic (Fig. 18). Infants are usually stillborn between 28 and 40 weeks. Liveborn infants take a few gasping respirations and then expire within the first hour after birth. They show the typical picture of hydrops fetalis with gross pallor, generalized oedema, and massive hepatosplenomegaly. There is a high frequency of other congenital abnormalities, and a very large, friable placenta, all due to severe intrauterine anaemia. The haemoglobin values are in the 6 to 8 g/dl range and there are gross thalassaemic changes of the peripheral blood film with many nucleated red cells. The haemoglobin consists of approximately 80 per cent haemoglobin Bart's and 20 per cent of the embryonic haemoglobin, Portland (z_2g_2). It is believed that these infants survive to term because they continue to produce embryonic haemoglobin at this level; haemoglobin Bart's is, as mentioned above, useless as an oxygen carrier.

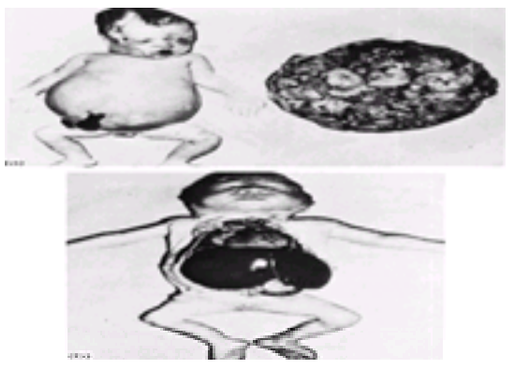

Fig. 18 The haemoglobin Bart's hydrops syndrome: (a) a hydropic infant with massively enlarged placenta; (b) autopsy findings with an enlarged liver. (Reproduced by permission of Professor P. Wasi.)

This syndrome is also characterized by a high incidence of maternal toxaemia of pregnancy and considerable obstetric difficulties due to the presence of the large, friable placenta. Both parents have thalassaemic red cell changes with normal haemoglobin A_2 values, that is the characteristic finding of the heterozygous state for a° thalassaemia.

Haemoglobin H disease

As mentioned earlier, haemoglobin H is a tetramer of normal b chains with the formula b_4. It is produced when there is a marked reduction of a chain synthesis. Haemoglobin H disease usually results from the inheritance of a° thalassaemia from one parent and a^+ from the other. It may also result from the inheritance of a° thalassaemia and haemoglobin Constant Spring or from the homozygous state for a severe, non-deletion form of a thalassaemia. The latter form of inheritance is particularly common in Saudi Arabia.

There is a variable degree of anaemia and splenomegaly but it is most unusual to see severe thalassaemic bone changes or the growth retardation characteristic of homozygous b thalassaemia. Patients usually survive into adult life although the course may be interspersed with severe episodes of haemolysis associated with infection, or worsening of the anaemia due to progressive hypersplenism. Oxidant drugs such as sulphonamides may increase the rate of precipitation of haemoglobin H and therefore exacerbate the anaemia.

Haemoglobin values range from 7 to 10 g/dl. The blood film shows typical thalassaemic changes. There is a moderate reticulocytosis. Incubation of the red cells with brilliant cresyl blue generates numerous inclusion bodies by precipitation of the haemoglobin H under the redox action of the dye. After splenectomy large, preformed inclusions can be demonstrated on incubation of blood with methyl violet. The haemoglobin consists of from 5 to 40 per cent haemoglobin H together with haemoglobin A and a normal or reduced level of haemoglobin A_2.

Usually one parent is heterozygous for a° thalassaemia and the other for a^+ thalassaemia, the deletion or non-deletion varieties. Less commonly, both parents are heterozygous for a non-deletion form of a^+ thalassaemia.

The haematological findings in the a° and a^+ thalassaemia traits are summarized in Table 4. They can only be identified with certainty by analysis of the a globin genes.

a Thalassaemia and mental retardation

There is an increasingly important group of a thalassaemias which are not restricted to individuals from tropical backgrounds. They are observed in all racial groups and have been best characterized in those of north European origin. These conditions are characterized by variable degrees of mental retardation, dysmorphic features, and a thalassaemic blood pictures. They follow a completely different form of inheritance to the commoner genetic forms of a thalassaemia and constitute a increasingly heterogeneous group of disorders. There are two major varieties of this condition. The first is due to lesions that involve the a globin gene cluster on chromosome 16, ATR-16. There is another group that result from mutations on the X chromosome, ATR-X.

The ATR-16 disorders are characterized by a very variable degree of mental retardation and equally variable dysmorphic features. The blood film shows mild a thalassaemic changes and some cells which contain typical haemoglobin H inclusion bodies. It is now clear that they have a heterogeneous molecular pathology. In some cases the condition results from long deletions which remove the end of the short arm of chromosome 16 and extend for one to two megabases. Occasionally they also include the genes that are involved in tuberous sclerosis and adult polycystic disease of the kidney. In other cases, the loss of the end of the short arm of chromosome 16 is the result of an inherited cytogenetic abnormality, including translocations and other rearrangements.

The ATR-X syndrome is characterized by a much more consistent series of dysmorphic features and more severe mental retardation. These infants often suffer from convulsions after birth. They develop typical facial features, genital abnormalities, and a very mild form of haemoglobin H disease. This condition is inherited as a typical sex-linked disorder which affects males. It results from mutations of a gene on the X chromosome called *ATR-X* which is now known to act as a regulator of transcription via an effect on the structure of chromatin. Female carriers may show a very small proportion of red cells containing haemoglobin H bodies. This condition should be thought of in any child with severe mental retardation and dysmorphic features whose blood film shows evidence of a very mild form of a thalassaemia.

Thalassaemia intermedia

Definition and pathogenesis

The term thalassaemia intermedia is used to describe patients with the clinical picture of thalassaemia which, although not transfusion dependent, is associated with a much more severe degree of anaemia than that found in carriers for a or b thalassaemia. Many of the conditions which have been described previously in this section follow this clinical course, for example haemoglobin C or E thalassaemia, the various †b thalassaemias and haemoglobin Lepore disorders, and the wide variety of conditions which can result from the interactions of the different b and †b thalassaemia determinants. However, some children with this condition have parents with typical heterozygous b thalassaemia blood pictures and elevated haemoglobin A_2 levels. These patients appear to be homozygous for b thalassaemia, yet they run a much milder course than is usually the case with this condition. Some of them have inherited an a thalassaemia determinant as well as being homozygous for b thalassaemia. This reduces the overall degree of globin chain imbalance and consequently the severity of the dyserythropoiesis which usually accompanies homozygous b thalassaemia; hence these children run a milder clinical course. In other cases, particularly in African races, relatively mild forms of homozygous b thalassaemia seem to reflect the action of less severe b thalassaemia mutations. Finally, some intermediate forms of b thalassaemia seem to result from the coinheritance of a gene for unusually effective haemoglobin F production.

Clinical and haematological changes

The clinical features of the intermediate forms of thalassaemia are extremely variable. At one end of the spectrum are patients who are virtually symptom free except for moderate anaemia. At the other end there are patients who have haemoglobin values in the 5 to 7 g/dl range and who develop marked splenomegaly, severe skeletal deformities due to expansion of bone marrow, and, as they get older, become heavily iron loaded because of increased intestinal absorption of iron. Recurrent leg ulceration, folate deficiency, symptoms due to extramedullary haemopoietic tumour masses in the chest and skull (Fig. 19), gallstones, and a marked proneness to infection are particularly characteristic of this group of thalassaemias.

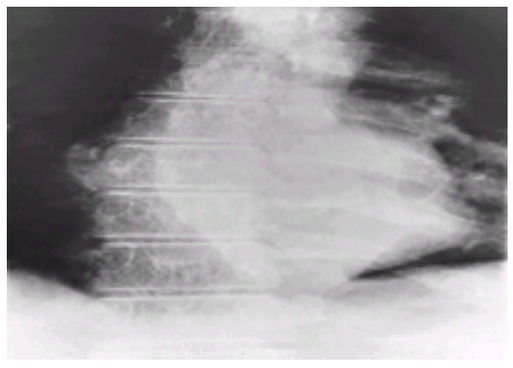

Fig. 19 An extramedullary haemopoietic mass in a patient with b thalassaemia intermedia.

Because of the heterogeneity of these disorders, it is only possible to determine the course that is likely to evolve in any individual patient by following the disorder very carefully from early childhood.

Differential diagnosis of the thalassaemias

There are few conditions which are likely to be confused with the more severe forms of homozygous b thalassaemia or haemoglobin H disease. The racial background of the patient, the presence of anaemia from early life, and the characteristic haematological changes make the diagnosis relatively easy. Once thalassaemia is suspected, the parents and near relatives should be examined for the carrier states for a or b thalassaemia. Both disorders can be distinguished from simple iron deficiency by the finding of a normal serum iron or ferritin level and by the associated changes in the haemoglobin pattern. It should be remembered, however, that in some groups iron deficiency and heterozygous thalassaemia frequently occur together in the same person, particularly during pregnancy. The sideroblastic anaemias can be easily distinguished from thalassaemia by the morphological appearances of the red cells and the presence of ring sideroblasts in the bone marrow. It should be remembered that there are some rare forms of acquired haemoglobin H disease in elderly patients with leukaemia.

The laboratory diagnosis of thalassaemia

The thalassaemias should be suspected when a typical thalassaemic blood picture is found in an individual of an appropriate racial group. The homozygous states for the severe forms of b thalassaemia are easily recognized by the haematological changes associated with very high levels of haemoglobin F; haemoglobin A_2 values vary so much that they are of no diagnostic help. The heterozygous states are recognized by microcytic hypochromic red cells and an elevated level of haemoglobin A_2. The †b thalassaemias are characterized by the finding of 100 per cent haemoglobin F in homozygotes and 5 to 15 per cent haemoglobin F together with a normal level of haemoglobin A_2 in heterozygotes (see Table 3).

When b thalassaemia is diagnosed, a quantitative haemoglobin electrophoresis should be carried out to exclude the presence of an abnormal haemoglobin variant such as haemoglobin E or Lepore.

The haemoglobin Bart's hydrops syndrome is recognized by the finding of a hydropic infant with a severe anaemia, a thalassaemic blood picture, and 80 per cent or more haemoglobin Bart's on haemoglobin electrophoresis. Haemoglobin H disease is identified by the finding of a typical thalassaemic blood picture with an elevated reticulocyte count, generation of multiple inclusion bodies in the red cells after incubation with brilliant cresyl blue, and the finding of variable amounts of haemoglobin H on haemoglobin electrophoresis. There are no really useful, simple diagnostic tests for the different a thalassaemic carrier states although a° thalassaemia heterozygotes usually have typical thalassaemic red cell changes with a normal haemoglobin A_2 value. It is essential for counselling purposes to diagnose the different carrier states for a thalassaemia, blood samples should be referred to a laboratory that can carry out DNA analysis of the globin genes.

Prevention and treatment

Thalassaemia produces a severe public health problem and a serious drain on medical resources in many populations. Since there is no definitive treatment, most countries in which the disease is common are putting a major effort into programmes for its prevention.

Prevention

There are two major approaches to the prevention of the thalassaemias. Since the carrier states for the b thalassaemias can be easily recognized, it is at least theoretically possible to screen populations and provide genetic counselling about the choice of marriage partners. If b thalassaemia heterozygotes marry other carriers, one in four of their children will have the severe, transfusion-dependent homozygous disorder. While large-scale programmes of this type have been set up in Italy, the results are not yet available, and in smaller pilot studies in Greece the outcome has not been encouraging. Until more is known about the usefulness of this form of prospective genetic counselling, most countries are developing screening programmes at antenatal clinics. When heterozygous carrier mothers are found, the husbands are tested and if they are also carriers the couple are offered the possibility of prenatal diagnosis and termination of pregnancies carrying fetuses with severe forms of thalassaemia.

Prenatal diagnosis

Prenatal diagnosis can be offered to couples at risk for having children with severe forms of b thalassaemia. Because of the serious obstetric complications and the trauma of carrying a hydropic fetus to term there is also a good case for prenatal diagnosis for the haemoglobin Bart's hydrops syndrome. Termination of pregnancies at risk for milder forms of thalassaemia is also undertaken, but should only be considered after very careful counselling of the parents. Some children with intermediate forms of thalassaemia are symptom free and develop normally; others have more severe anaemia and bone deformity. There has been some success in determining which particular molecular defects and interactions are associated with these different clinical courses. When in doubt, parents should be referred for expert analysis of their variety of thalassaemia and appropriate counselling.

Prenatal diagnosis of thalassaemia can be carried out in several ways. The diagnosis can be made by globin-chain-synthesis studies of fetal blood samples obtained by fetoscopy at 18 to 20 weeks gestation. The diagnosis can also be made by fetal DNA analysis on amniotic fluid cells obtained by amniocentesis earlier in the second trimester. More recently, it has been possible to carry out prenatal diagnosis of thalassaemia and sickle cell anaemia by direct analysis of fetal DNA obtained by chorion biopsy at about the 12th week of gestation. This approach has largely replaced fetal blood sampling or amniocentesis for the prenatal diagnosis of the thalassaemias. First trimester diagnosis is much more acceptable to many women. This reduces the long period of uncertainty, during which the fetus is growing and the mother and her relatives and friends are coming to accept that she is to have a child, and because late second trimester terminations are often difficult. Prenatal diagnosis of thalassaemia is now carried out in many countries, and in Sardinia, Greece, and Cyprus has significantly reduced the number of new cases of thalassaemia in the community.

Because prenatal diagnosis of thalassaemia is now well established it is very important to discuss the genetic implications of the condition when carriers are detected by chance, regardless of the individuals's racial background. They should also be given a letter explaining, in simple terms, the pattern of inheritance and the dangers for their children. This approach should always be followed, even for sporadic cases in low incidence regions, such as northern Europe. Because of the increasing movements of populations they might still marry another carrier and have severely affected children.

Symptomatic treatment

The symptomatic management of severe b thalassaemia requires regular blood transfusion, the judicious use of splenectomy if hypersplenism develops, and the administration of chelating agents to reduce iron overload. When the diagnosis of severe b thalassaemia is suspected during the first year of life, the infant should be followed for several weeks to make sure that the haemoglobin level is fallen to a level at which regular transfusion will be necessary. It is difficult to be dogmatic about

exactly when transfusions should be started. A severely anaemic infant who is feeding poorly, inactive, or otherwise failing to thrive, will almost certainly need to be transfused. The object is to maintain the pretransfusion haemoglobin level at about 9.5 g/dl. This usually requires transfusion of 10 to 15 mg/kilo red cells every 4 weeks. Washed red cells should be used. Whole blood should be avoided because of the danger of sensitization to serum or white cell components. The rate of transfusion should not exceed 4 to 5 ml/kg per h. In patients who are profoundly anaemic or show evidence of cardiac insufficiency, the rate should be no more than 2 ml/kg per h. It is important to calculate the annual blood consumption by dividing the total volume of blood transfused over 12 months by the patients weight in the middle of the year. If it is higher than 200 ml/kg body weight, splenectomy should be considered. All blood should be screened for hepatitis B and C, and for HIV.

Hypersplenism is becoming much less common if children are maintained on an adequate transfusion regimen. Increasingly blood requirements, or evidence of hypersplenism, pancytopenia for example, should prompt one to consider splenectomy. It should be avoided before the age of 6 years because of the particularly high incidence of infection in asplenic children. Two to three weeks before splenectomy the child should be given: (1) pneumococcal vaccine; (2) *Haemophilus influenzae* type B vaccine; (3) meningococcal A and C vaccine. After the operation the children should be maintained on oral penicillin V, 125 mg twice daily, increasing to 250 mg twice daily for older children. For those who are allergic to penicillin, erythromycin should be given.

The only effective chelating agent for the prevention or treatment of iron overload in thalassaemia is desferrioxamine (Desferal). It is now clear that this drug should not be given too soon because toxic effects are observed at low body iron loads. Ideally, the hepatic iron concentration should be measured at about 1 year after regular transfusion has started. Chelation should be initiated in patients with hepatic iron concentrations of above 7 mg/g liver dry weight. Where this is not possible, the drug should be given when the serum ferritin value has reached or exceeded 1000 µg/l although it is becoming increasingly clear that the serum ferritin level is a very imprecise estimate of body iron load. The initial dose should not exceed 25 to 35 mg/kg body weight per 24 h. Iron excretion is potentiated if children receive 100 mg vitamin C by mouth on the days of the infusion. Ideally, progress should be monitored by regular estimates of the hepatic iron concentration but if this is not possible the serum ferritin level should be maintained below 2000 µg/l. In patients who become iron loaded, it is possible to increase the rate of iron excretion considerably but the daily dose of desferrioxamine should not exceed 15 mg/kg body weight. Patients should be monitored continuously for side effects of desferrioxamine; these include retinal damage, ototoxicity, and interference with growth.

There are no entirely satisfactory alternatives to desferrioxamine as a chelating agent. The most widely studied, the oral chelator deferiprone (L1), does not appear to control iron accumulation in a proportion of patients, and causes neutropenia in about 5 per cent of cases. Its long-term toxicity and true place in the management of thalassaemia remains to be determined.

It is very important to monitor transfusion-dependent patients for hepatitis B and C and HIV infection. The management of these conditions is considered elsewhere in this book. Other complications relating to iron load, including hypoparathyroidism, diabetes, and delayed puberty and hypogonadism, require expert endocrinological assessment with appropriate replacement therapy.

Increasing experience with bone marrow transplantation has suggested that, if done early with adequate HLA matching, the results are extremely good. Patients who have become iron loaded and who have liver damage have a less good prognosis but, as more experience has been gained, there appears to be a place for transplantation in older patients.

The intermediate forms of thalassaemia should be treated by careful observation, folic acid supplementation, and, in the face of a falling haemoglobin and increasing spleen size, the judicious use of splenectomy. It is important to monitor the iron status regularly because some of these patients become iron loaded due to increased intestinal absorption later in life and chelation therapy may be necessary.

Currently, a number of experimental approaches to the treatment of the thalassaemias are being pursued, including the use of intrauterine or later stem cell therapy, the stimulation of fetal haemoglobin production, and, in the longer term, the possibility of somatic gene therapy.

Structural haemoglobin variants

Over 400 structural haemoglobin variants have been described, most of which result from single amino acid substitutions. Many of them are harmless and have been discovered during surveys of the electrophoretic patterns of human haemoglobin. Of course, this approach underestimates the number of variants because it only identifies those in which the amino acid substitution alters the charge of the haemoglobin molecule.

Single amino acid substitutions cause clinical disorders only if they alter the stability or functional properties of the haemoglobin molecule. A classification of these diseases is shown in Table 5. They include the sickling disorders, chronic or drug-induced haemolytic anaemia associated with unstable haemoglobins, and polycythaemia or congenital cyanosis, associated with high and low oxygen affinity haemoglobin variants, respectively. There is a rare group of haemoglobin variants that produce methaemoglobinaemia. We shall consider the different varieties of genetic methaemoglobinaemias at the end of this chapter.

Nomenclature

Originally, the structural haemoglobin variants were named by letters of the alphabet. By the late 1950s there were none left; it was decided to designate new haemoglobin variants by the place of origin of the first patient in whom they were characterized. It is customary to call the heterozygous carrier state the 'trait' and the homozygous condition the 'disease'. For example, haemoglobin S heterozygotes (genotype AS) are said to have the sickle cell trait, while those homozygous for the sickle cell mutation (genotype SS) are said to have sickle cell disease. In practice it is very important to distinguish between the carrier state and the homozygous or compound heterozygous state for a haemoglobin variant; carriers are usually asymptomatic.

The sickling disorders

Sickling disorders (Table 6) consist of the heterozygous state for haemoglobin S, sickle cell trait (AS), the homozygous state or sickle cell disease (SS), and the compound heterozygous state for haemoglobin S together with haemoglobins C, D, E, or other structural variants. Several disorders result from the inheritance of the sickle cell gene together with different forms of thalassaemia.

Pathogenesis

Haemoglobin S differs from haemoglobin A by the substitution of valine for glutamic acid at position 6 in the b chain. Although this has been known for nearly half a century, it is still not absolutely clear how it gives rise to the sickling phenomenon. The latter appears to be due to the unusual solubility characteristics of haemoglobin S which undergoes liquid crystal (tactoid) formation as it becomes deoxygenated. In this state, aggregates of sickled haemoglobin molecules arrange themselves in parallel, rod-like fibres, made up of a complex solid core about 21 nm in diameter, composed of 14 filaments arranged as seven pairs of double filaments. Much is now known about the complex interactions whereby the b6 valine substitution stabilizes the molecular stacks in the deoxy configuration of haemoglobin. There is considerable variation in the extent to which different haemoglobins are able to participate with haemoglobin S in the sickling process. This accounts for some of the clinical variability of the different sickling conditions. For example haemoglobin F is almost completely excluded from the sickling process; increasing concentrations in the red cell reduce the rate of sickling.

The pathophysiology of sickling is an extremely dynamic process. Red cells containing sickle haemoglobin at a high concentration endure a series of cycles of sickling and desickling with progressive membrane damage and loss of plasticity. Finally these dry, rigid cells become irreversibly sickled (Fig. 20). Sickling of this type has two main effects. First, sickled erythrocytes have a shortened survival leading to a chronic haemolytic anaemia. Second, and more importantly, these abnormal red cells tend to adhere to the various receptors on the walls of small blood vessels with the production of aggregates, blockage of the vessels, vascular stasis, and, ultimately, tissue damage.

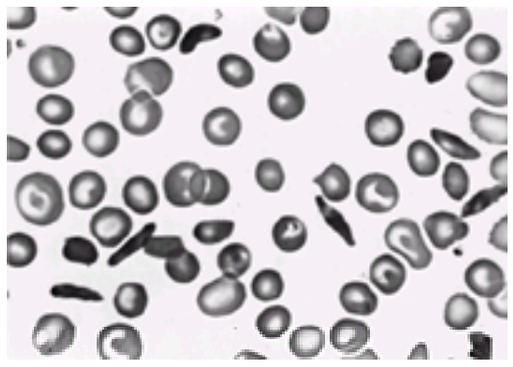

Fig. 20 Irreversibly sickled cells in the peripheral blood (×1000, Leishman stain).

Distribution

The sickling disorders occur very frequently in African populations and, sporadically, throughout the Mediterranean region and the Middle East. There are extensive pockets in India but the disease has not been seen in Southeast Asia. The high frequency of the sickle cell gene occurs because carriers are more resistant than normal individuals to *P. falciparum* malaria.

Clinical features

Except in conditions of extreme hypoxia, such as flying in an unpressurized aircraft the sickle cell trait causes no clinical disability. However, it is possible for individuals to suffer vaso-occlusive episodes if they become oxygen deprived under anaesthesia. Therefore all individuals of the appropriate racial background should have a sickling test (see below) before receiving an anaesthetic. If the test is positive, the anaesthetic should be given with adequate oxygenation and special care should be taken to avoid postoperative dehydration.

Sickle cell anaemia runs an extremely variable clinical course. At one end of the spectrum it is characterized by a crippling haemolytic anaemia interspersed with severe exacerbations, or crises. On the other hand, it may be extremely mild and only found by chance on routine haematological examination. The reason for these remarkable differences in phenotypic expression, which are only partly understood, include the level of haemoglobin F, coinheritance of a thalassaemia, climate, and, probably most important, socioeconomic factors such as availability of early treatment of infection.

Typically, sickle cell anaemia presents in infancy with symptoms related to anaemia or infection. A common presenting symptom is the hand and foot syndrome . It occurs early in infancy and is characterized by a painful dactylitis with swelling of the fingers or feet. Epiphyseal damage during one of these episodes may lead to chronic shortening of a digit. Infants are anaemic from about the third month of life. During early development they often have significant splenomegaly that gradually resolves due to repeated infarction. Indeed, it is most unusual to feel the spleen after the end of the first decade. Typically, the haemoglobin levels are in the 6 to 8 g/dl range with a reticulocyte count of 10 to 20 percent. There is chronic, mild icterus with an elevated bilirubin level. Examination of the peripheral blood film shows anisochromia and poikilocytosis with a variable number of sickled erythrocytes (Fig. 20). As the children grow older the haematological changes of hyposplenism develop with the appearance of pits on the surface of the red cells, Howell–Jolly bodies, and distorted red cells. The white cell and platelet counts are usually normal or slightly elevated.

Growth and development are usually otherwise normal although there may be some skeletal deformities, including frontal bossing of the skull due to expansion of the bone marrow. In some series, children have tended to be short for their age, while postadolescents were usually tall. Inequalities between upper and lower segments, stressed in the early literature, are unusual. The only other physical finding is chronic leg ulceration; this is discussed below.

Complications

The chronic haemolysis of sickle cell disease is interspersed with acute exacerbations of the illness called sickling crises. Furthermore, there are a series of serious and life-threatening, long-term complications which develop in many patients with sickle cell anaemia.

The different forms of sickle cell crises are summarized in Table 7. The commonest is the painful crisis. This is sometimes precipitated by infection, dehydration, or exposure to cold, although quite often no underlying cause can be found. The episode starts with vague pain, often in the back or bones of the limbs. The pain gradually worsens and its bizarre distribution may cause a major diagnostic puzzle. The pain is almost certainly due to blockage of small vessels with sickled erythrocytes; aspiration over areas of bone tenderness has shown infarction of marrow tissue. Occasionally, abdominal pain is the major symptom and this may be associated with distension and rigidity, a picture very similar to an acute abdominal emergency. The diagnostic difficulties in distinguishing between an abdominal crisis and a surgical abdomen are compounded by the fact that the bowel sounds are often diminished during abdominal crises. Two other serious forms of thrombotic crisis are known as the 'chest' and 'brain' syndromes. The 'chest' syndrome, characterized by acute dyspnoea and pleuritic pain together with infiltrates on the chest radiograph, is due to sequestration of sickle cells in the pulmonary circulation. It is sometimes accompanied by a fall in the PCV and platelet count which also may reflect sequestration of sickled cells in the pulmonary vessels. Neurological involvement may present in a variety of ways including fits with or without focal neurological signs. Cerebral infarction is commoner in children, while haemorrhage, due to microaneurysms which develop round infarctions ('moya moya') is commoner in adults.

During painful crises there may be a marked increase in the rate of haemolysis with a fall in the haemoglobin level. Such haemolytic episodes are uncommon. Much more serious are periods of transient bone marrow aplasia called aplastic crises. These seem to result from intercurrent infection, particularly due to parvovirus, and frequently affect more than one sibling in the same family.

Finally, and most serious, are the sequestration crises. Occurring mainly in babies and young children, they are characterized by a rapid enlargement of the spleen or liver, which become engorged with sickled erythrocytes. As the crisis progresses a large proportion of the total red cell mass may be trapped in the spleen or liver. Death may occur due to profound anaemia. These episodes show a tendency to recur in the same individual. Hepatic sequestration, which may occur in adults, is easily overlooked if the liver size is not monitored carefully.

The commonest cause of death in sickle cell anaemia appears to be a sequestration crisis or acute infection, or both. It is not absolutely clear why patients with this disorder are so prone to infection although reduced splenic function may play a role. Abnormalities of the alternate pathway of complement activation have also been described. A variety of organisms are involved, particularly the pneumococcus, and, mainly in tropical countries, typhoid infection of bone infarcts leads to typhoid osteomyelitis. Despite the relative resistance of heterozygotes to *P. falciparum* malaria, deaths due to malaria are extremely common in Africa.

Pregnancy may be uneventful, or associated with an increased incidence of painful crises. There is slightly increased incidence of maternal mortality and a definite increase in the rate of fetal loss.

Chronic complications

The chronic complications of sickle cell anaemia result largely from infarcts following repeated episodes of vascular occlusion. Almost any organ can be involved. Those at particular risk are areas which rely largely on small vessels for their blood supply. The bones are particularly prone to infarction. Aseptic necrosis of the humeral or femoral heads may lead to gross deformity of the shoulder and hip joints (Fig. 21). Bone infarcts may result in chronic sequestra formation which may become secondarily infected with the production of osteomyelitis. Infarction of the bone marrow does not seem to have any long-term sequelae, although occasionally pieces may break off and embolize to the lungs. Chronic leg ulceration is a common problem.

Fig. 21 Aseptic necrosis of the left femoral head in sickle-cell thalassaemia. (Reproduced by courtesy of Dr Graham Serjeant.)

Another organ at particular risk is the kidney. During early childhood renal function may be impaired but this can be corrected by blood transfusion, suggesting that it is due to reversible changes in the renal vasculature. These alterations in renal function are not reversible in later life. Chronic renal failure due to damage of the renal vessels is one of the commonest causes of death in adults with sickle cell anaemia. A typical nephrotic syndrome may develop at some stage during the illness. Pulmonary infarction occurs quite frequently, but repeated episodes leading to severe pulmonary hypertension and right heart failure are unusual, although this complication has been well documented.

There is usually some degree of cardiomegaly. A variety of flow murmurs may be heard but most of these signs seem to be the result of chronic anaemia. Myocardial infarction or fibrosis is not a feature of the disease. Recurrent attacks of painful priapism may lead to permanent deformity of the penis. Occular manifestations are also relatively common in sickle cell anaemia although they tend to be more serious in haemoglobin SC disease; they will be considered with the later disorder in a later section. Finally, there is increased evidence that, unless the neurological crises are treated energetically, permanent brain damage may result.

Course and prognosis

There are still large gaps in our knowledge about the natural history of sickle cell anaemia. Prognosis seems to depend on the racial background of the patient, socioeconomic and ill-defined genetic factors, and, especially the availability of good paediatric care in the early years.

In rural East Africa, the disease still has a high mortality in the first year or two of life. In Jamaica there appears to be a 10 per cent mortality in the early years although survival into adult life and old age is common. This is also the case in some urban parts of Africa and in the United States and Europe. Data from the United States Cooperative Study of Sickle Cell Disease suggest that the median age at death for males is 42 years and for females 48 years. In Saudi Arabia and India, a particularly mild form of the condition occurs. Mortality is extremely low in childhood and a normal survival seems to be common. It is becoming increasingly apparent that the commonest cause of death in the first year or two of life is infection, often associated with splenic sequestration. Later in life infection is still a frequent cause of death, although studies in Jamaica indicate that chronic, progressive renal failure may be responsible for a significant number of deaths. The introduction of prophylactic penicillin has made a major inroad into early deaths from infection (see below).

Laboratory diagnosis

Sickle cell trait causes no haematological changes and is diagnosed by the finding of a positive sickling test together with haemoglobins A and S on electrophoresis (Fig. 22). Sickle cell anaemia is diagnosed by the finding of a variable degree of anaemia, an elevated reticulocyte count, sickled erythrocytes on the peripheral blood film, a positive sickling test, and a haemoglobin electrophoresis pattern characterized by the absence of haemoglobin A and a preponderance of haemoglobin S with a variable amount of haemoglobin F (Fig. 22). The diagnosis is confirmed by finding sickle cell trait in both parents.

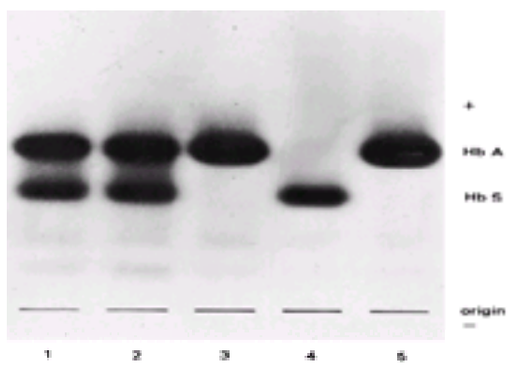

Fig. 22 The haemoglobin pattern in the sickling disorders (starch gel electrophoresis, protein stain, pH 8.5). The following are shown (left to right): (1 and 2) the sickle-cell trait; (3) normal; (4) sickle-cell anaemia; (5) normal.

There is a variety of simple sickling tests available. For ward laboratories the simplest it to take a drop of blood, mix it with two volumes of freshly prepared 2 per cent sodium metabisulphite, place a coverslip over the mixture, seal the edges with vaseline, and examine the slide for sickling after 1 h.

Control and management

There is very little experience of prospective genetic counselling and education of communities as an approach to reducing the number of carriers of sickle cell disease. Although prenatal diagnosis of sickle cell disease can be carried out by DNA analysis following chorion villus sampling, it has not been taken up as extensively as is the case for the thalassaemias. We need to know a great deal more about the factors which modify the clinical prognosis before the place of prenatal diagnosis is clarified.

It is very important that the babies of 'at risk' pregnancies are screened at birth and that the diagnosis is made as early as possible. This is because early deaths due to infection and the frequency of crises may be reduced by the administration of oral penicillin. This should be given to all affected babies at a dosage of 62.5 mg three times a day, up to 1 year of age, 125 mg twice a day from the age of 1 to 3 years, and 250 mg twice a day thereafter. It is also now standard practice for these babies to receive pneumococcal vaccine; in many centres they also receive vaccines against meningococcus and *Haemophilus influenzae*.

Patients with sickle cell anaemia adapt well to their low haemoglobin levels and regular blood transfusion is not required. Particularly in populations in which the diet is low in folate, regular folate supplements should be given. Patients should be given access to a centre that has expertise in the management of this disorder and advised to present at the first sign of a painful crisis. They should also be given a card to carry which states their haemoglobin genotype.

All but the mildest painful crisis should be managed in hospital. Patients should be examined in detail at regular intervals for evidence of underlying infection and given adequate rehydration, oxygen, antibiotics where appropriate, and, in particular, analgesia. The haemoglobin level and reticulocyte count should be estimated at frequent intervals to anticipate an aplastic crisis or pulmonary sequestration episode. While a mild crisis may be managed with first-line analgesics, stronger pain relief is often necessary. There has been concern about the possible dangers of the use of pethedine; it has become fashionable to administer diamorphine by slow, titratrated intravenous infusion. This has to be done under constant surveillance with regular monitoring of respiration and blood gases. It is very unusual for a painful crisis to last more than a few days.

Pulmonary sequestration requires urgent treatment in an intensive care unit. Oxygen should be administered and the blood gases monitored. An exchange transfusion should be initiated unless the haemoglobin level is lower than 4 to 5 g/dl, when the same result can be achieved by rapid transfusion up to 10 to 12 g/dl. Similarly, cerebral complications should be treated by exchange or top-up transfusion. There is evidence that this complication may be prevented by regular Doppler analysis of cerebral blood flow followed, where appropriate, by regular transfusion. Transfusion therapy also prevents recurrence of the cerebral episodes. Hypertransfusion or exchange transfusion should also be used to cover major surgical emergencies or for patients who are having recurrent crises. Occasionally, and most often in young children, the spleen may enlarge to such a degree that secondary hypersplenism develops and splenectomy is required. Splenic sequestration crises require urgent transfusion. Because they tend to recur, they may require splenectomy.

There is no special management required during pregnancy. Occasionally, if the haemoglobin level falls to a value at which symptoms of anaemia occur, or if there are recurrent crises, a regular transfusion regimen should be started to cover pregnancy and delivery.

Ocular manifestations, particularly proliferative retinopathy, require expert ophthalmological treatment. The current place for prophylactic zenon arc or argon laser therapy remains uncertain. Chronic disability due to aseptic necrosis of the femoral head may require hip replacement, although results are often disappointing and this complication requires a great deal more study. Surgical procedures should be undertaken with great caution. It is vital to maintain adequate oxygenation and hydration; limb torniquets should be avoided. Major procedures are best carried out after exchange transfusion. Haeamaturia usually resolves without treatment. Terminal renal failure should be managed as for any other form of renal insufficiency; renal transplantation has been shown to be successful in several studies.

Recurrent priapism is a major problem. Nearly two-thirds of major episodes are preceded by stuttering attacks and therefore it has been suggested that effective therapy at this stage may reduce the risk of sustaining a major attack, with danger of permanent deformity of the penis. Several approaches to management have been suggested although none have been studied in sufficient detail. One approach has been to commence stilboestrol, 5 mg daily, during the stuttering phase. Other forms of treatment at this stage that have been reported to give benefit are the use of opioid analgesics with benzodiazepine or pseudoephedrine hydrochloride. As well as these approaches, the patient should be hydrated, given analgesia, and, possibly, exchange transfusion. Centres with experience of this complication suggest that conservative treatment should be restricted to 24 h at the most. If there is no improvement, surgical correction is recommended, with a cavernosus–spongiosum shunt, a relatively minor procedure that may produce a good cosmetic result.

The management of leg ulcers is unsatisfactory. They may heal with bed rest and debridement but often relapse. Skin grafting does not always give good results and controlled trials have shown that transfusion does not appear to increase the rate of healing.

Experimental forms of treatment have shown some promise. Bone marrow transplantation has been carried out with reasonably good results. However, because of the inherent risks, and the uncertainty of the prognosis, the precise indications are not yet clear. Other studies have been directed at trying to elevate fetal haemoglobin. In a placebo-controlled trial involving adult patients it was found that the administration of hydroxyurea caused a significant reduction in the number of painful crises. This may have resulted from the modest elevation in fetal haemoglobin in response to the drug but other factors such as the reduced white count and increased red cell volume may have played a role. Currently, this drug has been licensed for treatment by the Federal Drug Administration in the United States for adult patients. It has also been used effectively in children but because of its possible leukaemogenic effects its use earlier in life is still restricted to clinical trials.

Other sickling disorders

The other sickling disorders include the interaction of haemoglobin S with haemoglobins C, D, and some of the rarer haemoglobin variants. The interactions with the different forms of b thalassaemia were described above. In many of these conditions, the clinical manifestations are little different from the sickle cell trait, but haemoglobin SC disease and SD disease more closely resemble sickle cell anaemia.

Haemoglobin SC disease

This disease is found in West Africa and less frequently in North Africa. Characterized by a milder anaemia than sickle cell disease, it often goes unrecognized until adult life. It may present with a complication resulting from damage to the microvasculature, probably because of the relatively high haemoglobin level and the combined effects of sickling and red cell rigidity caused by haemoglobin C (see below). Aseptic necrosis of the femoral or humeral heads and unexplained haematuria are the most common complications. Widespread thrombotic episodes, particularly involving the lungs, may occur during intercurrent infection or in pregnancy or the puerperium. Repeated blockage of the retinal vessels may lead to retinitis proliferans, retinal detachment, and permanent blindness.

Haemoglobin SC disease is diagnosed by finding a mild anaemia with splenomegaly and characteristic morphological changes of the red cells, including many target forms, intracellular crystals, and sickle cells. The sickling test is positive and haemoglobin electrophoresis shows haemoglobins S and C in about equal proportions. One parent shows the sickle cell trait and the other the haemoglobin C trait.

Severe thrombotic episodes, particularly in pregnancy, should be treated by exchange transfusion. The role of anticoagulants has never been established. Retinal disease is treated by laser.

Haemolysis due to other common haemoglobin variants

After haemoglobin S the second commonest variant in West Africa is haemoglobin C. Haemoglobin C, because of its relatively low solubility, appears to exist in a precrystalline state in red cells causing their rigidity and premature destruction in the microcirculation. The homozygous state, haemoglobin C disease, is characterized by a mild haemolytic anaemia with splenomegaly, and 100 per cent target cells on the blood film. Haemoglobin analysis shows haemoglobin C with small amounts of haemoglobin F. This is a mild disorder and no specific treatment is required.

The commonest haemoglobin variant throughout Southeast Asia and the Indian subcontinent is haemoglobin E. The homozygous state for this variant, haemoglobin E disease, is characterized by a very mild degree of anaemia with a slight reticulocytosis. The blood film shows mild morphological changes of the red cells which are hypochromic and microcytic, resembling the changes seen in b thalassaemia. No treatment is required.

Haemoglobin variants which migrate in the position of haemoglobin S but which do not sickle have been given the general title of haemoglobin D. There are several different molecular varieties of this variant; the commonest is haemoglobin D Los Angeles. The homozygous state is associated with moderate anaemia, splenomegaly, and a mild degree of haemolysis. The compound heterozygous state with haemoglobin S produces a disorder very similar to sickle cell anaemia. It is diagnosed by finding one parent with the haemoglobin D trait and the other with the sickle cell trait.

The unstable haemoglobin disorders

The unstable haemoglobin disorders are a rare group of inherited haemolytic anaemias which result from structural changes in the haemoglobin molecule that cause intracellular precipitation with the formation of Heinz bodies. Their true incidence is not known. There have been several well-documented families in which patients with one of these haemoglobin variants have had no affected relatives, suggesting that the condition has arisen by a new mutation.

Aetiology and pathogenesis

Most of the unstable haemoglobin variants result from single amino acid substitutions at critical areas of the molecule. For example substitutions in or around the haem pocket can disrupt the normal anatomy and allow in water with subsequent oxidative damage to haem which leads to precipitation of the haemoglobin. Some substitutions, such as those involving proline residues, cause a marked disruption of the secondary structure of a globin chain. A few of these variants result from deletions of either single or several amino acid residues. For example in haemoglobin Gun Hill, five amino acids are missing including the haem binding site. As the unstable haemoglobins precipitate in the red cells or their precursors, they produce intracellular inclusions, or Heinz bodies, which make the cells more rigid causing their premature destruction in the microcirculation (Fig. 23). The degradation products of the precipitated haemoglobin, notably haem and iron, cause oxidative damage to the red cell membrane proteins in much the same way as the excess a and b chains produced in the thalassaemias.

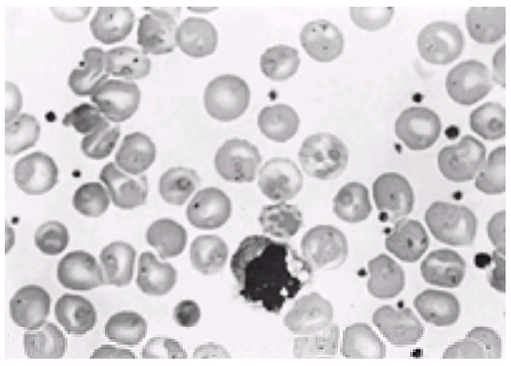

Fig. 23 The peripheral blood film of a patient with an unstable haemoglobin disorder, haemoglobin Hammersmith. This is a postsplenectomy film, which shows small inclusions in many of the red cells (×1000, Leishman stain).

Clinical features

All these conditions are characterized by a haemolytic anaemia of varying severity and splenomegaly. There may be a history of the passage of dark urine, particularly during episodes of infection. Like all chronic haemolytic anaemias, there is an increased incidence of pigment gallstones. The condition may become worse during periods of intercurrent infection. In the more severe forms, such episodes are associated with life-threatening anaemia. Patients with unstable haemoglobins are at particular risk of haemolytic episodes following the administration of oxidant drugs. Apart from intermittent icterus and splenomegaly there are no characteristic physical findings.

Laboratory diagnosis

This condition should be thought of in any familial haemolytic anaemia, particularly if a red cell enzyme deficiency cannot be demonstrated. The peripheral blood film shows the features of haemolysis but the red cell morphology may be relatively normal. Occasionally there is a mild degree of hypochromia and microcytosis. Unless splenectomy has been carried out, Heinz bodies are not seen in the peripheral blood (Fig. 23).

The most characteristic feature of the unstable haemoglobins is their heat instability. If a dilute haemoglobin solution is heated at 50°C for 15 min, most of the unstable haemoglobins precipitate as a dense cloud. A similar phenomenon can be induced by isopropanalol. Some variants can be identified by haemoglobin electrophoresis but others, because they result from the substitution of a neutral amino acid, produce no electrophoretic changes and can only be demonstrated by the heat precipitation test.

Treatment

Because these conditions are so rare there has been very little experience of the effects of splenectomy. From the information that is available, and from the author's personal experience, it appears that if a child has had several life-threatening episodes of anaemia or is running a steady-state haemoglobin level which is impairing development or well-being, splenectomy should be undertaken. It is interesting to note that some of these haemoglobin variants produce a 'right shift' in the oxygen dissociation curve, and a measurement of the P_{50} as part of the presplenectomy assessment may help to decide whether to proceed to surgery; a marked right shift, that is an increased P_{50}, indicates that the anaemia should be more easily tolerated than if the oxygen dissociation curve is moved in the opposite direction with a low P_{50}. An accurate history from the child or its parents is probably more helpful, however.

Haemoglobin variants which cause abnormal oxygen binding

In 1966, an 81-year-old man presented at Johns Hopkins Hospital, Baltimore with mild angina and a haemoglobin value of 19.9 g/dl. No cause could be found for his polycythaemia but it was noted that he had an abnormal haemoglobin. The oxygen dissociation curve of his blood was found to be displaced to the left. This suggested that the abnormal haemoglobin might have a high oxygen affinity and that the patient's increased red cell count might be compensating for a primary defect in oxygen unloading. Further studies showed that this was the case, documenting a new cause for secondary polycythaemia. Since then over 40 haemoglobin variants of this type have been defined, all associated with familial polycythaemia.

Aetiology

The high-oxygen-affinity haemoglobin variants result from single amino acid substitutions at critical parts of the haemoglobin molecule which are involved in the configuration changes that underlie haem/haem interaction and the production of a sigmoid oxygen dissociation curve. Many occur at the junctions between the a and b subunits. Others involve the amino acids which are involved with the binding of 2,3-diphosphoglycerate (2,3-DPG) to haemoglobin. As mentioned earlier, increasing concentrations of 2,3-DPG tend to push the oxygen dissociation curve to the right; fetal haemoglobin has a high oxygen affinity (left-shifted curve) because it cannot interact with 2,3-DPG; mutations of the DPG binding sites have a similar effect.

Pathophysiology

The high-oxygen-affinity variants have a left-shifted oxygen dissociation curve with a reduced P_{50}. Thus the variant haemoglobin holds on to oxygen more avidly than normal haemoglobin. This leads to tissue hypoxia. This in turn causes an increased output of erythropoietin and an elevated red cell mass.

Clinical features

Many patients with high-oxygen-affinity variants are completely healthy and are only found to carry the variant when a routine haematological examination shows an unusually high haemoglobin level or packed cell volume. There have been one or two reports of arterial or venous occlusive disease in these patients. However, this is uncommon. Most patients are asymptomatic. There is no splenomegaly and no other associated haematological findings. Although it might be expected that a high-oxygen-affinity haemoglobin would cause defective oxygenation of the fetus none of the reported families has had a history of frequent stillbirths.

Diagnosis

The condition should be suspected in any patient with a pure red cell polycythaemia associated with a left-shifted oxygen dissociation curve. The diagnosis can be confirmed by haemoglobin analysis.

Treatment

In asymptomatic patients with high-oxygen-affinity haemoglobin variants no treatment is necessary. The difficulty arises if the patient has associated vascular disease with symptoms of coronary or cerebral artery insufficiency. There is insufficient published information to make any dogmatic statements about how this complication should be managed. The author has seen several patients of this type who seem to have responded to venesection; more experience is required before this form of treatment can be recommended however. These patients require a high haemoglobin level for oxygen transport; half their haemoglobin is physiologically useless.

Low-oxygen-affinity variants

At least six haemoglobin variants with reduced oxygen affinity have been reported. The first to be described, haemoglobin Kansas, was found in a mother and son with unexplained cyanosis. The subjects were asymptomatic and had normal haemoglobin levels without any evidence of haemolysis. Like many of the high affinity variants, the amino acid substitution in this variant was at the interface between the a and b globin chains. For reasons which are not clear, some substitutions in this

region give rise to variants with a relatively low oxygen affinity. This condition should be thought of in any patient with an unexplained congenital cyanosis; the differential diagnosis is considered below.

Methaemoglobinaemia, carboxyhaemoglobinaemia, and sulphaemoglobinaemia

Methaemoglobinaemia is a condition characterized by increased quantities of haemoglobin in which the iron of haem is oxidized to the ferric (Fe^{3+}) form. Carboxyhaemoglobinaemia (carbonmonoxyhaemoglobinaemia) results from the binding of carbon monoxide to the haem molecules. Sulphaemoglobinaemia is a rare condition in which there is a mixture of haemoglobin derivatives whose structure is poorly characterized but which can be defined by their specific spectral characteristics.

Pathogenesis

As mentioned earlier, each haemoglobin molecule has four haem moieties. At first sight it is not clear why the oxidation of a proportion of the iron atoms, or the fact that they are liganded to carbon monoxide, should cause such profound changes in oxygen transport. However, oxidation of 30 per cent of the haem molecules has a much more serious effect on tissue oxygenation than a reduction of the haemoglobin level by the same amount. This is because, if a single haem is oxidized, it so alters the conformation of the haemoglobin molecule that the oxygen affinity of the other three haems is increased. Thus methaemoglobin, carboxyhaemoglobin, and cyanmethaemoglobin all have very high oxygen affinities with 'left shifted' oxygen dissociation curves, and hence are associated with impaired unloading of oxygen to the tissues.

Methaemoglobinaemia

Methaemoglobin causes a variable degree of cyanosis. It should be suspected in any patient with significant central cyanosis in whom there is no evidence of cardiorespiratory disease. The degree of cyanosis produced by 5 g/dl of deoxygenated haemoglobin can be produced by 1.5 g/dl methaemoglobin and 0.5 g/dl of sulphaemoglobin. Methaemoglobin concentrations of 10 to 20 per cent are tolerated quite well. It is useless as an oxygen carrier; levels above this are thus often associated with dyspnoea and headache. Much depends on the rapidity at which it is formed; many patients with life-long methaemoglobinaemia are asymptomatic while individuals who have accumulated a similar level of methaemoglobin acutely may be acutely dyspnoeic. For reasons which are not clear, it is unusual for patients with chronic methaemoglobinaemia to have an increased haemoglobin level or red cell count.

Methaemoglobinaemia may arise as a result of a genetic defect in red cell metabolism or haemoglobin structure, or may be acquired following the ingestion of various oxidant drugs and toxic agents.

Genetic methaemoglobinaemia

There are two forms of inherited methaemoglobinaemia. The first results from a deficiency of red cell NADH-diaphorase, the second from a structural alteration in either the a or b globin chains of haemoglobin.

NADH-diaphorase catalyses a step in the major pathway for methaemoglobin reduction. The enzyme reduces cytochrome b_5 using NADH as a hydrogen donor. The reduced cytochrome b_5 reduces, in turn, methaemoglobin to haemoglobin. There are several different molecular forms of NADH-diaphorase deficiency which have been identified by electrophoretic analysis of NADH-diaphorase in the red cells of affected patients. The condition is inherited as an autosomal recessive. Homozygotes have elevated levels of methaemoglobin and are cyanotic from birth. Heterozygotes do not have elevated levels of methaemoglobin but seem to be unusually susceptible to the oxidant action of drugs. For example severe cyanosis has been precipitated by the use of antimalarial drugs.

There are several abnormal haemoglobin variants which are associated with genetic methaemoglobinaemia, all of which are designated haemoglobin M, and further identified by their place of discovery, for example haemoglobin M Boston, M Milwaukee. These variants usually result from amino acid substitutions near the haem pocket. Normally, haem lies between two histidine residues, one called the proximal histidine to which it is attached, and the other called the distal histidine. Oxygen is bound to haem at a site opposite to the distal histidine. If the latter is substituted by tyrosine, as occurs in the a chain variant haemoglobin M Boston and in the b chain variant M Saskatoon, a stable bond is formed between the haem iron and the phenolic ring of the tyrosine. The iron atom is 'fixed' in the Fe^{3+} state. These variants are associated with cyanosis which is present from early life. In the case of the a chain variants it is present from birth, while the b chain haemoglobin variants only produce cyanosis after the first few months of life as adult haemoglobin synthesis becomes established. Unlike NADH diaphorase deficiency, which is inherited as a recessive trait, the haemoglobin Ms have a dominant form of inheritance. Thus it is very simple to make the diagnosis of genetic methaemoglobinaemia and to determine the likely molecular basis by taking a good history; even the affected globin chain can be ascertained!

The diagnosis is confirmed by spectroscopic examination of the blood and by determination of methaemoglobin levels. The precise cause can be established by an assay of NADH-diaphorase or by haemoglobin analysis under appropriate conditions.

Genetic methaemoglobinaemia due to NADH-diaphorase deficiency is readily treated by the administration of ascorbic acid, 300 to 600 mg daily by mouth in divided doses, or by the administration of methylene blue, either intravenously (1 mg/kg body weight) or by mouth 60 mg three to four times daily. On the other hand, the genetic methaemoglobinaemias due to structural haemoglobin variants do not respond to ascorbic acid, methylene blue, or any other treatment. Most affected individuals go through life asymptomatic and require no treatment.

Acquired methaemoglobinaemia

Acquired methaemoglobinaemia usually results from the administration of drugs or exposure to chemicals which cause oxidation of haemoglobin. There are many agents which are capable of exceeding the red cells' ability to reduce methaemoglobin. They include ferricyanide, bivalent copper, chromate, chlorate, quinones, and certain dyes with a high oxidation–reduction potential. Nitrite, often used as a preservative, is one of the most common methaemoglobin-forming agents. Nitrates, after conversion to nitrites in the gut, may cause serious methaemoglobinaemia in infants. Other agents which commonly cause methaemoglobinaemia include phenacatin, primaquine, sulfonamides, and various analine dye derivatives.

If any of the agents listed above is given in low dose over a long period of time it may lead to chronic methaemoglobinaemia with or without a haemolytic anaemia. However, after exposure to a large amount of these agents, and the development of in excess of 50 to 60 per cent methaemoglobin, the symptoms of acute anaemia develop because methaemoglobin lacks the capacity to transport oxygen. Thus the clinical picture may be characterized by vascular collapse, coma, and death.

Methaemoglobinaemia with haemolytic anaemia

The haemolytic action of oxidant drugs is described elsewhere. Chronic methaemoglobinaemia with haemolytic anaemia, characterized by Heinz body formation and fragmented red cells, occurs commonly in patients receiving dapsone, salazopyrine, or phenacatin. This condition is usually innocuous and can be modified by adjusting the dose of the drug.

Occasionally, acute intravascular haemolysis associated with methaemoglobinaemia and intravascular coagulation occurs. It usually follows the ingestion or infusion of a strong oxidizing agent such as chlorate or arsine. There is gross intravascular haemolysis and methaemoglobinaemia together with evidence of disseminated intravascular coagulation. The haemoglobin level may fall very rapidly and may be complicated by renal failure.

Treatment

In cases of chronic acquired methaemoglobinaemia, the drug or chemical agent should be removed where possible. If continued therapy is required, it should be administered at a lower dose.

Acute toxic methaemoglobinaemia presents a serious medical emergency. Methylene blue should be administered in a dose of 1 to 2 mg/kg intravenously over a 5-min period. Repeated doses may be needed. Toxicity is uncommon although doses of over 15 mg/kg may cause haemolysis in young infants. The drug should not be used if the methaemoglobinaemia is due to chlorate poisoning as it may convert the chlorate to hypochlorite which is an even more toxic compound. In cases of

acute methaemoglobinaemia with intravascular haemolysis, haemodialysis with exchange transfusion is the treatment of choice.

Carboxyhaemoglobinaemia

Carbon monoxide (CO) has an affinity for haemoglobin approximately 210 times that of oxygen. Following acute exposure it is so tightly bound that it takes about 4 h for an individual with normal ventilation to expel half of it. At levels of 5 to 10 per cent there may be no symptoms, but above 20 per cent there is usually headache and weakness. Levels of 40 to 60 per cent or more lead to unconsciousness and death.

Carbon monoxide poisoning is discussed in Chapter 8.1 and secondary polycythaemia due to chronic exposure is considered elsewhere in this chapter.

Sulphaemoglobinaemia

This poorly-defined condition derives its name from the fact that it can be produced *in vitro* by the action of hydrogen sulphide on haemoglobin. It has not been reported as a genetic disorder. It is usually associated with the administration of drugs, particularly sulfonamides or phenacetin. It has also been reported in patients with chronic constipation or malabsorption syndromes (enterogenous cyanosis) although its relationship to these disorders is far from clear.

Other acquired abnormalities of the structure or synthesis of haemoglobin

Glycosylated haemoglobin, haemoglobin AIc

Haemoglobin may undergo post-translational modification in patients with diabetes. The abnormal haemoglobin, haemoglobin AIc, is formed by the non-enzymic combination of glucose with the N-terminus of the b chain, forming first a Schiff base which then undergoes a rearrangement to form a stable ketoamine. The level of haemoglobin AIc is raised in diabetics and is related to the blood sugar level over the previous weeks. The value of the estimation of haemoglobin AIc as an index of the control of diabetes is considered elsewhere.

Haemoglobin Pb

Some children with lead poisoning develop a modified haemoglobin which migrates rapidly on alkaline electrophoresis. The precise structural alteration is not known but, if present, this variant is a useful indicator of severe lead poisoning.

Fetal haemoglobin production in adult life

A number of haematological disorders are associated with a reversion to fetal haemoglobin production after the neonatal period. These include juvenile myeloid leukaemia, other forms of leukaemia, and congenital hypoplastic anaemias. Haemoglobin F may also appear transitorily during rapid regeneration of the bone marrow after drug induced hypoplasia, virus infection, or bone marrow transplantation.

22.5.8 Anaemias resulting from defective red cell maturation

James S. Wiley

Erythroid cell maturation is specialized towards the co-ordinated synthesis of large amounts of haem and globin necessary to attain the high concentration of haemoglobin found in the mature red cell. Hereditary or acquired defects in the production of either of these cause a maturation block, which leads to ineffective erythropoiesis in which many of the developing nucleated erythroblasts are destroyed in the marrow before they can reach the circulation. Thus in thalassaemia, defective synthesis of either a or b globin leads to unbalanced production of the other chain which precipitates and leads to destruction of the precursor erythroblast. Defective haem synthesis in the sideroblastic anaemias also leads to an anaemia which is characterized by ineffective erythropoiesis (Table 1). Abnormalities of DNA synthesis in the developing erythroid cells, such as produced by vitamin B_{12} or folic acid deficiency, blocks cell division required for erythroid maturation and produces morphological and biochemical evidence of ineffective erythropoiesis.

Ineffective erythropoiesis may be recognized by the characteristic erythroid hyperplasia of the bone marrow with normal or only slight increase in reticulocyte numbers. Some other features of ineffective erythropoiesis may be variably present: a mild increase in bilirubin, decrease in haptoglobin, and increased serum lactic dehydrogenase activity. As a result, iron absorption is increased, serum iron and ferritin become elevated, and, after many years, iron overload develops which is indistinguishable from idiopathic haemochromatosis. However, the degree of iron overload does not depend on either the severity of the anaemia or the presence of the characteristic mutation (Cys282Tyr) of the *HFE* gene associated with genetic haemochromatosis.

The sideroblastic anaemias

Sideroblastic anaemias are a group of hereditary or acquired anaemias of varying severity diagnosed by the finding of ring sideroblasts in the bone marrow aspirate. The peripheral blood film shows hypochromic red cells which are microcytic in the hereditary form (Fig. 1), but are often macrocytic in the acquired forms of the disease. Normochromic and normocytic red cells are also present which gives the film a dimorphic distribution of red cell sizes. The diagnostic procedure is bone marrow aspirate followed by staining of the smear with Prussian Blue iron reagent. Ring sideroblasts are diagnostic (Fig. 2) and are defined as erythroblasts containing iron-positive granules arranged in a perinuclear location around one-third or more of the nucleus. Electron microscopy reveals that the iron-containing granules are mitochondria containing precipitated ferric phosphate and ferric hydroxide. The sideroblastic anaemias have diverse aetiologies (Table 2) but have in common an impaired biosynthesis of haem in the erythroid cells of the marrow. Most sideroblastic anaemias are acquired as a clonal disorder of erythropoiesis, with varying degrees of myelodysplasia. The hereditary forms are uncommon. Most are found in males with an X-linked pattern of inheritance. A number of drugs have been associated with reversible sideroblastic anaemia, chiefly in patients with alcohol abuse (Table 2).

Hereditary sideroblastic anaemias

Aetiology and pathogenesis

Haem biosynthesis occurs by a cascade of eight enzymes (Fig. 3). In man, mutations affecting the first enzyme of this pathway produce hereditary sideroblastic anaemia. Inborn errors that occur in later enzymes in this pathway result in metabolic disorders known as the porphyrias (Fig. 3). The pathway begins with the condensation of glycine with succinyl CoA to form 5-aminolaevulinic acid (ALA), a step which is under the control of the mitochondrial enzyme ALA synthase. This enzyme requires pyridoxal phosphate as a cofactor. Two isoenzymes of ALA synthase have been identified. One is found in liver and other tissues (ALAS 1). The second is confined to erythroid cells of the bone marrow (ALAS 2). The gene for the erythroid-specific ALAS 2 isoenzyme resides on the X chromosome and is now known to be the site of most mutations giving rise to X-linked hereditary sideroblastic anaemia. Several dozen different mutations have been described in different families. All result from a single amino acid alteration arising from a point mutation in the ALAS 2 coding region of DNA. In nearly half the families with hereditary sideroblastic anaemia, the structure of the ALAS 2 gene is normal, suggesting that other defects may be involved, such as the import of ALAS 2 from the cytosol or its anchoring within the mitochondrial matrix. In most families, males are affected with an X-linked pattern of inheritance consistent with a mutation on the X chromosome (Fig. 4). However, occasionally the disease is transmitted as an autosomal dominant; there are even well-documented families in which only females are affected.

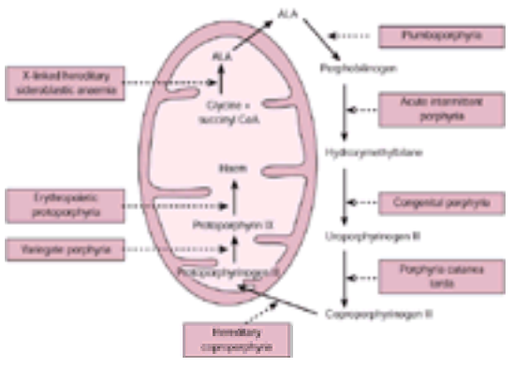

Fig. 3 Pathway of haem biosynthesis in mammalian cells. The first step in the pathway is catalysed by ALAS and occurs within the mitochondrion using pyridoxal 5'-phosphate as a cofactor. ALA then leaves the mitochondrion and is converted by ALA dehydratase to give a monopyrrole, porphobilinogen. Four molecules of this are converted by porphobilinogen deaminase to a linear tetrapyrrole, hydroxymethylbilane. This molecule is then cyclized by uroporphyrinogen III synthase to uroporphyrinogen III, which is then decarboxylated to coproporphyrinogen III. This molecule enters the mitochondrion and is oxidized in succession by coproporphyrinogen III oxidase and protoporphyrinogen III oxidase. The product is protoporphyrin IX, a substrate for ferrochelatase, which catalyses the insertion of Fe^{2+} to form haem. The defective steps associated with specific porphyrias and X-linked hereditary sideroblastic anaemias are shown. (Reproduced from Hoffman R *et al.*, eds. (1999). *Hematology: basic principles and practice*, 3rd edn. WB Saunders Co., Philadelphia, with permission.)

Clinical and laboratory features

Typically the anaemia presents in infancy or childhood but when the anaemia is mild, the diagnosis may not be made until adult life. Occasionally, such patients may present with features of iron overload such as diabetes or cardiac failure. Others may be found in family surveys, which should be undertaken when this anaemia is diagnosed. Slight enlargement of the liver or spleen may occur. The degree of anaemia is variable, ranging from severe (less than 80 g/l haemoglobin) to mild (more than 100 g/l haemoglobin) but even with mild or no anaemia the mean corpuscular volume (MCV) is below the normal range. Blood film shows a population of cells with hypochromic, microcytic morphology. Female carriers may show the characteristic red cell dimorphism. White cell counts are normal while platelet counts are normal or slightly elevated. Serum iron and ferritin concentrations are invariably increased and transferrin shows an increased percentage saturation with iron. The differential diagnosis includes idiopathic haemochromatosis, since both diseases have evidence of iron overload. Examination of the blood film, the MCV, and the bone marrow should establish the diagnosis.

Treatment and prognosis

A trial of pyridoxine, 100 to 200 mg/day taken orally, is indicated for 3 months in all patients with proven or suspected hereditary sideroblastic anaemia. About 25 per cent of patients experience a full or partial correction. This vitamin should be continued lifelong in responders but at a lower maintenance dosage. Regular transfusions of packed red cells are the mainstay of treatment of severe anaemia. These should be given to relieve symptoms and allow normal childhood development. Splenectomy is contraindicated in this condition. Iron overload progresses rapidly once transfusions begin. Chelation therapy with desferrioxamine should thus be commenced after the first 10 to 20 transfusions. Iron removal may greatly benefit patients with mild or moderate anaemia and evidence of iron overload. Intermittent phlebotomy of 100 to 200 ml blood should be attempted as this is more effective than chelation therapy in removing iron and should be continued if symptoms allow until the serum ferritin becomes normal. Finally, patients should avoid alcohol and ascorbic acid supplements, both of which enhance iron absorption.

Acquired idiopathic sideroblastic anaemia (refractory anaemia with ring sideroblasts)

Acquired idiopathic sideroblastic anaemia is a refractory anaemia with a hypercellular marrow containing ring sideroblasts which may either be idiopathic or develop following chemotherapy or irradiation (Table 2). Since nearly all cases also show evidence of dyserythropoiesis, this anaemia is now classified as one of the myelodysplastic syndromes and termed refractory anaemia with ring sideroblasts by the French–American–British Group. This classification is supported by the demonstration that the defective haematopoiesis is clonal, both in acquired idiopathic sideroblastic anaemia and the other myelodysplastic syndromes. Clonal haematopoiesis has also been shown in acute erythroleukaemia, in which bizarre dysplastic changes and ineffective erythropoiesis are seen in the developing erythroblasts. These comprise a majority (more than 50 per cent) of all nucleated marrow cells. The fact that more than 20 per cent of the myeloid cells are blasts distinguishes acute erythroleukaemia from one of the myelodysplastic syndromes.

Aetiology and pathogenesis

The cause of the defective haem synthesis in acquired sideroblastic anaemia is unclear. Recent reports indicate that levels of ALAS in bone marrow are normal. Indirect evidence points to an acquired defect in the mitochondrial respiratory chain that impairs the reduction of Fe^{3+} to Fe^{2+} since ferrous iron is essential for the terminal ferrochelatase reaction (Fig. 3). Clonal haematopoiesis has been demonstrated in this anaemia by both molecular and karyotypic analysis. Thus a single glucose-6-phosphate dehydrogenase (G6PD) isoenzyme was found in erythrocytes of a woman heterozygous for G6PD who expressed two isoenzymes in her somatic tissues. Clonal chromosome changes are also found in bone marrow cells in many patients with acquired sideroblastic anaemia. Characteristic changes include monosomy 7, trisomy 8, deletions involving chromosomes 5, 7, 11, 13, or 20, and a number of translocations. When sideroblastic anaemia is acquired secondary to chemotherapy or irradiation, chromosomal changes are nearly always found and tend to be multiple. However, they are probably a late event in the course of this anaemia and may be preceded by the expansion of a clone of genetically unstable stem cells.

Clinical and laboratory features

Acquired sideroblastic anaemia typically has an insidious onset. Most patients are middle aged or elderly, but young adults can be affected. Mild splenomegaly may be present. White cell and platelet counts are usually normal; some patients may have thrombocytosis. The bone marrow shows erythroid hyperplasia with varying degrees of dyserythropoiesis, including irregular nuclear contour, nuclear fragmentation (karyorrhexis), bi- or trilobed nuclei, and internuclear bridges. Iron stain of the aspirate shows ring sideroblasts which should total more than 15 per cent of the nucleated erythroid cells to make the diagnosis. Dysplasia of myeloid precursors or megakaryocytes may be present. When associated with leucopenia and/or thrombocytopenia the more descriptive term 'refractory cytopenia' is sometimes used. If the overall blast count exceeds 5 per cent or the peripheral blood monocyte count exceeds 1.0×10^{9}/l, the condition falls within a different category of the myelodysplastic

syndrome. Thus, ring sideroblasts may be seen in other myelodysplastic conditions such as refractory anaemia with excess blasts. Distinguishing acquired idiopathic sideroblastic anaemia from a mild hereditary sideroblastic anaemia presenting in adult life can be difficult. However, careful examination of the marrow for dysplastic changes, the MCV, possible response to pyridoxine, and a family survey all help to distinguish these two entities.

Treatment and prognosis

Transfusions of packed red cells should be given for relief of symptomatic anaemia. A trial of pyridoxine, 100 to 200 mg/day for 3 months, is worthwhile but few patients respond to this vitamin. Acquired idiopathic sideroblastic anaemia and the closely related refractory anaemia have the most favourable outlook among the myelodysplastic syndromes, with a median survival of 42 to 76 months and a 3 to 12 per cent incidence of progression to acute leukaemia. A simple prognostic scoring system has been developed in which two or more of the following place the patient in a poor prognostic category:

1. haemoglobin less than 100 g/l;
2. neutrophils less than 1.5×10^9/l;
3. platelets less than 100×10^9/l; and
4. blasts more than 5 per cent.

Karyotypic analysis of marrow aspirates is valuable since a normal karyotype confers a favourable prognosis. The karyotype is now included in an international prognostic scoring system.

Defective red cell maturation secondary to alcohol and drugs

Alcohol has a direct toxic effect on erythropoiesis, manifested by the macrocytosis which characterizes red cells of subjects chronically ingesting alcohol in excess. Malnourished and anaemic alcoholics may exhibit ring sideroblasts in the bone marrow as well as vacuolation of erythroblasts. These manifestations gradually disappear over 4 to 12 days when alcohol is withdrawn, although the macrocytosis may take several months to normalize. The antibiotic chloramphenicol when given in dosages greater than 2 g/day produces a reversible inhibition of erythropoiesis associated with ring sideroblasts and vacuolation of erythroblasts. This effect, due to inhibition of mitochondrial protein synthesis, is quite separate from the rare idiosyncratic side-effect of aplastic anaemia. Protracted exposure to the antituberculous drug isoniazid has been occasionally associated with development of a sideroblastic anaemia.

Defective red cell maturation secondary to lead, arsenic, or zinc ingestion or copper deficiency

Patients suffering lead poisoning show clinical and laboratory evidence of reduced haem biosynthesis. Basophilic stippling of red cells is prominent. Mild hypochromic, microcytic anaemia may develop. Red cell protoporphyrin, increased due to inhibition of the terminal step in the haem pathway, provides a sensitive measure of lead exposure. The peripheral neuropathy of lead poisoning may be a result of reduced haem biosynthesis, as in the porphyrias. Acute or chronic arsenic ingestion can cause anaemia with marked dyserythropoiesis. Basophilic stippling of red cells is characteristic while neutropenia and thrombocytopenia may be present. Copper deficiency has been described only in malnourished premature infants or in patients receiving long-term, parenteral hyperalimentation. This syndrome consists of anaemia and neutropenia associated with marrow findings of ring sideroblasts and vacuolated erythroid and myeloid precursors. Large quantities of ingested zinc interfere with copper absorption and reproduce the sideroblastic anaemia and neutropenia characteristic of copper deficiency.

Congenital dyserythropoietic anaemias (CDA)

This rare group of inherited refractory anaemias are characterized by gross multinuclearity of erythroid precursors in the marrow, ineffective erythropoiesis, and associated iron overload. Three types have been described based on morphology of the bone marrow and serological features. The most common, Type II, is also known as HEMPAS (hereditary erythroblast multinuclearity with positive acidified serum test) since red cells are lysed by acidified (pH 6.8) serum from about 30 per cent of normal subjects. In CDA Type II, a defect in glycosylation of erythroblast membrane proteins has been identified. Most patients are diagnosed in late childhood or adolescence with mild to moderate anaemia, with intermittent jaundice or in older patients with manifestations of iron overload. Splenomegaly or hepatomegaly may be variably present. CDA carries a good prognosis with few patients requiring transfusions. The degree of iron overload should be monitored and treated when appropriate.

22.5.9 Haemolytic anaemia - congenital and acquired

Frank J. Strobl and Leslie Silberstein

Introduction

The mechanisms of haemolysis

Following release into the circulation, normal red cells survive for approximately 120 days. As the circulating red-cell mass decreases (anaemia), less oxygen is transported from the lungs to other tissues of the body. In response, the kidneys increase their synthesis and secretion of erythropoietin, which stimulates erythropoiesis, in order to restore normal red-cell mass and oxygen delivery. A deficient red-cell mass results from inadequate production (hypoplasia), loss (haemorrhage), or premature destruction (haemolysis) of the red cells. In cases where red-cell survival is reduced to such an extent that normal bone marrow cannot compensate, a haemolytic anaemia results. The haemolytic anaemias are either genetically determined or acquired. As will be described in this chapter, premature destruction of red cells occurs through two primary mechanisms. First, decreased erythrocyte deformability secondary to membrane defects, metabolic abnormalities, exogenous oxidizing agents, or pathological antibodies provokes red-cell sequestration and extravascular haemolysis in the spleen and other components of the reticuloendothelial system. Second, exposure to pathological antibodies, activated complement, mechanical forces, chemicals, and infectious agents may lead to red-cell membrane damage and intravascular haemolysis.

The consequences of haemolysis

The clinical and laboratory changes associated with haemolysis reflect the physiological mechanisms responsible for restoring red-cell mass and removing free haemoglobin from the plasma. These changes are outlined in Table 1. Within several days of the onset of haemolysis and the development of anaemia, increased erythropoiesis results in erythroid hyperplasia (decreased myeloid/erythroid ratio) in the bone marrow and reticulocytosis (polychromasia and macrocytosis) in the peripheral blood. The peripheral blood film will also often exhibit microspherocytes, fragmented red blood cells, and nucleated red blood cells. If the haemolysis and anaemia begin early in life and persist, extramedullary erythropoiesis can develop in the spleen, liver, and lymph nodes. Chronic anaemia and the resulting marrow hyperplasia can also result in long-bone deformities. Free haemoglobin in the circulation binds to the serum protein haptoglobin. Haptoglobin–haemoglobin complexes are removed from the intravascular space by the reticuloendothelial system. If the rate of haemolysis is greater than the liver's ability to synthesize haptoglobin, serum haptoglobin levels fall. In patients with severe haemolysis, haemoglobinaemia and haemoglobinuria may develop. At low plasma haemoglobin levels, much of the free haemoglobin is reabsorbed in the proximal renal tubules. The renal tubular cells catabolize the haemoglobin converting iron into haemosiderin, which is eventually shed along with renal tubular cells into the urine resulting in haemosiderinuria. Haemosiderinuria is a reliable indicator of chronic intravascular haemolysis. At higher levels, free haemoglobin is found in the urine. Within the reticuloendothelial system, haemoglobin is metabolized and released into the serum as unconjugated bilirubin. The bilirubin is conjugated in the liver, excreted in the gut, converted to faecal urobilinogen, partially reabsorbed, and excreted by the kidneys as urinary urobilinogen. The intracellular enzyme lactate dehydrogenase is released from lysed red cells into the plasma.

Congenital anaemias

Congenital anaemias result from inherited defects in the red-cell membrane, red-cell enzymes, or haemoglobin. The haemoglobinopathies and thalassaemias are discussed in Chapter 22.5.7.

Disorders of the red-cell membrane

Introduction

The strength and flexibility required of the red-cell membrane is provided by the lipid bilayer and a proteinaceous, membrane-bound cytoskeleton. The membrane skeleton forms an underlying lattice which both supports and stabilizes the plasma membrane. Figure 1 provides a schematic model of the erythrocyte membrane and membrane-skeleton. The major, integral membrane proteins are band 3 and the glycophorins. Band 3 functions as a transmembrane channel for the diffusion of anions and glucose. The physiological role of the glycophorins is unknown. Cytoplasmic proteins located adjacent to the plasma membrane include spectrin, actin, band 4.1, ankyrin, and band 4.2. Spectrin, a heterodimeric protein composed of a and b subunits, is the principal component of the membrane-skeleton. The heterodimers of spectrin are bound to each other, head-to-head, to form heterotetramers and larger oligomers. The spectrin tetramers are cross-linked at their ends by actin. This interaction is strengthened by band 4.1. Band 4.1 also binds the cytoplasmic domain of glycophorin to spectrin. Ankyrin binds band 3 to the b chain of spectrin. Band 4.2 probably strengthens this interaction. A deficiency in any of these cytoskeletal proteins would be expected to result in defects in erythrocyte shape and deformability.

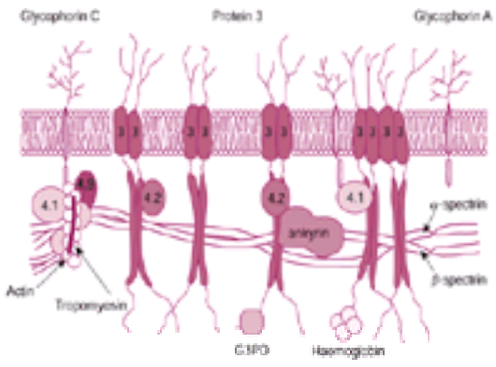

Fig. 1 Schematic illustration of the major components of the red-cell membrane and membrane skeleton. (Reproduced from Lux SE (1989). Hereditary disorders of the red-cell membrane skeleton. *Trends in Genetics* **5**, 222–7, with permission.)

Hereditary spherocytosis

Aetiology

Hereditary spherocytosis is inherited primarily in an autosomal dominant manner. Up to a quarter of cases, however, exhibit a non-dominant or recessive pattern of inheritance. The disorder is characterized by small spherocytic red cells with reduced deformability. The increased rigidity results in entrapment of the spherocytes,

primarily in the microcirculation of the spleen. The aetiology of hereditary spherocytosis appears to be heterogeneous. In most cases, the abnormal deformability is associated with defects in a- and b-spectrin or the proteins that bind spectrin to the plasma membrane: ankyrin, band 3, band 4.1, and band 4.2.

Clinical features

Hereditary spherocytosis occurs in all races but is most common in individuals of northern European descent. The prevalence of hereditary spherocytosis is estimated at 1:5000. Patients usually present in childhood with mild to moderate haemolysis. The main clinical features are anaemia, jaundice, and splenomegaly. The peripheral smear shows reticulocytosis and a variable degree of spherocytosis (Fig. 2). The red cells demonstrate increased osmotic fragility. The persistently elevated serum bilirubin levels often lead to the formation of bilary calculi and recurrent cholecystitis. Infrequent complications include ulcers, dermatitis, extramedullary haematopoietic tumours, cardiomyopathy, mental retardation, renal tubular acidosis, and neurological/muscular abnormalities. Less than 5 per cent of patients have severe disease. Severe haemolytic episodes are associated with infection. Rare aplastic crises are associated with parvovirus infection. Rare megaloblastic crises are associated with folate deficiency, especially during pregnancy.

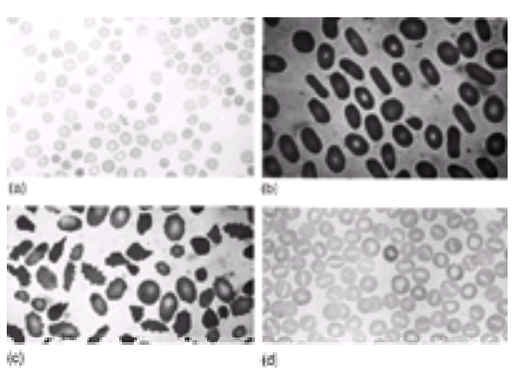

Fig. 2 Altered red-cell morphology: (a) spherocytes; (b) elliptocytes; (c) poikilorytes; (d) stomatocytes.

Treatment

The shortened red-cell survival and resulting anaemia of hereditary spherocytosis can be corrected in almost all cases by splenectomy. In patients with severe hereditary spherocytosis, the haemolysis may only be partially corrected following splenectomy. Except for asymptomatic patients, splenectomy should be performed as early as possible after the age of 3 years. Although erythrocyte survival returns to normal, red-cell morphology and deformability remain abnormal following splenectomy. All patients undergoing splenectomy should receive pneumococcal, meningococcal, and *Haemophilus influenzae* vaccinations several weeks preoperatively. Postsplen-ectomy, antibiotic therapy to protect against pneumococcal sepsis is also recommended. All patients with haemolytic anaemia should take 1 mg of folic acid each day to prevent folate deficiency. Typically, regular red-cell transfusions are only required for patients with severe disease. Phototherapy and/or exchange transfusions can be used to treat hyperbilirubinaemia in the neonatal period.

Hereditary elliptocytosis

Aetiology

Hereditary elliptocytosis is a genetically heterogeneous disorder characterized by elliptical red cells and haemolysis. Autosomal dominant and rare autosomal recessive forms of the disease have been identified. The clinical severity ranges from an asymptomatic condition to a severe haemolytic anaemia (see hereditary pryopoikilocytosis below). In most cases, defects in both a-spectrin and b-spectrin have been implicated. These point mutations or deletions, which occur at the N-terminus of a-spectrin and the C-terminus of b-spectrin, interfere with spectrin self-association. Partial and complete deficiencies of membrane protein 4.1 are also associated, respectively, with mild and severe forms of hereditary elliptocytosis.

Clinical features

Hereditary elliptocytosis is most common in individuals of African and Mediterranean ancestry with a prevalence of approximately 1:2500. Less than 10 per cent of cases exhibit significant haemolysis. Symptomatic individuals with hereditary elliptocytosis exhibit moderate to severe anaemia, splenomegaly, and reticulocytosis. The peripheral blood smear contains elliptocytes, 'pencil cells', and other abnormally shaped red cells (Fig. 2). The osmotic fragility is normal in mild hereditary elliptocytosis but increased in more severe forms of hereditary elliptocytosis with significant poikilocytosis. Rarely, neonates with hereditary elliptocytosis experience severe haemolysis, which gradually improves during the first year of life. This improvement shadows the normal loss of fetal red cells during infancy. Increased concentrations of 2,3 diphosphoglycerate in fetal red cells probably interfere with spectrin-protein 4.1 interactions, thereby further destabilizing the red-cell membrane.

Treatment

Asymptomatic individuals with hereditary elliptocytosis require no treatment. Symptomatic individuals often obtain some degree of benefit from splenectomy. Recommendations for folate administration, presurgical immunizations, and antibiotic prophylaxis noted earlier for hereditary spherocytosis are similar for patients with hereditary elliptocytosis.

Hereditary pyropoikilocytosis

Hereditary pyropoikilocytosis is inherited in an autosomal recessive fashion. Individuals with hereditary pyropoikilocytosis demonstrate severe haemolytic anaemia characterized by marked red-cell fragmentation, microcytosis, poikilocytosis, and spherocytosis (Fig. 2). The osmotic fragility of red cells is increased. These heat-sensitive cells undergo fragmentation and haemolysis when warmed to greater than 41°C. Red cells from normal individuals do not undergo haemolysis or fragmentation until the temperature nears 50°C. Hereditary pyropoikilocytosis results from homozygosity or compound heterozygosity for the a-spectrin defects involved in hereditary elliptocytosis.

Hereditary spherocytic elliptocytosis

This form of hereditary elliptocytosis is characterized by mild to moderate haemolytic anaemia with both elliptocytes and spherocytes. The molecular basis of this disorder has yet to be identified. The osmotic fragility is increased. Splenectomy may be useful in symptomatic individuals.

Hereditary stomatocytosis

Several families have been identified with members exhibiting moderate to severe anaemia and circulating stomatocytes (Fig. 2). This rare, autosomal dominant disorder results from a defect in membrane permeability that allows increased Na^+ and H_2O influx and results in cellular swelling and increased osmotic fragility. An integral membrane protein, stomatin (band 7.2b), has been reported to be decreased or absent in affected individuals. Symptomatic individuals may obtain some benefit from splenectomy. A number of patients with hereditary stomatocytosis, however, have developed hypercoagulability and thrombosis following splenectomy. Stomatocytosis and mild to moderate haemolytic anaemia are also seen in rare individuals who have either absent (Rh_{null}) or markedly reduced Rh antigen expression.

Hereditary xerocytosis

Hereditary xerocytosis is a rare, autosomal dominant disorder characterized by red-cell dehydration and decreased osmotic fragility. The cellular dehydration appears

to be caused by a defect in membrane K+ permeability that leads to intracellular K^+ and H_2O loss. The crenated cells are cleared by the reticuloendothelial system resulting in moderate to severe haemolysis. Splenectomy may provide therapeutic benefit. As with hereditary stomatocytosis, the risk of hypercoagulability and thrombosis are increased following splenectomy in patients with xerocytosis.

Acanthocytosis

Acanthocytes or spur cells are red cells with many thorn-like projections of the membrane surface. Changes in the composition of membrane lipids within the membrane lipid bilayer appear to be responsible for the development of acanthocytosis. Acanthocytosis and haemolytic anaemia are seen in severe liver disease, abetalipoproteinaemia, and the McLoed syndrome. Infrequently, patients with severe liver disease accumulate free cholesterol in the outer leaflet of the red-cell membrane resulting in spur cell shape, trapping of the acanthocytes in the spleen, and rapidly progressive anaemia. Abetalipoproteinaemia is an autosomal recessive disorder characterized by acanthocytosis (>50 per cent on peripheral blood film), fat malabsorption, mild anaemia, retinitis pigmentosa, and progressive ataxia. The McLoed syndrome is characterized by variable acanthocytosis and mild anaemia. The disorder is X-linked and affected individuals appear to lack a membrane precursor of the Kell red-cell antigen that also acts as an integral membrane transporter.

Disorders of red-cell enzymes

Introduction

Erythrocytes circulate throughout the body for approximately 4 months lacking a nucleus, mitochondria, and ribosomes. As a result, red cells cannot synthesize protein nor take advantage of oxidative metabolism. Glucose metabolism is necessary to maintain the integrity of both the erythrocyte membrane and haemoglobin. In red cells, glucose is metabolized to lactate primarily through the anaerobic, Embden–Meyerhof pathway (Fig. 3). Eleven enzymes are required to break glucose down to lactate generating 2 moles of ATP and reducing 2 moles of NAD^+ to NADH. ATP is used primarily by membrane-associated ATPases which pump Na^+ and K^+ against their concentration gradients. NADH prevents the oxidation of iron in haemoglobin. 2,3-diphosphoglycerate (2,3-DPG) which binds to the b-subunits of haemoglobin and facilitates the release of oxygen is also a product of the Embden–Meyerhof pathway. In red cells, the production of 2,3-DPG is exaggerated in order to maintain intracellular concentrations equimolar with the concentration of haemoglobin. The production of 2,3-DPG occurs in a side pathway referred to as the Rapaport–Luebering shunt that branches from the main glycolytic pathway after the formation of 1,3-DPG. The other major red-cell energy pathway is the hexose–monophosphate shunt, which results in the reduction of $NADP^+$ to NADPH (Fig. 4). NADPH maintains adequate levels of reduced glutathione, which protects the red cells against oxidative damage.

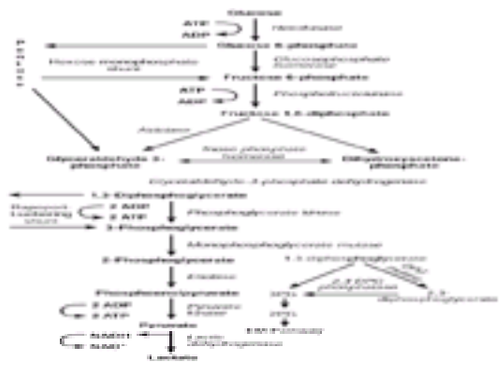

Fig. 3 The relationship between the main red-cell glycolytic pathway (Embden–Meyerhof) and the other metabolic pathways. The insert shows the production of 2,3-DPG in the Rapoport–Luebering shunt.

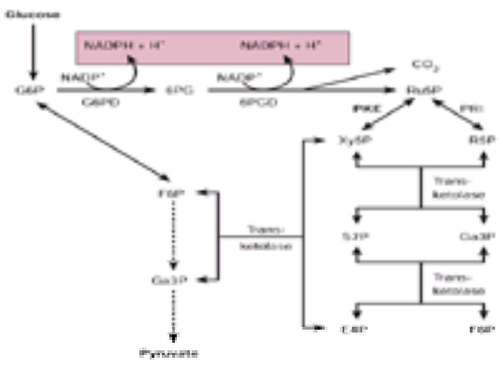

Fig. 4 The hexose monophosphate pathway. Intermediates: G6P, glucose 6-phosphate, F6P, fructose 6-phosphate; Ga3P, glyceraldehyde 3-phosphate; 6PG, 6-phosphogluconate; Ru5P, ribulose 5-phosphate; R5P, ribose 5-phosphate; Xy5P, xylulose 5-phosphate; S7P, sedoheptulose 7-phosphate; E4P, erythrose 4-phosphate. Enzymes: G6PD, glucose 6-phosphate deyhdrogenease; 6PGD 6-phosphogluconate dehydrogenase; PKE, epimerase; PRI, phosphoribose isomerase. Cosubstrates: $NADP^+$ and NADPH + H^+, oxidized and reduced forms of nicotinamide-adenine dinucleotide phosphate.

Many enzyme deficiencies are associated with haemolytic anaemia. Most of these enzyme deficiencies are not limited to the erythrocyte and, thus, are associated with multisystem disease (Table 2). The remaining enzyme deficiencies associated with haemolytic anaemia are clinically specific to the red cell. The majority of these enzyme deficiencies are rare, having been found in only a few families (Table 3). The two most common red-cell enzyme deficiencies—glucose-6-phosphate dehydrogenase deficiency and pyruvate kinase deficiency—are described below.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

Aetiology

G6PD catalyses the first step in the hexose–monophosphate shunt, which is responsible for reducing $NADP^+$ to NADPH. NADPH along with glutathione reductase maintains adequate supplies of reduced glutathione. Reduced glutathione is used by catalase and glutathione peroxidase to convert hydrogen peroxide to water. Oxygen radicals generated either through normal metabolism or by external oxidizing agents are converted to hydrogen peroxide, a highly oxidative agent. Therefore, through this series of enzyme reactions (Fig. 5) haemoglobin and other red-cell proteins are protected from oxidative damage. On the other hand, red cells deficient in G6PD are extremely sensitive to the oxidative actions of chemicals, drugs, infectious agents, and the bean *Vicia faba* (favism). G6PD deficiency is the most common hereditary enzyme deficiency of man affecting hundreds of millions of people world-wide. The disorder results from the X-linked, recessive inheritance of any one of a number of G6PD variants. The gene encoding G6PD is located on the long arm of the X chromosome (Xq28) and consists of 13 exons and greater than 18 kilobases. The G6PD protein is 514 amino acids long. The wild-type G6PD enzyme has been designated G6PD B. Nearly all G6PD mutations are the result of single point mutations that result in single amino acid substitutions. The rare exception consists of multiple point mutations or larger deletions. The altered protein structure most commonly results in decreased enzyme stability or, less commonly, decreased enzyme function. Males inheriting a mutant G6PD gene are affected. In female carriers, the levels of G6PD vary considerably as a result of random inactivation (lyonization) of the X chromosome. Female heterozygotes have two populations of red cells, those deficient in G6PD and those with normal levels of G6PD.

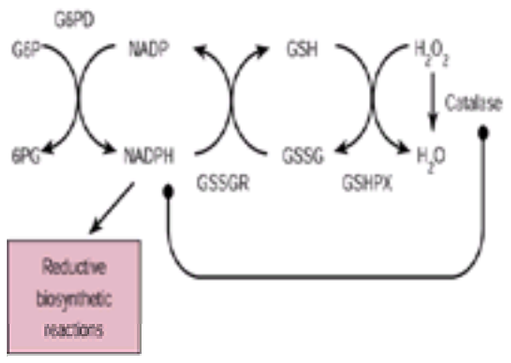

Fig. 5 The role of G6PD in red-cell metabolism: NADPH plays a dual role in (i) regeneration of glutathione (GSH) and (ii) stabilization of catalase (see also Chapter 22.5.12).

Clinical features

Since carriers of G6PD deficiency are more resistant to *Plasmodium falciparum* infection, the disorder has a geographical distribution similar to the haemoglobinopathies. G6PD deficiency is widespread in Africa, the Mediterranean, the Middle East, and Southeast Asia. More than 300 G6PD variants have been identified. Although most are clinically insignificant, a number of G6PD variants are associated with chronic anaemia or acute intermittent haemolysis. The two most common clinical forms of G6PD deficiency are an African variant (G6PD A-) and a family of Mediterranean variants. The African variant is synthesized in normal quantities, but is unstable and its levels decline slowly as the red cells age. Only the most senescent red cells are substantially lacking in enzyme activity. The Mediterranean variant has reduced enzyme activity, which also decreases with age. Newly released reticulocytes have significantly reduced G6PD activity, while mature erythrocytes lack any measurable enzyme activity. Both the African and the Mediterranean type are associated with little to no haematological abnormality under normal circumstances, but severe haemolysis and anaemia occur during periods of oxidant stress. Since only a small fraction of the circulating red cells are G6PD deficient in individuals with the African variant, the disorder is usually self-limited. In contrast, since all of the circulating red cells in the Mediterranean variant are G6PD deficient, these individuals may experience acute, life-threatening haemolysis. The onset of intravascular haemolysis often occurs within 24 h of exposure to the oxidizing agent and is accompanied by malaise, weakness, and abdominal/back pain. Within 2 to 3 days the patient develops anaemia, jaundice, haemoglobinuria, and, on rare occasions, acute renal failure. The peripheral smear often exhibits both anisocytosis and poikilocytosis, including spherocytes and blister cells (Fig. 6). Oxidant damage induces the formation of disulphide bridges within haemoglobin and leads to decreased solubility. Supravital staining with methylviolet demonstrates the presence of Heinz bodies. These intraerythrocytic inclusions consist primarily of denatured and precipitated haemoglobin. Favism is most common in areas where the *Vicia faba* bean grows, such as the Mediterranean and the Middle East. Two fava bean metabolites, divicine and isouramil, are believed to be oxidants. Favism occurs at any age, but is more common in children. Not all G6PD variants are susceptible to favism. Furthermore, every case of fava bean ingestion does not result in haemolysis. Mild haemolysis may also occur during the first weeks of life in G6PD-deficient infants. Occasionally, the jaundice is severe enough to cause kernicterus. Marked haemolysis can also occur in G6PD-deficient individuals during periods of illness, particularly during bacterial and viral infections. Rarely, G6PD deficiency is associated with chronic extravascular haemolysis and anaemia. These individuals retain both their sensitivity to oxidizing agents and, therefore, their risk of acute intravascular haemolysis.

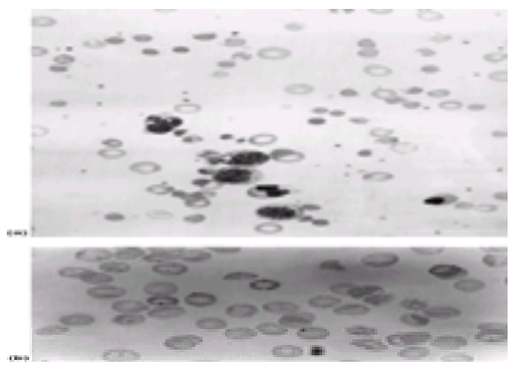

Fig. 6 Blood film in a case of acute haemolytic anaemia in a G6PD-deficient patient (favism). (a) Romanovsky stain, showing marked poikilocytosis, polychromatic macrocytes, bite cells, nucleated red cells, and a shift to the left in the granulocytic series. (b) Supravital stain with methyl violet, showing characteristic Heinz bodies.

Treatment

The diagnosis of G6PD deficiency depends on the demonstration of decreased red-cell G6PD activity. A rapid fluorescent screening assay is available to test at risk or suspected individuals during non-haemolytic periods. False-negative results can occur, especially following the resolution of an acute haemolytic episode when reticulocytes with increased enzyme activity predominate. All positive screening results should be confirmed by a quantitative spectrophotometric test based on the generation of NADPH from NADP. Molecular methods can be used accurately to diagnose female carriers heterozygous for G6PD deficiency. G6PD-deficient individuals should avoid substances known to induce haemolysis (Table 4). In newborns, severe jaundice should be treated with phototherapy and/or exchange transfusion. In all patients, blood transfusion should be considered during severe haemolytic episodes. Splenectomy may provide benefit in rare individuals with chronic haemolysis. Transfusion-dependent individuals should be carefully monitored for haemosiderosis and iron chelation should be initiated early.

Pyruvate kinase deficiency

Aetiology

Pyruvate kinase converts phosphoenol pyruvate to lactate and in the process generates ATP (Fig. 3). Therefore a deficiency in pyruvate kinase impairs the glycolytic pathway resulting in decreased production of ATP. An inadequate energy supply presumably leads to premature destruction of the red cells, particularly in the spleen and liver. There are four pyruvate kinase isoenzymes: M_1, M_2, L, and R. The R isoenzyme is unique to erythrocytes and is a product of the pk gene located on chromosome 1q21. Pyruvate kinase deficiency is inherited in an autosomal recessive fashion. The molecular basis of pyruvate kinase deficiency is quite heterogeneous, including single nucleotide substitutions, deletions, and insertions. Heterozygotes are unaffected, with variable but adequate levels of pyruvate kinase activity in their red cells. Homozygotes have little to no pyruvate kinase activity and exhibit haemolytic anaemia and splenomegaly. Many clinical homozygotes are actually compound heterozygotes with two different genetic lesions.

Clinical features

Pyruvate kinase deficiency occurs most commonly in individuals of northern European descent. The degree of haemolysis varies considerably with individuals and is often exacerbated by physiological stress such as pregnancy or infection. Severe pyruvate kinase deficiency usually presents at birth with haemolysis and jaundice. The haemolysis, anaemia, and jaundice continue throughout life, eventually resulting in splenomegaly, gallstones, and aplastic anaemia. Pyruvate kinase-deficient individuals appear to tolerate their anaemia better than individuals with comparable levels of anaemia due to other aetiologies. It is postulated that since the block in glycolysis occurs after the Rappaport–Leubering shunt, there is increased synthesis of 2,3-DPG in pyruvate kinase-deficient red cells. Increased synthesis of 2,3-DPG encourages the release of oxygen and thus more efficient oxygenation of tissues. The diagnosis of pyruvate kinase-deficiency is best confirmed by the detection of specific mutations at the genomic level.

Treatment

There is no specific therapy for pyruvate kinase deficiency. Periods of active haemolysis are treated with red-cell transfusions. Splenectomy often lessens the degree of haemolysis and anaemia. Splenectomy should be delayed until after the age of 3 years to reduce the risk of pneumococcal and meningococcal infections.

Acquired haemolytic anaemias

Immune haemolytic anaemias

Immune haemolysis may occur when IgG, IgM, or IgA antibodies and/or complement bind to the erythrocyte surface. The red-cell-bound antibodies may induce extravascular haemolysis, intravascular haemolysis, or both. Red cells coated with IgG typically undergo extravascular haemolysis during their transport through the reticuloendothelial system. Interactions between the Fc portion of IgG and surface Fc receptors allow the macrophages to phagocytose the coated erythrocytes. IgM, IgA, and, occasionally, IgG activate and fix complement to the erythrocyte surface. Macrophages also have receptors for the activated complement component C3b and, probably, phagocytose red cells through this pathway. The fixed complement can also induce intravascular haemolysis through activated membrane complex-mediated lysis.

The direct antiglobulin test or direct Coombs' test detects the presence of IgG antibody or complement on the red-cell surface. IgM and IgA antibodies are not directly detectable with standard testing methods. Rather, their presence is indirectly demonstrated by the detection of complement on the erythrocyte. In rare cases, the haemolytic anaemia is due to non-complement-fixing IgM or IgA antibodies. In this situation the direct antiglobulin test will be falsely negative. Eluates can be obtained from the antibody-coated red cells to determine the specificity of the antibody. Alternatively, the antibody may be free in the serum and its specificity determined by the indirect antiglobulin test or indirect Coombs' test. The presence of antibody or complement on the red cell, however, need not reflect ongoing haemolysis. Rather, the diagnosis of haemolytic anaemia rests on clinical findings and other laboratory data, such as red-cell morphology, haemoglobin, bilirubin, haptoglobin, LDH levels, reticulocyte count, and the presence or absence of haemoglobinaemia, haemoglobinuria, or haemosiderinuria. The serological findings provide information as to whether an immune basis exists and what type of immune haemolytic anaemia may be present. Autoantibodies, alloantibodies, and drugs may induce immune haemolytic anaemias.

Autoimmune haemolytic anaemia

Haemolytic antibodies directed against the individual's own red cells may arise as a primary/idiopathic event or may be secondary to lymphoid malignancies, connective tissue disorders, and infection. Autoimmune haemolytic anaemia is best classified according to the temperature at which the antibody optimally binds to the erythrocyte. The four major types of autoimmune haemolytic anaemia are warm autoimmune haemolytic anaemia, cold agglutinin syndrome, paroxysmal cold haemoglobinuria, and mixed-type autoimmune haemolytic anaemia

Warm autoimmune haemolytic anaemia

Aetiology

The offending antibody in warm autoimmune haemolytic anaemia is typically IgG and can be found on the red cell, in the serum, or both. The exact specificity of the antibody is often difficult to determine. With very rare exception, warm-reactive autoantibodies bind to all red cells tested, while others appear to have broad specificity within the Rh system. Occasionally, warm reactive autoantibodies will have relative specificity against an individual antigen such as Rh(D), Rh(C), or Kell.

Clinical features

Warm autoimmune haemolytic anaemia can arise at any age but is more common in older individuals, probably because of its association with lymphoid malignancies. Females are affected slightly more often than males. The direct antiglobulin test is positive for IgG and/or complement. In its mildest form the direct antiglobulin test is positive but red-cell survival is not significantly affected. Symptomatic patients present with anaemia, jaundice, and splenomegaly. Most patients with warm autoimmune haemolytic anaemia have a chronic, stable anaemia (haemoglobin < 8 g/dl). In its severest form, patients present with fulminant intravascular haemolysis, progressive anaemia, congestive heart failure, respiratory distress, and neurological abnormalities. As with other haemolytic anaemias, the peripheral smear often demonstrates anisocytosis and reticulocytosis with spherocytes and macrocytes (Fig. 7). The platelet count is usually normal except in patients with Evan's syndrome where the autoantibody destroys both red cells and platelets.

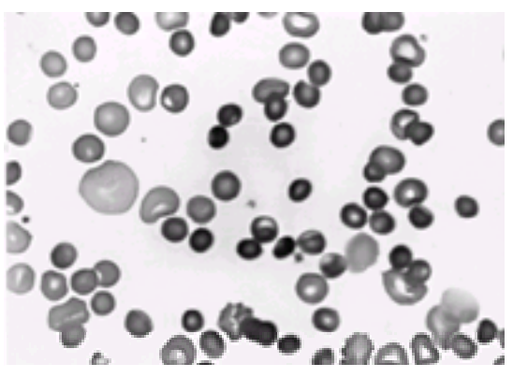

Fig. 7 The peripheral blood changes in autoimmune haemolytic anaemia. There is marked anisocytosis and anisochromia with many macrocytes and microspherocytes. The macrocytes reflect the reticulocytosis (×1000, Leishman stain).

Treatment

Corticosteroids, which presumably block macrophage Fc receptor activity and inhibit antibody production, are the primary therapy for autoimmune haemolytic anaemia. Prednisone at a dose of approximately 1 to 2 mg/kg body weight in divided doses is effective in most patients. Higher doses rarely provide additional benefit, but do increase the number and severity of side-effects. Treatment continues until the haemoglobin levels stabilize. The initial dose of prednisone can then be tapered at a rate of 5 to 10 mg per week. Once a dose of 10 mg/day is reached, the steroid taper should progress more slowly in order to determine the minimum controlling dose. Side-effects may be reduced by using an alternate-day schedule. Splenectomy should be performed only in steroid-refractory patients or patients requiring unacceptably high doses of prednisone to maintain remission. Alternative therapies including azathioprine, cyclophosphamide, intravenous immunoglobulin (IVIG), danazol, and plasma exchange should be reserved for patients unfit for splenectomy or who have failed to respond to steroids and surgery.

Transfusion with ABO and Rh compatible cross-match least incompatible red cells should be performed in patients with symptomatic anaemia. Transfusion should not be withheld because of serological incompatibility. Active serum autoantibodies, however, can mask the presence of clinically significant alloantibodies. Therefore, the most important consideration prior to transfusion is to confirm the presence or absence of alloantibodies in the patient's serum. Various autologous and allogeneic red-cell absorption techniques exist to remove the autoantibody from a sample of the patient's serum and allow identification of any existing alloantibodies. If clinically significant alloantibodies are present, red cells lacking the corresponding antigen(s) should be selected for transfusion. If the autoantibody has a definite specificity, red cells lacking that antigen may be selected. Transfusions in life-threatening situations should not be delayed if the above tests are not readily available or completed.

Cold agglutinin syndrome

Aetiology

Cold agglutinin syndrome accounts for approximately a quarter of all cases of autoimmune haemolytic anaemia. The disorder occurs as an acute or chronic condition. In cold autoimmune disorders the signs and symptoms of disease result from either the agglutination of red cells or from haemolysis. The autoantibodies are typically IgM and are most active at low temperatures. Rare examples of IgG and IgA cold-reactive autoantibodies have been reported. In the lower temperatures of the peripheral circulation, the IgM autoantibodies bind to red cells and activate complement. In warmer areas of the circulation, the IgM dissociates from the erythrocyte leaving activated complement fixed to the red-cell surface. The severity of the disorder depends on both the titre of the antibody and the thermal range at which it is most active. The autoantibody specificity in cold agglutinin syndrome is usually anti-I. Anti –i specificity is associated with infectious mononucleosis.

Clinical features

Acute cold autoimmune haemolytic anaemia is commonly seen in adolescents and young adults following infection with *Mycoplasma pneumoniae* or infectious mononucleosis. Haemolysis occurs approximately 1 to 2 weeks following infection and is most commonly associated with a rise in polyclonal anti-I IgM antibody with *Mycoplasma pneumonia* or polyclonal anti-i IgM antibody with infectious mononucleosis . Chronic cold autoimmune haemolytic anaemia occurs most commonly in the elderly, either idiopathically or associated with lymphoma, chronic lymphocytic leukaemia, or Waldenstrom's macroglobulinaemia. Patients may experience chronic intravascular haemolysis and anaemia that are exacerbated by cold temperature. Patients are often also plagued by episodes of Raynaud's phenomenon. Monoclonal IgM antibodies with kappa light chains and anti-I specificity usually cause the red-cell agglutination and haemolysis in this condition. Examination of the peripheral smear shows red-cell agglutination. The direct antiglobulin test is positive for complement.

Treatment

Treatment involves keeping the patient in a warm environment (>37°C). Steroids and splenectomy are of little benefit. Severe cold autoimmune haemolytic anaemia secondary to a B-cell neoplasm can be treated with chlorambucil, cyclophosphamide, or a-interferon. Blood transfusion should be avoided. In situations of life-threatening anaemia, the blood should be given slowly through a blood warmer. Plasma exchange is often helpful, but its effects should be expected to be temporary. Hypothermia must be avoided during surgery (especially surgical procedures involving extracorporeal circuits) in patients with cold autoimmune haemolytic anaemia.

Paroxysmal cold haemoglobinuria

Aetiology

Paroxysmal cold haemoglobinuria is the rarest form of autoimmune haemolytic anaemia. The disorder is caused by the complement-fixing Donath–Landsteiner IgG antibody. In the cold, this antibody binds to, and irreversibly fixes, complement to the red-cell membrane. Upon return to warmer temperatures, the antibody dissociates from the red cell leaving activated complement to lyse the cell. The Donath–Landsteiner antibody appears to have an anti-P specificity allowing it to bind to practically all red cells.

Clinical features

Patients present with acute intravascular haemolysis, abdominal pain, peripheral cyanosis, Raynaud's phenomenon, haemoglobinaemia, and haemoglobinuria after exposure to cold. In the past, paroxysmal cold haemoglobinuria was commonly associated with congenital syphilis but most cases are now associated with viral infections in children or are idiopathic in adults. During or shortly after a haemolytic episode, the direct antiglobulin test is positive for complement but negative for IgG.

Treatment

No specific therapy for paroxysmal cold haemoglobinuria exists; steroids are not useful. Most postinfectious cases of paroxysmal cold haemoglobinuria are self-limited and require only supportive care. Avoidance of cold ambient temperatures can help prevent recurrent attacks in patients with chronic paroxysmal cold haemoglobinuria. Transfusion is indicated only for severe haemolysis and life-threatening anaemia. Since the Donath–Landsteiner antibody rarely causes agglutination, most random donor blood units will be compatible with patient sera. Transfusions with extremely rare P-antigen-negative blood should be reserved only for those patients who do not respond to random donor blood. The use of a blood warmer should be considered.

Mixed-type autoimmune haemolytic anaemia

Aetiology

Approximately 8 per cent of all autoimmune haemolytic anaemias are of the mixed type. Both IgG and complement are present on the red cells. Both warm-reactive IgG autoantibodies and cold-reactive agglutinating IgM autoantibodies are present in the serum. The warm-reactive IgG autoantibodies are indistinguishable from antibodies encountered in warm autoimmune haemolytic anaemia. The IgM autoantibodies are unlike those in cold-agglutinin syndrome in that they generally have low titres at 4°C and have high thermal amplitudes, reacting at 30°C or above. These IgM autoantibodies usually have no distinguishable specificity, but on occasion have I or i specificities.

Clinical features

Mixed-type autoimmune haemolytic anaemia may be idiopathic or secondary, most commonly associated with systemic lupus erythematosus. The haemolytic anaemia is often severe and chronic with intermittent exacerbations. Exposure to cold does not increase the haemolysis.

Treatment

Steroids, splenectomy, or cytotoxic agents often provide therapeutic benefit in mixed-type autoimmune haemolytic anaemia. If blood transfusions are necessary, selection of blood should adhere to transfusion guidelines outlined earlier for warm autoimmune haemolytic anaemia. Administration of blood through a warmer should be considered.

Drug-induced haemolytic anaemia

Drugs may induce antibodies to bind to the erythrocyte surface resulting in a positive direct antiglobulin test or haemolysis. There are four mechanisms by which drugs can cause a positive direct antiglobulin test: (1) drug hapten, (2) immune complex formation, (3) autoantibody production, and (4) non-specific adsorption. Only the first three mechanisms are associated with haemolysis. Treatment and prevention are as straightforward as drug avoidance.

Drug hapten

Certain drugs bind to the red-cell membrane with a high affinity. Association of the drug with the membrane constituents allows the drug to act as a hapten. The antibodies produced are commonly IgG and are directed predominantly against the drug. Extravascular haemolysis develops gradually, but may be life-threatening if left untreated. After the offending drug is identified and withdrawn, the positive direct antiglobulin test and the haemolysis may persist for several weeks. Serum from these patients will not react with other red cells unless the drug is also present. Penicillin and the cephalosporins are the most notorious examples of this phenomenon. Approximately 3 per cent of patients receiving large doses of penicillin (millions of unit per day) intravenously will develop a positive direct antiglobulin test. Only the rare patient develops haemolytic anaemia.

Immune complex

Other drugs induce the binding of IgM or IgG antibodies that activate complement and cause intravascular haemolysis. The antibodies appear to recognize both the drug and a component of the red-cell membrane. The direct antiglobulin test is often positive for complement but not antibody. Haemoglobinaemia and haemoglobinuria are common. Renal failure occurs in about half of the cases. Once the offending drug is withdrawn, the haemolysis stops. Serum from these patients will lyse normal red cells only in the presence of the drug. Quinine, quinidine, phenacetin, chlorpropamide, and sulfonylureas are examples.

Autoantibodies

Some drugs stimulate the synthesis of red-cell autoantibodies. Patient serum and red-cell eluates react with normal red cells in the absence of the drug. The autoantibodies are indistinguishable from those found in warm autoimmune haemolytic anaemia. The direct antiglobulin test usually becomes positive after 3 to 6 months of drug administration. The haemolysis typically ceases within 2 weeks after the withdrawal of the drug, but the direct antiglobulin test can remain positive for up to 2 years. a-methyldopa, L-dopa, procainamide, mefenamic acid, and sulindac are examples of drugs that can stimulate the production of red cell autoantibodies.

Non-specific protein adsorption

Often a drug-induced positive direct antiglobulin test reflects non-immunological adsorption of protein, including immunoglobulins. First-generation cephalosporins were originally associated with this phenomenon. More recently, other drugs, including suramin, cisplatin, and sulbactam, have also been implicated. This mechanism is not associated with reduced red-cell survival.

Alloimmune haemolytic anaemias

Acute haemolytic transfusion reactions

Aetiology

The most catastrophic cases of alloimmune haemolysis occur following the transfusion of ABO-incompatible red cells. Naturally occurring IgM anti-A and anti-B antibodies bind to the incompatible red cells and activate complement resulting in intravascular haemolysis. Human error leading to the misidentification of patients, their blood samples, or the units of red cells to be transfused is responsible for virtually all cases of ABO incompatibility. Only rarely, do other non-ABO IgG alloantibodies cause acute, severe haemolysis.

Clinical features

Symptoms of an acute haemolytic transfusion reaction may begin after the infusion of as little as 10 ml of incompatible blood. The signs and symptoms include fever, chills, nausea, vomiting, hypotension, respiratory distress, haemoglobinuria, and chest or flank pain. Despite treatment, acute haemolytic transfusions reactions can result in renal failure, disseminated intravascular coagulation, and even death.

Treatment

Once an acute haemolytic transfusion reaction is suspected, the blood transfusion should be stopped immediately. Aggressive treatment of the hypotension with intravenous fluids and pressor agents (that is low-dose dopamine) is crucial. Other critical measures include monitoring the urine output and promoting renal blood flow with diuretics (furosemide or mannitol). Either heparin or the administration of platelets, plasma, and cryoprecipitate can be used to treat organ or life-threatening bleeding secondary to disseminated intravascular coagulation.

Delayed haemolytic transfusion reactions

Aetiology

Approximately 2 to 3 per cent of transfusion recipients become alloimmunized to non-ABO red-cell antigens. Haemolysis is not generally seen during the primary immune response since the transfused red cells often disappear from the circulation before antibody titres reach clinically significant levels. In the absence of further antigenic stimuli antibody titres may diminish to undetectable levels. Subsequent transfusion of red cells possessing the offending antigen, however, will induce an anamnestic response with reappearance of the IgG antibodies within hours to days. Binding of the IgG antibody to the transfused antigen-positive red cells results in a positive direct antiglobulin test and possibly mild to moderate extravascular haemolysis.

Clinical features

Most patients experiencing a delayed haemolytic transfusion reaction present with fever, jaundice, and decreasing haemoglobin levels 1 to 2 weeks following the transfusion of incompatible red cells. Delayed haemolytic transfusion reactions are often discovered during evaluation for fever of unknown origin or when the haemoglobin level fails to increase following transfusion.

Treatment

Treatment is rarely necessary; acute renal failure or disseminated intravascular coagulation are uncommon. If a delayed haemolytic transfusion reaction is suspected, both the patient's serum and an eluate from the circulating red cells should be tested for alloantibodies. If alloantibodies are present, their specificities should be determined. Donor red-cell units lacking the offending antigen should be selected for subsequent transfusions.

Passenger lymphocyte haemolysis

Aetiology

Recipients of a haematopoietic or a solid-organ transplant may experience delayed extravascular haemolysis. In this circumstance, lymphocytes of donor origin produce haemolytic antibodies against ABO or other red-cell antigens possessed by the recipient.

Clinical features

Haemolysis due to passenger lymphocytes is most commonly seen in out-of-group yet ABO-compatible liver and bone marrow transplants (group A or group B recipients of group O tissue) but can also occur in recipients of lung, heart, and kidney transplants. This haemolysis can begin within several days after the transplant and continue for several months.

Treatment

If significant ABO haemolysis occurs, patients should be transfused with group O red cells. If non-ABO haemolysis is present, elution of the patient's red cells may help to identify the antibody specificity and allow transfusion of antigen-negative red cells.

Haemolytic disease of the newborn (HDN)

Haemolytic disease of the newborn occurs when maternal IgG antibodies cross the placenta and bind to fetal red cells resulting in extravascular haemolysis. Usually these antibodies possess specificities within the Rhesus or ABO blood group systems. Occasionally the antibodies are directed against other red-cell antigens such as the Kell, Kidd, and Duffy. In the mildest cases, anaemia develops several weeks after birth and is of little clinical consequence. In more severe cases the neonate develops progressive anaemia and jaundice within the first week of life. If left untreated, bilirubin levels may reach levels associated with kernicterus causing brain

damage and death. In the most severe cases, the fetus develops profound anaemia as early as the fifth month of gestation and may be stillborn or delivered grossly oedematous (hydrops fetalis). An infant with hydrops fetalis also has ascites, hepatosplenomegaly, and erythroblastosis and usually dies shortly after birth.

Rhesus D incompatibility

Haemolytic disease of the newborn is most common and severe in rhesus-D-negative women carrying a rhesus-D-positive fetus. The mother develops anti-D IgG antibodies following exposure to the D antigen during a previous pregnancy, or as a result of the transfusion of D-antigen-positive red cells. One half of all cases of rhesus D alloimmunization are due to transplacental haemorrhage from the fetus at the time of delivery. Spontaneous transplacental haemorrhage can also occur during gestation, particularly during the third trimester. The risk of transplacental haemorrhage increases with ectopic pregnancy, spontaneous or therapeutic abortion, chorionic villus sampling, caesarean section, and trauma. Approximately 8 per cent of untreated D-negative women who deliver a D-positive child will become alloimmunized to the D antigen.

It is essential to identify pregnant women at risk for rhesus D haemolytic disease of the newborn and to prevent sensitization. All pregnant women should have their ABO and rhesus types identified as early as possible. Their serum should be screened for alloantibodies against the D antigen and other red-cell antigens. Pregnant women who are D-antigen-negative and have an initial negative antibody screen should have their serum retested for alloantibodies at 28 weeks gestation. If the initial antibody screen is found positive, antibody titres should be followed at 2 to 4-week intervals to determine whether further sensitization is occurring. The presence of an antibody, however, does not indicate on going haemolysis in all cases.

Naturally occurring IgM antibodies are common during pregnancy but do not cross the placenta. Furthermore, fetal red cells may lack the antigen corresponding to the mother's antibody. Molecular typing of the father's DNA or even fetal DNA is available for several red-cell antigens including D, E/e, C/c, Jk ^{a}/Jk^{b}, and K1/K2. A rising titre of anti-D antibody or other clinically significant red-cell alloantibodies indicates ongoing sensitization and possible haemolytic disease of the newborn.

From 18 weeks of gestation and onward, ultrasonography and fetal blood sampling can be used to assess the severity of haemolysis. After 28 weeks of gestation amniocentesis can be performed. If the fetus is experiencing significant haemolysis and anaemia, clinical intervention must be prompt. Prior to 34 weeks of gestation intrauterine transfusion with blood lacking the offending antigen should be performed. After 36 weeks gestation induced labour should be considered. Upon birth of a 'at risk' fetus a sample of cord blood should undergo a direct antiglobulin test and have measurements of haemoglobin and bilirubin performed. If the direct antiglobulin test on the cord blood sample is positive and the mother's antibody screen remains negative, haemolytic disease secondary to ABO incompatibility or antibodies against low-incidence red-cell antigens should be considered.

Infants with severe anaemia (haemoglobin <12 g/dl) or severe jaundice (bilirubin >14 mg/dl) should undergo exchange transfusion. Phototherapy can also be used to decrease bilirubin levels. A non-sensitized D-antigen-negative mother's blood should also be tested to determine the amount of fetomaternal haemorrhage at delivery. Administration of 300 µg of IgG anti-D (RhIg) within 72 h of delivery will protect 99 per cent of D-antigen-negative mothers from developing anti-D antibodies. Prophylactic administration of RhIg at 28 weeks gestation and following invasive procedures or traumatic events will virtually eliminate the chance of alloimmunization. Patients with large transplacental haemorrhages quantitated by the Kleihauer–Betke acid-elution technique should receive additional RhIg at a dose equivalent to 300 µg for every 15 cc of fetal red blood cells.

ABO incompatibility

Although 15 per cent of pregnancies are ABO incompatible, haemolytic disease of the newborn due to ABO incompatibility is rare. Mild to moderate haemolysis and hyperbilirubinaemia due to ABO incompatibility occurs in about 1.5 per 1000 pregnancies. Group A and group B infants of group O mothers are at greatest risk. Unlike with rhesus D antigen, ABO-haemolytic disease of the newborn occurs during the first pregnancy as often as subsequent pregnancies. Exchange transfusion with group O red cells is rarely required. Hydrops fetalis never occurs.

Non-immune acquired haemolytic anaemias

Red-cell survival may also be reduced by a number of non-inherited, non-immune mechanisms. As red cells circulate they are vulnerable to a variety of insults that may cause structural or metabolic alterations. These changes generally result in reduced red-cell deformability leading ultimately to extravascular haemolysis. These insults include infection, mechanical trauma, and exposure to chemicals, heat, or venom. They often also cause intravascular haemolysis by directly lysing the red-cell membrane. Other less understood causes of acquired non-immune haemolytic anaemias are listed in Table 5.

Infection

Infectious causes of haemolysis are primarily parasites and bacteria. Direct parasitization of red cells by *Plasmodium falciparum*, *Plasmodium vivax*, and *Plasmodium malariae* causes both intravascular haemolysis due to direct membrane destruction and extravascular haemolysis due to membrane alteration and activation of the reticuloendothelial system. Infrequently, *in utero* infection of the fetus with *Toxoplasma gondii* resembles severe haemolytic disease of the newborn. Infants are born hydropic and severely anaemic. Premature delivery and stillbirth are common. *Babesia microti*, endemic in areas of the Northeast and Midwest in North America, is transmitted by ticks and causes severe haemolysis during the erythrocytic phase of its life cycle. Bacterial infections, particularly Gram-negative organisms which produce endotoxin or proteolytic enzymes, may produce mechanical haemolysis by inducing disseminated intravascular haemolysis or red-cell membrane damage via degradation of membrane phospholipids and proteins. *Bartonella bacilliformis* endemic to western South America causes Oroya fever characterized by fever, chills, musculoskeletal pain, and acute intravascular haemolysis.

Chemical

Drugs and chemicals known to cause haemolysis through direct oxidative damage are summarized in Table 6. In most cases the strong oxidant activity of these chemicals overwhelm normally functioning reduction mechanisms responsible for protecting haemoglobin and the red-cell membrane. Variability in the absorption of the chemical or its metabolism determine whether a particular individual will develop chemical-induced haemolytic anaemia. Often it is the chemical's metabolite that is responsible for inducing haemolysis. The red cells of newborns do not have functional reduction mechanisms and thus are more sensitive to oxidant activity.

Mechanical

Mechanical fragmentation of erythrocytes can occur when foreign material is placed within the vasculature, when fibrin strands or platelet thrombi obstruct small blood vessels, or when direct physical forces compress superficial blood vessels.

Foreign material

Mechanical haemolysis occurs most commonly with artificial valvular prostheses, particularly when accompanied by turbulent blood flow. Bacterial endocarditis and associated valvular vegetations can also cause fragmentation of red cells. Haemolysis also occurs in up to 10 per cent of patients with transjugular intrahepatic portosystemic shunts (TIPS). Increased cardiac output as a result of anaemia, exercise, or medications can increase the rate of red-cell fragmentation. The peripheral smear usually demonstrates schistocytes and microspherocytes. Severe haemolysis usually requires surgical repair.

Microangiopathic haemolytic anaemia (MAHA)

MAHA describes a spectrum of disorders characterized by mechanical destruction of red cells resulting from thrombi that occlude the microvasculature. The red cells are probably fragmented during their forced passage through the meshwork of fibrin strands that make up the microthrombi. The degree of anaemia is variable. The peripheral smear reveals findings typical of mechanical haemolysis including schistocytes, microspherocytes, and a reticulocytosis (Fig. 8). The absence of a positive direct antiglobulin test along with significant thrombocytopenia helps to confirm the diagnosis. Two other major forms of MAHA are haemolytic uraemic syndrome and thrombotic thrombocytopenic purpura (TTP).

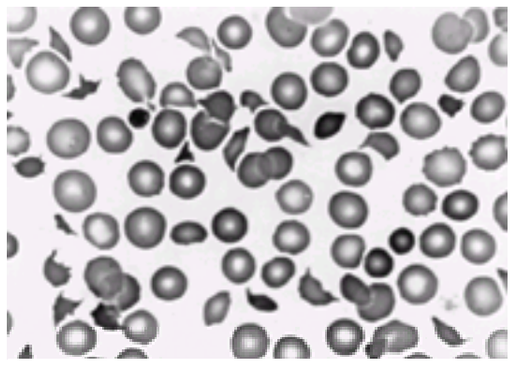

Fig. 8 The peripheral blood changes in microangiopathic haemolytic anaemia. This patient had recurrent thrombocytopenic purpura and the marked fragmentation of the red cells together with microspherocytosis is evident on the blood film (× 1000, Leishman stain).

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome is primarily, but not exclusively, a disease of childhood. The disorder consists of widespread damage to the vascular endothelium and fibrin deposition. These pathological changes are frequently most severe in the renal arterioles and glomerular capillaries. The disorder usually develops following a febrile illness. Numerous reports have documented the development of haemolytic uraemic syndrome following infections with toxin-secreting strains of *Escherichia coli* (strain O157:H7) or shigella. Initial nausea, vomiting, and diarrhoea can develop into severe abdominal pain and bloody diarrhoea. Acutely, the child may develop hypertension, oliguria, purpura, bleeding, and anaemia. If left untreated, convulsions, coma, and death may occur. Mortality rates as high as 10 per cent have been associated with haemolytic uraemic syndrome. The peripheral smear exhibits schistocytosis and thrombocytopenia. Therapy consists mainly of supportive care, transfusion, control of blood pressure, and dialysis.

Thrombotic thrombocytopenic purpura (TTP)

TTP is caused by either a congenital deficiency of, or an acquired inhibitor to, a serum metalloprotease which is responsible for cleaving unusually large multimers of von Willibrand's factor. Left uncleaved, the large von Willibrand's factor multimers induce TTP by causing the agglutination of circulating platelets. Most episodes of TTP occur without an obvious inciting event. However, TTP has been associated with infection, pregnancy, transplantation, AIDS, and drugs such as mitomycin C, ticlopidine, cyclosporine, and tacrolimus (FK506). TTP occurs mainly in adults and more commonly involves the central nervous system. The onset is often sudden with fever, purpura, petechiae, anaemia, thrombocytopenia, and neurological abnormalities. The neurological sequelae include convulsions, coma, paralysis, delirium, and stroke. The peripheral smear demonstrates schistocytes, thrombocytopenia, and a reticulocytosis. During acute episodes front-line therapy includes steroids and daily plasma exchange with fresh frozen plasma or virally-inactivated solvent-detergent plasma (SD plasma). Plasma exchange probably accomplishes one or more of the following:

1. removes the antibody to the protease;
2. removes large multimers of von Willibrand's factor; or
3. replenishes normal protease.

In patients who do not initially respond to plasma exchange with fresh frozen plasma, cryopoor-supernatant is often used as the replacement fluid. Cryopoor-supernatant contains markedly reduced levels of normal von Willibrand's factor which is believed to enhance the formation of microthrombi in some patients. Individuals with drug-induced TTP appear to be less responsive to therapy. Additional therapies in refractory or relapsing patients include vincristine, cytoxan, cyclosporine, and splenectomy. Anecdotal evidence suggests that platelet transfusion can exacerbate the disorder. Therefore, platelet transfusions should be avoided unless absolutely necessary to treat haemorrhage.

March haemoglobinuria

Haemoglobinuria can occur in soldiers or joggers following extended periods of marching or running on a hard surface or in karate or conga drummer enthusiasts following practice. This mechanical haemolysis appears to be the result of red-cell compression in superficial blood vessels during the period of contact between the extremity and the hard surface. The peripheral smear is normal. Treatment is unnecessary as the syndrome is otherwise symptomless and lacks significant clinical sequelae.

Thermal haemolysis

Normal red cells undergo fragmentation and lysis when heated to temperatures of 49°C or higher. The two most common clinical situations associated with heat-induced red-cell lysis are the use of faulty blood warmers during transfusion or patients who have sustained extensive burns.

Venom

Haemolysis has been observed following bee and wasp stings, spider bites, and snake bites. The haemolysis occurs secondary to disseminated intravascular coagulation or as a result of proteolytic enzymes contained within the venom.

22.5.10 Disorders of the red cell membrane

Patrick G. Gallagher Sara S. T. O. Saad, and Fernando F. Costa

The red cell membrane

Composition and function

Although the primary structure and a number of the important functions of the red cell membrane have been known for several years, its study continues to yield important insights into our understanding of membrane structure and function. The red cell membrane is composed of three major structural elements: a lipid bilayer primarily composed of phospholipids and cholesterol; integral proteins embedded in the lipid bilayer that span the membrane; and a membrane skeleton on the internal side of the red cell membrane.

The membrane and its skeleton provide the erythrocyte with the ability to undergo significant deformation without fragmentation or loss of integrity during its travel through the microcirculation. The membrane also assembles and organizes the proteins of the lipid bilayer and the membrane skeleton, allowing the red cell to participate in a wide range of functions. These include influencing cellular metabolism by selectively and reversibly binding and inactivating glycolytic enzymes, retaining organic phosphates and other vital compounds, removing metabolic waste, and sequestering the reductants required to prevent corrosion by oxygen. During erythropoiesis, the membrane responds to erythropoietin and imports the iron required for the synthesis of haemoglobin. The lipid bilayer provides an impermeable barrier between the cytoplasm and the external environment and helps maintain a slippery exterior so that erythrocytes do not adhere to endothelial cells or aggregate in the microcirculation. The membrane also participates in erythrocyte biogenesis and ageing. Finally, the membrane participates in the maintenance of pH homeostasis by participating in chloride–bicarbonate exchange.

Interactions of membrane proteins and disorders of red cell shape

Membrane protein–protein and protein–lipid interactions have been classified into two categories, vertical and horizontal interactions (Fig. 1). Vertical interactions stabilize the lipid bilayer membrane while horizontal interactions support the structural integrity of erythrocytes after their exposure to shear stress. The interactions between proteins and lipids of the erythrocyte membrane are more complex than this simplistic model, but it serves as a useful starting point for understanding red cell membrane interactions, particularly in membrane-related disorders. According to this model, hereditary spherocytosis (HS) is a disorder of vertical interactions. Although the primary molecular defects in HS are heterogeneous (see below), one common feature of HS erythrocytes is a weakening of the vertical contacts between the skeleton and the lipid bilayer. As a result, the lipid bilayer membrane is destabilized, leading to release of lipids in the form of skeleton-free lipid vesicles, which in turn results in membrane surface area deficiency and spherocytosis. In this model, hereditary elliptocytosis is a defect of horizontal interactions, primarily those involving spectrin dimer self-association. Defects of horizontal interactions disrupt the membrane skeletal lattice leading to elliptocytic shape in mild cases and skeletal instability and cell fragmentation in severe cases.

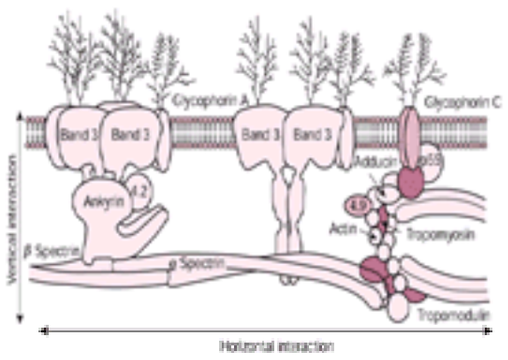

Fig. 1 Schematic diagram of the red cell membrane (not to scale). Membrane–protein and membrane–lipid interactions can be divided into two categories: (1) vertical interactions, which are perpendicular to the plane of the membrane and involve spectrin–ankyrin–band 3 interactions, spectrin–protein 4.1–glycophorin C interactions, and weak interactions between spectrin and the lipid bilayer, and (2) horizontal interactions, which are parallel to the plane of the membrane. Hereditary spherocytosis

Introduction

Hereditary spherocytosis (HS) refers to a group of inherited disorders characterized by the presence of spherical-shaped erythrocytes on peripheral blood smear. HS occurs in all racial and ethnic groups. It is the most common inherited anaemia in individuals of northern European descent, affecting approximately 1 in 2500 individuals in the United States and England. It is much more common in Caucasians than in individuals of African descent. Clinical, laboratory, biochemical, and genetic heterogeneity characterize the spherocytosis syndromes.

Aetiology and pathogenesis

The primary defect in HS is loss of membrane surface area relative to intracellular volume, accounting for the spheroidal shape and decreased deformability of the red cell. This loss of surface area results from increased membrane fragility due to defects in erythrocyte membrane proteins. Increased fragility leads to membrane

vesiculation and membrane loss. Splenic destruction of these non-deformable erythrocytes is the primary cause of haemolysis experienced by HS patients. Physical entrapment of erythrocytes in the splenic microcirculation and ingestion by phagocytes have been proposed as mechanisms of destruction. Furthermore, the splenic environment is hostile to erythrocytes. Low pH, glucose, and ATP concentrations, and high local concentrations of toxic free radicals produced by adjacent phagocytes, all contribute to membrane damage.

Membrane loss is due to defects in several membrane proteins, including ankyrin, band 3, a-spectrin, b-spectrin, and protein 4.2. Combined spectrin and ankyrin deficiency is the most common defect observed, followed by band 3 deficiency, isolated spectrin deficiency, and protein 4.2 deficiency. The genetic defects underlying HS are heterogeneous. Multiple genetic loci are implicated and various abnormalities, including point mutations, defects in mRNA processing, and gene deletions, have been described. Except for a few rare exceptions, HS mutations are private, that is each individual kindred has a unique mutation.

Clinical features

The clinical manifestations of the spherocytosis syndromes vary widely. The typical picture of HS combines evidence of haemolysis (anaemia, jaundice, reticulocytosis, gallstones, and splenomegaly) with spherocytosis (spherocytes on peripheral blood smear, positive osmotic fragility) and a positive family history (Table 1). Mild, moderate, and severe forms of HS have been defined according to differences in haemoglobin, bilirubin, and reticulocyte counts correlated with the degree of compensation for the haemolysis (Table 2). Initial assessment of a patient with suspected HS should include a family history and questions about history of anaemia, jaundice, gallstones, and splenectomy. Physical examination should seek signs such as scleral icterus, jaundice, and splenomegaly. After diagnosing a patient with HS, family members should be examined for the presence of HS.

HS typically presents in childhood, but may present at any age. In children, anaemia is the most frequent presenting complaint (50 per cent), followed by splenomegaly, jaundice, or a positive family history. Two-thirds to three-quarters of HS patients have incompletely compensated haemolysis and mild to moderate anaemia. The anaemia is often asymptomatic except for fatigue and mild pallor. Jaundice is seen at some time in about half of patients, usually in association with viral infections. When present, it is acholuric, that is there is unconjugated hyperbilirubinaemia without detectable bilirubinuria. Palpable splenomegaly is detectable in most (75–95 per cent) older children and adults. Typically, the spleen is modestly enlarged but it may be massive.

About 20 to 30 per cent of HS patients have 'compensated haemolysis,' that is erythrocyte production and destruction are balanced. Although the erythrocyte life span may only be about 20 to 30 days, these patients adequately compensate for their haemolysis with increased marrow erythropoiesis. They are not anaemic and are usually asymptomatic. Many of these individuals escape detection until adulthood, when they are being evaluated for unrelated disorders or when complications related to anaemia or chronic haemolysis occur. Haemolysis may become severe with illnesses that cause splenomegaly, such as infectious mononucleosis, or may be exacerbated by other factors such as pregnancy. Because of the asymptomatic course of HS in these patients, diagnosis of HS should be considered during evaluation of splenomegaly, gallstones at a young age, or anaemia from viral infection.

Approximately 5 to 10 per cent of HS patients have moderate to severe anaemia. Patients with 'moderately severe' disease typically have a haemoglobin of 6 to 8 g/dl, reticulocytes about 10 per cent, bilirubin 2 to 3 mg/dl, and 40 to 80 per cent of the normal red cell spectrin content. This category includes patients with both dominant and recessive HS and a variety of molecular defects. Patients with 'severe' disease, by definition, have life-threatening anaemia and are transfusion-dependent. They almost always have recessive HS. Most have isolated, severe spectrin deficiency. In addition to the risks of recurrent transfusions, these patients often suffer from haemolytic and aplastic crises and may develop complications of severe uncompensated anaemia including growth retardation, delayed sexual maturation, or aspects of thalassaemic faces.

The parents of patients with recessive HS are clinically asymptomatic and do not have anaemia, splenomegaly, hyperbilirubinaemia, or spherocytosis on peripheral blood smears ('Trait', Table 2). Most have subtle laboratory signs of HS including: slight reticulocytosis and slightly elevated osmotic fragility. The incubated osmotic fragility test is probably the most sensitive measure of this condition, particularly the 100 per cent lysis point (0.43 ± 0.05 g NaCl/dl compared to control 0.23 ± 0.07). It has been estimated that at least 1.4 per cent of the population are silent carriers.

Inheritance

The genes responsible for HS include ankyrin, b spectrin, band 3 protein, a spectrin, and protein 4.2. In approximately two-thirds to three-quarter of HS patients, inheritance is autosomal dominant. In the remaining patients, inheritance is non-dominant due to autosomal recessive inheritance or a *de novo* mutation. Cases with autosomal recessive inheritance are due to defects in either a spectrin or protein 4.2. A surprising number of *de novo* mutations have been reported in the HS genes. A few cases of 'double dominant' HS due to defects in band 3 or spectrin that result in fetal death or severe haemolytic anaemia presenting in the neonatal period have been reported. In general, affected individuals of the same kindred experience similar degrees of haemolysis.

Complications

Gallbladder disease

Chronic haemolysis leads to the formation of bilirubinate gallstones, the most frequently reported complication in HS patients. Although gallstones have been detected in infancy, most occur between 10 and 30 years of age. Management should include interval ultrasonography to detect gallstones, as many patients with cholelithiasis and HS are asymptomatic. Timely diagnosis and treatment will help prevent complications of symptomatic biliary tract disease including biliary obstruction, cholecystitis, and cholangitis.

Haemolytic, aplastic, and megaloblastic crises

Haemolytic crises are usually associated with viral illnesses and typically occur in childhood. They are generally mild and are characterized by jaundice, increased splenomegaly, decreased haematocrit, and reticulocytosis. Intervention is rarely necessary. When severe haemolytic crises occur, there is marked jaundice, anaemia, lethargy, abdominal pain, and tender splenomegaly. Hospitalization and erythrocyte transfusion may be required.

Aplastic crises following virally-induced bone marrow suppression are uncommon, but may result in severe anaemia with serious complications including congestive heart failure or even death. The most common aetiological agent in these cases is parvovirus B19. Parvovirus selectively infects erythropoietic progenitor cells and inhibits their growth. Parvovirus infections are frequently associated with mild neutropenia, thrombocytopenia, or even pancytopenia. During the aplastic phase, the haemoglobin and the production of new red cells fall, the cells that remain age, and microspherocytosis and osmotic fragility increase. Aplastic crises usually last 10 to 14 days (about half the life span of HS red cells), the haemoglobin typically falls to half its usual level before recovery occurs. In patients with severe HS, the anaemia may be profound, requiring hospitalization and transfusion. As the marrow recovers, granulocytes, platelets, and, finally, reticulocytes return to the peripheral blood. Aplastic crisis brings many patients to medical attention, particularly asymptomatic HS patients with normally compensated haemolysis. Because parvovirus may infect several members of a family simultaneously, leading to aplastic crises, there have been reports of 'outbreaks' of HS.

Megaloblastic crisis occurs in HS patients with increased folate demands, for example the pregnant patient, growing children, or patients recovering from an aplastic crisis. With appropriate folate supplementation, this complication is preventable.

Diagnosis

The laboratory findings in HS are heterogeneous. Initial laboratory investigation should include a complete blood count with peripheral smear, reticulocyte count, Coombs' test, and serum bilirubin. When the peripheral smear or family history is suggestive of HS, an incubated osmotic fragility should be obtained. Rarely, additional, specialized testing is required to confirm the diagnosis.

Peripheral blood smear

Erythrocyte morphology is quite variable. Typical HS patients have blood smears with obvious spherocytes lacking central pallor (Fig. 2(a)). Less commonly, patients present with only a few spherocytes on peripheral smear or, at the other end of the spectrum, with numerous small, dense spherocytes and bizarre erythrocyte morphology with anisocytosis and poikilocytosis (Fig. 2(b)). Specific morphological findings have been identified in patients with certain membrane protein defects

such as pincered erythrocytes (band 3) or spherocytic acanthocytes (b spectrin).

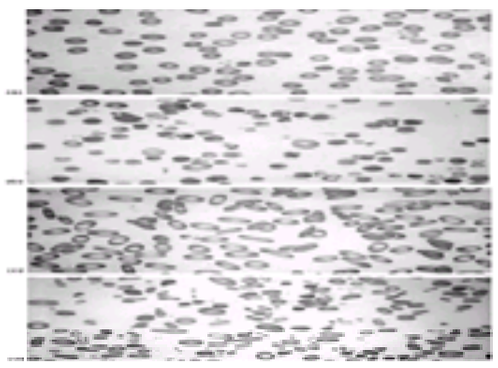

Fig. 2 Peripheral blood smears. (a) Typical hereditary spherocytosis. (b) Severe, recessively-inherited spherocytosis. (c) Hereditary elliptocytosis. (d) Hereditary pyropoikilocytosis.

Erythrocyte indices

Most patients have mild to moderate anaemia. The mean corpuscular haemoglobin concentration is increased (between 35 and 38 per cent) due to relative cellular dehydration in approximately 50 per cent of patients, but all HS patients have some dehydrated cells. The Technicon H1 blood counter and its successors (Technicon, Tarrytown, NY) provide a histogram of mean corpuscular haemoglobin concentration that has been claimed to be accurate enough to identify nearly all HS patients. Finally, the mean corpuscular volume (MCV) is usually normal except in cases of severe HS, when it is slightly decreased.

Osmotic fragility

In the normal erythrocyte, membrane redundancy gives the cell its characteristic discoid shape and provides it with abundant surface area. In spherocytes, there is a decrease in surface area relative to cell volume, resulting in their abnormal shape. This change is reflected in the increased osmotic fragility found in these cells (Fig. 3). Osmotic fragility is tested by adding increasingly hypotonic concentrations of saline to red cells. The normal erythrocyte is able to increase its volume by swelling, but spherocytes, which are already at maximum volume for surface area, burst at higher saline concentrations than normal. Approximately 25 per cent of HS individuals will have a normal osmotic fragility on freshly drawn red cells, with the osmotic fragility curve approximating the number of spherocytes seen on peripheral smear. However, after incubation at 37°C for 24 h, HS red cells lose membrane surface area more readily than normal because their membranes are leaky and unstable. Thus incubation accentuates the defect in HS erythrocytes and brings out the defect in osmotic fragility, making incubated osmotic fragility the standard test for diagnosing HS. When the spleen is present, a subpopulation of very fragile erythrocytes, which have been conditioned by the spleen, form the 'tail' of the osmotic fragility curve; this disappears after splenectomy (Fig. 3). Osmotic fragility testing suffers from poor sensitivity as about 20 per cent of mild cases of HS are missed after incubation. It is unreliable in patients with small numbers of spherocytes, including those who have been recently transfused. It is abnormal in other conditions where spherocytes are present.

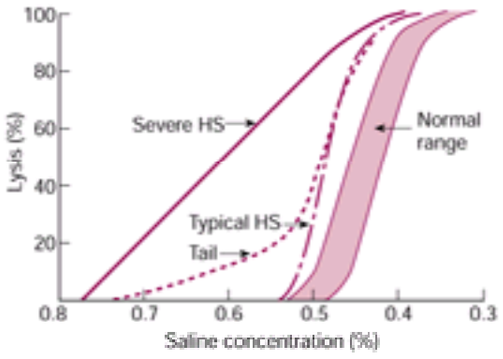

Fig. 3 Osmotic fragility curves in hereditary spherocytosis. The shaded region is the normal range. Results representative of both typical and severe spherocytosis are shown. A tail, representing very fragile erythrocytes that have been conditioned by the spleen, is common in many spherocytosis patients prior to splenectomy.

Additional testing

Other investigations, such as the autohaemolysis test, the hypertonic cryohaemolysis test, and the acidified glycerol test, suffer from lack of specificity and are not widely used. Specialized testing, such as membrane protein quantitation, ektacytometry, and genetic analyses, are available for studying difficult cases or cases where additional information is desired.

Other laboratory manifestations in HS are markers of ongoing haemolysis. Reticulocytosis, increased bilirubin, increased lactate dehydrogenase, increased urinary and faecal urobilinogen, and decreased haptoglobin reflect increased erythrocyte production or destruction.

Differential diagnosis

HS should be able to be distinguished from other haemolytic anaemias by additional diagnostic testing, such as autoimmune haemolytic anaemia via a Coombs' test. Other causes of haemolytic anaemia (Table 3) should be viewed in the appropriate clinical context. Occasional spherocytes are also seen in patients with a large spleen (such as in cirrhosis, myelofibrosis) or in patients with microangiopathic anaemias, but the differentiation of these conditions from HS is not usually difficult.

Treatment

Splenectomy

Splenic sequestration is the primary determinant of erythrocyte survival in HS patients. Thus splenectomy cures or alleviates the anaemia in the overwhelming majority of patients, reducing or eliminating the need for transfusions and decreasing the incidence of cholelithiasis. Postsplenectomy, spherocytosis and altered osmotic fragility persist, erythrocyte lifespan nearly normalizes, and reticulocyte counts fall to normal or near normal levels. Typical postsplenectomy changes, including Howell–Jolly bodies, target cells, and acanthocytes, become evident on peripheral smear. Postsplenectomy, patients with the most severe forms of HS still suffer from shortened erythrocyte survival and haemolysis, but their clinical improvement is striking.

Early complications of splenectomy include local infection, bleeding, and pancreatitis due to injury to the tail of the pancreas incurred during surgery. Overwhelming postsplenectomy infection (OPSI), typically from encapsulated organisms, is an uncommon but significant late complication of splenectomy, especially in the first few years of life. The introduction of pneumococcal vaccines and the promotion of early antibiotic therapy for febrile children who have had a splenectomy have led to decreases in the incidence of OPSI.

Indications for splenectomy

In the past, splenectomy was considered routine in HS patients. However, the risk of OPSI and the recent emergence of penicillin-resistant pneumococci have led to a re-evaluation of the role of splenectomy in the treatment of HS. Considering the risks and benefits, a reasonable approach would be to splenectomize all patients with severe spherocytosis and all patients who suffer from significant signs or symptoms of anaemia including growth failure, skeletal changes, leg ulcers, and extramedullary haematopoietic tumours. Other candidates for splenectomy are older HS patients who suffer vascular compromise of vital organs.

Whether patients with moderate HS and compensated, asymptomatic anaemia should have a splenectomy remains controversial. Patients with mild HS and compensated haemolysis can be followed and referred for splenectomy if clinically indicated. The treatment of patients with mild to moderate HS and gallstones is also debatable, particularly since new treatments for cholelithiasis, including laparoscopic cholecystectomy, endoscopic sphincterotomy, and extracorporal choletripsy, lower the risk of this complication.

When splenectomy is warranted, laparoscopic splenectomy is the method of choice as it results in less postoperative discomfort, shorter hospitalization, and decreased costs. Partial splenectomy via laparotomy has been advocated for infants and young children with significant anaemia associated with HS. The goals of this procedure are to allow for the palliation of haemolysis and anaemia while maintaining some residual splenic immune function. Long-term follow-up data for this procedure are lacking.

Prior to splenectomy, patients should be immunized with vaccines against pneumococcus, *Haemophilus influenzae* type b, and meningococcus, preferably several weeks preoperatively. The use and duration of prophylactic antibiotics postsplenectomy is controversial. Presplenectomy, and in severe cases, postsplenectomy, HS patients should take folic acid to prevent folate deficiency.

Elliptocytosis, pyropoikilocytosis, and related disorders

Introduction

Hereditary elliptocytosis (HE) is characterized by the presence of elliptical or cigar-shaped erythrocytes on peripheral blood smears of affected individuals. The world-wide incidence of HE has been estimated to be 1 in 2000 to 4000 individuals. The true incidence of HE is unknown because most patients are asymptomatic. It is common in individuals of African and Mediterranean ancestry, presumably because elliptocytes confer some resistance to malaria. In parts of Africa, the incidence of HE approaches 1 in 100. HE is typically inherited in an autosomal dominant pattern. Rare cases of *de novo* mutations have been described.

Hereditary pyropoikilocytosis (HPP) is a rare cause of severe haemolytic anaemia with erythrocyte morphology reminiscent of that seen in severe burns. Initial studies of erythrocytes from these patients revealed abnormal thermal sensitivity compared to normal erythrocytes. HPP occurs predominantly in patients of African descent. There is a strong relationship between HPP and HE. Approximately one-third of parents or siblings of patients with HPP have typical HE. Many patients with HPP experience severe haemolysis and anaemia in infancy that gradually improves, evolving toward typical HE later in life.

Aetiology and pathogenesis

The principle defect in HE/HPP erythrocytes is an intrinsic mechanical weakness or fragility of the erythrocyte membrane skeleton due to a defect of horizontal interactions (see above). This is due to defects in the red cell membrane proteins a spectrin, b spectrin, protein 4.1, or glycophorin C. The majority of defects occur in spectrin, the principal structural protein of the membrane skeleton. A variety of mutations in the genes encoding these proteins have been described, with several mutations identified in a number of individuals on the same genetic background, suggesting a 'founder effect' for these mutations.

Clinical features

The clinical presentation of HE is heterogeneous, ranging from asymptomatic carriers to patients with severe, transfusion-dependent anaemia. Most patients with HE are asymptomatic and are typically diagnosed incidentally during testing for unrelated conditions. The erythrocyte life span is normal in most patients. The 10 per cent of patients with decreased red-cell lifespan are the ones who experience haemolysis, anaemia, splenomegaly, and intermittent jaundice. Many of these symptomatic patients have parents with typical HE and thus are homozygotes or compound heterozygotes for defects inherited from each of the parents. Symptomatology may vary between members of the same family, indeed, it may vary in the same individual at different times. To explain these observations, modifier alleles have been hypothesized to influence spectrin expression and clinical severity. One such allele, a ^{LELY} (low expression Lyon), has been identified and characterized.

Diagnosis

The hallmark of HE is the presence of elliptocytes on peripheral blood smear (Fig. 2(c)). These normochromic, normocytic elliptocytes number from a few to 100 per cent. The degree of haemolysis and anaemia do not correlate with the number of elliptocytes present. A few ovalocytes, spherocytes, stomatocytes, and fragmented cells may also be seen. Elliptocytes may be seen in association with several disorders including megaloblastic anaemias, hypochromic microcytic anaemias (iron deficiency anaemia and thalassaemia), myleodysplasic syndromes, and myelofibrosis; however, elliptocytes are generally less than one-third of red cells in these conditions. History and additional laboratory testing usually clarify the diagnosis of these disorders. In addition to the peripheral blood smear findings found in HE, HPP erythrocytes are bizarre-shaped with fragmentation and budding (Fig. 2(d)). Microspherocytosis is common and the MCV is frequently decreased (50–65 mm^3).

The osmotic fragility is abnormal in severe HE and HPP. Other laboratory findings in HE are similar to those found in other haemolytic anaemias and are non-specific markers of increased erythrocyte production and destruction. When indicated, specialized testing, such as membrane protein quantitation, ektacytometry, spectrin analyses, and genetic studies can be performed.

Treatment

Therapy is rarely necessary. In rare cases, occasional red blood cell transfusions may be required. In cases of severe HE and HPP, splenectomy has been palliative. The same indications for splenectomy in HS can be applied to patients with symptomatic HE or HPP. Postsplenectomy, patients with HE or HPP experience increased haemoglobin, decreased haemolysis, and improvement in clinical symptoms.

During acute illnesses, patients should be followed for signs of haematological decompensation. Ultrasonography at regular intervals to detect gallstones should be performed. In patients with significant haemolysis, folate should be administered daily.

South-east Asian ovalocytosis (SAO)

SAO is characterized by the presence of oval erythrocytes with a central longitudinal slit or transverse bar on peripheral blood smears of affected individuals. It is common in parts of the Philippines, Indonesia, Malaysia, and New Guinea and is inherited in an autosomal dominant fashion. Incredibly rigid, SAO erythrocytes are resistant to invasion by malaria parasites. The underlying defect is a mutation in a critical region of band 3. Haematologically, patients with SAO are asymptomatic, with little or no evidence of haemolysis or anaemia. Osmotic fragility is normal. The finding of characteristic ovalocytes in the peripheral blood of an asymptomatic individual from one of the above mentioned ethnic backgrounds is highly suggestive of the diagnosis. Biochemical and DNA diagnostic techniques are available to detect this condition.

Stomatocytosis

The hereditary stomatocytosis syndromes are a heterogeneous group of disorders characterized by mouth-shaped (stomatocytic) erythrocyte morphology on peripheral blood smear (Fig. 4). The clinical severity of stomatocytosis patients is variable; some patients experience haemolysis and anaemia, while others are asymptomatic. The red blood cell membranes of stomatocytosis patients usually exhibit abnormal permeability to the cations sodium and potassium, with consequent modification of intracellular water content, ranging from dehydrated to overhydrated erythrocytes. The underlying defect(s) leading to abnormal cation permeability

and red cell dehydration in these patients is unknown.

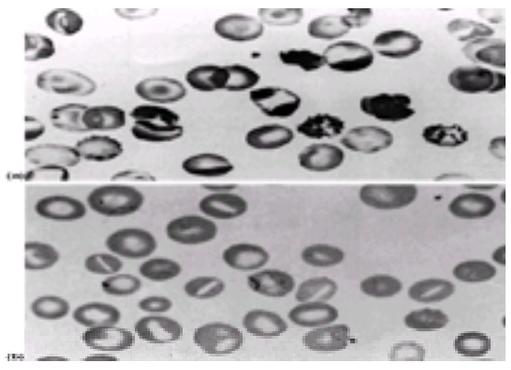

Fig. 4 Peripheral blood smears. (a) Dehydrated stomatocytosis. (b) Overhydrated stomatocytosis. (Reprinted from Lande and Mentzer, 1985, with permission.)

Other conditions

Other conditions associated with hereditary stomatocytosis include the Rh deficiency syndromes and familial deficiency of high-density lipoproteins. Acquired stomatocytosis has been observed in a large number of conditions, particularly hepatobiliary disease and acute alcoholism. Acquired stomatocytosis has also been seen in patients with various malignant neoplasms, cardiovascular disease, and after the administration of vinca alkaloids.

22.5.11 Erythrocyte enzymopathies

Ernest Beutler

Erythrocytes are living cells that contain a large number of enzymes required to carry out a variety of metabolic processes. Some inherited deficiencies of these enzymes are called red-cell enzymopathies. They may cause haematological disorders, including haemolytic anaemias, polycythaemia, and methaemoglobinaemia. Other deficiencies do not produce haematological disorders, but instead mirror important metabolic disorders such as galactosaemia and are therefore of diagnostic value. Some deficiencies, for example those of lactate dehydrogenase or inosine triphosphatase (ITPase) are, as far as has been determined, 'non-diseases'.

This section deals with those red-cell enzyme defects that cause haemolytic anaemia. Many have been described; most are rare but some are sufficiently common that several hundred cases have been documented. Although the enzymatic bases of these defects are very different, the clinical presentation is similar and relatively nondescript. It is impossible to differentiate the enzymatic defects from one another by clinical or routine laboratory methods.

Red-cell metabolism

The two major pathways of red-cell glucose metabolism are illustrated in (Fig. 1).

Glucose is phosphorylated to glucose-6-phosphate in the hexokinase reaction. It is then either metabolized in the anaerobic Embden–Myerhoff pathway or is oxidized in the glucose-6-phosphate dehydrogenase (G6PD) reaction, entering the hexose monophosphate pathway.

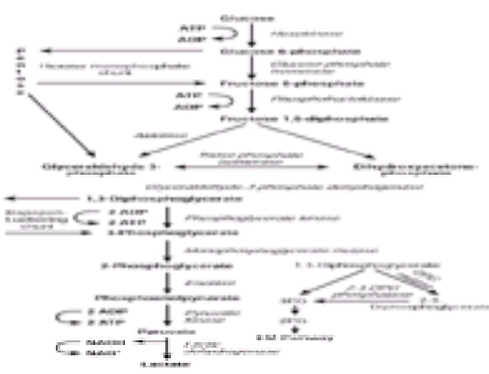

Fig. 1 The relationship between the main red-cell glycolytic pathway (Embden–Meyerhof) and the other metabolic pathways. The insert shows the production of 2,3-DPG in the Rapoport–Luebering shunt.

Anaerobic metabolism of glucose reduces NAD and, by phosphorylating ADP to ATP, provides energy to maintain erythrocyte shape and to transport molecules into and out of erythrocyte. The hexose monophosphate pathway serves to maintain glutathione and protein sulphydryl groups in the reduced state. These pathways are similar in red cells, as in other tissues and in lower organisms. However, the 2,3-diphosphoglycerate (2,3 DPG) shunt is a unique feature of the Embden–Myerhoff pathway in erythrocytes. This 'energy clutch' of erythrocyte metabolism not only allows flexibility in the amount of ATP that is generated in glycolysis, but also provides a source of 2,3-DPG, the key modulator of haemoglobin oxygen affinity. The pathway also reduces NAD to NADH, which serves to reduce methaemoglobin to haemoglobin. The hexose monophosphate pathway, on the other hand, reduces NADP to the NADPH needed to maintain sulphydryl compounds in the reduced state. There are, in addition, many other metabolic functions that the erythrocyte must carry out. Among these are the synthesis of glutathione, the synthesis and degradation of nucleotides and nucleosides, the detoxification of active oxygen radicals, and the transport of small molecules into and out of the cell.

Genetics

Half of the normal activity of red-cell enzymes is generally sufficient for normal function. Thus, haemolytic anaemias due to red-cell enzyme deficiencies occur as autosomal recessive or sex-linked disorders. Only two of the deficiencies, those of G6PD and phosphoglycerate kinase are encoded by genes on the X chromosome; all of the others are autosomal. Extensive mutation analysis at the DNA level has been performed on patients with some of the enzyme defects; notably, deficiencies of G6PD, pyruvate kinase, glucosephosphate isomerase, and triosephosphate isomerase. The vast majority of mutations of the genes encoding these enzymes are missense mutations or nonsense mutations, but a few deletions, insertions, and splicing mutations have been described. So far, with the possible exception of one mutation of triosephosphate isomerase, no regulatory mutations have been documented. DNA-based diagnosis has assumed an increasingly valuable role in the diagnosis of these disorders.

Specific red-cell abnormalities that may cause haemolytic anaemia

Table 1 summarizes a some of the clinical and genetic characteristics of red-cell enzyme deficiencies.

The more common red-cell enzyme abnormalities

G6PD deficiency

This enzymopathy is described in Chapter 22.5.12.

Pyruvate kinase deficiency

Pyruvate kinase deficiency can be considered the clinical prototype of the non-spherocytic haemolytic anaemias caused by red-cell enzymopathies. The severity of the anaemia varies greatly from patient-to-patient. At one extreme, the anaemia can be quite mild; at the other, the patient may be entirely transfusion-dependent. Indeed, the circulating red cells in such patients may have normal pyruvate kinase activity because there are scarcely any of the patient's own cells present; it appears that most of the patient's cells are destroyed before they leave the marrow and it may be only the transfused cells that are sampled and sent to the laboratory

for diagnosis. Pyruvate-kinase-deficient patients have the usual stigmata of haemolytic anaemia; that is, pallor, lack of energy, jaundice, and sometimes gallstones. In those patients who are transfusion-dependent, haemochromatosis occurs with some frequency, probably more so than in patients with many other types of haemolytic anaemia. Patients with pyruvate kinase deficiency usually enjoy a fairly good response to splenectomy. This response is less complete than is observed in hereditary spherocytosis, but may be clinically quite helpful, particularly in reducing the requirement for transfusions.

Pyruvate kinase deficiency is probably the most difficult of all of the red-cell enzymopathies to diagnose, because the enzyme is a complex one with allosteric properties. The residual enzyme activity is not always greatly reduced. Cases have been described in which the residual pyruvate kinase activity is actually higher than is found in normal individuals. In such cases, establishing the diagnosis may depend upon showing that the level of 2,3 DPG or of 3-phosphoglyceric acid in the erythrocytes is greatly elevated, a finding that is characteristic of pyruvate kinase deficiency. It is also useful to measure the thermal stability of the residual enzyme; mutant enzymes are very often unstable on heating. Many different mutations have been documented in patients with pyruvate kinase deficiency. In European populations, the most common of these is a G® A mutation at nucleotide 1529 coding for a Arg®Gly substitution at amino acid 510. This mutation has not been detected among Asians with pyruvate kinase deficiency; among Gypsies the characteristic mutation is a deletion of exon 11.

The less common red-cell enzyme abnormalities

Glucosephosphate isomerase deficiency

Patients with glucosephosphate isomerase deficiency generally have a milder haemolytic disorder than patients with pyruvate kinase deficiency. The response to splenectomy is usually satisfactory. Although milder in general, this enzymopathy seems to be associated with hydrops fetalis more frequently than the other red-cell enzyme defects. Diagnosis is generally straightforward. A fluorescent screening test can be used to detect the deficiency. Several different mutations have been documented. With few exceptions, they are different in each family.

Pyrimidine 5'-nucleotidase deficiency

Basophilic stippling is the hallmark of pyrimidine 5'-nucleotidase deficiency. Interestingly, this enzyme is very sensitive to inhibition by lead. The stippling that is so characteristic of lead poisoning may be the consequences of inhibition of this enzyme. Pyrimidine 5'-nucleotidase is the most age-sensitive all of the red-cell enzymes; this one alone is decreased in activity in aplastic anaemia or other disorders, such as transient erythroblastopenia of childhood, in which the mean red cell age is greatly increased. This can lead to misdiagnosis; while it is not uncommon to encounter enzyme activities of one-half normal in patients with decreased erythropoiesis, these patients do not suffer from clinically significant pyrimidine 5'-nucleotidase deficiency. Accumulation of pyrimidine nucleotides, which can be documented by measuring the ultraviolet absorption spectrum, does not occur in such patients.

Triosephosphate isomerase deficiency

Triosephosphate isomerase deficiency is the most devastating all of the red-cell enzymopathies. With few exceptions, patients with this abnormality die by the time they are 4 years of age. All tissues are affected, and death is usually due to cardiopulmonary complications. It is been suggested, on the basis of enzyme activities and genetic studies, that the heterozygous state for this deficiency is very common among African-Americans. This has not been confirmed. Many different mutations have been detected in patients with triosephosphate isomerase deficiency; one, at genomic nucleotide 1591, accounts for approximately 50 per cent of the patients with this disorder. Polymorphic changes occur in the promoter region of the triosephosphate isomerase gene, but the significance of these mutations is not yet clear. No treatment has been effective.

The rare red-cell enzyme deficiencies

Hexokinase deficiency

Hexokinase deficiency is one of the more difficult red-cell enzymopathies to diagnose, because the activity of this enzyme is much higher in young red cells than in older erythrocytes. As a result, red-cell hexokinase activity is usually increased in patients with haemolytic anaemia of any type. In patients with hexokinase deficiency, this often gives rise to the anomalous finding that the red-cell hexokinase activity in the affected patient is normal, usually higher than that found in the heterozygous parents. The diagnostic hallmark is normal, rather than elevated, hexokinase activity in the face of a high reticulocyte count and high levels of other red-cell enzymes.

Enzymes of glutathione synthesis

Erythrocytes synthesize glutathione from the amino acids glutamate, cysteine, and glycine in two consecutive enzymatic reactions, each of which utilizes ATP. In the first step, catalysed by g-glutamylcysteine synthetase, a peptide bond is formed between the g-carboxyl group of glutamic acid and cysteine. Several patients deficient in this enzyme have been found. In addition to haemolytic anaemia, spinocerebellar degeneration was documented in the initial patient described, but neurological symptoms have not been present in subsequent patients. Defects of the second step of glutathione synthesis, the formation of a peptide link between g-glutamyl-cysteine and glycine, catalysed by the enzyme glutathione synthetase, appear in two clinical forms. In some patients, the deficiency is limited to the erythrocytes. Haemolytic anaemia appears to be the sole clinical manifestation. In other patients, the deficiency is generalized. These patients excrete large amounts of pyroglutamic acid (5-oxyproline); this product of g-glutamylcysteine degradation is overproduced in the absence of the feedback inhibition of g-glutamylcysteine synthetase by glutathione. Patients with the generalized defect have severe neuromuscular manifestations in addition to haemolytic anaemia.

Glutathione reductase deficiency

Only a single family with a severe, hereditary deficiency of glutathione reductase has been described. No haemolysis was present except after the ingestion of fava beans. Low activity of red-cell glutathione reductase, a flavin enzyme, are found when the intake of riboflavine is suboptimal, but this mild or moderate enzyme deficiency has no clinical consequences.

Phosphofructokinase kinase deficiency

Erythrocytes contain two types of genetically distinct phosphofructokinase subunits, L (liver) and M (muscle). Deficiency of the M subunit causes haemolysis, but the haemoglobin level in the blood is often normal or even higher than normal because of the diminished 2,3 DPG levels that are characteristic of this disorder. Muscle enzyme activity is also compromised and a myopathy results. This disorder is sometimes designated Tarui disease or type VII glycogenosis. Deficiency of the L subunit of phosphofructokinase has also been reported, but did not have any clinical consequences.

Aldolase deficiency

A few cases of aldolase deficiency been reported. An association with mental retardation was noted in one case, but it is not clear whether a cause-and-effect relationship exists.

Phosphoglycerate kinase deficiency

Phosphoglycerate kinase shares with G6PD deficiency the distinction of being an X-linked enzymopathy. In addition to haemolytic anaemia, behavioural disturbances have been noted.

Diphosphoglycerate mutase deficiency

The result of diphosphoglycerate mutase deficiency is more frequently erythrocytosis than haemolytic anaemia, because a lack of this enzyme prevents the formation of 2,3 DPG. Consequently, the oxygen affinity of the red cells is increased, stimulating erythropoiesis.

High adenosine deaminase activity

Haemolytic anaemia, inherited as an autosomal dominant disorder, has rarely been found to be associated with greatly elevated red-cell adenosine deaminase levels. The adenosine deaminase that is formed appears to be normal. The abnormality that causes this tissue-specific increase in enzyme activity has not yet been discovered.

Adenylate kinase deficiency

A number of patients with familial haemolytic anaemia have been documented to have markedly decreased levels of red-cell adenylate kinase. However, one very well-studied patient with virtually absent enzyme activity had no clinical disorder. The relationship between this enzyme deficiency and haemolytic anaemia remains unclear.

Specific red-cell abnormalities that do not cause haemolytic anaemia

Severe deficiencies of many red-cell enzymes do not produce haematological abnormality or, indeed, in many cases, no clinical abnormality of all. Included are deficiencies of 6-phosphogluconate dehydrogenase, †-aminolevulinic acid dehydrase, acetylcholinesterase, AMP deaminase, carbonic anhydrase, catalase, galactokinase, galactose-1-phosphate uridyltransferase, glutathione peroxidase, hypoxanthine-guanine phosphoribosyltransferase, ITPase, and phosphoglucomutase. Discussion of these enzyme deficiencies is beyond the scope of this chapter.

Diagnosis

The diagnosis of red-cell enzymopathies has been carried out at four levels: morphological observations, study of autohaemolysis, quantification of red-cell enzyme activity, and DNA analysis.

Morphological observations

The appearance of erythrocytes on a stained blood film may be useful in determining whether haemolytic anaemia is present and in ruling out some causes of haemolysis, such as hereditary spherocytosis, ovalocytosis, or microangiopathic haemolytic anaemia. The presence of prominent red-cell stippling suggests a diagnosis of pyrimidine 5' nucleotidase deficiency.

The autohaemolysis test

The autohaemolysis test is performed by incubating sterile, whole blood with and without glucose for 24 h and observing the degree to which the red cells are lysed. This test outlived its usefulness as a tool for differentiating enzymatic cause of haemolytic anaemia many years ago. Although it is true that the haemolysis of pyruvate-kinase-deficient red cells occurring *in vitro* after incubation for 24 h is not usually corrected by glucose, this is by no means always the case, nor is this pattern specific for pyruvate kinase deficiency.

Qualitative and quantitative estimations of red-cell enzyme activity

The most generally useful means for differentiating red-cell enzyme defects from one another and from defects other than known enzyme deficiencies is to semiquantitate or quantitate the red-cell enzyme activities. Fluorescent screening tests have been developed that allow the non-specialized laboratory to detect decreases in the activity of enzymes such as G6PD, pyruvate kinase, glucosephosphate isomerase, or triosephosphate isomerase with a high degree of reliability. The accumulation of pyrimidine nucleotides can be detected by measuring the ultraviolet spectrum of a perchloric acid extract of red cells. This can be used by non-specialized laboratories to detect this abnormality.

Quantification of red-cell enzyme activities is a more specialized task that can be accomplished by the use of standardized techniques in an experienced laboratory. There are a number of caveats that must be taken into account, both with respect to the performance of red-cell enzyme assays and the interpretation of the results. Leucocyte pyruvate kinase and red-cell pyruvate kinase are encoded by different genes. Moreover, the activity of the white cell enzyme is very high. Thus, contamination of a red-cell suspension with a relatively small number of white cells may obscure the diagnosis of red-cell pyruvate kinase deficiency. The interpretation of the results of red-cell enzyme assays may also be confounded by the fact that the blood of patients with haemolytic anaemia is enriched with reticulocytes and young erythrocytes. Since many of the mutations that cause red-cell enzymopathies result in the production of unstable enzymes, the young erythrocytes that circulate may actually contain normal or near-normal levels of enzyme. It is therefore essential to take into account the age of the circulating cells. It may be helpful to obtain blood samples from parents or children of the patient to determine whether half normal activities can be documented.

Problems in interpretation may also arise when the activity of an enzyme as measured *in vitro* does not accurately reflect its intracellular *in vivo* activity. This comes about because of the necessity of using unphysiologically high substrate concentrations for *in vitro* assays. This difficulty is particularly prone to arise in the case of pyruvate kinase deficiency, because this is a complex allosteric enzyme that not only has binding sites for two substrates, ADP and phosphoenolpyruvate, but also for fructose diphosphate, an allosteric effector.

Finally, there is the confounding effect of red-cell transfusions. It is clearly best to wait until just before a transfusion to draw blood for testing.

DNA-based diagnosis

With the development of PCR-based technologies for the detection of mutations, and for the sequencing of DNA, mutation analysis at the DNA level has played an increasing role in the diagnosis of red-cell enzyme defects. DNA is extracted from peripheral blood leucocytes and the exons of the gene of interest are amplified. Alternatively, RNA may be reverse transcribed and the cDNA amplified. Because the stability of DNA is greater than that of RNA, and samples may need to be transported to distant, specialized laboratories, direct DNA amplification of genomic DNA rather than of cDNA is generally the preferred technology. DNA-based diagnosis is not particularly difficult to perform in laboratories experienced with the techniques involved. It has some advantages over enzyme assay-based diagnosis. First of all, DNA is very stable, even before it is purified. Therefore, shipping of blood is less of a logistical problem. Transfused red cells do not pose a problem in performing DNA-based diagnosis, since transfused leucocytes do not persist in the circulation. Once the mutation has been established, family studies are more readily performed; heterozygote detection using quantitative enzyme levels is often of a dubious reliability. Prenatal diagnosis, too, is more readily accomplished utilizing DNA-based diagnosis.

There are some major disadvantages in DNA-based diagnosis of red-cell enzymopathies. While it is quite straightforward to identify a known mutation in the coding region of one of the red-cell enzymes, doing so by examining the genes that encode all of the enzymes that may be involved as a cause of haemolytic anaemia would be a daunting task. Even if the entire coding region of the enzyme is sequenced, one cannot be certain that the mutation was not be in a promoter, an enhancer, or in a splice site.

A general approach to diagnosis of red-cell enzymopathies

The first step is to make certain that the patient has a haemolytic anaemia. The reticulocyte count should be elevated, unless it has been temporarily suppressed by infection. If the patient's history suggests that the anaemia is chronic in nature, a positive family history can be very helpful. Dominant inheritance suggests that an enzymopathy is not the cause; only the very rare anaemia caused by elevated adenosine deaminase levels falls into this category. Instead, dominant inheritance suggests that the patient either has an unstable haemoglobin or hereditary spherocytosis. Sex-linked inheritance may also appear as though it is dominant, but is excluded if there is father-to-son transmission. G6PD deficiency and phosphoglycerate kinase deficiency are the only red-cell enzymopathies that are sex-linked. Often there is no clear-cut family history. Before trying to establishing whether or not a red-cell enzymopathy is present, hereditary spherocytosis, haemoglobinopathies, and other disorders, such as a paroxysmal nocturnal haemoglobinuria, should be excluded.

Fluorescent screening tests are appropriate starting points for the diagnosis of the red-cell enzymopathies. Screening tests for G6PD deficiency, pyruvate kinase

deficiency, glucosephosphate isomerase deficiency should be carried out. If the patient is a child with neuromuscular disease, a fluorescent test for triosephosphate isomerase deficiency is also indicated. Stippling of the red cells suggests that the patient may have pyrimidine 5' nucleotidase deficiency. In this instance the ultraviolet spectrum of a perchloric acid of extract of the red cells should be examined. A clear-cut positive screening test for one of the red-cell enzymopathies, carried out with appropriate controls, is adequate for diagnosis. Quantitative assays for red-cell enzymes can be performed by specialized laboratories and the may include those enzymes for which no screening tests have been developed.

When a diagnosis has been established, either by performing a screening test or by quantitative assay, it is sometimes useful to identify the mutation at the DNA level. This need not be done in every case, but is particularly useful in the case of young couples who hope to have more children and desire genetic counselling and prenatal diagnosis.

22.5.12 Glucose-6-phosphate dehydrogenase (G6PD) deficiency

Lucio Luzzatto

Definition

Glucose-6-phosphate dehydrogenase (**G6PD**) is a key enzyme in redox metabolism. G6PD deficiency is an inherited condition in which red cells have a markedly decreased activity of G6PD, which predisposes to haemolytic anaemia.

Epidemiology

G6PD deficiency is distributed worldwide. Areas of high prevalence are found in Africa, Southern Europe, the Middle East, South-East Asia, and Oceania. In the Americas and in parts of Northern Europe, G6PD deficiency is also quite prevalent as a result of migrations that have taken place in relatively recent historical times.

Genetics

The inheritance of G6PD deficiency has long been known to have a mendelian X-linked pattern, and the gene encoding G6PD has been mapped to the telomeric region of the long arm of the X chromosome (band Xq28), physically very close to the genes for haemophilia A, dyskeratosis congenita, and colour blindness. At the genomic level, the G6PD gene consists of 13 exons and spans some 18.5 kb (kilobases). Structural and functional studies have revealed features of a 'housekeeping gene'; this is in accord with the fact that G6PD is found in all cells.

X linkage of the G6PD gene has important implications. First, as males have only one G6PD gene (being hemizygous for this gene), they must be either normal or G6PD deficient. By contrast, females, having two G6PD genes, can be either normal or deficient (homozygous), or intermediate (heterozygous). Moreover, as a result of the phenomenon of X-chromo-some inactivation, heterozygous females are genetic mosaics, and this in turn has clinical implications. Indeed, in most other (autosomal) enzyme deficiencies, heterozygotes are asymptomatic because cells with an enzyme level close to 50 per cent of normal are biochemically normal. But in the case of G6PD, as a result of X inactivation, the abnormal cells of a woman heterozygous for G6PD deficiency are just as deficient as those of a hemizygous deficient man, and therefore just as susceptible to pathology. Thus, although G6PD deficiency is still often referred to as an X-linked recessive trait, this is a mismomer because a recessive trait is, by definition, not expressed in a heterozygote; instead, G6PD deficiency is expressed in heterozygotes both biochemically and clinically—although it is true that heterozygotes are generally less severely affected.

Clinical manifestations

Acute haemolytic anaemia

In view of the large number of people who carry a G6PD deficiency gene, it is fortunate that the vast majority remain clinically asymptomatic throughout their lifetime. However, they are all at risk of developing acute haemolytic anaemia in response to three types of triggers: (i) drugs (Table 1), (ii) infections, and (iii) broad (fava) beans. Typically, a haemolytic attack starts with malaise, sometimes associated with more or less profound weakness, and abdominal or lumbar pain. After an interval of several hours to 2 or 3 days (usually the onset is more abrupt in children) the patient develops jaundice and dark urine, due to haemoglobinuria. In the majority of cases the haemolytic attack, even if severe, is self-limiting and tends to resolve spontaneously. In the absence of additional or pre-existing pathology the bone marrow response is prompt and effective. Depending on the proportion of red cells that have been destroyed (reflected in the severity of the anaemia), the haemoglobin level may be back to normal in 3 to 6 weeks. The most serious threat in adults is the development of acute renal failure (this is exceedingly rare in children). The anaemia is usually normocytic and normochromic, and it varies from moderate to extremely severe (haemoglobin levels of 4 g/dl or less have been recorded); it is due largely to intravascular haemolysis, and hence it is associated with haemoglobinaemia, haemoglobinuria, and low or absent plasma haptoglobin. The blood film shows anisocytosis, polychromasia, and other features associated with acute haemolysis, including spherocytes (Fig. 1); in severe cases the poikilocytosis is very marked, with bizarre forms, numerous red cells that appear to have unevenly distributed haemoglobin ('hemighosts'), and red cells that appear to have had parts of them bitten away ('bite cells' or 'blister cells'). Supravital staining with methyl violet, if done promptly, reveals the presence of 'Heinz bodies', consisting of precipitates of denatured haemoglobin (Fig. 1; apart from the rare cases when they are formed because of a genetic haemoglobin abnormality, Heinz bodies can be regarded as a signature of oxidative damage to red cells). The white blood cell count may be elevated, with predominance of granulocytes. The platelet count may be normal, increased, or moderately decreased. The unconjugated bilirubin is elevated but the 'liver enzymes' are usually normal.

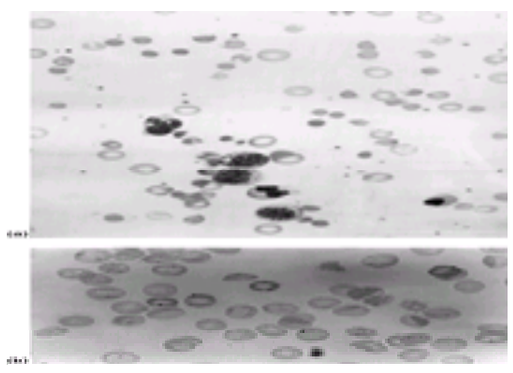

Fig. 1 Blood film in a case of acute haemolytic anaemia in a G6PD-deficient patient (favism). (a) Romanovsky stain, showing marked poikilocytosis, polychromatic macrocytes, bite cells, nucleated red cells, and a shift to the left in the granulocytic series. (b) Supravital stain with methyl violet, showing the characteristic Heinz bodies.

Favism

This is perhaps the most spectacular form of acute haemolytic anaemia associated with G6PD deficiency; it can occur at any age, but more commonly in children. The

child initially becomes very fractious; then he may develop fever, abdominal pain, diarrhoea, and sometimes vomiting; then he may become lethargic. Haemoglobinuria develops within 6 to 24 h from the onset of symptoms. Physical examination reveals pallor, tachycardia, jaundice, and an enlarged spleen; in severe cases there may be evidence of hypovolaemic shock or, more rarely, of high-output heart failure. The cause of favism is the presence in broad beans (or fava beans: *Vicia faba*) of vicine and convicine, two b-glycosides having as aglycones the substituted pyrimidines divicine and isouramil, which produce free radicals in the course of their auto-oxidation. Thus, haemolysis is highly specific for broad beans; other beans are safe. G6PD-deficient subjects (especially when they are adults) do not develop an acute attack of favism every time they eat broad beans; the reasons for this are not yet clear, but important factors are the quantity and quality of broad beans consumed. On the other hands, the widespread notion that favism occurs only with some G6PD-deficient variants and not with others is incorrect. For instance, favism has now been well documented with the 'African' variant A–, and even with G6PD Seattle, a variant associated with milder enzyme deficiency.

Neonatal jaundice

Not every G6PD-deficient baby becomes jaundiced after birth; however, the risk of developing neonatal jaundice is much greater in G6PD-deficient than in G6PD-normal neonates. The extent of the association between G6PD deficiency and neonatal jaundice appears to vary greatly in different populations. The clinical picture of neonatal jaundice related to G6PD deficiency differs from the 'classic' Rhesus-related neonatal jaundice in two main respects: (i) it is very rarely present at birth, and the peak incidence of clinical onset is between day 2 and 3; and (ii) jaundice is more prominent than anaemia, and the anaemia is very rarely severe. The severity of G6PD-related neonatal jaundice varies enormously, from subclinical to overlapping with 'physiological jaundice' to imposing the threat of kernicterus if not treated. The reasons for this are not clear, but prematurity, infection, and environmental factors (for instance, naphthalene–camphor balls used in babies' bedding and clothing) certainly play a part in making neonatal jaundice more severe and more dangerous. From the point of view of public health, it is important to realize that in some parts of the world G6PD deficiency is the commonest cause of severe neonatal jaundice; in addition, if not correctly managed, severe neonatal jaundice can produce permanent neurological damage.

Chronic non-spherocytic haemolytic anaemia

In contrast to the large majority of G6PD-deficient subjects who have minimal and subclinical haemolysis in the steady state, a small minority have chronic anaemia of very variable severity. The patient is always male, and in general he presents because of unexplained jaundice. Frequently the onset is at birth, and a diagnosis is made of neonatal jaundice (Fig. 2), which may be severe enough to require exchange transfusion. Subsequently the anaemia recurs and the jaundice fails to clear completely; or the patients is only reinvestigated much later in life, perhaps because of gallstones in a child or in a young adult. Usually the spleen is moderately enlarged in small children, and subsequently it may increase in size sufficiently to cause mechanical discomfort, or hypersplenism, or both. The severity of anaemia ranges in different patients from borderline to transfusion dependent. The anaemia is usually normochromic but somewhat macrocytic; because a large proportion of reticulocytes (up to 20 per cent or more) will cause an increased mean corpuscle volume and a shifted, wider than normal, size-distribution curve. The red cell morphology is not characteristic, and for this reason it is referred to in the negative as being 'non-spherocytic'. The bone marrow is normoblastic, unless the increased requirement of folic acid associated with the high red cell turnover has caused it to become megaloblastic. There is chronic hyperbilirubinaemia, decreased haptoglobin, and increased lactate dehydrogenase. In this condition, unlike in the acute haemolytic anaemia described above, haemolysis is mainly extravascular. However, the red cells of these patients are naturally also vulnerable to acute oxidative damage, and therefore the same agents that can cause acute haemolytic anaemia in people with the ordinary type of G6PD deficiency will cause severe exacerbations with (sometimes massive) haemoglobinuria in people with the severe form of G6PD deficiency.

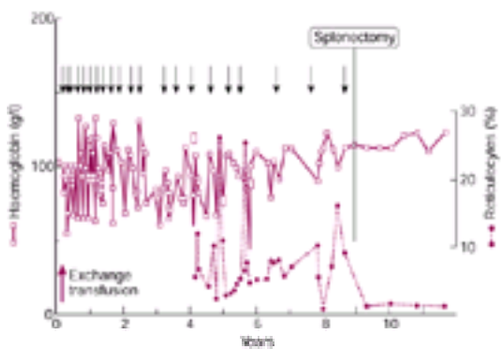

Fig. 2 Clinical course of a patient with chronic non-spherocytic haemolytic anaemia caused by severe G6PD deficiency, illustrating the high transfusion requirement, which was alleviated after splenectomy.

Laboratory diagnosis

Although the clinical picture of favism and of other forms of acute haemolytic anaemia associated with G6PD deficiency is quite characteristic, the final diagnosis must rely on the direct demonstration of decreased activity of this enzyme in red cells. With neonatal jaundice and chronic non-spherocytic haemolytic anaemia the differential diagnosis is much wider, and therefore this test is even more important. The most popular screening tests are the dye decolorization test, the methaemoglobin reduction test, and the fluorescence spot test. Any of these, provided it is properly standardized and subjected to quality control, is perfectly adequate for diagnostic purposes in patients who are in the steady state; but these semiquantitative tests are not adequate for patients in the acute haemolytic or in the posthaematolytic period, or with other complications; nor can they be expected to identify all heterozygotes. Ideally, every patient found to be G6PD deficient by screening should then be retested for confirmation by a quantitative assay. In normal red cells the range of G6PD activity, measured at 30°C, is 7 to 10 iu/g of haemoglobin. In G6PD-deficient males (or homozygous females) the level of G6PD in the steady state is, by definition, less than 50 per cent of normal; but with most variants it is less than 20 per cent and with some it is practically undetectable. In heterozygous females the level is intermediate and extremely variable; therefore, in some cases the diagnosis may be difficult without family studies or DNA analysis. However, for practical purposes it is most unlikely that a woman will have clinical manifestations if her G6PD level is more than 70 per cent of normal.

Biochemistry and pathophysiology

Red cells are very vulnerable to oxidative damage for two reasons. First, oxygen radicals are generated continuously from within the red cells as haemoglobin cycles from its deoxygenated to its oxygenated form. Second, red cells are directly exposed to a variety of exogenous oxidizing agents. Oxygen radicals produced by such compounds are converted by superoxide dismutase to hydrogen peroxide, which is itself highly toxic. G6PD, the first enzyme of the pentose phosphate pathway (Fig. 3), catalyses the conversion of glucose-6-phosphate (G6P) and NADP to 6-phosphogluconolactone and NADPH. The most important product of the G6PD reaction, certainly in red cells, is NADPH because, by producing glutathione via glutathione reductase, it is crucial for the operation of glutathione peroxidase; in addition, it stabilizes catalase: these are the two enzymes able to detoxify hydrogen peroxide (by converting it to water). Normally, G6PD activity in red cells is such that NADPH is maintained at a high level and there is practically no NADP: the NADPH/NADP ratio plays a large part in the intracellular regulation of G6PD activity.

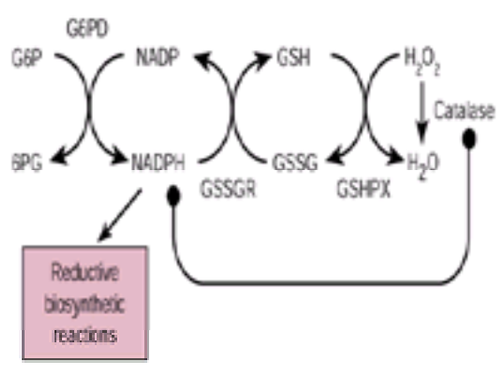

Fig. 3 The role of G6PD in red cell metabolism: NADPH plays a dual role in (i) regeneration of glutathione (GSH) and (ii) stabilization of catalase.

The enzymatically active form of G6PD is either a dimer or a tetramer of a single protein subunit of 514 amino acids with a molecular mass of 59 096 Da. Some regions of the molecule critical for its functions have been identified because they are highly conserved in evolution. The G6P-binding site and the active centre of the enzyme are located near lysine 205. Recently the three-dimensional structure of G6PD has been solved. In the dimer structure the two subunits are symmetrically located across a complex interface of b-sheets. The NADP binding site is near the N-terminus, and bound NADP is important for the stability of G6PD.

Acute haemolytic anaemia associated with G6PD deficiency clearly results from the action of an exogenous factor on intrinsically abnormal red cells. Although the sequence of events ending in haemolysis is not completely understood, we know that oxidative agents cause glutathione depletion in G6PD-deficient red cells. This is followed by oxidation of sulphydryl groups and consequent denaturation of haemoglobin (hence the Heinz bodies) and probably of other proteins, which eventually causes irreversible damage to the membrane of red cells and hence their destruction, partly in the bloodstream and partly through phagocytosis by macrophages. An important feature of haemolysis in G6PD-deficient patients depends on the fact that G6PD decays gradually during red cell ageing (for instance, in normal blood, reticulocytes have about five times more activity than the 10 per cent oldest red cells), and this process is accelerated with many G6PD variants. Thus, a haemolytic attack selectively destroys older red cells because they have a more severe shortage of G6PD. This phenomenon can be so marked with certain G6PD variants that patients in the posthaemolytic state are found to have a significant increase in G6PD activity (hence the risk of misclassification), sufficient to make them relatively resistant to further challenge. By contrast, with some other variants the steady-state level of G6PD is so low that, even in the absence of any oxidant challenge, it becomes limiting for red cell survival: this is the case in patients with chronic non-spherocytic haemolytic anaemia, who may have a red cell lifespan of between 10 and 50 days.

Molecular basis of G6PD deficiency

Since the discovery of G6PD deficiency, one might have expected that some mutations would be located in regulatory regions of the gene, producing a reduction in the amount G6PD produced, without changes in its structure (analogous to thalassaemias); whereas others would be located in the coding region of the gene, thus producing qualitative (or structural) as well as quantitative changes in G6PD (analogous to structural haemoglobinopathies). In fact, whenever G6PD from G6PD-deficient individuals has been subjected to careful biochemical characterization (for example by analysing electrophoretic mobility, substrate affinity constants, or thermostability), qualitative differences have invariably been detected, predicting structural mutations.

By sequencing the G6PD gene from G6PD-deficient subjects it has been verified that all mutations are structural (Fig. 4). The current database of some 130 mutants consists, with few exceptions, of single point mutations in the coding region of the gene, entailing single amino acid replacements in the G6PD protein. The exceptions have been small deletions of one to eight amino acids, and a few instances in which two point mutations rather than one are present (for instance, in G6PD A-, the variant most commonly encountered in Africa). Regulatory mutations have not yet been discovered. Amino acid replacements can cause G6PD deficiency either by affecting its catalytic function or by decreasing the *in vivo* stability of the protein, or by both of these mechanisms. Enzyme instability is the most common mechanism (Table 2). The molecular basis of chronic non-spherocytic haemolytic anaemia associated with G6PD deficiency is highly specific, in the sense that the underlying mutations, while still within the coding region of the G6PD gene, are not the same as those underlying asymptomatic G6PD deficiency. The more severe clinical phenotype can be ascribed in some cases to adverse qualitative changes (for instance, a decreased affinity for the substrate, glucose-6-phosphate); or simply to the fact that the enzyme deficit is more extreme, because of severe instability of the enzyme. For instance, a cluster of mutations map to the dimer interface, and it is clear that they severely compromise the formation of the dimer.

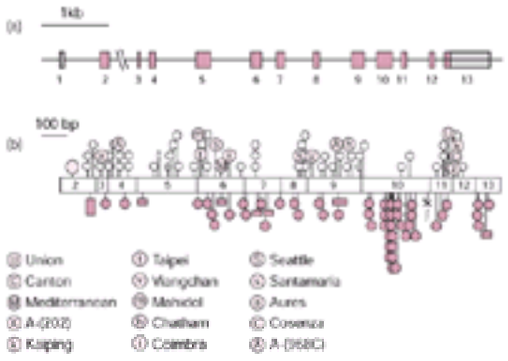

Fig. 4 Hetereogeneity of G6PD deficiency. The 13 exons of the *G6PD* gene are drawn approximately to scale; the introns (not drawn to scale) are shown by thin lines connecting the exons. The location of the mutations for the variants listed in Table 2 are shown; plus that of G6PD Sunderland, as example of an English sporadic variant associated with chronic non-spherocytic haemolytic anaemia and due to a deletion of a triplet of bases, corresponding to codon 35.

Because the G6PD gene is X linked, frequencies of G6PD deficiency in males are identical to gene frequencies, and they are as high as 20 per cent or more in some of the areas just mentioned. The frequency of homozygous females is of course lower, but the frequency of heterozygous females is higher (according to the Hardy–Weinberg rule) than that of G6PD-deficient males. Different G6PD variants underlie G6PD deficiency in different parts of the world: for instance, G6PD Mediterranean on the shores of this sea, in the Middle East, and in India; G6PD A- in Africa and in Southern Europe; G6PD Mahidol in South-East Asia; G6PD Canton in China; and G6PD Union worldwide. It is also important to realize that in some populations several different polymorphic variants coexist. The overall geographical distribution of G6PD deficiency and its heterogeneity, together with findings from clinical field studies and *in vitro* experiments, strongly support the view that this common genetic trait has been selected by *Plasmodium falciparum* malaria, by virtue of the fact that it confers a relative resistance to heterozygotes against this highly lethal infection.

Management

Prevention

The acute haemolytic anaemia of G6PD deficiency is largely preventable by avoiding exposure to triggering factors of previously screened subjects. Of course, the practicability and cost-effectiveness of screening depends on the prevalence of G6PD deficiency in each individual community. Favism is entirely preventable by not eating broad beans. Prevention of drug-induced haemolysis is possible in most cases by choosing alternative drugs. A common practical problem is the need to give primaquine for eradication of malaria due to *Plasmodium vivax* or *P. malariae*; in these cases the administration of a lower dose of the drug for a longer time is the recommended approach: this will still cause haemolysis, but of an acceptably mild degree.

Treatment of acute haemolytic anaemia and favism

A patient with acute haemolytic anaemia may present a diagnostic problem, that once solved, does not require any specific treatment at all; or he or she may be present as a medical emergency requiring immediate action. With severe anaemia, immediate blood transfusion is definitely indicated. If there is acute renal failure, haemodialysis may be necessary. Recovery is the rule.

Management of neonatal jaundice

This does not differ from that of neonatal jaundice due to other causes than G6PD deficiency. In most cases, prompt phototherapy is highly effective and sufficient; but with bilirubin levels above 300 µmo1/1 (or even less in babies who are premature, or who have acidosis or infection), exchange blood transfusion is imperative to

prevent neurological damage.

Management of chronic non-spherocytic haemolytic anaemia

In general terms, this does not differ from that of chronic non-spherocytic haemolytic anaemia due to other causes, for example pyruvate kinase deficiency. If the anaemia is not severe, regular folic acid supplements and regular haematological surveillance will suffice. It will be important to avoid exposure to potentially haemolytic drugs, and blood transfusion may be indicated when exacerbations occur, mostly in conjunction with intercurrent infection. In rare patients the anaemia is so severe that regular blood transfusion is necessary, probably at approximately 2-month intervals, in order to keep the haemoglobin in the 8 to 10 g/dl range. A hypertransfusion regimen aiming to maintain a normal haemoglobin level is not indicated (as there is no ineffective erythropoiesis in the bone marrow). However, in patients requiring regular transfusions, appropriate iron chelation should be instituted by the age of 2 years, and must be continued as long as transfusion treatment is necessary; sometimes the transfusion requirement may decrease after puberty. Although, unlike in hereditary spherocytosis, there is no evidence of selective red cell destruction in the spleen, splenectomy has proved beneficial in severe cases. When a diagnosis of chronic non-spherocytic haemolytic anaemia is made, the family must be given genetic counselling, and an effort should be made to establish whether the mother is a heterozygote; if she is, the chance of recurrence is 1:2 for every subsequent male pregnancy. Prenatal diagnosis can be made by DNA analysis if the mutation is first identified in an affected relative.

22.6.1 The biology of haemostasis and thrombosis

Harold R. Roberts and Gilbert C. White

Introduction

Fluid blood is contained within the vascular tree, but as a result of minor trauma that occurs during the wear and tear of everyday living, leaks occur in the vessel wall that must be sealed by a solid, impermeable fibrin clot in order to prevent significant blood loss. The clot is formed from factors in flowing blood and is located and restricted to the site of the leak without dissemination throughout the vascular tree. This is the process of haemostasis, an exquisitely controlled mechanism that requires components of the vessel wall, blood platelets, and soluble procoagulant and anticoagulant proteins. The haemostatic plug consists of a mass of platelets, red blood cells, and leucocytes enmeshed in interlocking strands of fibrin fibres that plug the leak.

Once formed, the haemostatic plug is gradually replaced by new tissue that results in wound healing. This process requires lysis of the blood clot by the fibrinolytic system and subsequent ingrowth of new cells. Thus, haemostasis is not an isolated phenomenon, but is one component of the defence mechanisms that include inflammation and eventual wound healing.

Thrombosis, as opposed to haemostasis, is a pathological state in which the normal clotting system is disturbed to the extent that a clot is formed that partially or completely obstructs the flow of blood within the blood vessel and sometimes dislodges to become an embolus.

To understand the biology of haemostasis and thrombosis, it is necessary to know the roles of the vessel wall, the platelets, the coagulation and fibrinolytic systems, and their respective inhibitors.

Blood vessel wall

The anatomy of the wall of both an artery and a vein is shown schematically in Fig. 1. All blood vessels are lined by an intima consisting of a monolayer of endothelial cells that rest upon a loose network of tissue called the extracellular matrix. In addition to the intima, larger and intermediate arteries contain two other layers: the media, composed mostly of smooth muscle cells, and the adventitia, consisting largely of connective tissue, nerves, and nutrient vessels. While these three layers also exist in veins, the media and adventitia are much less distinct and are not visible in the smaller arterioles and capillaries.

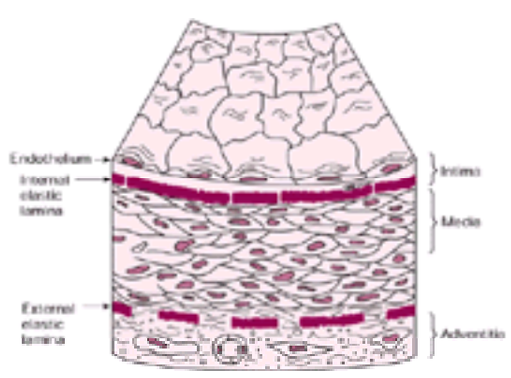

Fig. 1 A schematic diagram of a vessel wall consisting of the intima, the media (smooth muscle cells), and the adventitia. The intima consists of a layer of endothelium that is exposed to the circulating blood. The subendothelial matrix lies below the endothelium and is separated from the media by the internal elastic membrane. See text for detailed description of each layer. (Reprinted by permission, *Robbins pathological basis of disease*, 4th edn, (1989), p.554, WB Saunders Co.)

Endothelial cells

Endothelial cells form the basis of vascular development and are derived from embryonic mesoderm. Embryonic endothelial cells (angioblasts) develop under the influence of growth hormones including basic fibroblast growth factor and vascular endothelial growth factor, both of which interact with receptors on the cell membrane termed receptor tyrosine kinases. These early blood vessels expand into a vascular tree under the influence of two major hormones, angiopoietin 1 and 2, that bind to a family of tyrosine kinase receptors called tie-1 and tie-2 (tyrosine kinase plus Ig and epidermal growth factor-like domains) on endothelial cells. To fully develop into an intact vascular tree, endothelial cells must interact with the extracellular matrix and other cells, a process that requires cell–cell adhesion that is dependent upon cell surface cytoadhesive molecules such as platelet–endothelial cytoadhesive molecule-1, and vascular endothelial cell cadherin. Endothelial cell structure is also dependent upon the integrin family of molecules and interactions with the extracellular matrix.

Endothelial cells are heterogeneous in appearance, function, and genetic regulation. In the brain, endothelial cells form very tight junctions with one another to preserve the blood–brain barrier; in the spleen and liver, the interendothelial gaps are wide, permitting soluble and cellular trafficking between blood and the extravascular space. Not all endothelial cells synthesize the same proteins. Tissue plasminogen activator is synthesized by only about 3 per cent of cells. Von Willebrand factor, often regarded as a specific marker for endothelial cells, is not expressed in all cells. The microenvironment also plays an important role in regulating endothelial cell function. Haemodynamic forces, including hydrostatic pressure, and shear stresses and strains can influence endothelial cell structure and

function. Haemodynamic forces can even regulate endothelial cell gene expression. For example there is a shear stress response element in the gene governing the synthesis of the b chain of the platelet-derived growth factor. Other endothelial cell genes responsive to shear forces include those for: tissue plasminogen activator, intercellular adhesion molecule, and vascular cell adhesion molecule-1.

Endothelial cells contribute to haemostasis by their contributions to vascular tone, procoagulant, anticoagulant, fibrinolytic, and antifibrinolytic activities.

Vascular tone

Vasoregulatory substances produced by endothelial cells are shown in Table 1. The most important vasoregulators are nitric oxide, previously known as endothelial cell-derived relaxation factor and prostacyclin. Nitric oxide and prostacyclin are also important antiplatelet agents. On the other hand, the most important vasoconstrictors are endothelin and angiotensin 2. Endothelin is also a mitogen for smooth muscle cells.

Procoagulant properties

Procoagulant properties of the endothelial cell are depicted in Table 2. von Willebrand factor is synthesized constitutively by endothelial cells and is essential for platelet adhesion to the vessel wall and as a carrier for blood clotting factor VIII. von Willebrand factor is stored in Weibel–Palade bodies, as depicted in Fig. 2. It is released into the circulation in multimers of heterogeneous molecular weight ranging from one to about 20 million. Endothelial cells also secrete very large von Willebrand factor multimers abluminally into the extracellular matrix.

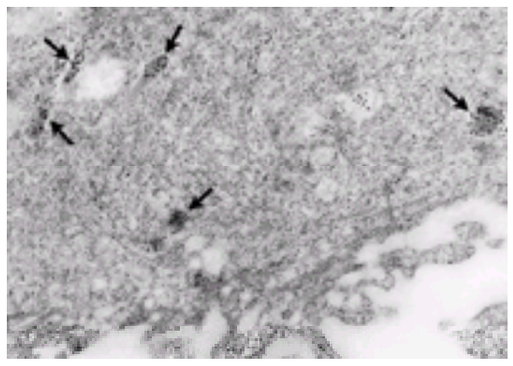

Fig. 2 Electron micrograph of an endothelial cell. Weibel–Palade bodies containing multimers of von Willebrand factor are depicted by the arrows.

Tissue factor acts as a binding protein for factor VII and is essential for the initiation of coagulation. It is not constitutively produced by endothelial cells, but it can be induced by tissue necrosis factor, endotoxin, and other inflammatory substances.

Anticoagulant properties

Anticoagulant properties of the endothelial cells are also shown in Table 2. Prostacyclin not only causes vasodilation, but it is a potent inhibitor of platelet aggregation. Nitric oxide has a similar effect. An important anticoagulant function of endothelial cells is due to the expression of thrombomodulin, a transmembrane-bound protein that acts as a receptor for thrombin. The thrombomodulin/thrombin complex is the physiological activator of protein C, which inactivates clotting factors Va and VIIIa to turn off coagulation. Tumour plasminogen activator (t-PA) is also synthesized by endothelial cells and serves to convert plasminogen to plasmin, the active fibrinolytic enzyme.

Endothelial cells contribute to the control of coagulation by synthesizing tissue factor pathway inhibitor (TFPI), which inhibits the tissue factor-mediated initiation of the clotting reactions. They also secrete glycosaminoglycans, such as heparan sulphate and other proteoglycans that inhibit thrombin. In addition, they express vascular adenosine triphosphate diphosphohydrolase, otherwise known as CD39, on their surface. CD39 acts in concert with 5'ectonucleotidase to convert ATP/ADP to AMP and then to adenosine, which inhibits platelet aggregation.

Receptor function

The receptor function of endothelial cells plays an important role in haemostasis and thrombosis (Table 3). They express a thrombin receptor termed protease-activated receptor 1 (PAR-1). Thrombin cleaves the carboxyterminal end of the receptor, which then binds to the remaining cell-associated protein (a so-called tethered ligand) and triggers intracellular signalling through G proteins, resulting in activation of endothelial cells. The thrombin–thrombomodulin complex not only activates protein C, but also activates a protein known as the thrombin-activatable fibrinolytic inhibitor (TAFI), a procarboxypeptidase that functions to inhibit fibrinolysis. Endothelial cells also express a protein C receptor different from thrombomodulin that acts to modulate the activity of activated protein C. Urokinase plasminogen activator receptors are not found on resting endothelial cells, but are found on those involved in angiogenesis. There are a number of adhesive receptors on the surface of endothelial cells as shown in Table 3. The adhesion of neutrophils is dependent upon the expression of P-selectin. P-selectin is rapidly internalized by the endothelial cell, but this is followed by expression of another cytoadhesive molecule, E-selectin, which is necessary for continued adherence and rolling of neutrophils along the endothelial cell surface. Intercellular adhesion molecule and vascular cell adhesion molecule are receptors for leucocytes and are important for the interaction of leucocytes and the vessel wall.

Extracellular matrix

The extracellular matrix is a complex, heterogeneous structure beneath the endothelium with many interactions related to haemostasis and thrombosis. The matrix consists of a network of collagens, elastins, proteoglycans, and glycoproteins, including fibronectin, vitronectin, laminin, tenascin, thrombospondin, von Willebrand factor, and osteopontin, among others, as shown in Table 4. The matrix proteins promote platelet adhesion, cellular migration, cell proliferation, and endothelial and smooth muscle cell interactions.

Collagens are the most abundant proteins in subendothelial connective tissue. Collagen types I, II, III, IV, V, VI, and VII have been identified in various matrix tissues. The collagens are synthesized by endothelial cells, smooth muscle cells, and by adventitial fibroblasts. The various collagens contribute to the integrity of the vessel wall, but they also play a role in platelet activation and, in some instances, coagulation. For example collagen IV has been shown to be a specific high-affinity binding protein for blood coagulation factor IX, although the function of this complex is not known.

The proteoglycans constitute a heterogeneous group of molecules composed of a core protein attached to a glycosoaminoglycan. These include decorin, biglycan, heparan sulphate, dermatan sulphate, and others. Heparan sulphate, for example, can combine with antithrombin III and inhibit thrombin. The precise role of all of the protoglycans is not known, but some attach to collagen and are necessary for maintaining the structure of the vessel wall.

The matrix also contains elastin, which is secreted by endothelial and smooth muscle cells as tropoelastin that is converted to mature elastin in the matrix where it is assembled into fibres. One function of elastin is simply to maintain the elastic structure of the vessel wall. This substance is found interspersed between smooth muscle cells as well as the matrix. It may also function in cell migration from the vessel wall to the extravascular space.

Fibronectin, vitronectin, and laminins are also components of the extracellular matrix which function in fibrinolysis and platelet adhesion.

Within the extracellular matrix there are a number of matrix metalloproteinases (MMP), which are a group of enzymes useful in matrix degradation and repair. They are secreted as proenzymes and converted to active enzymes that are zinc- or calcium-dependent. They have several functions, as listed in Table 5. Their activities

in matrix degradation and repair are controlled by tissue inhibitors of metalloproteinases.

Smooth muscle cells

The smooth muscle cell layer, found in medium and larger sized vessels and more prominently in arteries, has several functions related to the biology of haemostasis and thrombosis. Smooth muscle cells possess contractile, biosynthetic, and proliferative functions. Contractile properties, governed by such substances as nitric oxide, prostacyclin, and endothelin, play important roles in vasodilation and vasoconstriction, respectively. Smooth muscle cells, like endothelial cells, synthesize growth factors such as vascular endothelial growth factor, insulin-like growth factors, epidermal growth factors, activins, and others that are important in smooth muscle cell generation. Smooth muscle cell proliferation is a hallmark of the atherosclerotic lesion. Biosynthetic products of the smooth muscle cells include various types of collagens, elastin, glycoproteins, and proteoglycans. When exposed to injury, smooth muscle cells can also produce tissue factor.

The adventitia

The adventitia is composed of a loose network of cells consisting of fibroblasts, adipocytes, and mast cells. Collagens I and III, glycoproteins, and elastin are synthesized by fibroblasts. Fibroblasts also contain tissue factor. Adipocytes secrete collagen I and III and synthesize lipids.

Platelets

Platelets are the smallest of the circulating blood cells, about 0.5 µ in diameter. They are derived from the cytoplasm of megakaryocytes and are an essential component of the haemostatic plug. Although they are anucleate and appear to be single cells composed of cytoplasm, a surface canalicular system, and storage granules († or dense granules and a granules); they are, nevertheless, complicated cells with a variety of very important functions essential for normal haemostasis. These can be broadly divided into the following:

1. platelet adhesion, defined as platelets adhering to the damaged area of the vessel wall where subendothelial matrix tissue is exposed;
2. platelet activation, both by agents within the matrix as well as by soluble agonists;
3. platelet aggregation, defined as platelets sticking to one another in an aggregated mass, forming a platelet plug.

The following sections describe each of these broad areas of platelet function in more detail.

Platelet adhesion

The initial platelet response to vascular injury is adhesion to the vessel wall. Resting, non-activated platelets are not attracted to the vessel wall. However, following vascular damage, platelets rolling along the endothelium rapidly adhere to the subendothelial interstitial matrix. A number of matrix proteins, such as von Willebrand factor, fibronectin, fibrinogen, and thrombospondin, are also present in platelet granules and circulate in plasma.

Platelets possess numerous mechanisms for adhering to the subendothelial matrix (Fig. 3). Adhesion is accomplished by a number of protein receptors on the surface of platelets as described below.

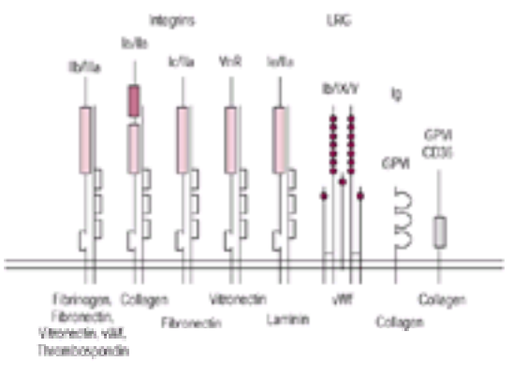

Fig. 3 Receptors mediating the interaction of platelets with subendothelial matrix proteins. Adhesion receptors on platelets include members of the integrin family, leucine-rich glycoproteins (LRG), members of the immunoglobulin (Ig) family, and others. Integrins on the surface of platelets are glycoproteins (GP) IIb/IIIa, which binds multiple ligands; GPIa/IIa, a collagen receptor, GPIc/IIa, which binds fibronectin; VnR, which is a receptor for vitronectin; and GPIc'/IIa, a laminin binding site. Glycoproteins Ib/IX/V are leucine-rich glycoproteins. Glycoprotein VI (GPVI) is a member of the immunoglobulin family and a collagen receptor. Glycoprotein IV (GPIV, CD36) is also a collagen receptor.

Glycoprotein Ib–IX–V (CD42a–d)

The main function of the platelet membrane glycoprotein Ib–IX–V complex is to act as a receptor that mediates von Willebrand-dependent binding of platelets to collagen, resulting in adhesion of platelets to the vessel wall. Glycoproteins Iba, Ibb, IX, and V are members of the leucine-rich glycoprotein family and are characterized by the presence of a common structural motif in the extracellular domain composed of a leucine-rich sequence, PXXLLXXXXXLXXLXLSXNXLXXL *. GPIba contains seven leucine-rich repeats, GPV contains 15 leucine-rich repeats in the extracellular domain, while GPIbb and GPIX each contain a single leucine-rich repeat, all in the extracellular domains. GPIba, GPIbb, GPIX, and GPV are synthesized as separate gene products which coassociate in a ratio of 2:2:2:1 during transit through the endoplasmic reticulum. Coassociation of GPIba, GPIbb, and GPIX, but not GPV, is required for the complex to be expressed on the surface of cells. The role of GPV, a substrate for thrombin, in the function of the complex is uncertain, and mice deficient in GPV bind von Willebrand factor normally and have normal platelet adhesion.

Adhesion to von Willebrand factor-coated surfaces through GPIb–IX–V is increased by shear, which is thought to induce a structural change in the receptor that enhances the interaction with von Willebrand factor. The A1 domain of von Willebrand factor forms the principal site that interacts with GPIb. The site in GPIb that binds von Willebrand factor is less well defined. Binding occurs in the amino-terminal, 45-kDa, tryptic fragment from GPIba. Within this region of GPIba, an anionic site, YDYYPEE^{282}, containing two sulphated tyrosine residues at tyrosines 278 and 279, has been further implicated in von Willebrand factor binding. The A3 domain of von Willebrand factor mediates the interaction with collagens type I and III. A model derived from the crystal structure of the von Willebrand factor A3 domain suggests that the von Willebrand factor–collagen interaction is primarily between negatively-charged residues in the A3 domain and positively-charged residues in collagen. Plasma von Willebrand factor does not interact with unstimulated circulating platelets. For binding to occur, platelets have to be activated and plasma von Willebrand factor must undergo a conformational change. After secretion by endothelial cells, von Willebrand factor binds to underlying connective tissue matrix, providing an active surface for platelet attachment after the vessel wall is damaged.

Glycoprotein IIb–IIIa (aIIb/b3)

Under conditions of low shear, platelets can adhere to matrix-bound von Willebrand factor through a mechanism that involves platelet GPIIb–IIIa. GPIIb and IIIa are members of the integrin superfamily, a conserved family of heterodimeric surface receptors, each composed of a larger two-chain a subunit and a smaller b subunit, bound non-covalently. Integrins were initially identified by an ability to bind adhesive glycoproteins containing a tripeptide sequence, arginine–glycine–aspartic acid (RGD), although subsequent work has identified other ligand sequences recognized by integrins. The interaction of von Willebrand factor with GPIIb–IIIa is mediated by an RGD sequence in the C1 domain of von Willebrand factor. GPIIb–IIIa is also able to bind fibronectin, thrombospondin, and vitronectin and may therefore represent an adhesion receptor with broad specificity.

Glycoprotein Ia–IIa (a2b1)

GPIa–IIa is a receptor for types I and IV collagen and mediates platelet adhesion to the vessel wall independent of von Willebrand factor. The integrin sequences that mediate the interaction with collagen reside in a broad sequence called the I domain in the extracellular portion of the molecule. GPIa–IIa is constitutively active and does not require activation to interact with collagen.

Glycoprotein VI–Fc receptor g-chain complex

GPVI–FcRg is the major platelet receptor mediating collagen-induced activation of platelets. GPVI is a member of the immunoglobulin superfamily and is characterized by immunoglobulin domains, a transmembrane domain, and a short cytoplasmic tail that lacks known signalling components. GPVI is associated on the platelet surface with FcRg, apparently in a 1:1 stoichiometry. The complex binds collagen and mediates collagen-generated signals, presumably through the ITAM (or immunoglobulin receptor tyrosine-based activation motif) of FcRg. Crosslinking of GPVI–FcRg leads to tyrosine phosphorylation of the ITAM sequence by Src kinase. Syk, another tyrosine kinase, binds to the phosphorylated ITAM sequence through Syk sulphydryl domains, initiating a signal that leads to tyrosine phosphorylation of phospholipase Cg2 and the generation of inositol phospholipids.

Glycoprotein IV (CD36)

CD 36 is a highly glycosylated transmembrane protein present on platelets, monocytes, endothelial cells, and nucleated erythrocytes, which binds thrombospondin and collagen. The thrombospondin-binding site has been mapped to a single disulphide loop in the extracellular domain of GPIV, but the collagen-binding site is unknown. Although GPIV is a receptor for collagen *in vitro*, individuals with a deficiency of GPIV have no apparent defect in platelet function.

Other adhesion receptors

Platelets can also adhere to subendothelial matrix through glycoprotein Ic–IIa (VLA-5, a5b1), glycoprotein Ic'–IIa (VLA-6, a6b1), or the vitronectin receptor (avb3, VnR). GPIc–IIa is a constitutively active receptor for fibronectin that does not require cell activation. There are two sequences in fibronectin which interact with GPIc–IIa: an RGD sequence in the tenth type III repeat which interacts primarily with the GPIIa (b1) subunit and a synergy sequence in the adjacent ninth type III repeat which interacts primarily with the GPIc (a5) subunit. GPIc'–IIa is a laminin receptor which is expressed on platelets. Immunoprecipitation studies suggest that GPIc'–IIa may exist on the cell surface in a complex with proteins with four transmembrane domains, so-called TM4 proteins, such as CD9, CD81, and NAG-2. The nature of these interactions is presently unclear. GPIc'–IIa recognizes a sequence in the long arm E8 fragment of laminin obtained after elastin digestion. The binding requires the presence of divalent cations which bind to specific sites on the integrin a subunit. Small numbers of the vitronectin receptor are expressed on platelets.

Current evidence indicates that all of these adhesion mechanisms may be important. The redundancy in adhesion receptors may:

1. provide backup mechanisms to protect against blood loss;
2. generate different signals in response to interaction with different matrix proteins; or
3. represent different systems at work in different parts of the vascular tree.

An example of the latter might be the relative roles of GPIb–IX–V and GPIIb–IIIa in the von Willebrand factor-mediated adhesion of platelets to collagen. Under high shear conditions, as found in capillaries and small arterioles, GPIb–IX–V may be the predominant mechanism mediating platelet adhesion to collagen and von Willebrand factor-dependent adherence whereas, under low shear conditions, like those found in large veins and in arteries, GPIb–IX–V may be less effective and other mechanisms that require a shorter residence time of platelets on the subendothelial matrix, including GPIc–IIa interaction with fibronectin and GPIa–IIa interaction with collagen, may be important. The presence of multiple receptors for collagen on the platelet surface, including GPIb–IX–V, GPIIb–IIIa, GPIa–IIa, GPIV, and GPVI, is interesting and raises the possibility of different collagen responses. Vitronectin also appears to be important for adhesion at high shear, and can bind to both GPIIb–IIIa and specific vitronectin receptors. Recent evidence suggests that platelet adhesion to collagen types I and III in flowing blood is dependent on both von Willebrand factor and fibronectin. Collagen types I, II, and III have been shown to bind von Willebrand factor.

Platelet activation

Following adhesion and in response to soluble agonists such as thrombin, platelets undergo a series of complex biochemical reactions leading to cell activation. As a result, platelets undergo changes in shape, alterations in surface lipid composition leading to the generation of platelet coagulant activity and thrombin generation, and secretion of the contents of intracellular granules leading to the release of ADP. The thrombin generated at the platelet surface and ADP secreted from platelet granules lead to activation of additional platelets. These reactions involve the metabolism of membrane inositol phospholipids, changes in cellular levels of calcium, activation of contractile proteins, stimulation of heterotrimeric and low molecular weight GTP-binding proteins, and tyrosine and serine–threonine phosphorylation of proteins, among other events. These biochemical reactions initiate second messenger signals that drive the functional changes that occur in platelets which transform them from the resting state to an activated one, and which play a crucial role in haemostasis. Some of these signalling pathways are described in the following sections (see Fig. 4).

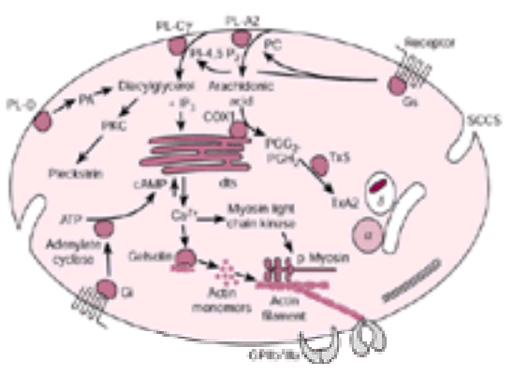

Fig. 4 Signalling pathways involved in platelet activation. Following the interaction of agonist with receptor, there is G protein (Gs)-coupled activation of phospholipid metabolic pathways through phospholipase A_2 (PL-A2), phospholipase Cg (PL-Cg), and phospholipase D (PL-D) leading to generation of thromboxane A_2 (TXA2), inositol trisphosphate (IP_3), diacylglycerol, and phosphatidic acid (PA). Arachidonic acid generated by the action of phospholipase A_2 is converted by cyclo-oxygenase-1 (COX-1) to prostaglandin endoperoxides G_2 (PGG_2) and H_2 (PGH_2) which are, in turn, converted to thromboxane A_2 through the action of thromboxane synthase (TXS). Thromboxane generated through arachidonate metabolism is thought to play a role in secretion, through the fusion of a-granule (a) and dense granule (†) membranes with the membrane of the surface-connected canalicular system (SCCS). Granule contents, including adenosine diphosphate, are emptied into the SCCS and make their way to the outside of the cell. Diacylglyerol stimulates activation of protein kinase C (PKC), resulting in serine–threonine phosphorylation of proteins such as pleckstrin. Inositol trisphosphate stimulates calcium release from storage sites in the dense tubular system (dts). The release of calcium from the dense tubular system is antagonized by cyclic AMP, generated through G protein (Gi)-coupled inhibitory receptor activation of adenylate cyclase. Calcium, released in response to IP_3, activates gelsolin, an actin-capping and -severing protein, which generates actin monomers that then serve as nucleation sites for formation of actin filaments and assembly of the activation-dependent cytoskeleton. Assembly of the cytoskeleton and interaction of the cytoskeleton with surface integrins such as glycoproteins IIb and IIIa (GPIIb/IIIa) may be involved in integrin activation. Calcium also activates myosin light chain kinase which phosphorylates myosin light chain-generating actinomyosin contraction, important for changes in platelet shape and the secretion process.

Phospholipid metabolism

Metabolism of membrane phospholipids is one of the first signalling pathways identified in platelets and remains one of the most important. Platelet stimulation by a

variety of agonists results in activation of membrane-associated phospholipases, including phospholipases C, A2, and D, which cleave fatty acids from the phospholipid. The lipid products generated by these pathways are signalling compounds which are important for changes in cytoplasmic calcium and activation of kinases and phosphatases.

The most intensively studied of these pathways is the metabolism of inositol phospholipids through phospholipase C. Membrane phosphatidylinositol (PI) exists in multiple phosphorylation states: PI, PI-P, PI-P2 which is phosphorylated in the 3,4 or 4,5 positions, and PI-P3 which is phosphorylated in the 3,4,5 positions. Phosphatidylinositol-specific kinases and phosphatases maintain pools of phosphorylated phosphoinositides in a proper concentration range. Platelets contain several isoforms of phospholipase C which are activated by different mechanisms. All cleave phosphatidylinositol 4,5-bisphosphate (PI 4,5-P2) and, later, phosphatidylinositol, as well as phosphatidylinositol 4-phosphate (PI 4-P), to yield diglyceride and inositol trisphosphate (IP3). Phospholipase Ca and Cb are coupled to heterotrimeric G proteins where phospholipase Cg is coupled to growth factor receptors. Inositol trisphosphate (IP_3) generated by phospholipase C cleavage of inositol phospholipids has been implicated in the release of calcium from intracellular storage sites in the platelet-dense tubular system. The other product of phospholipase C cleavage, diacylglycerol, activates protein kinase C, which phosphorylates pleckstrin, a 47 000-dalton protein, and other proteins.

Phospholipase A2 is linked to G-protein coupled receptors and cleaves fatty acids in the *sn*-2 position in membrane phospholipids, primarily phosphatidylcholine. In most individuals in western society, the fatty acid in this position is arachidonic acid. Arachidonic acid, liberated by the action of phospholipase A2, is converted to a variety of possible products by the microsomal enzymes, cyclo-oxygenase and lipoxygenase. Cyclo-oxygenase converts arachidonic acid to prostaglandin endoperoxides, prostaglandins F_2, E_2, and D_2, whose main fate in platelets is rapid conversion to thromboxane A_2 by thromboxane synthase. Thromboxane A_2 is believed to play an important role in the release of intracellular granules by acting as a membrane fusogen, fusing granule membranes with the membrane of the surface connected canalicular system and permitting secretion of the granule contents to the outside of the cell. Thromboxane A_2 is also an exceptionally potent constrictor of vascular smooth muscle and a strong platelet-aggregating agent.

Inhibition of the arachidonate pathway has been a primary target for platelet inhibition. Cyclo-oxygenase is irreversibly inhibited by aspirin, which acetylates serine 340, and reversibly inhibited by non-steroidal anti-inflammatory agents. Inhibition of cyclo-oxygenase inhibits thromboxane formation and results in inhibition of the release of intracellular granules. The mechanism by which aspirin is thought to act as an anti-atherosclerosis agent is by inhibition of the release of platelet-derived growth factor.

Phospholipase D acts primarily on phosphatidylcholine to produce choline and phosphatic acid. Protein kinase C and PI-P2 play an important role in activation of phospholipase D. Phosphatidic acid is an intracellular messenger which is proposed to play a role in platelet activation. In addition, phosphatidic acid can be converted to lysophosphatidic acid through the action of phospholipase A2. Like phosphatidic acid, lysophosphatidic acid is an intracellular messenger which is involved in phospholipase activation, ras signalling, and cytoskeleton reorganization.

Calcium metabolism

In resting platelets, the cytoplasmic concentration of calcium is maintained at a low level by active transport of calcium both outside the cell and into the dense tubular system, a sarcoplasmic reticulum-like fraction in platelets. This transport is accomplished by a plasma membrane sarcoplasmic-endoplasmic-reticulum-like calcium ATPase (SERCA2-b), a dense tubular system SERCA3, a sodium-calcium exchange pump in the plasma membrane, and passive calcium fluxes. During platelet activation, inositol trisphosphate (IP_3), generated by metabolism of membrane inositol phospholipids, induces the rapid release of calcium stored in the dense tubular system. This increase in cytoplasmic calcium is essential for platelet activation, and agents that inhibit increases in cytoplasmic calcium inhibit platelet activation while agents that increase cytoplasmic calcium stimulate platelet activation.

Calcium functions as a major intracellular messenger in platelets, mediating calcium-dependent reactions important in almost all phases of platelet activation. An increase in the concentration of cytoplasmic free calcium activates gelsolin, the calcium-dependent actin capping and severing protein, which plays an important role in reorganization of the cytoskeleton. Calcium also activates the calcium and calmodulin-dependent myosin light chain kinase, leading to phosphorylation of myosin light chains, activation of actin-stimulated myosin ATPase activity, and the development of contractile forces. The contraction generated by actin and myosin mediates changes in platelet shape and is important for events leading to platelet secretion. In the absence of calcium ions, tropomyosin inhibits the interaction of myosin with actin, and this may be an additional regulatory role of calcium in platelets. Calpain, a calcium-dependent thiol protease, hydrolyzes numerous proteins involved in platelet signalling. Activation of calpain is believed to be important both for regulation of cytoskeletal events and integrin-mediated signalling.

Cytoskeletal reorganization

Resting platelets are discoid in shape and feature a cellular cytoskeleton that consists of a network of actin filaments that fill and shape the cytoplasm of the cell and a single microtubule coil at the margin of the disc. Upon activation, platelets undergo remarkable morphological changes (Fig. 5). There is an initial change from the normal discoid shape of the resting platelet to a sphere as calcium levels in the cell increase. Filamentous actin appears in the form of stress fibres, and the cellular content of filamentous actin increases. Membrane ruffles form as well as long cellular projections called pseudopodia. Actin cables are present in these pseudopodia, extending to the end of the projections. Also during activation, microtubules contract and 'squeeze' granules toward the centre of the cell.

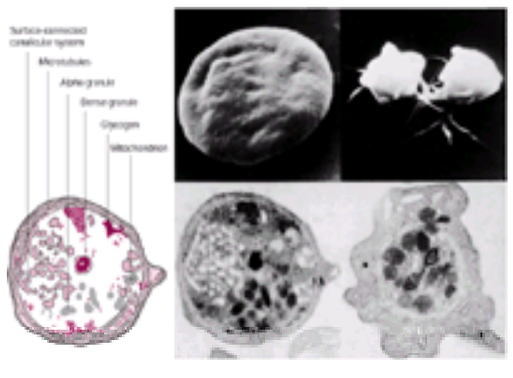

Fig. 5 Platelet morphology. Platelets are small, anucleate cells. In the resting state (a), platelets are ducoid shaped and contain a marginal rim of microtubreles. After activation (b), platelets undergo changes in shape, becoming more rounded and extending cytoplasmic projections, called pseudopods, outward.

The energy for contraction is provided by a magnesium ion-dependent ATPase present in myosin and stimulated by actin. Contraction occurs by actin filaments and myosin rods sliding over one another. Myosin light-chain phosphatase may switch off myosin. Membrane glycoproteins GPIIb–IIIa, GPIb–IX–V, and other membrane proteins are associated with the cytoskeleton and provide direction for the contractile process. This activation-dependent cytoskeleton is more than just a structural scaffold for platelet shape changes. Numerous signalling proteins are incorporated into the cytoskeleton and may function in specialized compartments by virtue of their association with the cytoskeleton.

Platelet coagulant activity (platelet factor 3)

Platelet membranes have an asymmetrical distribution of phospholipids, with almost all of the acidic (negatively charged) phospholipids, such as phosphatidyl serine and phosphatidyl inositol, located in the inner leaflet of the plasma membrane. After platelet activation, the acidic phospholipids are translocated to the outer half of the membrane, while phosphatidylcholine moves to the inner half, in a phenomenon known as a 'flip-flop' reaction. This transbilayer movement of phospholipids in the platelet membrane is not well understood, but evidence for a 'flipase' which enzymatically contributes to it has been presented. There is also a translocase enzyme that works in the opposite way and is capable of restoring the acidic phospholipids to the inner leaflet of the membrane bilayer.

The exposed phosphatidyl serine and other negatively-charged phospholipids account for some of the activity traditionally known as platelet factor 3 by contributing to surface properties for binding of factor X and prothombin activation complexes. This interaction with platelet phospholipids increases the rate of factor X activation and prothrombin activation nearly a thousand fold. In addition to phospholipids on the platelet membrane, there appear to be other specific binding proteins for blood

clotting factors.

Secretion

A primary endpoint of platelet activation is the secretion of platelet granule contents to the outside of the cell. During platelet activation, the granules are 'squeezed' to the centre of the cell where the granules fuse with the surface-connected canalicular system, a series of intracellular canals that are connected to the cell surface. The contents of the granules make their way to the outside of the cell. Secretion requires prostaglandin metabolism and is dependent on contractile events. Products of prostaglandin metabolism, primarily thromboxane A2, may act in the fusion of the granule membrane with that of the surface-connected canalicular system.

Platelets possess two types of storage granules (Table 6), both of which are involved in secretion of active ingredients that modulate platelet function. One type is the dense granule, so called because it is dense by electron microscopy. The other type is the a-granule.

Dense granules contain adenine nucleotides, calcium, and serotonin. Adenine nucleotides are sequestered in the dense granules mainly as adenosine diphosphate (ADP) and adenosine triphosphate (ATP) in a complex with calcium ions and pyrophosphate, and are not interchangeable with the nucleotides involved in general cell metabolism. ADP released from platelet-dense granules activates additional platelets and recruits them to the growing platelet thrombus. Serotonin, a potent modulator of vascular tone and integrity, is also a constituent of dense granules.

a-Granules contain platelet-derived growth factor, b-thromboglobulin, platelet factor 4, fibrinogen, factor V, von Willebrand factor, and thrombospondin. Platelet-derived growth factor is mitogenic for smooth-muscle cells and when released from platelets at a site where the vessel wall is damaged, it stimulates proliferation and migration of smooth-muscle cells in the intima, contributing to the atherosclerotic process. b-Thromboglobulin and platelet factor 4 are basic, lysine-rich proteins which interact with glycosaminoglycans such as heparan sulphate, dermatan sulphate, and chondroitin sulphate, which are components of the endothelial cell surface. Platelet factor 4 has a strong heparin-neutralizing activity and has been implicated in the aetiology of heparin-induced thrombocytopenia. Thrombospondin is a major a-granule glycoprotein, but it is also secreted by fibroblasts, endothelial, and smooth-muscle cells. Thrombospondin is a high-molecular-weight adhesive protein which binds to glycosaminoglycans, fibrinogen, plasminogen, histidine-rich glycoprotein, type V collagen, and calcium ions. It associates with cell surfaces and extracellular matrices and facilitates cell–cell and cell–matrix interactions.

cAMP pathway

The major mechanism for down-regulation of platelet function is the stimulation of adenylate cyclase, which increases cAMP concentrations. Adenylate cyclase is mainly localized in microsomal fractions and is stimulated by adenosine, prostacyclin, and prostaglandin E_1. cAMP inhibits platelet aggregation, platelet secretion, and platelet adhesion to the vessel wall. These effects are probably exerted by inhibiting calcium flux and/or promoting calcium reuptake.

Activation by soluble agonists

In addition to activation through interaction with subendothelial connective tissues, platelets may also be activated by soluble agonists. These include adenosine diphosphate (ADP), epinephrine, and thrombin. In general, this activation occurs through the interaction between soluble agonist and specific receptors on the platelet surface.

Thrombin is one of the most powerful of platelet agonists. Generated during blood coagulation, thrombin activation of platelets occurs through a novel family of receptors called protease-activated receptors (PARs). These are G protein-coupled, seven-membrane-spanning molecules which are activated by proteolysis. Thrombin cleaves the amino terminal exodomain, unmasking a new amino terminal, which functions as a tethered peptide agonist. The tethered peptide binds intramolecularly to the remainder of the receptor to trigger activation. Four members of the PAR family of receptors have been identified. PAR 1 and PAR 4 mediate activation of human platelets by thrombin.

Thrombin interacts with other proteins on the surface of platelets, but the nature of these interactions is uncertain. Glycoprotein V, part of the GPIb–IX–V complex is a substrate for thrombin although the absence of GPV does not appear to inhibit thrombin activation of platelets. GPIb is an equilibrium binding site for thrombin. Patients with a deficiency of GPIb have been reported to have changes in the rate of activation of platelets by thrombin which is overcome at higher concentrations of agonist.

There are at least three receptors for ADP on platelets, all members of the seven membrane-spanning purinergic (P2) receptor family, either P2Y (G-protein-coupled purinergic receptors) or P2X (ligand-gated channel receptors). One receptor, designated P2Y1, is coupled to phospholipase C, probably through Gq. A second receptor, $P2T_{AC}$, is coupled to adenylate cyclase, probably through Gi. The third receptor, P2X1, is coupled to rapid calcium influx and is a member of the intrinsic ion channel family. Full platelet activation by ADP probably involves an interaction of ADP with all three receptors. ADP-induced activation of the GPIIb-IIIa on platelets requires both P2Y1 and $P2T_{AC}$ and concomitant signalling through GTP-binding proteins, Gq and Gi.

Platelet aggregation

Platelet aggregation, the interaction of one platelet with another, is a major function of platelets and is very important in the haemostatic process. The formation of an aggregated platelet-mass at the site of injury provides a physical plug that occludes the defect in the vessel wall and prevents blood loss.

Aggregation is mediated by two glycoproteins on the platelet surface, GPIIb–IIIa, which constitute a receptor for fibrinogen–fibrin. Thus, GPIIb–IIIa on one platelet binds fibrinogen or fibrin which, by virtue of its dimeric structure, interacts with GPIIb–IIIa on another platelet. On resting platelets, GPIIb–IIIa is in an inactive state and is unable to bind fibrinogen. Following platelet activation, GPIIb–IIIa becomes activated through a process that involves calcium, protein kinase C, and heterotrimetric G proteins. Activation of GPIIb–IIIa requires energy and is a multistep process. Fibrinogen binding to GPIIb–IIIa occurs through a carboxy-terminal dodecapeptide sequence, HHLGGAKQAGDV, in the g chain of fibrinogen where the AGDV sequence has been suggested to have structural similarity to the RGD sequence.

Blood coagulation

The blood coagulation system consists of a number of zymogens (proenzymes) that are proteolytically converted to active enzymes in a series of steps involving activators and cofactors. The coagulation reactions are initiated by tissue factor in complex with activated factor VII (VIIa). The tissue factor /VIIa complex then activates both factor IX and factor X, which, in the presence of their respective cofactors (factors VIII and V), lead to the rapid conversion of prothrombin to thrombin. The latter converts fibrinogen into a solid fibrin clot that finally undergoes cross-linking by activated factor XIII to become a stable haemostatic plug. Platelets are essential in several steps of the clotting mechanism and form the surface for activated clotting factors, which lead to the explosive generation of thrombin.

Understanding the modern concept of the clotting reactions requires a detailed knowledge of each factor. Table 7 depicts the clotting factors and their inhibitors, including the vitamin K-dependent clotting proenzymes, the non-vitamin K-dependent zymogens, the cofactors, the inhibitors of the clotting factors, and the structural proteins.

The vitamin K-dependent zymogens

The vitamin K-dependent blood clotting zymogens include: prothrombin, factor VII, factor IX, factor X, and protein C; their characteristics are listed in Table 7 and their schematic structures in Fig. 6. A common feature of all these clotting factors is the presence of gamma carboxyglutamic acid (Gla) domains in the amino terminal region of the molecules. Glutamic acid residues in these proteins undergo carboxylation, a post-translational event that is effected by hepatic carboxylase that requires reduced vitamin K as a cofactor. The vitamin K-dependent factors are highly homologous in terms of amino acid sequence. Factors VII, IX, X, and protein C have a similar domain structure with a Gla domain, two epidermal growth factor-like (EGF) domains, and a catalytic domain (Fig. 6). Prothrombin differs from other vitamin K-dependent factors in that it has two kringle domains (Fig. 6). Both factor X and protein C are secreted as two-chain zymogens while the others are single-chain proteins.

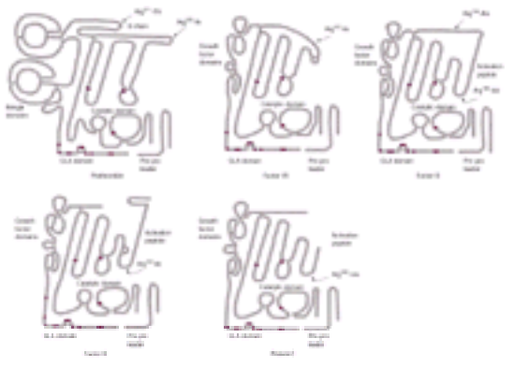

Fig. 6 Schematic diagram of the vitamin K-dependent factors, prothrombin and factors VII, IX, X, and protein C. •, closed circles are gamma carboxyglutamic acid residues; _, represents active site triad of serine, histidine, and aspartic acid; arrows denote cleavage site. (Reprinted by permission of McGraw-Hill Companies from Roberts HR *et al*. (2001). Molecular biology and biochemistry of the coagulation factors. *Williams Hematology*, 6th edn, p.141.)

The Gla domains of these factors are necessary for binding to phospholipid membranes. Calcium ions occupy the Gla domain to result in a conformational change in the protein that favours binding to platelet membrane surfaces. Phosphatidylserine is the major phospholipid in these reactions.

The vitamin K zymogens are all serine proteases with the typical active site: a serine/histidine/aspartic acid triad. Exposure of the active site requires that the zymogen be activated by cleavage of specific arginyl residues. As a result, all the activated vitamin K-dependent zymogens become two-chain enzymes linked by disulphide bonds, as depicted in Fig. 6. Despite the high degree of sequence homology of these proteins, they are highly specific in their interaction with their cofactors and substrates.

Prothrombin

Prothrombin is synthesized in the liver and has a molecular weight of about 72 000 daltons. The molecule has 10 Gla residues that play a role in the binding of the prothrombin to the surface of activated platelets where it is converted to the active enzyme, thrombin, by the so-called 'prothrombinase complex' consisting of factors Xa/Va/Ca^{++} on the platelet surface. Thrombin is a potent enzyme with a molecular weight of about 38 000 that rapidly converts fibrinogen to a fibrin clot. Thrombin also has many other actions including its role as: a potent activator of platelets; an activator of factor V, VIII, and XIII; an activator of protein C in the presence of its cofactor, thrombomodulin; an activator of procarboxypeptidase to form a thrombin-activatable fibrinolytic inhibitor (TAFI); and as a growth factor. The primary inhibitor of thrombin is antithrombin III.

Factor VII

Factor VII is synthesized in the liver and has a molecular weight of about 50 000 daltons. It has a very short half-life of about 3.5 h. The specific receptor for factor VII is tissue factor found on the surface of many cells such as fibroblasts, activated monocytes, and many other cell types. The physiological activator of factor VII is unknown, although it has been suggested that it might be activated by factor Xa. The factor VII/tissue factor complex activates both factors IX and X. The factor VII–tissue factor –Xa complex is inhibited by tissue factor pathway inhibitor (TFPI). Factor VIIa is not appreciably inhibited by antithrombin III except in the presence of heparin.

Factor IX

Factor IX is synthesized by hepatocytes and has a molecular weight of about 57 000 daltons. Its plasma half-life is 18 to 24 h. The molecule has 12 Gla residues. About 40 per cent of the factor IX molecules carry a b-hydroxyaspartic acid at position 64 of the molecule. It is activated by VIIa–tissue factor and by activated factor XI, both of which cleave an arginyl bond at position 145 and 180 of the molecule to release an activation peptide of about 10 000 daltons. Factor IXa in complex with its cofactor, activated factor VIII, cleaves factor X to Xa. Antithrombin III will inhibit factor IXa, but the inhibition is not as rapid as the antithrombin III inhibition of thrombin or factor Xa.

Factor X

Factor X is also synthesized by hepatocytes and has a molecular weight of 59 000. It is secreted as a two-chain molecule linked by disulphide bonds. It has 11 Gla residues. When activated by factor IXa or VIIa–tissue factor, an activation peptide is cleaved from the heavy chain to expose the serine-active site on the heavy chain. Factor Xa, in the presence of its cofactor (factor Va), rapidly converts prothrombin to thrombin. The primary inhibitor of factor Xa is AT III.

Protein C

Protein C, unlike the other vitamin K-dependent zymogens, is not a procoagulant, but, when activated by the thrombin–thrombomodulin complex on the surface of endothelial cells, it becomes an anticoagulant by proteolytically cleaving factors Va and VIIIa, thus inhibiting coagulation. To function in this way as an anticoagulant, activated protein C (APC) requires a cofactor, protein S. Protein C is synthesized in the liver and has a very short half-life of about 6 h. It contains nine Gla residues and has a molecular weight of 59 000 daltons. The primary inhibitor of APC is the protein C inhibitor (PCI), also known as plasminogen activator inhibitor-3 (PAI-3).

The non-vitamin K-dependent zymogens

Factor XI

Factor XI is synthesized in the liver as a dimeric protein composed of identical subunits. It has a molecular weight of 160 000 daltons and a plasma half-life of about 72 h (Table 7). In plasma, factor XI circulates in complex with high molecular weight kininogen (HK), a non-enzymatic cofactor. The physiological activator of factor XI is thought to be thrombin, although *in vitro*, this factor can be activated by factor XIIa. The main function of factor XIa is to boost thrombin generation by activating factor IX on the surface of platelets, over and above the factor IX activated by the VIIa–tissue factor complex. Some patients with factor XI deficiency have no bleeding tendency, and those who do usually exhibit mild bleeding when compared to severely affected haemophilic patients.

Factor XII and prekallikrein (PK)

These factors have been collectively referred to as contact factors since it appears that activation of factor XII is enhanced by contact with a surface. Factor XII and PK are zymogens, which, when activated, expose a serine-active site (Table 7). HK is a non-enzymatic protein cofactor that circulates in complex with factor XI and PK. All of these factors are synthesized in the liver. Unlike the vitamin K-dependent proteins, factors XI, XII, and prekallikrein all possess so-called 'apple domains' that have specific functional characteristics. Deficiencies of factor XII and PK are not associated with bleeding tendencies in patients with complete deficiency of these factors. However, deficiency of each factor is associated with a marked prolongation of the partial thromboplastin time (PTT). In this test and in the presence of glass, ellagic acid, or some inert earth material, factor XII can activate factor XI. These factors may not play a major physiologic role in haemostasis, but there is evidence that they do participate in inflammatory responses that involve blood coagulation, fibrinolysis, and kinin generation.

The cofactors

Some of the cofactors are soluble and exist in circulation, namely protein S, protein Z, factors V and VIII, high molecular weight kiningen (HK), and von Willebrand factor (Table 7). Others are cell-bound, such as tissue factor and thrombomodulin.

Protein S

Protein S is synthesized in the liver and endothelial cells. It circulates in plasma and is also found in platelets. It has a molecular weight of 75 000 daltons and a plasma half-life of about 42 h. It contains 11 Gla residues in the amino terminal region. In structure, protein S differs dramatically from the other vitamin K clotting factors in that the carboxy terminal end is homologous to growth hormone. Protein S acts as a cofactor for activated protein C. Protein S exists in two forms: one form is bound to C4b-binding protein and the other exists as a free form in the circulation. Free protein S is a cofactor for protein C and is in equilibrium with the bound form.

Protein Z

Protein Z is synthesized in the liver and has a molecular weight of 62 000 daltons. There is now convincing evidence that when protein Z is incubated with factor Xa, the activity of the latter is reduced. The inhibition of factor Xa activity is due to the presence of a protease inhibitor that requires protein Z as a cofactor. Whether protein Z has other functions is unknown.

Factor V

Factor V is synthesized in the liver and has a biological half-life reported to be between 12 and 36 h. It is a large glycoprotein with a molecular weight of 330 000 daltons. Factor V is highly homologous to factor VIII. A schematic diagram of the structure is shown in Fig. 7. As can be seen, it is composed of A, B, and C domains. The A domains are homologous to the copper-binding protein, ceruloplasmin, so it is not surprising that this domain of factor V is involved in binding to calcium and copper. The C domains are homologous to fat globule proteins and are involved in the binding of factor V to phospholipid-rich platelet membranes. The A and C domains are homologous to similar domains in factor VIII, but the B domain is completely different from that of factor VIII. For factor V to act as a cofactor for factor Xa, it must be activated by thrombin with cleavage of arginyl bonds at positions 708, 1018, and 1545 as shown in Fig. 7. It is inactivated by activated protein C that cleaves bonds at 306 (slow) and 506 (fast).

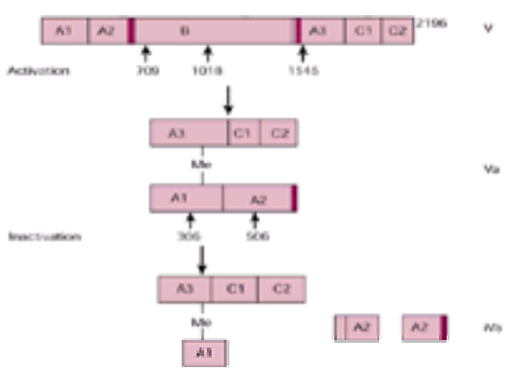

Fig. 7 Schematic diagram of factor V. Factor V is activated by thrombin to factor Va. Factor Va is inactivated by activated protein C (i Va). Activation of factor V by thrombin results in loss of the B chain and formation of a heterodimeric molecule covalently linked by metal ions (Me). Inactivation is by activated protein C that cleaves arginyl bonds at positions 306 and 506. (Reprinted by permission of McGraw-Hill Companies from Roberts HR *et al*. (2001). Molecular biology and biochemistry of the coagulation factors. *Williams Hematology*, 6th edn, p.1419.)

Factor VIII

Like factor V, factor VIII is synthesized in the liver. It is a large glycoprotein with a molecular weight similar to that of factor V. Again, like factor V, factor VIII has A, B, and C domains with the A domain homologous to caruloplasmin and the C domain homologous to fat globule proteins (Fig. 8). The A domain of factor VIII is essential for binding to phospholipid membranes. The B domain of factor VIII is cleaved during activation and has no known function. To act as a cofactor for factor IXa, factor VIII must be activated by thrombin or factor Xa. Unlike activated factor V, activated factor VIII exists as a heterotrimer composed of A1, A2, and C1-C2 domains linked by calcium ions. Factor VIII circulates in a non-covalent complex with von Willebrand factor and has a biologic half-life of 8 to 12 h. In the complete absence of von Willebrand factor, such as occurs with type III von Willebrand disease, the half-life of factor VIII is less than 1 h. When activated factor VIII is released from von Willebrand factor, it binds to the surface of activated platelets where it interacts with factor IXa.

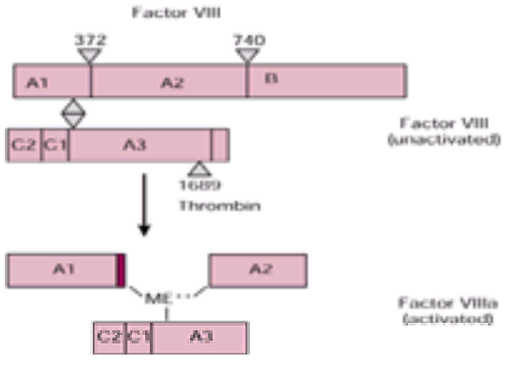

Fig. 8 Schematic representation of factor VIII. Activation by thrombin (or factor Xa) results in a heterotrimer non-covalently linked by metal ions (Me). Like factor Va, factor VIIIa is inactivated by activated protein C. (Reprinted by permission of McGraw-Hill Companies from Roberts HR *et al*. (2001). Molecular biology and biochemistry of the coagulation factors. *Williams Hematology*, 6th edn, p.1420.)

von Willebrand factor

von Willebrand factor is synthesized by endothelial cells and stored in Weibel–Palade bodies. It binds to glycoprotein Ib on platelets and is required for normal platelet adhesion to components of the vessel wall such as collagen. A schematic diagram of von Willebrand factor is shown in Fig. 9. Although synthesized as a prepolypeptide with A, B, C, and D domains, it is secreted into the plasma in multimeric form with molecular weights ranging from 1 million to 15 to 20 million. Higher molecular weight forms of von Willebrand factor are secreted to the abluminal surface of the endothelial cell as one component of the extracellular matrix. The higher molecular weight multimers are very effective in promoting platelet adhesion. von Willebrand factor is also important in platelet aggregation. A major function of von Willebrand factor is to act as a carrier protein for factor VIII. Factor VIII is associated with von Willebrand factor multimers of all sizes.

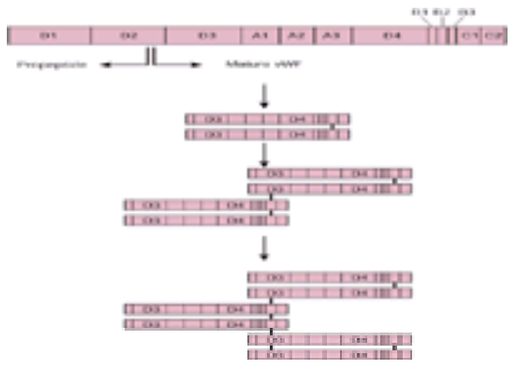

Fig. 9 Schematic diagram of von Willebrand factor. The formation of multimeric forms of von Willebrand factor occurs through links of dimers via D_3 domains. (Reprinted by permission of McGraw-Hill Companies from Roberts HR *et al*. (2001). Molecular biology and biochemistry of the coagulation factors. *Williams Hematology*, 6th edn.)

High molecular weight kininogen (HK)

High molecular weight kininogen circulates in plasma, and part is bound to factor XI and prekallikrein. HK is a cofactor for both of these zymogens. Deficiency of HK is not associated with a bleeding tendency, although the partial thromboplastin times of affected subjects are prolonged.

Tissue factor

Tissue factor, unlike other cofactors, is associated with cell surfaces. It is composed of 263 amino acids and with a 219-amino acid extracellular domain, a 23-amino acid transmembrane domain, and a 21-amino acid intracytoplasmic domain. The characteristics of tissue factor are shown in Table 7. It has a molecular weight of about 46 000 and is constituitively expressed on several extravascular tissues such as fibroblasts and smooth muscle cells. It is not constitutively expressed on cells exposed to the circulating blood, but can be induced in endothelial cells by certain inflammatory cytokines and certain bacterial products such as endotoxin. It can also be induced in blood leucocytes. Tissue factor functions as a receptor for factor VII. When factor VII binds to tissue factor, it is rapidly converted to factor VIIa, although the precise mechanism for its activation is not clear. The VIIa–tissue factor complex is now thought to be the main physiological initiator of blood coagulation by activating both factor IX and factor X, each of which plays a distinct role in subsequent coagulation reactions as described below. On some cells, tissue factor exists in a 'latent' form sometimes referred to as 'encrypted tissue factor' as suggested by the fact that tissue factor antigen levels on cells may be higher than tissue factor functional activity. 'De-encryption' can be accomplished by exposure of cells to agents such as calcium ionophores and various cytokines, but the physiological mechanism by which this process takes place is not known.

Thrombomodulin

Thrombomodulin is a transmembrane protein synthesized by and localized to endothelial cells although it has also been found on mesothelial cells, monocytes, and squamous epithelial cells. It has a molecular weight of about 78 000 daltons. A chondroitin sulphate moiety is attached to thrombomodulin via a serine residue. The major characteristics of thrombomodulin are depicted in Table 7. It serves as a receptor on endothelial cells for thrombin. Thrombin bound to thrombomodulin undergoes a structural transformation such that it no longer activates platelets or clots fibrinogen, but rather activates protein C. The principle function of the thrombomodulin /thrombin complex is to prevent the extension of the haemostatic clot past the site of a break or leak in the vessel wall and as such represents an important control mechanism to restrict the haemostatic plug precisely to the point of injury. Thus, under normal conditions, clot formation does not occur on the endothelial cell surfaces.

Fibrinogen

Fibrinogen is synthesized in the liver and has a molecular weight of 340 000 daltons. It is a dimeric glycoprotein consisting of two sets of identical chains, the a, b, and g chains. The synthesis of each fibrinogen chain is governed by a separate gene as depicted in Table 7. The normal plasma half-life of fibrinogen is about 3 to 5 days. It is also found in the a granules of platelets as a result of endocytosis. Fibrinogen is the soluble plasma precursor of the solid fibrin clot that is so necessary for haemostasis and normal wound healing. The dimeric structure of fibrinogen is composed of two monomers, each containing disulphide-linked a, b, and g chains. A schematic diagram of fibrinogen is shown in Fig. 10. It is a triodular structure with a central E domain that includes the disulphide-linked amino termini of all six polypeptide chains. The E domain is linked to the carboxyterminal domains referred to as the D domains.

Fibrinogen conversion to fibrin is accomplished by thrombin cleavage of two fibrinopeptides (fibrinopeptide A and fibrinopeptide B) from each of the two a and b chains, respectively, leading to the formation of the fibrin monomer. The molecular weight of each fibrinopeptide A and B is about 2500 daltons. The soluble fibrin monomer then undergoes spontaneous polymerization by forming side-to-side and end-to-end anastomoses, resulting in protofibrils that aggregate into a visible fibrin clot composed of thicker, branched fibres. During fibrin clot formation, other proteins are occluded in the clot, including plasminogen, fibronectin, thrombospondin, and von Willebrand factor. The fibrin polymerization is enhanced by calcium ions, but the polymerization process alone does not lead to a stable and impermeable fibrin clot since the fibres are held together weakly by hydrogen bonds and electrostatic forces. A stable fibrin clot requires cross-linking of the a and g chains of fibrin by the action of activated factor XIII.

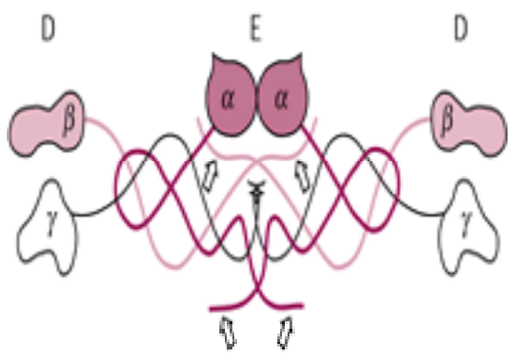

Fig. 10 A diagram of the structure of fibrinogen. The three chains, a, b, g, are shown. The E domain occurs at the amino termini while the D domains are found at the carboxytermini. Arrows represent cleavage sites for fibrinopeptide A from the a chain and fibrinopeptide B from the b chain.

Factor XIII

Factor XIII is a proenzyme which circulates in the plasma as a heterotetramer composed of two A chains and two B chains (Table 7). Factor XIII has a molecular weight of 320 000 daltons and has a half-life of about 10 days. It circulates in plasma in association with fibrinogen. The A chain contains the active site cysteine, while the B chain is enzymatically inactive and serves as a carrier for the A chain. The A chain is found in platelets where it is not associated with the B chain. Upon activation by thrombin, the A and B chains are separated. In addition, thrombin cleaves the A chain so as to expose the active site cysteine. The active component then cross-links the a and g chains of fibrin to form a stable, impermeable fibrin clot resistant to lysis by plasmin.

Inhibitors of the coagulation reactions

Tissue factor pathway inhibitor (TFPI)

TFPI is synthesized by endothelial cells. It has a molecular weight of about 34 000 to 40 000 daltons and serves to inhibit the initiation of coagulation (Table 7). TFPI can inhibit factor Xa in a slow reaction and also inhibits the VIIa–tissue factor–Xa complex. It exists in the circulation in at least three pools. One is bound to plasma lipoproteins; one pool is bound to proteoglycans on the vessel wall; and one exists in platelets. The TFPI bound to proteoglycans can be released by heparin. TFPI is a Kunitz-type inhibitor that is essential for control of coagulation.

Antithrombin III

The characteristics of antithrombin are also depicted in Table 7. Antithrombin belongs to a family of protease inhibitors known as 'serpins' that inhibit many proteases with a serine-active site. It is synthesized in the liver and has a plasma half-life of approximately 65 h. Its major function is to inhibit thrombin and factor Xa, although it will also inhibit the other coagulation serine proteases less well. The inhibitory action of antithrombin III is greatly enhanced by heparin, which accelerates the rate of inhibition of the serine proteases.

Protein Z-dependent protease inhibitor

This inhibitor inhibits factor Xa in the presence of calcium, phospholipids, and protein Z. It has a molecular weight of about 72 000 daltons. It, like antithrombin III, is also a member of the serpin family of serine protease inhibitors.

Other inhibitors of clotting factors

The major inhibitor of factor XIa is thought to be a-1-antitrypsin since it has the highest affinity for the enzyme. However, other inhibitors, namely C-1 esterase inhibitor, will also inhibit factor XIa. The other inhibitors that are of some importance in coagulation are also listed in Table 7.

The coagulation pathways

The coagulation reactions have been viewed as a sequential series of steps in which a enzymatic precursor (zymogen) clotting factor is converted to an active enzyme which, in turn activates another precursor, finally ending in the rapid conversion of prothrombin to thrombin. Early models of the coagulation reactions are shown in Fig. 11. As can be seen, when viewed in this manner, the clotting reactions appear as a waterfall or cascade, hence the terms waterfall or cascade hypotheses. Since tissue factor was extrinsic to the blood stream, the activation of factor X by the VIIa–tissue factor complex was termed the extrinsic system. The intrinsic system consisted entirely of clotting factors within the circulation and, upon conversion of factor IX to IXa by factor XIa, the factor IXa–VIIIa complex could also convert factor X to Xa in the presence of phospholipids. While this concept of coagulation was essentially correct, it did not explain why patients with factor XII deficiency had no bleeding tendency nor why factor XI-deficient patients had only a mild bleeding tendency. It was also pointed out that defects in the intrinsic system could lead to haemorrhage in affected patients even though the extrinsic system was intact and vice versa. The demonstration that the VIIa–tissue factor complex could activate both factor IX and factor X led several groups to conclude that the clotting reactions were, in fact, initiated by VIIa–tissue factor and that the intrinsic and extrinsic systems did not exist *in vivo*. Further work demonstrated that the clotting reactions leading to a haemostatic plug were controlled, in large part, by cell surfaces which modulated the reactions.

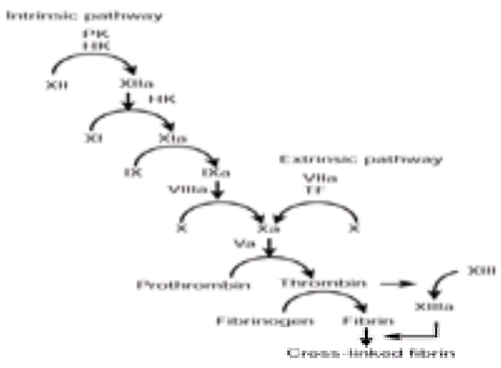

Fig. 11 An earlier model of blood coagulation reactions. The cascade or waterfall hypothesis of coagulation. (Reprinted by permission of McGraw-Hill Companies from Roberts HR *et al*. (2001). Molecular biology and biochemistry of the coagulation factors. *Williams Hematology*, 6th edn.)

The role of the tissue factor cell

When a blood vessel is injured or ruptured, flowing blood is exposed to tissue factor, which is bound through a transmembrane and cytoplasmic tail to cells exposed as the result of injury, for example fibroblasts and other connective tissue cells. Factor VII binds to the tissue factor-bearing cell and is activated. As a result, the VIIa–tissue factor complex on the tissue factor cell activates both factor IX and factor X as shown in Fig. 12(a). The factor Xa and IXa formed in the milieu of the tissue factor cell play very different and distinct roles in subsequent reactions.

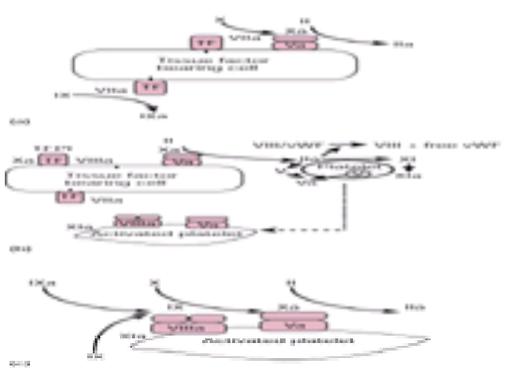

Fig. 12 (a) Tissue factor, a transmembrane protein expressed on tissue factor-bearing cells, acts as a receptor for factor VII, which is rapidly converted to factor VIIa. The tissue factor–VIIa complex then accomplishes two major functions: (1) activation of factor X to Xa and (2) activation of factor IX to IXa. Factor Xa activates factor V on the tissue factor-bearing cell and the resulting Xa–Va complex converts small amounts of prothrombin to thrombin. (b) This small amount of thrombin formed in the vicinity of the tissue factor cell acts as a 'primer' for coagulation by: (1) activating platelets; (2) dissociating factor VIII from von Willebrand factor and activating factor VIII; (3) activating factor V; and (4) activating factor XI. The activated platelets then adhere to the site of vascular injury and bind the cofactors, factors VIIIa and Va. Factor XIa also binds to platelets. The tissue factor–VIIa–Xa complex is then inhibited by TFPI (tissue factor pathway inhibitor). (c) Factor IXa formed by the tissue factor–VIIa complex associates with VIIIa on the platelet surface and recruits additional factor X from plasma to form factor Xa. The factor Xa then associates with its cofactor, factor Va, on the platelet surface to rapidly convert prothrombin to large amounts of thrombin sufficient to clot fibrinogen.

The role of factor Xa on the tissue factor cell

Factor Xa, in concert with its cofactor Va (which is found in the vicinity of tissue factor cells) then converts prothrombin to very small amounts of thrombin as shown in Fig. 12(b). This amount of thrombin, though insufficient to clot fibrinogen, can, however, act as a 'primer' of subsequent coagulation reactions to accomplish the following: activate platelets; activate more factor V; dissociate factor VIII from von Willebrand factor and activate factor VIII; and activate factor XI as shown in Fig. 12(b). Factor Xa alone and in complex with VIIa–tissue factor is then inhibited by TFPI. The activated cofactors resulting from the priming amount of thrombin in the milieu of the tissue factor cell then occupy binding sites on the activated platelet as shown in Fig. 12(b). Thus the main function of factor Xa formed as the result of the VIIa–tissue factor complex is to furnish a priming amount of thrombin sufficient to initiate further subsequent reactions which take place on the activated platelet surface.

The role of factor IXa on the tissue factor cell

Factor IXa formed by the VIIa–tissue factor on the tissue factor-bearing cell diffuses away from the tissue factor cell and occupies a site on the activated platelet adjacent to its cofactor VIIIa (Fig. 12(c)). This factor IXa then plays a primary role in the subsequent burst of thrombin generation on platelet surfaces as noted below.

The role of the activated platelet

The activated platelet mass is the primary site of thrombin generation, which is highly dependent upon the amount of factor IXa formed both by the VIIa–tissue factor cell and factor XIa, which also occupies sites on the platelet. Factor IXa in the presence of its cofactor VIIIa then recruits more factor X from solution and activates it on the activated platelet surface. This factor Xa in the presence of its cofactor Va then converts large amounts of prothrombin to thrombin sufficient to clot fibrinogen. All of these reactions are summarized in Fig. 13. The mass of aggregated platelets upon which these reactions take place is localized to the damaged area of the vessel wall.

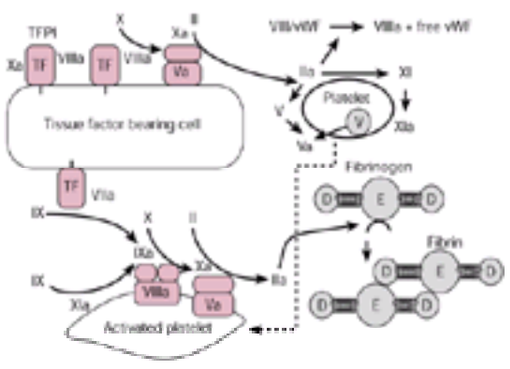

Fig. 13 The clotting reactions summarized. After thrombin formation, fibrinogen is converted to fibrin.

The role of the endothelial cells, vessel wall, and inhibitors

The mass of platelets interspersed with fibrin forms a plug at the site of a leak in the vessel wall where the endothelial cell monolayer is disrupted. The question arises as how the haemostatic plug is confined to the damaged area of the vessel wall. A schematic diagram of these events is shown in Fig. 14. The endothelial cells express thrombomodulin, which traps thrombin to form thrombomodulin–thrombin complex that controls the procoagulant stimulus by activating the protein C system, resulting in inactivation of both factors Va and VIIIa on the endothelial cell surface. In addition, endothelial cells contain glycosoaminoglycans, some of which inhibit thrombin. Antithrombin III also circulates in solution to inhibit any thrombin that escapes from the haemostatic plug. In this way the fibrin clot sealing a leak in a blood vessel wall is confined precisely to that site such that extension of the clot does not occur under normal circumstances.

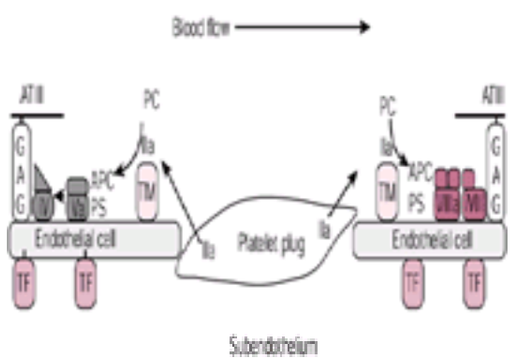

Fig. 14 A diagram of the haemostatic plug and the control mechanisms that restrict this plug to the site of injury and prevent extension of the clot to normal endothelium. TM, thrombomodulin; IIa, thrombin; GAG, glycosoaminoglycans; PC, protein C; APC, activated protein C; PS, protein S; TF, tissue factor; Platelet plug = haemostatic plug. iVa and iVIIIa refer to inactivated Va and VIIIa by APC.

On-going coagulation *in vivo*

It is well known that products of the coagulation reactions are found in the circulation under normal (basal) conditions. Small, but definite levels of fibrinopeptides A and B can be measured. Fragment 1+2 derived from the amino terminal portion of prothrombin after thrombin is formed can also be detected. Activation peptides from several of the coagulation factors as well as complexes of activated factors with their inhibitors can also be found in the circulation. These observations strongly suggest that small leaks in blood vessels that occur during the stress and strain of everyday living are repaired by the on-going formation of haemostatic fibrin clots. This has been termed 'basal' coagulation, a process that allows the blood to remain fluid within the vascular tree and at the same time permitting small, exquisitely controlled and confined fibrin clots to plug small leaks in the vasculature without dissemination. The fibrin plug is then removed by the fibrinolytic system following the formation of new tissue.

The fibrinolytic system

The fibrinolytic system is shown schematically in Fig. 15. The components of the system and their characteristics are depicted in Table 8. The active enzyme in the fibrinolytic system is plasmin, which is derived from its precursor, plasminogen. Plasminogen is activated to plasmin by activators. The physiological activator is single-chain tissue plasminogen activator (t-PA), which cleaves plasminogen into two-chain plasmin. Another activator of plasminogen *in vivo* is single-chain urokinase, but this appears to be more important for degradation of matrix proteins. The physiological inhibitor of plasmin is a $_2$-antiplasmin.

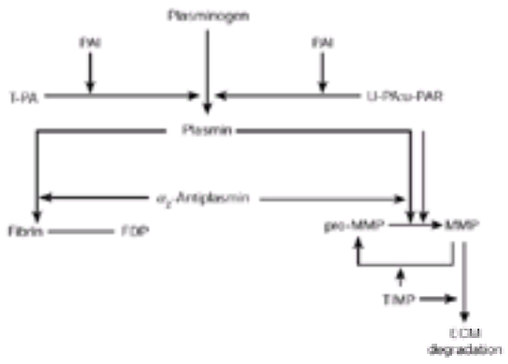

Fig. 15 The fibrinolytic system. Plasminogen is converted to plasmin by activators, including plasminogen activators (t-PA) and urokinase (u-PA). The activators are inhibited mainly by plasminogen activator inhibitor-1 (PAI-1). Plasmin degrades fibrin and activates matrix metalloproteinases (MMP), which degrades extracellular matrix (ECM). Plasmin is inhibited by a_2-antiplasmin. FDP, fibrin degradation product; TIMP, tissue inhibitors of metalloproteinases; U-PAR urokinase protease-activated receptor. (Reprinted by permission of FK Schatter from Collen D. (1999). The plasminogen (fibrinolytic) system. *Thrombosis and Hemostasis* **82**, 261.)

Plasminogen and t-PA associate in the circulation with fibrinogen. Thus when fibrinogen is converted to fibrin, the clot is rich in both of these proteins, which are protected from the inhibitory action of a_2-antiplasmin. Thus, clots can be lysed without interference from inhibitors, yet free plasmin in the circulation will be rapidly inhibited by its inhibitor.

Plasminogen

Plasminogen is synthesized in the liver and has a molecular weight of about 92 000 daltons. It is composed of a single chain and exists in two forms in the circulation: glu-plasminogen and lys-plasminogen. Glu-plasminogen has an amino-terminal glutamic acid and is a larger molecular weight than lys-plasminogen, which is formed in the circulation by plasmin cleavage of an arginyl bond at position 78 of the Glu form, leaving lysine as the amino-terminal residue. Lys-plasminogen rapidly binds to fibrin via lysine binding sites. Thus, lys-plasminogen is in close proximity to fibrin and protected from the action of antiplasmin. When activated, plasminogen is converted to active two-chain plasmin with a serine-active site on the heavy chain that is connected to the light chain by disulphide bonds.

The proteolytic action of plasmin is usually characterized by the proteolysis of fibrinogen and fibrin, but it can also degrade several other proteins including factor VIII, factor V, von Willebrand factor, and others. The cleavage of fibrinogen and fibrin leads to the formation of fibrin(ogen) degradation products. Fibrin(ogen) fragments resulting from plasmin cleavage are shown in Fig. 16. Fragment X is the first and largest fragment of plasmin digestion of fibrinogen. It is still clottable by thrombin, although much slower than native fibrinogen. Fragment X gives rise to fragment Y and D, and fragment Y is further proteolyzed to give rise to a second fragment D plus fragment E. These fragments can be detected in a simple laboratory test using antifibrinogen antibodies coated on latex particles. However, the test is non-specific and does not distinguish between the fibrinogen or fibrin degradation products which are quite similar, since the only difference between fibrin and fibrinogen is the absence of the small fibrinopeptides A and B in fibrin. A better test for detection of fibrin fragments is the so-called D-dimer test, which detects D-dimers resulting from the cross-linking of fibrin by factor XIIIa.

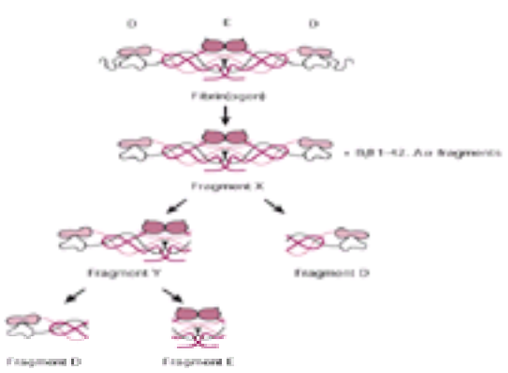

Fig. 16 Plasmin digestion of fibrin(ogen) results in fibrin degradation products: X, Y, D, and E. The final protolytic fragments resulting from plasmin degradation of fibrin are two molecules of fragment D and one of E. (Reprinted by permission from Francis CW, Marder VJ. In: Colman RW *et al*., eds. *Hemostasis and thrombosis: basic principles and clinical practice*, 3rd edn. JP Lippincott and Co.)

Tissue plasminogen activator (t-PA)

Tissue-type plasminogen activator is considered to be the physiological activator of plasminogen. It is synthesized in endothelial cells and has a molecular weight of about 68 000 daltons. It has high affinity for plasminogen. T-PA circulates for the most part in complex with its inhibitor, plasminogen activator inhibitor-1 (PAI-1). The t-PA–PAI-1 complex can be dissociated during the process of coagulation, and free t-PA associates with fibrin, which enhances t-PA activity. Single-chain t-PA has catalytic activity, but when activated to the two-chain form by plasmin, the activity is increased by three-fold.

Urokinase plasminogen activator

Urokinase plasminogen activator exists as a single-chain zymogen and is found in the kidney, the urine, and fibroblast-like cells. It activates plasminogen by proteolysis of an arginyl residue at position 561. Its main function is in wound healing and vasculogenesis, and it is active in proteolysis of the extracellular matrix. Urokinase plasminogen activator associates with the urokinase plasminogen-activator receptor.

Plasminogen activator inhibitor-1 (PAI-1)

PAI-1 is the physiological inhibitor of t-PA. It belongs to the serpin family of inhibitors. It is synthesized in endothelial cells and has a molecular weight of 52 000 daltons. Elevated levels of this inhibitor have been associated with arterial and venous thromboses. PAI-2, found in the placenta, also inhibits t-PA, but not as efficiently as PAI-1. PAI-3 is also known as the protein C inhibitor and inhibits plasminogen activators less efficiently than PAI-1.

a_2-Antiplasmin

a_2-Antiplasmin is the physiological inhibitor of plasmin. It has a molecular weight of about 58 000 daltons and is synthesized in the liver. As an inhibitor, it has three major functions: to inhibit plasminogen binding to fibrin; to inhibit the proteolytic activity of plasmin; and to bind to fibrin in a covalent manner by the action of factor XIIIa. By binding to fibrin, a_2-antiplasmin competitively inhibits the binding of plasminogen to fibrin. However, when plasminogen within the fibrin clot is converted to plasmin, the latter is protected from inhibition by antiplasmin. On the other hand, free plasmin formed in the circulation is rapidly inhibited.

Thrombin-activatable fibrinolytic inhibitor (TAFI)

TAFI is also known as plasma procarboxypeptidase B, and it is activated to carboxypeptidase B by large amounts of thrombin in a reaction dependent upon thrombomodulin. TAFI down-regulates fibrinolysis after clot formation and serves as an important regulatory mechanism for the fibrinolytic system. TAFI acts primarily

by reducing the number of high-affinity plasminogen binding sites on fibrin, the end result of which is decreased fibrinolysis.

The fibrinolytic and coagulation systems are closely interrelated. Under normal conditions, fibrin clot formation is always accompanied by fibrinolysis. The formation of the fibrin clot leads to localization of t-PA and plasminogen leading to activation of the fibrinolytic system. It also appears that activated factor XI and factor XII enhance fibrinolytic activity. The action of the protein C system to decrease thrombin formation down-regulates the thrombin activatable fibrinolytic inhibitor which would favour increased fibrinolysis. Although much is still unknown, it is generally accepted that both the coagulation and fibrinolytic systems are related to the general process of inflammation involving several other host defence mechanisms.

22.6.2 Evaluation of the patient with a bleeding diathesis

Gilbert C. White, II, Harold R. Roberts, and Victor J. Marder

Introduction

The approach to the bleeding patient should be designed to determine if the bleeding tendency is inherited or acquired, systemic or local, and due to coagulation, platelet, or vessel wall defects (see Box 1). One should use the history, physical examination, and laboratory tests to derive answers to these questions.

Box 1 Questions to answer in the evaluation of a bleeding diathesis

- Is the bleeding acquired or congenital? Patients with congenital bleeding will often give a history of lifelong bleeding. This may be spontaneous or may be in the setting of previous surgical procedures or trauma. With acquired bleeding disorders, the onset of bleeding is usually recent and the patient often remarks that remote surgical procedures and trauma were not associated with bleeding. The family history is also important in determining if the bleeding is acquired or congenital. It is important to determine if unusual bleeding occurs in parents, grandparents, siblings, aunts, uncles, and children. A positive family history for bleeding favours a congenital disorder.
- Is the defect systemic or local? Bleeding from multiple sites suggests a systemic defect, whereas bleeding from a single site may result from local abnormalities.
- Is there a coagulation, platelet, or vessel wall defect? Bleeding due to coagulation defects tends to be in joints, soft tissues, or internal organs. Poor wound healing may suggest a disorder of fibrinogen or factor XIII. Platelet disorders are characterized by the presence of purpura and petechias.

The history

A history of both recent and remote bleeding should be sought. The nature of the bleeding, including the site or sites, severity, duration, association with trauma including surgical or dental procedures, and necessity for treatment of the bleeding, should be determined. Cutaneous, soft tissue, nasal, oropharyngeal, bronchial, genitourinary, gynaecological, joint, and intestinal bleeding should all be included in the history, as well as other more unusual sites. How much blood was lost? Were transfusions required? Was supplemental iron needed? If the bleeding followed surgery, what type of surgery? Excessive bleeding following tonsillectomy is common even in normal individuals and is harder to interpret than excessive bleeding following an appendicectomy. Spontaneous bleeding is more indicative of a bleeding diathesis than bleeding following a surgical or dental procedure, although persistent bleeding following trauma or surgery is often a sign of a coagulation abnormality.

The site of bleeding may provide clues to the cause. Joint bleeding is typical of haemophilia A and B and is much less common in other congenital and acquired bleeding disorders. Umbilical vein bleeding at birth is characteristic of factor XIII and fibrinogen deficiencies. Recurrent intestinal bleeding may be seen in hereditary haemorrhagic telangiectasia (Rendu–Osler–Weber disease) and is also seen in von Willebrand's disease and with certain platelet defects, but intestinal bleeding in general is most commonly due to a structural lesion. Recurrent bleeding from the same site is more consistent with a structural defect, whereas bleeding from multiple sites suggests a systemic haemostatic disorder.

The pattern of bleeding is also important. Delayed bleeding is typically seen with factor XIII deficiency and with a $_2$-antiplasmin deficiency. The initial clot forms normally, but is unstable and breaks down with normal fibrinolysis, causing bleeding after several days. With mild and moderate forms of haemophilia A and B, there is delayed bleeding and wound healing may be impaired, causing wound breakdown 5 to 7 days after surgery or injury.

The whole picture is more informative than a single event. An individual who has a lifelong history of easy bruising, bleeding following extraction of several teeth, recurrent epistaxis, and a long-standing history of menorrhagia is more likely to have a bleeding disorder than an individual that bled excessively following tonsillectomy but has no history of bruising and no bleeding with other dental or surgical procedures.

A family history is very important. It is not enough to ask if individuals in the family bleed. One should ascertain the number of brothers, sisters, aunts, uncles, parents, and grandparents who are known and determine bleeding histories for each person. In the evaluation of a male with possible haemophilia, a single brother who does not have a bleeding history is not very informative; if there are 10 brothers who have no bleeding history, the diagnosis is questionable. It is also important to determine haemostatic stresses in family members. A brother who has undergone an appendicectomy and suffered internal injuries from a motor vehicle accident without bleeding is more informative than a brother who has had no haemostatic stresses. The pattern of inheritance is also important. A sex-linked pattern of inheritance suggests haemophilia A or B. An autosomal pattern suggests other forms of inherited bleeding.

While the bleeding history is important and may provide clues to the nature of the disorder, it can also be misleading. Normal individuals will often report easy bruising that can be indistinguishable from that reported by individuals with congenital disorders. Epistaxis is frequent in children with nasal allergies whether or not there is an underlying bleeding defect and may suggest a congenital defect when there is none. Even bleeding following surgical and dental procedures can be misleading. For example, blood loss during and after tonsillectomy can be especially prominent, even in normal individuals. Blood loss after dental procedures can also be prominent, especially in individuals with poor dental hygiene.

The physical examination

The skin is a window to the blood coagulation system and careful examination of the skin is important in the evaluation of a bleeding diathesis. Ecchymosis, purpura, petechias, telangiectasia, the appearance of scars, and other cutaneous changes may provide an indication of the presence and type of bleeding disorder. The bleeding manifestations of patients with vascular disorders, thrombocytopenia, or functional platelet disorders mainly occur as spontaneous subcutaneous and mucous membrane haemorrhage and petechiae. In contrast, patients with clotting factor defects such as haemophilia develop deep, spreading haematomas, joint bleeding, and retroperitoneal bleeding.

The term 'purpura' is is a general term used to describe cutaneous extravasations of blood (Plate 1). The smallest of these are petechiase, pinpoint extravasations of blood that are round and do not blanch with pressure. They are most commonly found on the lower extremities where hydrostatic pressure is the greatest. Petechias in which there is a characteristic perifollicular distribution are typical of severe scurvy, or vitamin C deficiency. Patients with scurvy may also have excessive bleeding from multiple sites including the gums, alimentary tract, joints, and brain. More extensive cutaneous bleeding is called 'ecchymosis', or bruising, and may be seen with clotting factor abnormalities as well as platelet and vascular abnormalities.

Telangiectases are dilated small blood vessels that may be found in the skin and in the mucous membranes of the nose, lips, mouth, the whole of the gastrointestinal tract, urinary tract, and vagina in various forms of chronic liver disease, hereditary haemorrhagic telangiectasia (Rendu–Osler–Weber disease), and with hyperoestrogen syndromes. Bleeding from telangiectasia may cause recurrent epistaxis or prolonged and progressive gastrointestinal bleeding from multiple sites, which leads to refractory chronic iron-deficiency anaemia. Other cutaneous abnormalities with which bleeding may be associated are cavernous haemangiomas—large thin-walled venous abnormalities. These may precipitate chronic activation of the coagulation mechanism, causing chronic diffuse intravascular coagulation.

Cutaneous changes also characterize connective tissue disorders, including the Ehlers–Danlos syndrome, pseudoxanthoma elasticum, osteogenesis imperfecta, and Marfan's syndrome, that can all present or be associated with defects of primary haemostasis because of abnormal interactions of platelets with vessel wall connective tissue elements. The characteristics of cutanous scars may provide a clue to an underlying bleeding disorder. Congenital dysfibrinogenaemia and factor XIII deficiency may be associated with proliferative scars or keloids. Characteristic 'cigarette paper'-like scars are seen in the Ehlers–Danlos syndrome. Characteristic thickened skin papules and plaques are also seen with pseudoxanthoma elasticum, along with angioid streaks in the ocular retina.

Primary and secondary amyloid can both cause skin purpura, called 'pinch-purpura' because of the characteristic appearance on the cheeks. Amyloid may be found infiltrating the small blood vessels and has also been shown to cause platelet functional abnormalities due to membrane coating by the amyloid fibrils. The lesions often show a propensity for the periorbital tissues and on the skin may be distributed in linear streaks. Splenomegaly may also cause a mild thrombocytopenia. Occasionally there is evidence of factor X deficiency, secondary to binding to the abnormal amyloid fibrils.

Long-term administration of corticosteroids causes atrophy of the collagen fibres that support the blood vessels in the skin. This causes widespread purpura and bruises, usually on the extensor surfaces on the hands, arms, and thighs. The purpura is similar in aetiology to the senile type. A similar distribution may also be seen in Cushing's syndrome.

Certain acute infections may be associated with a purpuric eruption. The bacterial infections include meningococcal septicaemia, streptococcal septicaemia, and diphtheria. In meningococcal infection, the haemorrhage may extend to the adrenal cortex causing the Waterhouse–Friderichsen syndrome associated with acute adrenal insufficiency. If the purpuric lesions are extensive, purpura fulminans may develop with the skin lesions becoming necrotic and the patient entering an acute, shock-like state. An acute diffuse intravascular coagulation may occur, as bacterial products such as endotoxin or immune complexes will directly activate the clotting system. Immune complexes may also coat the platelet membrane causing an immune-mediated platelet destruction and interfering with platelet function. Several acute viral infections, including smallpox, chickenpox, and measles, as well as more recently described haemorrhagic fevers caused by Ebola virus, Rift valley virus, and Lassa virus may also cause similar purpuric lesions. These patients have a grossly prolonged bleeding time, thrombocytopenia, and abnormalities of platelet function.

Various allergic vasculitic purpuras are caused by inflammation and infiltration of the blood vessel wall as an anaphylactic reaction to a variety of agents including chemicals, toxins, infections, and physical stimuli. Henoch–Schönlein purpura is probably the most common and involves skin, joints, alimentary tract, kidneys, heart, and central nervous system. There is often a preceding upper respiratory tract infection caused by a b-haemolytic streptococcus producing a rising antistreptolysin-O titre. Epidemics may occur in young children, with a fever followed by a purpuric rash that is often raised to the touch and classically affects the fronts of the legs, thighs, and buttocks. In addition, the patient may develop acute arthritis, gastrointestinal pain, and nephritis associated with proteinuria. The skin lesions may continue to form over several weeks. The most serious acute complications are central nervous bleeding, acute intussusception, or renal failure. The disease is usually self-limiting but the symptoms and purpura may respond to steroid therapy. Tests of haemostasis including studies of platelet function are usually within normal limits.

Bizarre bleeding and purpuric problems are reportedly associated with several psychological factors, so-called 'psychogenic purpura'. These include self-induced bleeding, hysterical bleeding, religious stigmas, and autoerythrocyte sensitization. Most of these patients have a disturbed or overanxious personality and very often the diagnosis is only suspected after numerous investigations have been made with all the results within the normal range. Autoerythryocyte sensitization is frequently associated with severe pain preceding the onset locally of skin bleeding and bruising. The lesion may be produced by the injection of a weak solution of the patient's own washed red cells or free haemoglobin solution subcutaneously into an area of the body, such as the back, with which the patient cannot directly interfere. To distinguish this condition from self-induced injury, it is important to include a negative saline control injection.

Purpuric lesions frequently occur in normal people, usually women. Single or multiple bruises appear spontaneously, mainly on the arms or legs, which rapidly resolve without any specific treatment. Senile purpura is frequent in older people, usually on areas exposed to mild but recurrent trauma such as the backs of the hands, the forearms, and the face. The purpura is caused by atrophy of the subcutaneous tissue with progressive loss of collagen and elastin fibres in the skin leading to inadequate support of the subcutaneous blood vessels. The lesions retain their dark colour, often for several weeks. There are no abnormalities in the haemostatic screening tests.

Laboratory tests

Laboratory investigations are required to identify the precise nature of an underlying bleeding disorder after a patient with a suspected haemorrhagic state has been clinically evaluated. Laboratory tests can be conveniently divided into screening tests and special tests, with the latter applied to the study of any individual patient according to the nature and clinical circumstances of the bleeding, and following the results of prior screening assays.

Screening tests

The most common screening tests performed in the initial assessment of a bleeding tendency are the activated partial thromboplastin time (**aPTT**), prothrombin time (**PT**), thrombin clotting time (**TCT**), platelet count, and bleeding time. Table 1 and Table 2 show the results of screening tests in inherited and acquired clotting factor abnormalities.

The aPTT measures the intrinsic clotting system and the 'common pathway', the latter being the confluence of intrinsic and extrinsic systems at the point of prothrombin (factor II) conversion to thrombin (IIa). The aPTT is prolonged by deficiencies or abnormalities of high-molecular-weight kininogen, prekallikrein, factors XII, XI, IX, VIII, X, V, and II (prothrombin), fibrinogen, and by inhibitors of blood coagulation, such as the 'lupus inhibitor', heparin, and fibrin/fibrinogen degradation products. The aPTT is sensitive to activities of about 20 per cent or less of the factors listed above.

The prothrombin time measures the extrinsic clotting system. The prothrombin time is normally about 12 ± 2 s. The prothrombin time is prolonged with deficiencies of plasma factors VII, X, V, and II (prothrombin) and fibrinogen, and by inhibitors of these factors, whether iatrogenic (such as with heparin administration—acting through antithrombin III) or pathological (such as with antibodies against factor V). The test is affected by a decrease in factor VII more than by a decrease in prothrombin or fibrinogen in that it is not significantly prolonged with a fibrinogen level of about 100 mg/dl or with a prothrombin concentration above 30 per cent, but is significantly prolonged when factor VII, V, or X is less than 50 per cent of normal.

The thrombin clotting time measures the thrombin-induced conversion of fibrinogen to fibrin. A normal result requires effective release of fibrinopeptides from fibrinogen and unimpeded polymerization of fibrin monomers to form a polymer gel. The TCT is normal even in the presence of severe coagulation abnormalities that involve the coagulation pathway leading to but not including the conversion of fibrinogen to flbrin. Thus, it is normal in haemophilia (factor VIII or IX deficiency) and factor VII deficiency, and even with a decrease in multiple factors associated with vitamin K deficiency. However, the TCT is abnormal in patients with hypofibrinogenaemia or afibrinogenaemia, whether acquired or congenital, or dysfibrinogenaemia, and in the presence of inhibitors such as heparin, myeloma proteins, and fibrin/fibrinogen degradation products, which block either thrombin cleavage of fibrinopeptides or fibrin monomer polymerization.

Mixing studies using either the aPTT or the prothrombin time are used to detect the presence of an inhibitor of coagulation. If normal plasma, containing 1 unit/ml of a given clotting factor, is mixed with an equal volume of deficient plasma containing less than 0.01 unit/ml of that factor, the resulting mix will have 0.5 units/ml of the factor, and the aPTT or prothrombin time of the mixed plasmas will be normal since these tests are not sensitive to clotting factor levels of 40 per cent or above. Conversely, if normal plasma is mixed with plasma containing an inhibitor, the inhibitor will neutralize most of the factor in the normal plasma. As a result, the mix will have less than 0.5 units/ml of the factor, and.the aPTT or prothrombin time of the mixed plasmas will be prolonged. Thus, a prolonged mix is characteristic of an inhibitor, whether in the form of a non-specific inhibitor such as heparin or a lupus inhibitor or a specific inhibitor against a specific coagulation factor.

Although a prolonged mixing study is characteristic of an inhibitor, some inhibitors, especially those against factor VIII and V, display aberrant behaviour in that the aPTT mix may not be immediately prolonged. In such cases, demonstration of the inhibitor may require incubation of the mixed plasmas at 37°C for 1 to 2 h. Thus, inhibitors to factor VIII or V are said to be time- and temperature-dependent. This incubated aPTT forms the basis for the Bethesda assay for quantification of factor VIII inhibitors. Occasionally, the lupus inhibitor may display time and temperature dependence.

The platelet count is a simple first step for evaluating the cellular aspects of haemostasis. Although there is no absolute relationship between the platelet count and the frequency and severity of bleeding, spontaneous bleeding without evidence of trauma is not usually manifest unless the platelet count is less than 10 000/µl, and serious bleeding after trauma or from a local lesion is unusual at counts above 50 000/µl. If platelet-type bleeding occurs when the platelet count is above 50 000/µl, a functional platelet defect of a congenital or acquired nature may be present.

The bleeding time evaluates primary haemostatic competency and therefore reflects both platelet number and function. The bleeding time measures the interval required for haemostasis following a standard superficial incision (1 to 2 mm deep and up to 5 mm long) in the skin of the forearm, while venous pressure is maintained at 40 torr. Prolongation of the bleeding time from a normal between 4 and 7 min usually occurs at a platelet count of 35 000 to 50 000/µl, with progressive prolongation noted with greater decreases in number. At counts below 10 000/µl, the bleeding time is often 15 min or longer: The bleeding time is prolonged in thrombocytopenic states of any aetiology. The bleeding time is also prolonged in various congenital and acquired qualitative platelet disorders, such as Glanzmann's thrombasthenia, Bernard–Soulier syndrome, storage-pool disease, and drug-induced thrombocytopathies (for instance, non-steroidal anti-inflammatory agents, most commonly aspirin). In von Willebrand's disease, the bleeding time is usually prolonged, but to a variable degree, as a result of a decrease or abnormality of plasma von Willebrand factor, which is involved in the binding of platelets to matrix proteins or to other cells. The bleeding time is also prolonged in severe hypofibrinogenaemia, as fibrinogen is the principal ligand for binding platelets to each other.

Although the bleeding time is a useful test of platelet function, it is difficult to standardize. The platelet function analyser (**PFA**)-100 has recently been proposed as a sensitive and reproducible test of platelet function, which may be used as an *in vitro* bleeding time. Citrated whole blood is passed through a standardized hole in a disc made of collagen–epinephrine or collagen–ADP. The time to platelet closure of the hole is measured. The PFA-100 has been reported to be useful in the diagnosis of von Willebrand's disease and qualitative platelet defects.

Some bleeding disorders are not associated with any abnormality of the screening tests. Patients with deficiencies of factor XIII and a $_2$-antiplasmin have normal prothrombin time, aPTT, and TCT values, but specific assays for these respective proteins are available for definitive diagnosis. Since deficient factor levels of 20 to 25 per cent or less may be needed to prolong a screening test, patients with mild deficiencies may also have normal screening tests, and diagnosis is possible only by direct assay of the factor. The screening tests are also normal in disorders of the vessel wall, such as hereditary haemorrhagic telangiectasia.

Specific tests

Depending on the assessment of both the clinical facts and the screening laboratory assays, individual factor assays and other special tests may be chosen to isolate the cause of the haemostatic disorder. Specific assays for all of the clotting and fibrinolytic factors are usually available in standard coagulation laboratories. In general, functional clotting factor assays are based on the one-stage aPTT using deficient plasmas or a two-stage assay using chromogenic substrates. Immunological assays are also used to measure total levels of fibrinogen, von Willebrand factor, and proteins C and S. Interesting differences have been found between the one-stage and chromogenic assays in the measurement of levels of recombinant factor VIII that may be important in the treatment of haemophilia. The fibrinolysis system includes the inactive precursor protein, plasminogen, promoters of fibrinolysis such as tissue plasminogen activator, the serine protease plasmin, and inhibitors of both activator (plasminogen activator inhibitor) and of plasmin (a $_2$-antiplasmin). The total concentration of each protein can be measured immunologically or by functional assay, usually by fibrinolytic or chromogenic assay. Clot lysis times measure the action of plasminogen activators and plasmin in the blood and are usually performed on clots formed from the euglobulin fraction of plasma or whole blood. Abnormally short lysis times (less than 2 h for plasma euglobulin) reflect acute episodes of excessive fibrinolysis that accompany a variety of acquired disorders or that result from the administration of plasminogen activators such as streptokinase, urokinase, or tissue plasminogen activator. The degree of fibrinolysis can be assessed indirectly by the measurement of fibrin degradation products.

Aggregation of platelets is measured photometrically by changes in light transmission of a suspension of platelets in plasma following the addition of selected agonists, usually adenosine diphosphate (ADP), thrombin, adrenaline, collagen, arachidonic acid, and ristocetin. Specific patterns of response to these agonists are observed in patients with storage-pool disease, Glanzmann's thrombasthenia, and Bernard–Soulier syndrome. The evaluation of platelet granule contents and secretion relies on specialized assays for quantifying adenosine nucleotides, serotonin (both dense-body constituents), and trace quantities of platelet factor 4, b-thromboglobulin, or adhesive proteins that have counterparts in plasma such as fibrinogen, fibronectin, thrombospondin, and von Willebrand factor (a-granule components). Tests of a specific platelet enzyme system involved in the arachidonic acid pathway (such as prostaglandin synthesis) and calcium transport are usually not available outside research laboratories.

The assessment of von Willebrand's disease bridges the gap between plasma coagulation factor analysis and platelet function tests, since such patients often present with a long bleeding time and a low plasma factor VIII activity. Most such patients have an abnormal and/or decreased plasma von Willebrand factor. Since the latter serves as a carrier protein for factor VIII, the concentration of factor VIII usually parallels the decrease in plasma von Willebrand factor. The protein concentration and type of von Willebrand factor multimer may be measured immunologically by Laurell rocket electrophoresis and by a combined electrophoresis/radioautograph or immunoblot procedure, respectively. Functional assessment of von Willebrand factor activity is performed by the ristocetin cofactor assay, in which ristocetin is added to a standard source of preserved (formalinized) platelets in the presence of the test plasma, and the degree and rate of platelet aggregation are compared with those of normal plasma. Collagen binding assays are also used to measure the function of von Willebrand factor. Usually a defective von Willebrand factor is associated with a deficiency in 'ristocetin cofactor activity', although some patients have von Willebrand factor with high activity, and rare patients (those with 'pseudo-von Willebrand's disease') have von Willebrand factor-hyperactive platelets. Inhibitors to von Willebrand factor may also account for acquired von Willebrand's disease, and von Willebrand factor may also be depleted by virtue of adsorption on to cells, as in some patients with lymphoid tumours.

Special problems

Sometimes, in patients with central venous catheters or arterial lines that are flushed with small amounts of heparin, blood drawn through the catheter may become contaminated with heparin. It thus becomes necessary to distinguish a systemic coagulopathy from heparin contamination. The first clue that the abnormal clotting screens might be due to heparin contamination is the finding of a prolonged TCT and aPTT with a normal or nearly normal prothrombin time. Mixing studies will be prolonged. The easiest way to demonstrate heparin contamination is to redraw the sample, either through a peripheral vein or through the catheter, discarding the initial 5 to 10 ml. If tests on the repeat sample are normal, it can be assumed that the initial sample was contaminated with heparin. The presence of heparin in the sample can be confirmed by a reptilase time. Reptilase is a snake venom that clots fibrinogen; unlike thrombin, reptilase is not inhibited by heparin. Thus, with the effect of heparin, the TCT is prolonged, but the reptilase time is normal.

The diagnosis of diffuse intravascular coagulation also requires a special set of tests ('DIC screen'). Screening tests in diffuse intravascular coagulation will show prolonged clotting times (prothrombin time, aPTT, TCT), a decreased platelet count, and usually a low fibrinogen. Ancillary tests include fibrin degradation products, fibrinopeptide A, and fibrin D-dimer, all of which will be increased in diffuse intravascular coagulation. Fibrin degradation products are also elevated in many other disorders and are not specific for the diagnosis of diffuse intravascular coagulation. In liver disease, which may be complicated by and confused with diffuse intravascular coagulation, factor VII is decreased while factors V and VIII and fibrinogen are less affected and may even be normal.

Application of clinical observations and laboratory studies to diagnosis: illustrative cases

Case 1

A middle-aged man is admitted for surgery. A careful history reveals that on three previous occasions, dental extraction was associated with rebleeding that required repacking on several occasions. He has had no other operative procedures and no trauma of significance. The family history is negative. Because of the history of mild bleeding, coagulation screens are performed and reveal: aPTT 120 s (control 38 s), prothrombin time 12 s (control 12 s), TCT 12 s (control 12 s), platelet count 200 000/µl, and bleeding time 9 min (normal 4 to 7 min). An incubated aPTT mix reveals patient aPTT 112 s, control 36 s, mix 38 s; specific factor assays reveal: factor XII 105 per cent, factor XI 86 per cent, factor IX 94 per cent, factor VIII 5 per cent, von Willebrand factor antigen 40 per cent, and von Willebrand factor activity

25 per cent. Tests of prekallikrein and high-molecular-weight kininogen are normal.

One of the most common laboratory abnormalities is an isolated increase in aPTT. Initially, the test should be repeated, and it should be determined whether the patient is receiving small doses of heparin (minidose or heparin flushes), which can produce an aPTT prolongation. To induce the marked prolongation of aPTT in this case (120 s), relatively large amounts of heparin would be required, and other screening coagulation tests (prothrombin time and TCT) should also be prolonged. If the prolongation of the aPTT is reproducible, further laboratory studies should focus on components of the intrinsic pathway, including prekallikrein, kininogen, factors XII, XI, IX, and VIII, and inhibitors of these factors. If the patient is asymptomatic, four major possibilities should be considered: the patient may have a 'lupus' inhibitor or be deficient in high-molecular-weight kininogen, prekallikrein, or factor XII. These familial syndromes, especially high-molecular-weight kininogen and factor XII deficiency, can give a remarkably prolonged PTT in patients who have no clinical bleeding. Such an occurrence may unnecessarily deter a surgeon from operating.

If the patient has a bleeding diathesis, one should consider factor VIII, IX, or XI deficiency, or von Willebrand's disease. In this case, an incubated aPTT mix ruled out an inhibitor, and specific factor assays showed diminished levels of factor VIII and von Willebrand factor antigen and activity, data consistent with a diagnosis of von Willebrand's disease. An isolated prolongation of the aPTT is relatively common. In contrast, an abnormal prothrombin time as an isolated finding is unusual and, if the disorder is congenital, signifies factor VII deficiency. In contrast, an abnormal prothrombin time and aPTT is a common combination that may be due to isolated deficiencies of factors II, V, and X or fibrinogen and more complex conditions, such as vitamin K deficiency, warfarin therapy, diffuse intravascular coagulation, therapeutic fibrinolysis, and liver disease. Specific assays for factors II, V, and X and measurement of the thrombin time and fibrinogen degradation products may be used to define these problems. The combination of an abnormal aPTT and a long bleeding time suggests von Willebrand's disease, with the long aPTT caused by a low factor VIII level and the decrease in von Willebrand factor activity accounting for the long bleeding time, while other patients with von Willebrand's disease may have normal factor VIII activity and a normal aPTT but a long bleeding time. Variations in the same patient may even occur, which make this diagnosis more difficult in certain instances. In patients with no abnormalities of the screening tests but clinical evidence of a systemic bleeding state, one must consider factor XIII deficiency, a_2-antiplasmin deficiency, and other mild disorders.

This case raises several other important issues. First, should preoperative coagulation screening tests be performed routinely? The argument has been advanced that if a properly taken history is negative, coagulation screens should not be performed in all preoperative patients. This is a cost–benefit argument that presumes an adequate history is obtained, but too frequently this is not done. Therefore the question of routine screening tests is something that must be worked out individually at each institution. In this hypothetical case, the history was suggestive of a mild bleeding disorder, and this necessitated screening tests. Although all three components of the factor VIII complex were abnormal in this patient, the laboratory expression in von Willebrand's disease is highly variable; had the factor VIII antigen and von Willebrand factor activity been normal, von Willebrand's disease would still have been a possibility. Exclusion of von Willebrand's disease with certainty may require determinations on multiple occasions, as well as analysis of multimeric patterns and testing of family members. As for therapy, newer therapeutic modalities such as desmopressin make it possible to avoid transfusion of plasma products in some patients and thus reduce the risk of transfusion-mediated disorders such as hepatitis and AIDS.

Case 2

A 75-year-old man with severe coronary artery disease is admitted for bypass surgery. He has no history of a bleeding tendency and underwent gallbladder surgery 3 years previously without complication. Preoperative evaluation reveals a normal platelet count and normal coagulation screening tests. Surgery is without complication until the fourth hour, about 30 min after coming off the bypass pump, when increased oozing from the surgical site is noted. The activated whole-blood clotting time, which has been maintained at around 300 s during the course of surgery, is found to be greatly prolonged. Studies indicate a platelet count of 22 000/μl, aPTT more than 150 s, and TCT more than 60 s. A reptilase time is markedly prolonged, indicating that heparin alone does not account for the prolonged clotting tests. The blood smear shows about 20 schistocytes per high-power field. The presumptive diagnosis of diffuse intravascular coagulation is confirmed by factor assay, which revealed fibrinogen 75 mg/dl, factor VIII 15 per cent, and factor V 12 per cent, but factor VII 95 per cent.

The initial step in the evaluation of severe intraoperative or postoperative bleeding is to determine whether a systemic haemostatic disorder is present. The screening tests are very important in this determination because the history is often limited to immediate observations of the site, amount, and time of bleeding. If the screening tests are normal and the patient is bleeding briskly, it is unlikely that the bleeding is due to a haemostatic defect, and attention should then be turned to bleeding due to local causes. On the other hand, if the screening tests are abnormal but the patient appears to have highly localized bleeding, a structural defect may still be the cause, aggravated by the haemostatic defect. If the patient is bleeding from numerous sites, including non-operative sites, it is likely that a haemostatic defect exists.

Cardiac surgery in particular can have several effects on the haemostatic system. Coagulation defects may result from haemodilution, especially in cases in which blood loss is massive and replacement with plasma is inadequate relative to other fluids, from heparin administration during cardiac bypass, from diffuse intravascular coagulation and acute fibrinolysis, and from platelet defects or destruction as a result of interaction with the bypass circuit. In the present case, the screening tests showed marked abnormalities. Although heparin can cause similar abnormalities, the prothrombin time was greatly prolonged, and this occurs only with large heparin doses. The reptilase time, which is not sensitive to heparin, was prolonged. The normal factor VII level provided evidence against haemodilution. Although thrombocytopenia could result from consumption after cardiac bypass, it is more likely to be part of a general consumptive coagulopathy. Treatment for diffuse intravascular coagulation was initiated.

Case 3

A 25-year-old woman is referred for evaluation of lifelong easy bruising. While many of these episodes are associated with mild trauma, bruises develop without known trauma as well. There is a predilection for the extremities, but she also has noticed bruises on the trunk. Menses are heavy, and she has been given supplemental iron. Her only surgical procedure was extractions for orthodontic work at the age of 12. Six teeth were extracted over a 2-month period, and two required repacking because of bleeding. The patient's mother and a sister also bruise easily, although the mother underwent uncomplicated gallbladder surgery at the age of 50. Physical examination reveals several small bruises in various stages of healing on the arms and legs, scattered petechias, and scars on the knees from childhood trauma, which are normal in appearance. Coagulation screens reveal: aPTT 36 s, prothrombin time 12 s, TCT 13 s, platelet count 179 000/μl, and bleeding time 36 min. The blood smear shows adequate numbers of platelets that are normal in size and staining characteristics. Additional studies are obtained as follows: factor VIII 75 per cent, von Willebrand factor antigen 110 per cent with multimeric pattern normal, von Willebrand factor activity 86 per cent, and salicylate level 0. Platelet aggregation studies show a normal response to ristocetin, but adrenaline and low concentrations of ADP produce only a single wave of aggregation, and collagen and arachidonic acid produce shape change but no aggregation response. The patient is referred to a platelet research laboratory. The ADP and ATP content of platelets is normal, electron microscopy reveals normal numbers of dense granules and a-granules, and the production of prostaglandin endoperoxides and thromboxane from radiolabelled arachidonate is greatly diminished.

Easy bruising is a common symptom that is seen in patients with coagulation defects, platelet disorders, and vascular and endocrine disorders, but it is also seen in people with no underlying haemostatic defect. In the present case the initial screening tests revealed a prolonged bleeding time with a normal platelet count, indicating a qualitative platelet defect, von Willebrand's disease, or a vessel wall disorder. Some patients with von Willebrand's disease present with an isolated prolongation of the bleeding time, but this is uncommon. Defects of the vessel wall are rare but possible in patients with a prolonged bleeding time, normal platelet count, persistently normal von Willebrand factor studies (including those of family members), and normal *in vitro* platelet function. The most common cause of a long bleeding time with normal von Willebrand factor evaluation is a platelet disorder.

One can approach the diagnosis of a patient with a normal platelet count and a prolonged bleeding time in two ways. One approach studies platelet aggregation and secretion for a primary platelet abnormality, and the other measures factor VIII activity, von Willebrand factor, and ristocetin cofactor activity to diagnose von Willebrand's disease. A diverse array of normal and abnormal findings in factor VIII activity, von Willebrand factor content and multimer distribution, and ristocetin cofactor activity can exist in patients with von Willebrand's disease, but the key observation is the documentation of a plasma protein abnormality that mitigates against a primary platelet disorder of aggregation and/or release. The finding of a total absence of aggregation response to agonists such as ADP, adrenaline, and collagen is consistent with the diagnosis of Glanzmann's thrombasthenia, which can be confirmed by studies that document a defect or deficiency of the glycoprotein IIb–IIIa complex. An isolated absent response of platelet-rich plasma to ristocetin suggests von Willebrand's disease or the Bernard–Soulier syndrome, while an enhanced response occurs in the type 2B variant of von Willebrand's disease. Simple microscopic examination of the platelets may show the large size that is characteristic of the former. Impairment or lack of a second wave of aggregation and decreased dense-granule secretion (ATP or serotonin) may be due to a deficiency in dense-granule contents that may additionally be accompanied by a-granule disorders or by an abnormality in the mechanism of secretion, such as occurs with defects in thromboxane synthesis. The contents of a-granules and dense granules can be measured directly, as can the pathway of thromboxane synthesis, to identify more precisely the specific nature of the defect.

In this case, platelet aggregation studies suggested a release defect with typical inhibition of collagen and arachidonate responses. Further studies indicated that the granule compartment of the platelets was normal, as evidenced by the normal nucleotide levels and the normal electron-microscopic appearance of the platelets. Studies with labelled membrane lipids indicated that there was a defect in lipid metabolism with failure to generate prostaglandin endoperoxides or thromboxane A_2 in response to appropriate agonists. This suggests a defect in arachidonate metabolism as the cause of the release defect. Since radiolabelled arachidonate was not metabolized normally to prostaglandin endoperoxides, the most likely cause is a cyclo-oxygenase deficiency.

Case 4

A young rubber-company worker presents to the emergency department with a 2-week history of spontaneous bruising, intermittent epistaxis, and gum bleeding after tooth brushing. Four hours before admission he developed haematuria. His only medication is frusemide for hypertension. Coagulation screening tests reveal a prothrombin time of more than 60 s, aPPT more than 90.1 s, and TCT 12.8 s. The platelet count is 302 000/µl and the bleeding time is 3 min. Mixing studies reveal a prothrombin time of more than 60 s, mix 12 s. Liver function tests are normal. Specific factor assays are performed and are normal except for factor II 7 per cent, factor VII less than 1 per cent, factor IX 4 per cent, and factor X 2 per cent. A plasma coumadin level is 0. On further questioning, the patient denies the use of anticoagulants and does not have rat poison at home. Despite administration of vitamin K_1 in a dose of 15 mg subcutaneously and 2 mg intravenously twice daily, the prothrombin time and aPTT remain prolonged. The dose of vitamin K is increased to 5 mg intravenously every 4 h. Further history reveals that a new rodenticide containing a long-lasting coumarin, brodifacoum, has recently been used at the rubber-tyre company. Plasma is obtained that reveals the presence of brodifacoum at a level of 162 µg/ml. Although a supervised search of the patient and his room failed to reveal any suspicious material, his clotting times improved and eventually returned to normal after 25 days of isolation.

This case of surreptitious coumarin abuse illustrates some of the difficulties in establishing the diagnosis. Typically seen in health-care workers, the markedly prolonged prothrombin time and aPTT with a normal TCT are characteristic. The diagnosis is further suggested by the finding of reduced plasma levels of the vitamin K-dependent clotting factors in the absence of liver disease. Confirmation of the diagnosis, although strongly suggested by the previous constellation of findings, may require chemical demonstration of the drug in plasma. It is not unusual in such patients for self-administration of the drug to continue in the hospital. Once the question of surreptitious coumarin abuse is raised, one must be suspicious of the patient and family members, as well as friends and individuals at work. Psychiatric evaluation may be essential and, in cases where it is suspected that someone is trying to poison the patient, police involvement may be advised.

Brodifacoum is a member of a family of coumarin compounds termed 'super-warfarins'. They are used in rodenticides and are so termed because of their potency and very long biological half-life. For example, brodifacoum is about 100 times as potent as warfarin and has a half-life of about 22 days in humans, compared with warfarin's half-life of 1 day. As a result, a single dose of 1 to 2 mg of brodifacoum can produce a prothrombin time prolongation for up to 70 to 80 days.

In this case, plasma levels of brodifacoum were markedly increased, but a warfarin level was undetectable. The chemical structure of the coumarin compounds is such that many assays in commercial use are specific for a single compound and will not detect other coumarins. One must therefore have some clue to the agent in use and request a specific assay.

Case 5

A 60-year-old man with coronary artery disease presents with a 1-week history of easy bruising. He was initially seen 4 months earlier with new onset of atrial fibrillation. Following cardioversion, he was started on quinidine with maintenance of a stable cardiac rhythm. He denied other medications and had no history of viral or other illnesses. Laboratory evaluation reveals normal coagulation screens and a bleeding time of 14 min. The platelet count is 12 000/µl with a haematocrit of 42 and a white count of 6700/µl. A bone marrow examination is performed and is normocellular with adequate numbers of megakaryocytes. A test for antinuclear antibodies is negative. Platelet antibody testing is as follows: direct antiplatelet antibodies, 7450 molecules IgG/platelet (normal 0 to 2500); indirect antiplatelet antibodies, 1130 molecules IgG/platelet (normal 0 to 2500); and indirect antiplatelet antibodies in the presence of quinidine, 7140 molecules IgG/platelet.

Thrombocytopenia is a common cause of bleeding and easy bruising. The first step in the evaluation of a patient with thrombocytopenia is to determine if the defect is a failure of platelet production, increased platelet destruction, or splenetic sequestration. Liver disease and other potential causes of splenic enlargement should be considered and a careful examination should be made for splenomegaly. While a normal haematocrit and white count militate against global bone marrow failure, this condition can be excluded only by a bone marrow aspirate and biopsy. The biopsy in particular may be required to rule out aplastic anaemia and infiltrative processes. Other causes of thrombocytopenia, such as leukaemia, myeloma, and megaloblastic anaemias, can be diagnosed by an aspirate. If the marrow contains a normal number and distribution of cells and a reasonable quantity of morphologically normal megakaryocytes, the cause of the thrombocytopenia is unlikely to be reduced production, and one should look for causes of increased peripheral destruction.

Immune thrombocytopenia is diagnosed by the demonstration of a normal bone marrow, the absence of an enlarged spleen, and the absence of non-immune causes of thrombocytopenia. The presence of elevated levels of antiplatelet antibodies confirms the diagnosis, but elevated platelet antibodies may be seen in other causes of thrombocytopenia, and some cases of immune thrombocytopenia may not have elevated platelet antibodies. Immune thrombocytopenia may be seen in lupus erythematosus, chronic lymphocytic leukaemia, with certain drugs, especially quinidine, and by exclusion in idiopathic thrombocytopenic purpura (ITP).

Quinidine is one of the most common causes of drug-induced ITP. Patients may develop thrombocytopenia months or years after starting the drug, but re-exposure to quinidine may produce explosive thrombocytopenia. Although the diagnosis of quinidine purpura should be considered in any patient with thrombocytopenia and a history of exposure to the drug, the diagnosis can be established by either the demonstration of quinidine-dependent antiplatelet antibodies, as in this case, or by improvement in the platelet count on discontinuation of the drug. Typically, the platelet count improves within 4 to 5 days, but it may take up to 6 weeks.

Case 6

A 38-year-old woman is admitted for gallbladder surgery. Preoperative coagulation screens and platelet count are normal. Surgery is performed without complication. On the seventh postoperative day, she develops pain and swelling in the right leg, and a contrast venogram confirms the diagnosis of deep vein thrombosis. A bolus of 5000 units of heparin is given followed by infusion of 1000 units/h to maintain the aPTT in the range of 45 to 60 s. On the thirteenth postoperative day, 6 days after starting heparin, she experiences the sudden onset of increasing pain in the right arm. The arm is cool and dusky distally and the radial and ulnar pulses are markedly diminished. A platelet count is 40 000/µl. A transoesophageal echocardiogram demonstrates no evidence for a mural thrombus or for akinesis. The patient's plasma, but not normal plasma, induces aggregation of normal platelet-rich plasma in the presence of heparin, but not in the absence of heparin and contains heparin-dependent antibodies to platelet factor 4. Based on these findings, a diagnosis of heparin-induced thrombosis with thrombocytopenia is made and heparin is discontinued. The patient is started on argatroban and on warfarin. A white thrombus is successfully removed from the right brachial artery by Fogarty catheter. The platelet count improves steadily over the next 10 days. Following achievement of a therapeutic prothrombin time on warfarin, the argatroban is discontinued and the patient is discharged on warfarin for 3 months with the admonition that she should never again receive heparin.

Among the various complications of heparin, heparin-induced thrombosis with thrombocytopenia is one of the most catastrophic and dramatic. This uncommon complication of heparin therapy typically occurs 5 to 14 days after starting heparin, occurs more frequently with beef lung heparin than with porcine intestine heparin, and resolves when the heparin is discontinued. The usual presentation is isolated thrombocytopenia, but occasionally (as in this case) there is a complicating (arterial) thrombotic event, either arterial or venous. This thrombosis is unique in that it is typically a white thrombus composed predominantly of platelets and little fibrin.
