24.13.18.2Traumatic injuries of the head

Laurence Watkins and David G. T. Thomas

Epidemiology

It is estimated that each year in the United Kingdom approximately 1 million people attend hospital after a head injury. Almost half of these are children under 16 years old. Head injuries cause 9 deaths per 100 000 population per year in the United Kingdom. This represents 1 per cent of all deaths, but 15 to 20 per cent of deaths for those between 5 and 35 years old. Since mainly young people are affected, the prevalence of disability caused is very significant, with an estimated 135 000 people in the United Kingdom dependent on care after brain trauma.

In 1986, the Royal College of Surgeons of England published guidelines on the provision of surgical services for patients with head injuries. More recently, there have been concerns that inappropriate treatment might be leading to unnecessary death and disability. This possibility, together with increasing public expectation, led to a further working party which published updated guidelines in 1999. The availability of CT scanning has also increased, so that now it is considered essential for all hospitals which admit patients with head injuries to have 24-h CT scanning facilities.

Basic concepts

Primary and secondary injury

Primary injury is the damage caused to the brain at the moment of impact. It encompasses diffuse axonal injury and focal contusions. Medicine has little to offer for primary injury; prevention, however, is a major concern for health and safety legislation, town planning, and traffic laws (such as the compulsory wearing of seat belts and crash helmets). The focus of medical intervention is the prevention of secondary damage.

The causes of secondary brain damage can be divided into extracranial (hypoxia and hypotension) and intracranial (haematoma, brain swelling, and infection).

Grading the severity of injury

Only 20 per cent of patients are admitted to hospital and most of these are discharged in less than 48 h. About 1 in 500 of the patients attending hospital will develop intracranial haemorrhage. The doctor's task is to manage patients in such a way that the few with preventable causes of secondary injury are identified and treated effectively.

The British Society of Rehabilitation Medicine defines three broad groups depending on their Glasgow Coma Score (**GCS**) after initial resuscitation:

1. Mild—GCS 13 to 15;
2. Moderate—GCS 9 to 12; and
3. Severe—GCS 3 to 8.

This is a useful categorization for decision-making in head injury management. It should not be confused with other schemes, which are generally retrospective and used for epidemiological and statistical purposes.

The golden hour

Taking into account the practicalities of CT scanning, interhospital transfer, and preparation for theatre, the time available for initial assessment, resuscitation, and treatment of other injuries in the emergency department is less than 1 h. This is sometimes referred to as 'the golden hour' in which rapid action is critical to the patient's outcome.

In a typical series of patients who had surgery for acute subdural haematoma, over 70 per cent had a functional recovery (good recovery or moderate disability) if the delay from injury to operation was less than 2 h. If the delay was between 2 and 4 h, just over 60 per cent made a functional recovery. In contrast, for those whose operation was more than 4 h after the injury, less than 10 per cent made a functional recovery (Fig. 1).

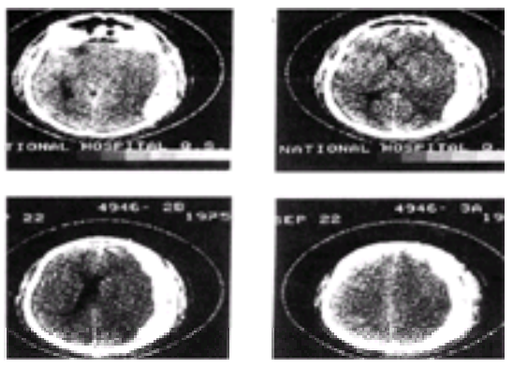

Fig. 1 Typical CT scan appearances of acute subdural haematoma. Fresh haemorrhage appears hyperdense (white). A subdural haemorrhage conforms to the surface of the brain, typically in a thin crescent. There is effacement of the lateral ventricle on the side of haematoma and midline shift away from it. An extradural haematoma, in contrast, usually appears biconvex, with well-defined edges since it is confined between the bone and dura.

Patients who 'talk and die'—the importance of deteriorating conscious level

A classic paper, by Jennett and his team, coined the phrase 'talk and die' to describe patients whose primary injury was mild, but who succumbed to secondary injury: usually an intracranial haematoma. Deterioration in conscious level is an urgent clinical sign that requires immediate action.

The Glasgow Coma Score (Table 1) is now widely used in the United Kingdom and elsewhere, giving objective recording of conscious level, with a high correlation between different observers. Any deterioration is thus more likely to be noticed. When communicating about a patient with head injury, it is good practice to specify observations of each parameter, rather than to use the corresponding numerical scores, which are open to misinterpretation.

Change in conscious level is the most useful clinical sign in head injury assessment. Generally, a patient with primary brain injury shows a gradually improving conscious level. A patient whose conscious level deteriorates is very likely to be suffering secondary brain injury and therefore requires further investigation and treatment. Conscious level must therefore be assessed at the earliest opportunity, and then reassessed at frequent intervals.

Early management of the patient with head injuries

Extracranial injuries

Life-threatening extracranial injuries always take priority over the head injury. However severe the head trauma, the patient needs to be stabilized for safe transfer. Also, hypotension and hypoxia are important causes of secondary brain injury. Time-consuming definitive surgery such as the internal fixation of limb fractures should, however, be postponed if possible.

Airway, breathing, and circulation are the first priorities. Management should follow the general recommendations taught in the Advanced Trauma Life-Support (ATLS) courses. In particular, assessment should include consideration of respiratory problems, shock, and possible internal injuries.

All patients with head injury should be assumed also to have a cervical spine injury until proven otherwise. Cervical immobilization should be established, unless the patient is fully conscious, co-operative, and able to convince the examining doctor that he has no neck pain or tenderness, a full range of cervical movement, and no neurological deficit. There are rare exceptions to this guideline: for example, a patient with a fixed flexion deformity due to ankylosing spondylitis might present with a cervical fracture; in that circumstance placing the neck in a 'neutral' position, in a cervical collar, might actually produce neurological injury.

Initial management of head injuries

After initial assessment, resuscitation, and stabilization of extracranial injuries, the patient is graded for the severity of their head injury. These categories then give a useful broad guide to management.

Severe

If the head injury is severe (GCS 3 to 8) then a member of the team should immediately refer to a neurosurgical unit. If the patient's best motor response is localization or obeying, then they may not necessarily require ventilation, provided that oxygen saturation can be maintained at more than 95 per cent, the PCO_2 at less than 6 kPa, and the PO_2 at more than 12 kPa on 40 per cent inspired oxygen. If the patient's best motor response is flexion or worse, or if any of the above criteria are not met, then the patient should be electively intubated and ventilated prior to transfer. Ventilation should be adjusted to maintain the PCO_2 in the range 4.0 to 4.5 kPa. At this stage, the intracranial pressure is unknown, but should be assumed to be high; therefore a mean arterial pressure of at least 90 mmHg should be maintained.

Whether a CT scan is performed at the referring hospital or on arrival at the neurosurgical unit will depend on the local availability of scanning facilities. This decision is based on whichever pathway is likely to produce the fastest response, given local conditions.

If, after discussion with the neurosurgical unit, a patient is accepted for transfer, they should be accompanied by personnel able to insert and manage an endotracheal tube and ventilation.

Moderate

If the head injury is moderate (GCS 9 to 13), then an urgent CT scan would be advisable. If the CT scan detects an intracranial abnormality, then urgent neurosurgical referral is appropriate and the immediate management will be similar to that for severe head injuries given above. If no abnormalities are detected on CT scan, care should be taken to exclude metabolic and other causes of reduced conscious level (such as hypoglycaemia or drug overdose). If it appears that diffuse brain injury is the only cause of depressed conscious level, then the care of the patient is discussed with the neurosurgical unit. In some cases transfer will be advised, while in others observation under the care of the emergency department will be appropriate. This will depend on local resources and practices. In either situation, if conscious level remains depressed at 48 h, the patient should be transferred to a neurosurgical unit for further assessment.

Mild

Most head injuries are mild (GCS 14 to 15). After initial assessment, the next decision is whether further investigation is required and whether this should be a skull radiograph and/or CT scan.

Patients who have a GCS of 15, have no history of loss of consciousness, and have none of the following criteria for investigation may be considered for discharge according to the local head injury protocol. They must be under the supervision of a responsible adult and written information must be provided concerning symptoms and signs which would warrant seeking further urgent medical advice.

In this context, the criteria for skull radiography include:

- GCS 14
- history of loss of consciousness or amnesia
- scalp swelling
- scalp laceration (to bone or more than 5 cm in length)
- high-energy mechanism of injury
- headache and/or vomiting which is not improving with time
- significant maxillofacial injuries.

In children, additional criteria include:

- fall from a height greater than twice the height of the child
- fall on to hard surface
- tense fontanelle
- any suspicion of non-accidental injury.

If no skull fracture is detected, then the patient should be observed until conscious level is normal and associated symptoms have resolved. If a fracture is seen on skull radiography, then the patient will require CT scanning and admission to hospital.

In addition to the presence of a skull fracture on the plain radiograph, the following are indications for CT scanning:

- focal neurological deficit
- Battle sign (bruising over the mastoid)
- periorbital haematoma ('raccoon eye' bruising)
- subconjunctival haemorrhage with no posterior limit
- blood or cerebrospinal fluid in ears or nostrils
- suspicion of penetrating injury
- seizure
- anticoagulation or known coagulopathy
- difficulty in assessment, whether due to extremes of age (very young or very old) or intoxication.

If the CT scan shows no abnormality, the patient should be admitted for observation for at least one night, and longer if symptoms persist. If the CT scan does show an intracranial abnormality, the care of the patient should be discussed with the neurosurgical unit. In most cases, transfer to the neurosurgical unit will be advised.

Management of intracranial complications

Intracranial haematoma

In almost all cases of intracranial haematoma, urgent evacuation is indicated, bearing in mind that the longer the delay, the greater the risk of death or disability. The above guidelines for observation/skull radiograph/CT scan/transfer to neurosurgical unit are all aimed at the earliest diagnosis of the minority of patients with an intracranial haematoma.

The risk of a traumatic intracranial haematoma depends on conscious level and whether a skull fracture is present (Table 2).

Infection

Meningitis and brain abscess can develop following any head injury in which a communication has been made between the environment and the intracranial contents. The most obvious example is a compound depressed fracture, where comminuted bone fragments have been forced inwards, breaching the dura. With some penetrating injuries (such as a fall on to a sharp object or assault with a pointed weapon) the visible wound may be small and appear insignificant. Since the injury may have been low velocity, the patient may have a deceptively normal conscious level. Such patients should always be referred for neurosurgical assessment.

A closed depressed fracture does not require surgery except for cosmetic reasons if it is on a visible part of the skull.

Cerebrospinal fluid rhinorrhoea or otorrhoea indicates that a skull base fracture has breached the dura. This places the patient at risk of meningitis while the cerebrospinal fluid leak continues. Ninety per cent of such cases close spontaneously within 2 weeks, and usually neurosurgical intervention is not considered until this time has elapsed. An exception is a fracture of the posterior wall of the frontal sinus, visualized on CT scan. Such cases should be discussed with the neurosurgeon or the craniofacial team (if one exists locally) with a view to possible early anterior fossa repair.

The use of antibiotics in cerebrospinal fluid leaks is controversial. In practice, most neurosurgical units still prescribe a penicillin or cephalosporin for 1 week or until the cerebrospinal fluid leak stops (which ever is longer). A working party reviewing the literature, however, concluded that the available evidence does not support the use of prophylactic antibiotics in patients with cerebrospinal fluid fistulas.

Follow-up and late complications of head injury

Cognitive symptoms

After head injury there is a variable period before memory function returns and ongoing memories again begin to be stored. This period is referred to as post-traumatic amnesia and is a useful measure of the severity of brain damage. For example, when questioned after recovery, a patient may not remember the accident but clearly recalls being placed on a stretcher and taken into the ambulance: this would suggest a relatively short post-traumatic amnesia of a few minutes. The post-traumatic amnesia is fixed for a given injury and memories of this period do not later 'recover'.

It is also common for a patient to lose memory of events immediately before the injury. This is known as retrograde amnesia. Unlike post-traumatic amnesia, the period of retrograde amnesia often progressively reduces as the patient recovers.

Incomplete recovery following head injury has behavioural, cognitive, emotional, social, and economic effects. For adults with severe head injuries, 85 per cent remained disabled at 1 year following the accident. In the intermediate group, 63 per cent remained disabled at 1 year. Even those with so-called 'minor' injuries can face considerable problems: at 3-month follow-up 79 per cent still have headaches, 59 per cent have symptomatic memory impairment, and 34 per cent have not returned to work.

The most widely used measure of outcome after head injury is the Glasgow Outcome Scale (Table 3). These are broad categories, which miss the subtleties of impairment in many who have had mild injuries, but its wide adoption and recognition make the Glasgow Outcome Scale invaluable for statistical comparisons.

Even 'mild' injuries, with early brief loss of consciousness and an initial GCS of 14 to 15, can lead to significant symptoms that can interfere with return to previous activities. These 'postconcussional symptoms' include headache, dizziness, poor concentration, memory impairment, and personality change. The patient's relatives often report personality changes, such as 'bad temper' and lack of motivation. Such symptoms usually improve over 6 months, especially if the patient and family are warned to expect such problems and reassured that they are eventually likely to resolve.

Rehabilitation after severe head injury requires multidisciplinary input from rehabilitation neurology, physiotherapy, occupational therapy, speech therapy, and neuropsychology. Other specialists and therapy services are accessed as appropriate for each individual patient. At least as far as the Glasgow Outcome Scale is concerned, 60 per cent of patients reach their final outcome category by 3 months after the injury. Ninety per cent reach their final score by the end of 6 months.

Epilepsy

Epilepsy is more common if there has been an intracranial haematoma, a depressed skull fracture, or post-traumatic amnesia of more than 24 h. A single seizure, within 1 week the injury, is of less significance than repeated seizures or those occurring after the first week. Any patient who has had a seizure, a craniotomy, or depressed skull fracture should be advised not to drive or operate dangerous machinery. They should also contact the Driving and Vehicle Licensing Authority.

Chronic subdural haematoma

The initial injury may have seemed very minor and may have occurred many weeks previously. The most common symptom is headache, progressively worsening and eventually accompanied by vomiting. There may also be a focal deficit, which can vary in severity. Increasing intracranial pressure may lead to cognitive impairment and eventually a depressed level of consciousness.

Whatever the pathophysiology, the treatment of choice is evacuation of the subdural collection and irrigation with isotonic saline at body temperature. This is a relatively small operation, which can even be performed under local anaesthetic, so even advanced age and general frailty do not contraindicate its use.

Hydrocephalus

Hydrocephalus occasionally occurs after head injury, particularly if there has been traumatic subarachnoid or intraventricular haemorrhage. It can be distinguished

from post-traumatic cerebral atrophy by the CT scan appearances: in hydrocephalus, the sulci will be small or effaced relative to the large ventricles and there may be periventricular lucency due to interstitial oedema.

24.13.19 Benign intracranial hypertension

N. F. Lawton

Synonyms

Pseudotumour cerebri and idiopathic intracranial hypertension are synonymous with benign intracranial hypertension.

Definition

Benign intracranial hypertension is a syndrome of raised intracranial pressure occurring in the absence of an intracranial mass lesion or enlargement of the cerebral ventricles due to hydrocephalus. The synonyms pseudotumour cerebri and idiopathic intracranial hypertension have both been preferred because the outcome is not invariably benign. Although rarely life-threatening, the rise in intracranial pressure may result in permanent visual loss due to optic nerve damage.

Incidence

Benign intracranial hypertension is a rare disease. The incidence is approximately 1 in 100 000 in the general population but rises to 19 in 100 000 in obese women of childbearing age. The disease is certainly more common in females, the preponderance over males ranging from 3:1 to 8:1. Although benign intracranial hypertension may occur in infants and the elderly, it is primarily a disease of young women between the ages of 17 and 44 years. Very rarely, it is familial and may occur in more than one generation.

Clinical features

It is the hallmark of benign intracranial hypertension that presenting symptoms and signs are those of raised intracranial pressure alone. The diagnosis should not be entertained in the presence of neurological features which suggest a focal lesion. Furthermore, there is a remarkable preservation of consciousness and intellectual function rarely encountered in patients with mass lesions or hydrocephalus. A history of epilepsy, either generalized or focal, virtually excludes the diagnosis of benign intracranial hypertension, although seizures may occur in the small group of patients with venous sinus thrombosis (see below). Preservation of cerebral function also distinguishes benign intracranial hypertension from acute viral or bacterial meningoencephalitis. atients with benign intracranial hypertension routinely present to outpatient departments and become a medical emergency when papilloedema is seen.

Headache

This is the most common symptom and is present to some degree in virtually every case. Characteristically the headache is typical of raised intracranial pressure. It is then generalized, throbbing, worse on waking, and aggravated by factors which temporarily increase cerebrospinal fluid pressure such as straining, coughing, or changing posture. Not infrequently, however, headache is mild and non-specific so that the distinction from common tension headache may be difficult. At presentation, headache has usually been present for weeks, although sometimes for months. Although up to 50 per cent of patients complain of nausea, typical early morning projectile vomiting is rare.

Obesity

Among the medical conditions associated with benign intracranial hypertension, obesity is sufficiently common to be a characteristic feature. Up to 90 per cent of patients in reported series are overweight, although a history of rapid weight gain immediately prior to the onset is unusual.

Papilloedema

This is a virtually universal finding and the importance of fundus examination in every patient with headache cannot be overemphasized. Papilloedema is usually moderate and may be unilateral. Occasionally the appearance of the optic discs may be equivocal, and fluorescein angiography is indicated to demonstrate the characteristic leakage of dye in true papilloedema.

The classic symptom of papilloedema, which is not specific to benign intracranial hypertension, is a transient obscuration of vision, often described as a fleeting greyness, a halo, or a more vivid episode of 'Catherine wheels' lasting for a few seconds. Obscurations may be provoked by straining or a change in posture, but may also occur spontaneously. Persistent blurring of vision may also occur and patients may describe scotomas in the field of vision associated with optic nerve damage. Occasionally, sudden and permanent loss of vision results from infarction of the optic nerve.

Visual obscurations, persistent blurring, or scotomas are reported by 30 to 70 per cent of patients. A history of obscurations is often only elicited by direct questioning.

Visual field defects

Visual field analysis is the essential investigation in the examination and follow-up of patients with benign intracranial hypertension. The most common defects are enlargement of the blind spots, generalized constriction of the fields, and scotomas caused by optic nerve damage. There may be a predilection for visual field loss in the inferior nasal quadrants.

Diplopia

About 30 per cent of patients complain of horizontal diplopia due to sixth nerve palsy, which may be bilateral. The cause is a false localizing sign of raised intracranial pressure.

Aetiology

In the majority of patients with benign intracranial hypertension no cause can be identified. Many clinical associations have been reported, but these may have occurred by chance. Preceding minor head injury and intercurrent infections come into this category. Furthermore, the known associations are rare with the exceptions of obesity and the predilection for females. A positive family history, vitamin deficiency, and drugs are each a factor in less than 2 per cent of cases.

Dural sinus thrombosis

Before the advent of antibiotics, benign intracranial hypertension was frequently associated with chronic middle-ear disease complicated by dural sinus thrombosis. The term 'otitic hydrocephalus' was coined to describe this syndrome on the erroneous assumption that ventricular enlargement was present.

Although true 'otitic hydrocephalus' is now rare, the syndrome of benign intracranial hypertension may still occur following venous thrombosis in dural sinuses or in the extracranial jugular system. Sinus thrombosis may complicate pregnancy, the use of oral contraceptives, head injury, venous occlusive disease due to hypercoagulability states, dehydration due to any cause, or mediastinal obstruction. Sinus thrombosis should be suspected clinically when the onset of headache is sudden and accompanied by focal signs or impaired consciousness. Occasionally, the syndrome of benign intracranial hypertension is a late presentation of undiagnosed sinus thrombosis. In the majority of patients, however, venous obstruction is not the predisposing cause and the cerebral venous system is normally patent.

Menstrual disorders

Apart from the complication of venous thrombosis, benign intracranial hypertension is associated with pregnancy *per se*. It is not clear whether an association with menstrual irregularity is more than would occur by chance in obese young women. An association with menarche has been reported.

In spite of the clinical associations which suggest an underlying disorder of female endocrinology, hormonal studies have not shown a consistent abnormality. The pituitary–adrenal axis is intact and occasional abnormal responses may be due to obesity rather than benign intracranial hypertension. Thyroid function and prolactin secretion both appear to be normal. Cerebrospinal fluid vasopressin levels are raised, but this is not specific and may occur in a variety of neurological diseases. Reports of a specific increase in cerebrospinal fluid oestrone, which might link benign intracranial hypertension with obesity because adipocytes are the major source of oestrone, have not been confirmed.

Deficiency states

A rare cause of benign intracranial hypertension in children is hypovitaminosis A due to generalized nutritional deficiency or malabsorption. In such cases the condition responds specifically to vitamin A supplements. Poisoning with vitamin A due to excessive consumption of fish or animal liver may also cause benign intracranial hypertension.

Drug-induced benign intracranial hypertension

Both tetracycline and the retinoids isotretinoin and etretinate, which are vitamin A derivatives, may cause benign intracranial hypertension during long-term treatment for acne. These drugs should not be used in combination. All-*trans*-retinoic acid in the treatment of acute promyelocytic leukaemia is also a cause in this category. Other drugs occasionally responsible for the syndrome include nalidixic acid, nitrofurantoin, and lithium. Corticosteroids may lead to benign intracranial hypertension during their withdrawal after chronic treatment and the syndrome may occur in Addison's disease.

Empty sella

It has been suggested that this association in about 4 per cent of cases is caused by raised intracranial pressure in combination with incompetence of the diaphragma sellae. The theory is supported by the finding of raised pressure at lumbar puncture in some patients with empty sella, suggesting chronic benign intracranial hypertension as the underlying cause. Clinical hypopituitarism does not occur, but occasionally the empty sella may harbour a prolactinoma.

Pathogenesis

The mechanism by which intracranial pressure rises is poorly understood and the contribution of various factors controversial. Since the intracranial contents are housed in a rigid container, an increase in cerebrospinal fluid pressure may result from an increase in blood volume, swelling of the brain parenchyma, or an increase in the cerebrospinal fluid volume due to overproduction or malabsorption. There is little evidence to suggest that increased blood volume or cerebrospinal fluid production are important factors.

Swelling of the brain parenchyma

Direct evidence of a swelling due to cerebral oedema is slight and a single report of oedematous changes in brain biopsies has not been confirmed. However, the tendency for the ventricles to be small may indicate an increase in cerebral volume secondary to leakage from the cerebral vascular bed rather than transudation of cerebrospinal fluid from the ventricular system. Brain imaging in benign intracranial hypertension does not show the periventricular leakage of cerebrospinal fluid that occurs in hydrocephalus. Although there is currently no direct evidence for vasogenic cerebral oedema, this factor cannot be ignored, because it is one mechanism for raised pressure which does not anticipate some degree of hydrocephalus.

Decreased absorption of cerebrospinal fluid

A defect of cerebrospinal fluid absorption is widely regarded as the important factor in the pathogenesis of benign intracranial hypertension. Apart from those cases in which there is dural sinus thrombosis, it is assumed that the defect lies in the arachnoid villi of the superior sagittal sinus where the bulk of cerebrospinal fluid absorption takes place. The delayed clearance of radio-iodinated human serum albumin from the ventricular system after injection into the lumbar subarachnoid space is indirect evidence of reduced cerebrospinal fluid absorption. Simultaneous cannulation of the superior sagittal sinus and the subarachnoid space has shown increased resistance to cerebrospinal fluid absorption in the majority of cases. Manometry has shown consistent hypertension in venous sinuses but it is not clear whether this is primary or secondary to raised intracranial pressure. Finally, vitamin A deficiency in rats and cows produces a rise in intracranial pressure associated with diminished absorption of cerebrospinal fluid and histological changes in the arachnoid villi which are reversible with vitamin A supplements.

The absence of hydrocephalus in benign intracranial hypertension has been cited as an objection to the theory of reduced cerebrospinal fluid absorption. It is probably more significant, however, that sinus thrombosis may cause the syndrome of benign intracranial hypertension by preventing cerebrospinal fluid absorption, and is similarly associated with normal or small ventricles.

Investigations

The diagnosis of benign intracranial hypertension can only be confirmed by measurement of cerebrospinal fluid pressure, but in suspected cases it is essential to exclude a mass lesion or hydrocephalus before proceeding to lumbar puncture.

Radiology

Characteristically, CT scanning shows small and slit-like cerebral ventricles which may increase in volume as intracranial hypertension resolves. A similar appearance is seen on magnetic resonance imaging. Sagittal sinus thrombosis may be visualized on CT scanning as the characteristic 'empty delta' sign due to clot within the sinus. MRI is far superior to CT and provides graphic images of sinus thrombosis. Occasionally MR or CT angiography may be needed to exclude sinus thrombosis or conventional venography if thrombolytic therapy is contemplated.

Cerebrospinal fluid pressure

At lumbar puncture the opening pressure is greater than 200 mm cerebrospinal fluid, but it is important to note that in simple obesity the cerebrospinal fluid pressure may be as high as 250 mm. The diagnostic significance of cerebrospinal fluid pressure must therefore be correlated with the clinical picture. In the few patients whose cerebrospinal fluid pressure is equivocal, continuous monitoring may demonstrate intermittent peaks of raised pressure.

Cerebrospinal fluid analysis

The composition of the cerebrospinal fluid in benign intracranial hypertension is entirely normal, and the presence of white cells or a raised protein concentration cast serious doubt on the diagnosis. An exception to this rule is the rare syndrome resembling benign intracranial hypertension which occurs in association with postinfective polyneuropathy and with spinal tumours. Both conditions may lead to raised intracranial pressure with papilloedema and normal-sized ventricles but a marked rise in cerebrospinal fluid protein. The syndrome may also complicate cryptococcal meningitis and meningoradiculopathy in HIV infection.

Management

Patients given a diagnosis of benign intracranial hypertension are usually bewildered and frightened. It is important to provide a simple explanation of the nature of the condition and the rationale for treatment. Anticoagulation with heparin may be effective in the treatment of acute sinus thrombosis, emphasizing the importance of angiographic diagnosis in this small group of patients. With the further exception of rare cases due to drug treatment, the management of benign intracranial hypertension is aimed at the symptomatic reduction of intracranial pressure to protect vision and relieve headache. The methods available are difficult to evaluate because of the high spontaneous remission rate and the lack of controlled trials. Choice of treatment is further complicated by the absence of reliable risk factors for visual loss. In particular, the height of the cerebrospinal fluid pressure at diagnosis is of no prognostic significance.

In the past, repeated therapeutic lumbar puncture every 2 to 5 days has been shown to reduce cerebrospinal fluid pressure temporarily and may occasionally lead to spontaneous remission. When acute medical treatment is indicated, prednisolone (40 to 60 mg daily) is effective in relieving headache and visual obscuration due to papilloedema. However, steroids are unsatisfactory as long-term treatment because of their complications, especially in obese young females. For this reason diuretics are widely used in patients with mild symptoms. Acetazolamide or a thiazide diuretic may relieve headache, but the efficacy of diuretics in preventing slowly progressive visual loss is unproven.

Because of the limitations of medical treatment, an increasing number of patients are treated surgically, progressive visual field loss and unrelieved headache being the indications for operation. Because of the difficulty of tapping small cerebral ventricles, a lumboperitoneal shunt is usually favoured. Unfortunately, the technical failure rate of lumboperitoneal shunts is high and surgical revision may be required in up to 20 per cent of patients. For this reason the alternative operation, in which the optic nerve sheath is decompressed, has recently been revived, particularly in North America. This procedure produces rapid improvement in papilloedema, occasionally in both eyes after unilateral surgery. It is not clear whether long-term improvement is due to the creation of a cerebrospinal fluid fistula into the orbit or fibrosis of the meninges preventing transmission of the high cerebrospinal fluid pressure to the optic nerve head. However, headache is often unrelieved by this procedure, and lumboperitoneal shunting may not be avoided. There is also a risk of further visual loss postoperatively, which is much less common after a shunt procedure.

Currently it would seem reasonable to begin treatment with diuretics, reserving steroids as a temporary medical treatment in patients with severe symptoms. If surgery becomes necessary, lumboperitoneal shunting seems a logical procedure, with resort to optic nerve sheath decompression in the event of repeated shunt failure. Occasionally, subtemporal decompression may be a last therapeutic resort.

Although the efficacy of weight loss *per se* has not yet been established, a weight-reducing diet is recommended in obese patients. In patients with extreme obesity, gastric bypass surgery has reportedly relieved intracranial hypertension.

Pregnancy

The main threat is to the fetus and the rate of spontaneous abortion is increased. Spontaneous remission of benign intracranial hypertension during pregnancy has been the rule, although the number of reported cases is small. It would seem reasonable to begin treatment with diuretics, although steroids and shunt operations may occasionally be required.

Prognosis

Benign intracranial hypertension is a chronic condition in most patients, but spontaneous relapse and remission of symptoms is common. There is evidence that raised intracranial pressure may be found at follow-up lumbar puncture in patients whose symptoms have been in remission for several years. Mortality from benign intracranial hypertension is nil in most series, although an underlying sagittal sinus thrombosis may lead to a fatal outcome. Permanent visual loss occurs in up to 50 per cent of patients and is a significant disability in 10 per cent. Because the choice of treatment is determined primarily by progression of optic nerve damage, serial visual field analysis is the important yardstick of clinical progression.

24.14.1 Bacterial meningitis

*D. A. Warrell, J. J. Farrar, and D. W. M. Crook**

Bacterial meningitis, also known as pyogenic, purulent, or cerebrospinal meningitis, is an inflammation of the leptomeninges with infection of the cerebrospinal fluid (**CSF**) within the subarachnoid space of the brain and spinal cord, and the ventricular system.

Anatomy of the subarachnoid space

In the absence of pathological blockages, bacteria entering the subarachnoid space at any point can spread over the surface of the brain and into the perivascular spaces of Virchow–Robin. After reaching the basal cisterns they can pass through the foramina of Luschka and Magendie into the fourth ventricle, and thence through the cerebral aqueduct of Sylvius to reach the third ventricle, and through the interventricular foramina of Monro to the lateral ventricles. Subdural empyema (pachymeningitis interna) or effusion complicating leptomeningitis can also spread freely because the arachnoid membrane and dura mater are almost entirely separated. By contrast, because of the tight application of the dura mater to the periosteum of the skull, epidural collections of pus are localized. In the spinal column, however, the epidural space is loose and contains fat, permitting the extension of a posterior spinal epidural abscess over several vertebral segments. Within the subarachnoid space and intraventricular system, infection may produce blockages of CSF circulation, especially at the various foramina or in the aqueduct, causing obstructive hydrocephalus or spinal block. If reabsorption of CSF across the subarachnoid granulations is prevented by a subarachnoid haematoma or empyema or thrombosis of the intracranial veins and venous sinuses, communicating hydrocephalus will result. In patients with meningitis, intracranial hypertension may be the result of cerebral oedema, the ventricular dilatation of hydrocephalus, or subdural or epidural collections of pus. Obstructive hydrocephalus and intracranial collections of pus carry a special risk of producing brain herniation after lumbar puncture.

Because they cross the inflamed basal meninges, the cranial nerves and cerebral blood vessels may be damaged. Cranial nerves may be compressed by intracranial hypertension (VI) or brain herniation (III) or suffer ischaemic damage from vasculitis. Cerebral veins and arteries may thrombose.

Acute bacterial meningitis

Classification

Pyogenic bacterial meningitis occurs in a number of clinical situations, each of which is associated with a particular pattern of infecting organisms, clinical presentation, and outcome. Spontaneous meningitis is the most important category and can be divided into neonatal meningitis or meningitis of childhood and adulthood. Post-traumatic meningitis follows neurosurgery or fractures of the skull. Device-associated meningitis complicates the use of CSF shunts and drains. Infection may also be considered as community acquired or nosocomial (hospital acquired) (Table 1).

Aetiological agents and epidemiology

The bacterial species that cause meningitis vary by geographical region and according to the categories mentioned above. Age and local social conditions influence the attack rate and mortality of spontaneous meningitis.

Neonatal meningitis is usually caused by three species: group B streptococci (*Streptococcus agalactiae*); K1 capsulate *Escherichia coli*; and *Listeria monocytogenes*. A wide range of other organisms has been reported to cause the disease. Infection mostly occurs in the postpartum period, but can occur as late as 6 weeks after birth. Prolonged rupture of membranes and low birth weight are important risk factors.

Spontaneous community-acquired meningitis in children (under 14 years of age) is usually caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*, or *Haemophilus influenzae.* However, national implementation of conjugated *H. influenzae* type b (**Hib**) capsular vaccine immunization programmes by many countries during the 1990s has dramatically reduced, or nearly eliminated, Hib meningitis. The introduction of the conjugate vaccine against *Neisseria meningitidis* Group C in 1998 reduced the incidence of meningococcal meningitis in England and Wales. Similarly, pneumococcal conjugate vaccination in the United States is reducing the incidence of pneumococcal meningitis in this age group. The highest attack rate of all three bacterial species is in children under 1 year of age and falls off rapidly with increasing age. The decrease in susceptibility with increasing age results from the acquisition of protective immunity, mainly as a result of nasopharyngeal carriage.

In most countries, more than 50 per cent of cases of spontaneous community-acquired meningitis in adults are caused by *N. meningitidis* and *S. pneumoniae* (Table 1). *Listeria monocytogenes,* aerobic Gram-negative bacilli (such as *Escherichia coli*), *H. influenzae*, and *Staphylococcus aureus* cause most of the remaining cases. The attack rate of endemic *N. meningitidis* meningitis is usually low (1–5 cases/10^5 persons per year), but occasionally the incidence of the infection may increase and even reach epidemic proportions (for example, >300 cases/10^5 persons per year). Crowding is thought to play a role in the epidemics occurring in military recruits, South African miners, and other groups of people crowded together in closed environments. The attack rate of *N. meningitidis* disease may increase secondarily to epidemics of influenza A. However, the precise origin of the major epidemics affecting countries such as Brazil (in the 1970s) and regions such as sub-Saharan Africa remains unexplained. The bacterial capsule plays a role in determining the pattern of invasive disease caused by *N. meningitidis.* Capsulate serogroups A, B, and C occur sporadically and cause outbreaks of invasive disease, while serogroups Y, W, Z, W-135, and 29-E cause only occasional cases.

The attack rate of *S. pneumoniae* meningitis (1–2 cases/10^5 persons per year) is remarkably constant around the world. It increases in patients over 70 years of age. A high proportion of pneumococcal cases exhibit an associated infective focus. Otitis media or sinusitis is found in approximately 30 per cent of cases and pneumonia in up to 25 per cent. Hypogammaglobulinaemia (primary or secondary, for example in nephrotic syndrome and chronic lymphocytic leukaemia), sickle-cell disease,

splenic dysfunction, and previous trauma to the skull (see below) are risk factors for developing pneumococcal meningitis.

Streptococcus suis (Group R haemolytic streptococcus) serotype 2 is an important cause of meningitis (and rarely infective endocarditis, and septicaemia) in the Far East (Hong Kong, Thailand, Vietnam) and in other countries. Infection is related to occupational contact with pigs or pork, but the precise epidemiology remains poorly understood. In Holland the incidence of *S. suis* meningitis among abattoir workers and pig breeders was 3.0/100 000 per year. It is now the commonest cause of adult bacterial meningitis in Hong Kong and Vietnam. Possible routes of entry include skin abrasions, found in 40 per cent of patients, and upper respiratory and gastrointestinal tracts. Splenectomized patients are particularly at risk, as with other capsulated Gram-positive organisms.

Worldwide, *Listeria monocytogenes* accounts for few cases of meningitis, with an attack rate of approximately 0.2 to 0.4 cases/10^5 persons per year or 1 to 5 per cent of the cases of meningitis. Increased attack rates have been associated with contaminated foods such as unpasteurized soft cheeses, pâté, and poorly refrigerated precooked chicken. People at the extremes of age, pregnant women, and those with altered host defence mechanisms from prolonged immunosuppression with corticosteroids or alkylating agents such as azathioprine are at increased risk of listeriosis. *Staphylococcus aureus* causes 1 to 5 per cent of the cases with spontaneous meningitis and usually occurs in association with infective endocarditis. Spontaneous cases of *H. influenzae* meningitis, both capsulate type b and non-capsulate strains, account for up to 5 per cent of adult cases of meningitis. Aerobic Gram-negative (for example, *E. coli*) meningitis occurs especially in aged, debilitated, and diabetic people. The source in these infections is usually thought to be the renal tract.

Post-traumatic meningitis occurs in patients with skull or spinal injuries (for example, skull fractures) or in those who have undergone head and neck or spinal surgery. It usually arises in association with a CSF leak and soon after injury, but may occur many years after the trauma. The risk of developing meningitis is as high as 25 per cent with a clinically apparent CSF leak. The aetiology depends on whether the infection is acquired nosocomially or in the community. The majority of hospital-acquired infections are caused by aerobic Gram-negative bacilli, such as *E. coli, Klebsiella pneumoniae,* other Enterobacteriaceae, *Acinetobacter* spp., and *Pseudomonas* spp. Less commonly, *S. pneumoniae, H. influenzae, S. aureus,* and other normal upper respiratory tract flora cause meningitis in patients in hospital. Post-traumatic meningitis acquired in the community is caused mainly by *S. pneumoniae* (>90 per cent) and *H. influenzae.*

Device-associated meningitis is a well-recognized entity occurring in patients with CSF drains and CSF shunts. Most infections are nosocomial and are caused by coagulase-negative staphylococci (50–60 per cent) and *S. aureus* (15–30 per cent). Aerobic Gram-negative bacilli, *Streptococcus* spp., *Corynebacteria* spp., and *Propriobacterium acnes* are encountered. These infections usually present within a few months of inserting the device. Occasionally, *S. pneumoniae, N. meningitidis,* and *H. influenzae* are responsible.

Recurrent meningitis is an unusual (<10 per cent of meningitis) but well-recognized clinical category. Such cases frequently have either an underlying anatomical defect (for example, CSF leak or spina bifida) or an immunological defect. The immune deficiencies that most often predispose to recurrent meningitis are hypogammaglobulinaemia and complement deficiencies. Consideration should be given to vaccinating such patients against the most common pathogens.

The increasing incidence of human immunodeficiency virus (**HIV**) infection has altered the presentation and pattern of aetiological agents causing meningitis. A large seriesof adult patients withmeningitis who presented totheQueen Elizabeth Central Hospital in Blantyre, Malawi, was reported in 1975. At that time,meningitis comprised 2.5 per cent ofmedical admissions, the most common pathogens being*N. meningitidis* and *S. pneumoniae*. Sincethen, the population ofMalawi has been very severely affected by the **AIDS** (acquired immunodeficiency syndrome) pandemic, and theHIV seroprevalence of antenatalwomen has climbed steadilythrough the 1980s to the present level of more than 30 per cent. Thechanged overall pattern inthis series is probablydue to the influenceof HIV infection; ina survey of 153patients with invasive pneumococcaldisease, HIV seroprevalence was 95 per cent. In South Africa, HIV-infected children have more antibiotic-resistant isolates and a different clinical presentation compared to HIV-uninfected children. In adults, the HIV epidemic was found to be responsible for increasing chronic infections such as tuberculous and cryptococcal meningitides.

Pathogenesis

The acquisition of infection and mode of invasion of the CSF vary with the type of meningitis. However, once infection is established, the inflammatory injury and pathophysiology are remarkably similar in all types of meningitis. Important steps in the pathogenesis of spontaneous meningitis are nasopharyngeal colonization and mucosal adherence and invasion involving receptors, bacterial fimbriae or pili, encapsulation, and other virulence factors that are blocked by secretory IgA and other host defences such as the complement system. Within the subarachnoid space, these defences are inadequate as there is no complement and concentrations of IgG antibodies are low. The cell walls of Gram-positive bacteria and lipopolysaccharides of Gram-negative bacteria cause inflammatory change, thereby increasing vascular permeability and leading to the development of cerebral oedema.

The organisms that cause neonatal meningitis are acquired by the baby from the vagina and perineum during delivery, or from the environment soon after birth. The three main infecting species, *S. agalactiae* (group B streptococci), *E. coli,* and *L. monocytogenes,* invade the host, cause septicaemia, and, as a result, produce meningitis. An unusual feature of *E. coli* and many *S. agalactiae* strains (capsular types K1 and III, respectively) is that their capsules consist of polysialic acid. The association of this unusual type of capsule with two virulent strains suggests a role in the pathogenesis of neonatal meningitis.

Causative organisms of spontaneous meningitis, *S. pneumoniae, H. influenzae,* and *N. meningitidis,* are acquired by person-to-person spread. Replication in the nasopharynx is the essential first step before invasion. Asymptomatic carriage implies a stable and well-adapted relationship between microbe and host. Fortunately, this is the usual outcome. Invasion and infection of the host resulting in disease represents a rare and potentially catastrophic breakdown in the relationship between the bacterium and host. Invasion of the host is particularly likely to occur early after acquisition of the organism, before the host has developed protective immunity. Carriage is sufficient to produce immunity and resistance to disease. The greatest risk of disease, therefore, is in the first few years of life, at a time when the non-immune host first encounters these pathogens. The precise anatomical site of invasion is not known for all three pathogens. Animal studies suggest that the nasopharynx is the probable site of systemic invasion for *H. influenzae* meningitis, associated with escape into the bloodstream of a single organism that multiplies and produces septicaemia. In a proportion of these bacteraemic cases, bacteria then gain access to the CSF. Invasion of the CSF is probably dependent on the concentration of organisms in the blood and on the species causing bacteraemia (for example, bacteria such as enterococci can cause high-intensity bacteraemia under some conditions but the organisms seldom enter the CSF, whereas *N. meningitidis, H. influenzae,* and *S. pneumoniae* frequently invade the CSF). The choroid plexus, a highly vascular tissue, is probably the site of CSF invasion. Once organisms have entered the CSF and multiplied, purulent meningitis is inevitable.

Organisms causing post-traumatic meningitis invade the CSF directly through an anatomical defect. Bacteraemia, which is common, is secondary to the meningitis. Shunt-associated meningitis is caused mainly by organisms that colonize the skin and contaminate the surgical wound and prosthetic material at the time of surgery. The infected shunt becomes coated with a film of adherent bacteria, commonly referred to as a 'biofilm', which is not susceptible to clinically achievable levels of antibiotic. Such infections are usually incurable unless the foreign material is removed.

Once bacteria have gained access to the subarachnoid space they multiply in the CSF relatively uninhibited by host defences. Neutrophils, which rapidly accumulate in the infected CSF, have little inhibitory effect on the growth of the infecting bacteria in experimental animals. Complement is found in such low concentrations in CSF that it is unlikely to have an antibacterial effect. Investigation of the mediators of this inflammatory response is incomplete, but studies of pneumococcal and *H. influenzae* meningitis have identified important features of this inflammatory reaction. The pneumococcal cell wall has been shown to be a potent inducer of inflammation. Since this reaction can be attenuated by cyclo-oxygenase inhibitors, prostaglandins are believed to be important. The role of cytokines in the CSF has not been fully elucidated in this type of meningitis. However, the pneumococcal cell wall is a potent inducer of systemic interleukin-1 (**IL-1**), but not of tumour necrosis factor (**TNF**). The exact role of these mediators in pneumococcal meningitis remains unresolved. The main bacterial component responsible for inducing inflammation in *H. influenzae* type b is lipopolysaccharide (**LPS** or endotoxin), a potent inducer of cerebrospinal fluid TNF and IL-1 which have been shown to mediate the inflammatory response in the subarachnoid space. There is a suggestion of a dose–response effect between lipopolysaccharide and the inflammatory mediators, and so interventions that release lipopolysaccharide may exacerbate the inflammatory reaction. It has also been suggested that certain antibiotics which produce an enhanced lipopolysaccharide release may temporarily exaggerate the inflammatory reaction in a type of Jarisch–Herxheimer reaction.

The inflammatory reaction in meningitis is associated with a number of severe alterations in the normal physiology of the CNS. First, permeability of the blood–brain barrier increases. This is best measured by the increased penetration of the CSF by albumin. Also, antibiotic penetration of the CSF is greatly enhanced. Second, increased intracranial pressure results from cerebral oedema secondary to an accumulation of interstitial fluid, and communicating hydrocephalus is caused by decreased CSF re-absorption and cellular swelling secondary to cell injury. Third, a vasculitis may affect mainly the large vessels traversing the subarachnoid space. This vascular injury may not only disrupt the normal autoregulation of cerebral blood flow, but, in severe cases, the vessel may become obstructed with thrombus, causing a cerebral infarct. The major impact of increased intracranial pressure and vasculitis is decreased cerebral perfusion, causing general hypoxic brain injury.

Pathology

There is diffuse acute inflammation of the pia-arachnoid, with migration of neutrophil leucocytes and exudation of fibrin into the CSF. Pus accumulates over the surface of the brain, especially around its base and the emerging cranial nerves, and around the spinal cord. The meningeal vessels are dilatated and congested and may be surrounded by pus. Pus and fibrin are found in the ventricles and there is ventriculitis, with loss of ependymal lining and subependymal gliosis. Dilatation of the ventricular system may result from obstructive or communicating hydrocephalus. Other abnormalities include subdural effusion or empyema, septic thrombosis of the cerebral venous sinuses, subarachnoid haematomas, compression of intracranial structures as a result of intracranial hypertension, and herniation of the temporal lobes or cerebellum. Gross changes, such as pressure coning, which would provide an obvious cause of death, are rarely found. In some cases death may be attributable to related septicaemia (Fig. 1), although the familiar finding of bilateral adrenal haemorrhage (Waterhouse–Friederichsen syndrome) may well be a terminal phenomenon rather than a cause of fatal adrenal insufficiency as was once imagined. Patients with meningococcal septicaemia may develop acute pulmonary oedema. Myocarditis was a common finding in some series of patients. Histological appearances were of an acute interstitial myocarditis, occasionally with myocardial necrosis and thrombosis of small arterioles. Pericarditis and pericardial effusion were features, particularly of group C meningococcal infections. Myocarditis and Waterhouse–Friederichsen syndrome also occur, less frequently than in meningococcal septicaemia, in septicaemia caused by *H. influenzae,* pneumococcal, streptococcal, and staphylococcal infections.

Clinical features

Acute bacterial meningitis carries a mortality in untreated patients of between 70 and 100 per cent. Delay in treatment greatly increases the risk of permanent neurological sequelae. The early diagnosis of this condition is, therefore, a formidable challenge to clinical acumen, but early clinical suspicion of meningitis may be impossible in many cases, especially in neonates and small children. When meningitis is secondary to infection elsewhere, such as pneumococcal pneumonia or *H. influenzae* otitis media, the presenting symptoms may be those of the original infection. The incubation period is only a few days. Progression is occasionally so rapid (*N. meningitidis*) that the patient becomes comatose within a few hours after the first symptoms. Early manifestations include non-specific malaise, apprehension, or irritability, followed by fever, usually without rigors, headache, myalgias, and vomiting. Convulsions occur in infants and children and meningitis must always be included in the differential diagnosis of childhood febrile convulsions. Photophobia, drowsiness, or more severe impairment of consciousness usually develop later. Headache quickly becomes more severe and is the dominant symptom. In older children and adults the symptoms most suggestive of meningitis are irritability, severe headache, and vomiting, but in the case of meningococcal infection, diarrhoea is a common non-specific symptom and the vasculitic rash is a crucial sign. An early symptom of meningococcal septicaemia is pain in the calves.

There is rarely any doubt that the child or adult with meningitis is severely ill and distressed. Meningism is best elicited by gentle passive flexion or rotation of the neck with the patient lying supine. If patients can shake their heads vigorously they are unlikely to have meningitis! To elicit Kernig's sign the lower limb is flexed at the hip. The patient with meningism will resist extension of the knee by contracting the hamstring muscles. Brudzinski's neck sign is best elicited while the patient sits up in bed with the legs stretched out. Gentle flexion of the neck will induce a compensatory flexion of the hips, knees, and sometimes the upper limbs. Later, the patient with marked meningism lies in a characteristic position with the neck and back fully extended (Fig. 2) as in tetanic opisthotonos. Local causes of neck stiffness, such as local sepsis (for example, in the nuchal muscles or cervical lymph nodes), cervical spondylitis (particularly common in the elderly), temporomandibular arthritis, dental problems, and pharyngeal lesions, should be considered. Meningism is not uncommon in patients without meningitis who have other febrile conditions such as pyelonephritis. Meningism may be reduced or absent in patients who are immunosuppressed. The optic fundi should be examined as a prelude to lumbar puncture. Papilloedema is suggestive of cerebral oedema or an intracranial space-occupying lesion, such as a cerebral abscess or a subdural or epidural collection of pus. The absence of papilloedema does not, however, exclude cerebral oedema and, if in doubt, and cerebral imaging is available, that investigation must precede a lumbar puncture. Retinal vein pulsation excludes intracranial hypertension. Hypertensive retinopathy will suggest hypertensive encephalopathy, and subhyaloid haemorrhages a subarachnoid haemorrhage. Patients with meningococcal meningitis associated with meningococcal antigenaemia have a petechial rash (Plate 1) which may appear first on the shins or volar surface of the forearms. Petechiae may be visible on the bulbar and tarsal conjunctivas (Plate 2) and palate. An identical rash is occasionally seen in patients with echovirus type 9, leptospirosis, *S. aureus, S. pneumoniae, S. suis* (Plate 3) *H. influenzae, Salmonella typhi,* and other infections, especially in those associated with infective endocarditis. The brownish or reddish geometrical, vasculitic rash of fulminant meningococcaemia is unmistakable (Plate 4 and Plate 5) and, characteristically, the toes and fingers become necrotic (Fig. 3). There is associated profound hypotension, shock with peripheral cyanosis, and spontaneous systemic bleeding. Herpes labialis is commonly seen in all forms of bacterial meningitis, because a fever is the rule and recurrences are provoked by fever (see Fig. 2 and Fig. 4). Physical examination must exclude otitis media, sinusitis, mastoiditis, and nasopharyngeal and other possible sites of sepsis. In patients with recurrent bacterial meningitis, a search should be made for a congenital dermal sinus, which is usually in the midline between the head and coccyx and is often marked by a tuft of long hairs. Watery discharge from the nose or ears should be collected and tested for glucose; the possibility of a basal skull fracture with cerebrospinal fluid leak should be excluded.

Fig. 3 Gangrene of the fingers in a man with fulminant meningococcaemia. Eventually, three of his limbs had to be amputated. (Copyright D.A. Warrell.)

Fig. 4 Nigerian man recovering from meningococcal meningitis. Note right VIth nerve lesion and herpes labialis. (Copyright D.A. Warrell.)

Cranial nerve lesions may become evident as the disease progresses. The commonest are VI (Fig. 4), III, VII, VIII, and II. Patients who become deeply comatose (meningoencephalomyelitis) may lose all signs of meningism and develop focal neurological signs, focal epileptiform convulsions, dysconjugate gaze, upper motor neurone signs, and involuntary movements. Vascular lesions may produce hemiparesis or quadriparesis, speech disorders, and visual field defects. Bilateral sensorineural deafness develops early, 2 to 9 days after the start of symptoms, in the majority of patients with *S. suis* type 2 meningitis. Initially associated with tinnitus and vertigo, this may progress to complete deafness within 24 h. Bacteria probably invade the cochlea via the cochlear aqueduct from the subarachnoid space to produce suppurative labyrinthitis and acute deafness. Associated clinical features of *S. suis* meningitis include third nerve palsy, septic arthritis (Plate 6), and purpuric skin lesions (Plate 3).

Papilloedema, with or without other symptoms and signs of intracranial hypertension (vomiting, postural headache, coma, high blood pressure, bradycardia, etc.) and localizing neurological signs, suggests a subdural effusion or empyema. This is particularly common in children under 2 years old with *H. influenzae* meningitis.

Neonates and infants

Meningitis is particularly difficult to diagnose in this age group. Infants may become irritable or lethargic, stop feeding, and are found to have a bulging fontanelle, separation of the cranial sutures, meningism, and opisthotonos, and they may develop convulsions. These findings are uncommon in neonates, who sometimes present with respiratory distress, diarrhoea, or jaundice.

Post-traumatic meningitis

This is often indistinguishable clinically from spontaneous meningitis. However, in obtunded or unconscious patients who have suffered a recent head injury, few clinical signs may be present. A fever and a deterioration in the level of consciousness or loss of vital functions may be the only signs of meningitis. Finding a CSF leak adds support to the possibility of meningitis in such patients, but this is undetectable in many cases.

Infections of CSF shunts

Patients may present with clinical features typical of spontaneous meningitis, especially if virulent organisms are involved. The more usual presentation is insidious, with features of shunt blockage such as headache, vomiting, fever, and a decreasing level of consciousness. Fever is a helpful sign, but is not a constant feature and may be present in as few as 20 per cent of cases. Shunts can be infected without causing meningitis, in which event the features of the infection will be determined by where the shunt drains. Infection of shunts draining into the venous system produces a disease similar to chronic right-sided infective endocarditis together with glomerulonephritis (shunt nephritis), while infection of shunts draining into the peritoneal cavity produces peritonitis.

Diagnosis

Examination of cerebrospinal fluid (see Chapter 24.7)

Examination of CSF is crucial for the diagnosis of meningitis. The main risk of lumbar puncture, fatal pressure coning, is greatest in patients with space-occupying lesions or post-traumatic cerebral oedema. Fortunately, it is a rare complication in cases of spontaneous meningitis, but caution should be exercised when contemplating spinal puncture. Patients with clinical features suggesting raised intracranial pressure (for example, papilloedema, loss of retinal vein pulsation, focal neurology, bradycardia, and coma) should be examined by CT or MRI of the head, if available, to exclude a space-occupying lesion or severe cerebral oedema. In meningitis, the CSF opening pressure is usually raised (>200 mm of CSF), and occasionally it is markedly raised (>500 mm of CSF), suggesting the potential danger of pressure coning. Other contraindications to lumbar puncture include local skin sepsis at the site of puncture and any clinical suspicion of spinal cord compression.

Frank turbidity of the first drop of CSF emerging from the lumbar puncture needle instantly suggests the diagnosis of bacterial (pyogenic) meningitis. Microscopic examination of CSF for white cells, red cells, and organisms; the measurement of glucose and protein; and culture are important investigations in a case of possible meningitis. A raised CSF white blood cell (**WBC**) count is present in the majority of patients with bacterial meningitis but, rarely, the count may be normal (<6 WBC/µl, all lymphocytes) but the CSF may still appear turbid becuase of the vast numbers of bacteria. A majority of cases (>90 per cent) present with a count of more than 100 WBC/µl. The white cell differential count is helpful. Most cases (>80 per cent) have over 80 per cent of neutrophils. A predominance of lymphocytes is occasionally found and is reported especially in early bacterial meningitis, in association with *L. monocytogenes* infection and in partially treated patients. Red blood cells and xanthochromia are sometimes present. A wide range of non-bacterial infections and non-infectious conditions lead to pleocytosis of the CSF. In this respect, early viral meningitis, parameningeal septic foci, meningeal or cerebral tumours, cerebral infarction, chemical meningitis, aseptic meningitis complicating immunoglobulin replacement, cerebral vasculitis, and demyelination may be indistinguishable from bacterial meningitis.

Detection of bacteria in CSF confirms the diagnosis of bacterial meningitis. Gram-staining of the CSF will reveal organisms in 50 to 80 per cent of cases. The Gram-stain appearance of bacteria may be characteristic of a particular species, but caution must be exercised for up to 10 per cent of smears are misinterpreted. It is prudent, therefore, to administer appropriate empirical therapy initially and to change to specific therapy only when the infecting organism has been isolated and identified. Culture of organisms has a sensitivity of approximately 80 per cent in untreated cases, and is aided by the culture of good volumes of CSF and minimizing the delay between the lumbar puncture and setting up of the culture. Organisms are recovered much less often from partially treated cases. Isolation of an organism is not only helpful in establishing the diagnosis, but allows the identification and susceptibility testing of the aetiological agent. The culture result can also be used to

decide on the need for antibiotic prophylaxis, contact tracing, and other public health control measures.

Measurement of CSF glucose is helpful in making the diagnosis of bacterial meningitis. A glucose concentration below 40 mg per cent is considered low and is found in 50 to 70 per cent of cases. In many cases, glucose may even be undetectable. As the CSF glucose concentration is a function of the serum glucose, a more reliable measure of hypoglycorrhachia (low CSF glucose) is the ratio of serum to CSF glucose concentration. A ratio below 0.31 for glucose concentrations of simultaneously obtained serum and CSF indicates hypoglycorrhachia. A few other conditions may lead to a reduced CSF glucose level. They are: tuberculous, syphilitic, parasitic, fungal, or mumps meningitis; herpes simplex encephalitis; carcinomatous meningitis; meningeal sarcoidosis; post-subarachnoid haemorrhage; severe systemic hypoglycaemia; and rare forms of central nervous system vasculitis.

An elevated CSF protein concentration is a common, but non-specific, finding. Similarly, measurement of CSF lactate is sensitive, but non-specific for meningitis. A range of rapid bacterial antigen tests may be helpful in detecting the presence of bacterial capsular polysaccharide antigens of pneumococci, meningococci, *H. influenzae*, and group B streptococci. These tests may reach a sensitivity and specificity of 90 per cent or greater for detecting specific causes of bacterial meningitis. However, in our experience these tests seldom add to the diagnostic yield of a good Gram stain performed on an adequate volume of CSF. PCR is also used.

The interpretation of the CSF test results depends on the clinical presentation and course of the disease. Acute viral meningitis is the most common differential diagnosis of bacterial meningitis. The CSF in viral meningitis typically contains a preponderance of lymphocytes, less than 1000 WBC/µl, and a normal glucose level. Fortunately, most patients with acute bacterial meningitis will exhibit a combination of clinical and CSF findings sufficiently characteristic to allow a reliable diagnosis. However, in some cases, it may be impossible to distinguish between aseptic meningitis, chronic meningitis, partially treated bacterial meningitis, and early acute bacterial meningitis. In these circumstances it may be necessary to initiate empirical antibiotic treatment. Depending on the clinical course of the patient, it may also be necessary to repeat the spinal tap and monitor the changes in glucose, lactate, and cell count in the CSF. These dynamic changes are particularly helpful now that antimicrobial resistance is an increasing problem and delayed response to treatment might occur requiring an early change of therapy. It is important to appreciate that CSF abnormalities secondary to bacterial meningitis, such as neutrophil pleocytosis, and raised protein levels, may persist for up to a week or longer, although the glucose and lactate levels should show signs of improvement within 48 to 72 h in patients receiving appropriate antibiotics. Since the pleocytosis and hypoglycorrhachia typical of acute bacterial meningitis may persist for a few days after treatment is started, it can be possible to diagnose partially treated meningitis despite negative Gram stain and culture. The difficulty arises when the neutrophil response switches to a lymphocytic one and the glucose starts to normalize after starting treatment for pyogenic meningitis. At this point it can be extremely difficult to distinguish partially treated bacterial meningitis from early tuberculous meningitis (**TBM**)). In these situations the importance of the clinical history (longer than 7 days—TBM), physical signs (lower cranial nerve signs—TBM), peripheral blood white cell count (elevated—pyogenic meningitis), and meticulous Gram and Ziehl–Neelsen stain of the CSF are crucial.

Other tests

Blood cultures should be obtained for all patients with suspected meningitis, as the aetiological agent may be grown. In patients with associated rash, a Gram stain and culture from fluid aspirated from the skin lesions may secure a microbiological diagnosis. A small amount of sterile saline should be injected under the lesion and immediately aspirated for staining and culturing. Radiological imaging of the central nervous system may be helpful. CT scanning can indicate whether or not a shunt is obstructed. Skull fractures or parameningeal septic foci (for example, sinusitis, spinal epidural abscess, or brain abscess) may also be detected by scanning.

Differential diagnosis

Meningeal irritation is seen in many acute febrile conditions, especially in children. Local infections of the nasopharynx, cervical lymph nodes, muscles, and spine may produce convincing neck stiffness. Tetanus may be easily confused with meningitis if the persisting rigidity and recurrent spasms go unnoticed. In all these conditions the CSF will be normal. Subarachnoid haemorrhage can present with sudden headache, neck stiffness, and deteriorating consciousness, and a less dramatic progression of symptoms is seen in patients with some intracranial tumours. Tuberculous and cryptococcal and other fungal meningitides usually develop more slowly than acute bacterial meningitis. They may be distinguished by examining CSF. Cryptococci and free-living amoebae may be mistaken for lymphocytes in the CSF unless an India-ink preparation is examined to reveal the capsule of cryptococcus and the characteristic movements of amoebae. Aseptic meningitis comprises a large number of conditions, many of them caused by viruses, in which there are clinical signs of meningism and the CSF is found to be abnormal. This group includes partially treated bacterial meningitis and the chemical meningitides, resulting from the introduction of irritants into the subarachnoid space (contrast media, antimicrobial agents, and contaminants of lumbar puncture and spinal anaesthesia). The CSF glucose concentration may be very low. Discharge of a tuberculoma may produce a sterile tuberculin reaction, and the discharge of the contents of a craniopharyngioma or epidermoid cyst into the CSF can also cause chemical meningitis. Lead encephalopathy may present with meningism, lymphocyte pleocytosis, and an increase in CSF protein.

Recurrent purulent meningitis

This usually suggests a congenital or traumatic defect providing access to the subarachnoid space, such as congenital occult spina bifida or fracture of the base of the skull. A CSF leak may be apparent in about 50 per cent of the cases with post-traumatic recurrent meningitis. The head trauma may have occurred many years earlier and a connection with the subarachnoid space may be clinically inapparent. *S. pneumoniae* and *H. influenzae* are the predominant aetiological agents for community-acquired cases. Gram-negative aerobic bacilli or *S. aureus* are the main causes in nosocomial cases.

Rarely, recurrent meningitis may arise from episodes of recurrent sepsis of a parameningeal focus (for example, sinusitis or mastoiditis) or from a complement deficiency. Deficiency in a number of the components of the complement pathway has been detected in patients with recurrent meningitis. *N. meningitidis* meningitis caused consecutively by different serogroups is the usual presentation in these cases.

Mollaret's meningitis (benign recurrent aseptic meningitis or benign recurrent lymphocytic meningitis) is mentioned here because it is an important differential diagnosis of recurrent bacterial meningitis. It is a sporadic condition presenting between the ages of 5 and 60 years. The symptoms are typical of acute meningitis—malaise, fever, vomiting, neck stiffness, convulsions, and coma. There is complete spontaneous recovery, usually within a few days, and symptom-free intervals lasting from a few days to years. About half the patients develop other neurological disturbances including hallucinations, diplopia, cranial nerve lesions, and signs of an upper motor neurone lesion. Pleocytosis is usually less than 3000/µl, with a predominance of lymphocytes, monocytes, and large endothelial ('Mollaret's') cells, but occasionally neutrophils are in the majority. The CSF protein level is mildly increased, with increased gammaglobulin. CSF glucose concentration may be decreased. Recently, evidence of herpes simplex type 1 and 2 has been obtained, using polymerase chain reaction (**PCR**) technology. Other causes of recurrent meningitis include Behçet's syndrome, Vogt–Koyanagi–Harada syndrome, sarcoidosis and systemic lupus erythematosus, and undiagnosed viral meningitis (for example, that due to encephalomyocarditis virus).

Management

Bacterial meningitis progresses rapidly and has a high mortality. Antimicrobial treatment must therefore be started as soon as possible after the diagnosis is suspected clinically. This is vitally important in meningococcal meningitis/septicaemia. If this condition is suspected by the practitioner (and in Britain the first doctor the patient meets is usually the general practitioner), the patient should **without delay** be given benzylpenicillin (intravenous or intramuscular (**IV**/**IM**)), cefotaxime (IV/IM), or ceftriaxone (IV). Although it is desirable that antibiotics are given following a blood culture their administration must not be delayed while waiting for the culture to be taken (Table 2). These drugs should be carried by general practitioners in their emergency bags. Antigen may still be detectable in the CSF later in hospital. Patients with no papilloedema or lateralizing neurological signs to suggest a space-occupying lesion, and with no other contraindications (see above), should undergo an immediate lumbar puncture. Again antimicrobial treatment should be started as soon as bacterial meningitis is suspected clinically and, if necessary, before the lumbar puncture is performed.

Antimicrobial treatment

Successful antimicrobial treatment of meningitis (Table 3 and Table 4) depends on the agents crossing the blood–brain barrier and achieving a concentration of more than tenfold the minimum bactericidal concentration in the CSF (a level which predictably sterilizes the subarachnoid space). Before the aetiological agent has been isolated, empirical treatment that will be effective against the likely bacterial causes should be started immediately the diagnosis is made. Once the pathogen has been isolated, specific treatment based on the susceptibility of the isolate can be substituted for the empirical regimen.

Empirical regimens (Table 3) depend on the clinical circumstances of the case and the local pattern of aetiological agents and their antibiotic susceptibility patterns. Neonatal meningitis is largely caused by group B streptococci, *E. coli*, and *L. monocytogenes*. Initial treatment, therefore, should consist of an aminoglycoside and

penicillin or ampicillin; alternatively, a third-generation cephalosporin, preferably cefotaxime or ceftriaxone, **and** penicillin or ampicillin (to cover *L. monocytogenes*) should be used.

In the community, children are at risk of meningitis caused by *N. meningitidis, S. pneumoniae*, and, rarely in Hib-vaccinated children, *H. influenzae.* Antimicrobial resistance has emerged among the three major bacterial pathogens causing meningitis. Recently, chloramphenicol resistance in the meningococcus has been described, and although intermediate penicillin resistance is common in some countries, the clinical importance of penicillin resistance in the meningococcus has yet to be established. b-Lactamase-producing *H. influenzae* are relatively common, and chloramphenicol resistance is emerging. Third-generation cephalosporins are required to treat meningitis caused by these resistant strains. Pneumococci resistant to penicillin and to chloramphenicol are widespread, and resistance to third-generation cephalosporins is found in many parts of the world. Correct management of these strains includes the addition of vancomycin or rifampicin to therapy with third-generation cephalosporins. It is crucial to have up-to-date information on the resistance patterns of these common pathogens within communities to guide antibiotic prescribing. Spontaneous meningitis in adults is usually caused by *S. pneumoniae* or *N. meningitidis*; however, in older patients (>50 years of age) and chronically immunosuppressed patients, there is an increased risk of *L. monocytogenes* and infection caused by Enterobacteriaceae (for example, *E. coli*). If infection with *L. monocytogenes* is possible, penicillin or ampicillin should be used. In all age groups, patients presenting with features of meningococcaemia should receive parenteral penicillin (for example, 2.4 g or 4 million units) immediately. *S. suis* remains sensitive to the b-lactams and should be treated with penicillin, cefotaxime, or ceftriaxone.

Community-acquired, post-traumatic meningitis is caused mainly by *S. pneumoniae, H. influenzae,* and a wide range of other bacterial species. Cefotaxime (2 g intravenously, every 6 h), ceftriaxone (2 g intravenously, every 12 h), or chloramphenicol (1 g, every 6 h) plus ampicillin (2–3 g intravenously, every 6 h) should be given. Nosocomial post-traumatic meningitis is mainly caused by multiresistant hospital-acquired organisms such as *K pneumoniae, E. coli, Pseudomonas aeruginosa,* and *S. aureus.* Depending on the pattern of susceptibility in a given hospital unit, ceftazidime (2 g intravenously, every 8 h), cefotaxime, ceftriaxone, or meropenem should be chosen. If *P. aeruginosa* infection seems likely, ceftazidime or meropenem is the preferred antibiotic.

Device- and shunt-associated meningitis is caused by a wide range of organisms, including methicillin-resistant staphylococci (mostly coagulase-negative staphylococci), multiresistant aerobic bacilli, and *Candida* sp. Cases with shunts and an insidious onset are probably caused by organisms of low pathogenicity, and empirical therapy is a less urgent requirement. For postoperative meningitis the first-line empirical therapy should be cefotaxime (3 g intravenously, every 8 h), or ceftriaxone (2 g intravenously, every 12 h), or meropenem (2 g intravenously, every 8 h). If the patient has received broad-spectrum antibiotics recently or if *P. aeruginosa* is suspected, ceftazidime (2 g intravenously every 8 h) or meropenem should be given. Meropenem should be used if an extended-spectrum, b-lactamase organism is suspected, and flucloxacillin or vancomycin if *S. aureus* is likely. The infected shunt or drain will almost certainly have to be removed urgently.

Once the aetiological agent has been isolated and its susceptibilities determined, the empirical treatment should be changed, if necessary, to an agent or agents specific for the isolate (Table 4). The optimal duration of treatment has not been determined by rigorous scientific investigation; however, treatment regimens that are probably substantially in excess of the minimum necessary to achieve cure have been arrived at through wide clinical experience.

Treatment of brain abscess (see Chapter 24.14.3)

Brain abscesses may arise as a result of direct spread from contiguous anatomical structures, following injury or local infection or metastasis from a distant source. Whenever an abscess is suspected a detailed search for the source of the infection is important. The middle ear and mastoid cavity and frontal, paranasal, ethmoidal, and sphenoidal sinuses are common sites for the primary focus. Metastatic abscesses can spread from foci in the heart (endocarditis), the lungs (bronchiectasis), dental abscesses, the pelvis, and gastrointestinal tract. Once diagnosed, surgical drainage remains the treatment of choice for almost all abscesses. Empirical therapy can be guided by consideration of the likely primary focus of the infection, but it should include penicillin or a third-generation cephalosporin (cefotaxime of ceftriaxone), and metronidazole. For abscesses complicating trauma, flucloxacillin or vancomycin should be added. It is unclear if there are any benefits to be gained by instilling antibiotics into the abscess cavity during drainage. Treatment should continue for a minimum of 6 weeks.

General management and treatment of complications

General treatment

In the conscious patient, the severe headache may need treatment with opiates and the associated pyrexia may require treatment with antipyretics or cooling with tepid sponging or fanning. Many patients are unconscious and should be managed accordingly. Their airway should be maintained and they may need intubation to protect the airway and maintain ventilation. A urethral catheter should be inserted.

The associated septicaemia in patients with meningitis may result in septicaemic shock. These patients require careful monitoring and treatment of shock. A combination of fluid administration to expand the intravascular volume, pressors, and inotropic support is needed. Multiple end-organ failure may develop, requiring intensive medical support, including ventilation and renal dialysis.

Treatment of complications

Raised intracranial pressure is a serious complication of meningitis. Clinically, altered consciousness, poorly reactive unequal or dilated pupils, cranial nerve palsies, bradycardia, and hypertension suggest its onset. Various measures can be used to lower a raised intracranial pressure, including elevation of the head of the bed to 30°, administration of mannitol, and endotracheal intubation and mechanical hyperventilation. These measures may be used to maintain an adequate perfusion pressure monitored by continuous intra-arterial and intracranial pressure monitoring. The effect of these measures on the outcome of patients with raised intracranial pressure have not been evaluated systematically. The role of corticosteroids in reducing intracranial pressure remains unresolved and no consistent approach to their use is accepted.

The use of corticosteroids aimed at reducing the sequelae of meningitis has received support from a number of studies. The most pronounced effect has been the reduction of deafness in children infected with *H. influenzae* and treated with cefuroxime (a less effective cephalosporin for meningitis than cefotaxime or ceftriaxone). In three recent studies of bacterial meningitis (mainly *H. influenzae*) in children treated with ceftriaxone, dexamethasone (0.4 mg/kg intravenously, every 12 h for 2 days starting 10 min before the first dose of antibiotic) reduced the incidence of neurological and audiological sequelae. Studies in Cairo suggested that dexamethasone significantly reduced the mortality and incidence of permanent sequelae in adult patients with pneumococcal meningitis but in Malawi, this drug did not prove to be an effective ancillary treatment in children with acute bacterial meningitis.

Seizures occur in as many as 40 per cent of patients with meningitis and subclinical fitting should be considered in patients with persisting coma. A prophylactic anticonvulsant might be justified in pneumococcal meningitis. Rapid control of seizures can be achieved by administering intravenous diazepam or lorazepam, but respiration may be depressed. Phenytoin should be used for the longer term control of seizure activity. Severe cases that fail treatment with these antiepileptic agents should undergo endotracheal intubation and receive high-dose phenobarbital.

Many patients with meningitis develop hyponatraemia as a result of the syndrome of inappropriate antidiuretic hormone secretion (**SIADH**). Such cases may require fluid restriction. Complications such as cerebral venous sinus thrombosis and cavernous sinus thrombosis may occur, but may be difficult to detect. Anticoagulants or fibrinolytics may be used in such patients with the hope of improving the outcome (Chapter 24.13.7).

Prognosis and sequelae

In Europe and North America the overall mortality of patients with meningitis caused by *N. meningitidis* is about 7 to 14 per cent; for *H. influenzae,* 3 to 10 per cent; *Strep. pneumoniae,* 15 to 60 per cent; and for group B streptococci and *L. monocytogenes* meningitis, above 20 per cent. The mortality is much higher in the very young and old, and in patients with debilitating illnesses. A study in Zaria, Nigeria, demonstrated that the mortality of pneumococcal meningitis was 32 per cent in patients who were fully conscious on admission, 40 per cent in those who were confused, 54 per cent in semiconscious patients, and 94 per cent in those who were comatose. In Vietnam, in a prospective study of 250 cases of adult bacterial meningitis, the overall mortality rate was 13 per cent.

Permanent neurological sequelae include mental retardation, deafness and other cranial nerve deficits, and hydrocephalus. The reported incidence of sensorineural deafness after meningitis ranges from 5 to 40 per cent. A large proportion of patients recover within a few months. *N. meningitidis* and *H. influenzae* are the main causes of this complication. Permanent deafness occurs in more than 50 per cent of patients with *S. suis* meningitis. It may be bilateral, complete, and associated with

vestibular involvement. *H. influenzae* used to be the major cause of acquired mental retardation in the United States. This complication was found in 30 to 50 per cent of children who had suffered from *H. influenzae* meningitis.

Prevention

Vaccination

Vaccines to the three major pathogens causing community-acquired meningitis are available. *H. influenzae* type b capsular conjugate vaccines are in wide use and are dramatically reducing the incidence of *H. influenzae* type b meningitis. In most countries where the *H. influenzae* type b meningitis vaccine has been introduced, Hib invasive disease has been essentially eliminated. A 7-valent pneumococcal conjugate vaccine is now widely available in the developed world, the efficacy of which is supported by a Californian Kaiser Permenete study in children. Studies in adults are being carried out in the developing world. A conjugate, type C meningococcal vaccine is available and has been used in the United Kingdom immunization schedule, producing a dramatic decline in group C meningococcal invasive disease including meningitis.

The purified capsular polysaccharide vaccines directed at *N. meningitidis* (serogroups A, C, Y, and W135) and *Strep. pneumoniae* (23-valent) are less effective than conjugate vaccines, especially in children under 2 years of age. No effective vaccine exists for *N. meningitidis* serogroup B. Vaccination of groups of adults at high risk, such as close contacts, military recruits, and migrant miners in Africa, has been highly effective in preventing meningococcal meningitis caused by serogroups A and C. The trials designed to assess the efficacy of population-based vaccination against *N. meningitidis* (serogroups A, C, Y, and W135) and *Strep. pneumoniae* are awaited with interest. The annual Muslim pilgrimage to Mecca (The Haj) is frequently associated with meningitis in returning travellers. It is advisable for people travelling to Mecca to be vaccinated with the polyvalent vaccine against *N. meningitidis* groups A, C, W135, and Y.

Since 1905, major epidemics of meningococcal meningitis have occurred in sub-Saharan Africa every few years, culminating in a massive epidemic in 1996 in which nearly 200 000 cases were reported. For epidemic meningitis control in sub-Saharan Africa, the World Health Organization recommends a strategy of emergency vaccination with meningococcal A+C polysaccharide vaccine when epidemic thresholds are exceeded. A recently derived model of how to respond to such epidemics has concluded that, given the relatively poor routine-vaccination coverage in this region, current strategies of vaccination campaigns that achieve higher coverage would generally be more effective and less costly than model routine-scheduled programmes, assuming that campaigns can be rapidly implemented. Until a better vaccine is available, countries in this region should aim to speed up the response times to outbreaks, perhaps through improved surveillance, and to bolster existing vaccination infrastructures.

Vaccination should be considered in all patients with recurrent meningitis, traumatic head injury, and in splenectomized patients.

Chemoprophylaxis

The attack rate of meningitis is higher in the immediate contacts of an index case of meningococcal (up to 1000-fold) or *H. influenzae* type b meningitis (500-fold only in children under 4 years of age) than in the population at large. The administration of rifampicin or ciprofloxacin eliminates the carrier state and is assumed to eliminate the risk of secondary cases of meningitis. A major preventive effect of sulfadiazine chemoprophylaxis has been shown in large outbreaks of meningococcal meningitis among military recruits; however, meningococci are now usually resistant to sulphonamides. Rifampicin and ciprofloxacin are assumed to produce a similar effect. Close adult contacts of meningococcal disease are given either rifampicin (300 mg, every 12 h for 2 days) or a single oral dose of ciprofloxacin (750 mg) (ciprofloxacin is still to be avoided in children, but is now accepted for prophylaxis). Contacts of *H. influenzae* type b disease (including adults) are given rifampicin for 4 days, and Hib vaccine is given to unvaccinated children under 4 years of age. However, in those countries where Hib vaccination has been implemented, the need for chemoprophylaxis is under review. Doctors, nurses, and other healthcare workers need not be given chemoprophylaxis unless they have given mouth-to-mouth resuscitation.

Although antibiotics are administered prophylactically to many cases of skull fracture with CSF leak, there is no evidence of benefit. Surgical closure of the leak is the only effective means of preventing meningitis in such cases. However, since many acute leaks heal spontaneously, this is necessary only in cases with large defects or in those with recurrent meningitis.

The prevention of device-associated meningitis relies on rigorous infection control. Ventricular and lumbar drains should be removed as soon as possible. Shunt insertion should be performed while adhering to a strict aseptic technique, and surgical antibiotic prophylaxis may also help to reduce shunt infection.

Tuberculous meningitis

Epidemiology

Tuberculous meningitis (**TBM**) has been a major problem and cause of death in developing countries. Human *Mycobacterium tuberculosis* is responsible for most cases. In Western countries, its incidence has fallen in parallel with tuberculosis as a whole. For example, in the late 1940s there were 2000 cases/year in England and Wales, accounting for 10 to 20 per cent of cases of bacterial meningitis; but by the early 1970s this had fallen to less than 4 per cent.

Most cases of TBM are in young children, but primary infection can be acquired at a later age and, in recent years, a larger proportion of patients with this condition have been adults. The disease is uncommon, but severe, in pregnant women.

There has been an increase in the incidence of tuberculosis in many parts of the world related to the epidemic of HIV infection. HIV-infected patients with tuberculosis are at increased risk of meningeal involvement. In some areas of endemic tuberculosis, TBM is an important complication in patients with HIV infection.

Pathogenesis

Small caseous microtubercles develop in the brain, meninges, or, less commonly, in the bones of the skull and vertebrae close to the meninges. This infection seeds through the bloodstream from the primary lesion or a site of chronic infection. Many patients develop miliary tuberculosis at the stage of haematogenous spread. Infection of the meninges results from rupture of a microtubercle with discharge of tuberculoprotein and mycobacteria into the subarachnoid space. This event will be marked by an episode of fever and meningeal irritation caused by the intrathecal tuberculin reaction. Subacute inflammation, especially of the basal meninges, then develops, producing cranial nerve lesions, cerebral arteritis causing infarction, impairment of CSF absorption, or obstruction to the CSF circulation causing hydrocephalus, and, in the spinal cord, spinal arachnoiditis, producing multiple radiculopathy or myelopathy.

Pathology

Meningeal miliary tubercles may be found on the brain surfaces of most victims of miliary tuberculosis. They are usually few in number and occur in the region of the sylvian fissure, while there may be larger caseous plaques deeper in the sulci. The brains of patients dying of TBM are usually oedematous. A mass of thick, greyish exudate encases the base of the brain, filling the basal cisterns. Within the ventricular system there is ependymitis with a similar exudate choking the choroid plexus. The exudate consists of lymphocytes, plasma cells, giant cells, and foci of caseation, but mycobacteria are usually scanty. At the base of the brain the cranial nerves and the internal carotid artery and its branches are trapped and damaged by the exudate. Arteries are obliterated by an endarteritis, with resulting ischaemia and infarction of superficial areas of the brain, internal capsule, basal ganglia, and brainstem. There is congestion and phlebitis of the meningeal veins. Both the inflammatory exudate and the arteritis are probably a delayed hypersensitivity reaction to the tuberculoprotein. Some degree of hydrocephalus develops in most cases. Usually the hydrocephalus is communicating in type and is caused by obliteration of the basal cisterns. Less commonly, blockage of the foramina of Luschka and Magendie in the fourth ventricle, or the aqueduct, causes obstructive hydrocephalus. The exudate may extend into the spinal cord, enveloping the nerve roots and spinal cord and producing spinal arachnoiditis and spinal block. Tuberculomas, single or multiple and varying in size, may be found in virtually any part of the brain (Plate 7).

Clinical features

Symptoms of meningitis are preceded by 2 to 8 weeks of non-specific prodromal symptoms which are unlikely to raise the suspicion of TBM. This phase of vague

malaise, irritability, insomnia, lethargy, anorexia, headache, abdominal pain, vomiting, and behavioural changes may develop after a head injury, surgical operation, or common childhood infection such as measles, influenza, or otitis media, suggesting that meningeal infection may be precipitated by these conditions. By the time patients have developed obvious symptoms and signs of meningitis, the disease is well advanced. They usually have low-grade fever, but severe pyrexia can occur. Half of the patients will have symptoms and signs of tuberculosis in the lungs or elsewhere. Rarely, TBM presents dramatically as an acute encephalopathy with severe headache, neck stiffness, vomiting, and seizures, mimicking acute bacterial meningitis, viral encephalitis, and subarachnoid haemorrhage.

During the second stage there is evidence of meningeal irritation (headache, vomiting, neck stiffness), cranial nerve damage, evolving hydrocephalus, and cerebral endarteritis. Infants are irritable with opisthotonos and a tense fontanelle. Cranial nerve lesions, seen in 25 per cent of cases, involve one or more of the following: II, III, IV, VI, VII, and VIII. The pupils may be dilated, unequal, and unresponsive, and many patients have a VIth nerve palsy (Fig. 5). Fundal examination reveals papilloedema in 40 per cent of cases and sometimes evidence of optic atrophy. Choroid tubercles are occasionally seen (Plate 8). Bilateral visual failure with optic atrophy is a feature of arachnoiditis in the cistern of the optic chiasm. Raised intracranial pressure, a common and serious complication of TBM, results from obstruction of the CSF circulation in the basal cisterns by the exudates or, less commonly, obstruction of the outlets of the fourth ventricle. Increasing headache, vomiting, and impairment of conscious level are mainly the result of intracranial hypertension rather than the meningeal irritation. Hydrocephalus, which often accompanies the increased intracranial pressure, is common and should be suspected in all patients with TBM. They often have severe headache, ocular palsy, pyramidal signs in the lower limbs, and incontinence of urine. If left untreated, the patients become stuporose or comatose and develop signs of brainstem damage, such as decerebrate rigidity, irregular breathing, and impairment of brainstem reflexes. About 20 per cent of the patients develop focal neurological signs such as hemiparesis, hemianaesthesia, aphasia, and hemianopia. These are the results of cerebral infarct, caused by the arteritis. Convulsive disorders are common in children but rare in adults. About 10 per cent of the patients develop symptoms and signs of spinal arachnoiditis (Fig. 6), which vary from radicular pain, radicular weakness of the lower limbs, and urinary retention, to paraplegia with sensory loss on the trunk. SIADH is common in patients with severe TBM. It produces impairment of consciousness, but decerebrate rigidity or other signs of brainstem damage are not found. Other uncommon neurological abnormalities include internuclear ophthalmoplegia, hemichorea, and hypothalamic disorders leading to loss of control of blood pressure and body temperature and diabetes insipidus.

Fig. 5 Bilateral VIth nerve palsies in a Thai girl with TBM. The cervical node biopsy was positive for acid-fast bacilli. (Copyright the late Prida Phuapradit.)

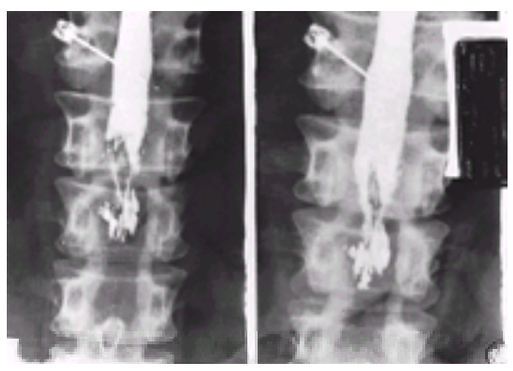

Fig. 6 Spinal arachnoiditis revealed by myelography in a Thai patient with TBM. (Copyright the late Prida Phuapradit.)

HIV-infected patients with tuberculosis are at a higher risk of developing the meningitis than non-HIV-infected patients. In HIV-infected patients, peripheral, intrathoracic, and intra-abdominal lymphadenopathy is more common, but the clinical manifestations of TBM do not seem to be modified by the HIV infection.

Diagnosis

The blood count is usually normal, but marked leucocytosis of more than 20 000/µl ('leukaemoid picture') may occasionally be found in TBM and miliary tuberculosis. Examination of CSF is crucial. Lumbar puncture does not seem to pose the same dangers as in acute bacterial meningitis and, apparently, lumbar puncture has been repeated safely as a treatment of raised intracranial pressure in patients with TBM even when there is papilloedema. The CSF opening pressure is raised in the majority of patients, but it may be low or fall in those developing block from spinal arachnoiditis. The CSF is clear or slightly turbid, and may form a spider's web clot on standing. The mechanism of the cobweb formation is unclear, but it does not appear to be caused by the high protein concentration *per se*. In patients with spinal block the fluid may be xanthochromic with a very high protein concentration and may quickly form a jelly (Froin's syndrome). Total cell counts range between 10 and 1000/µl. Both lymphocytes and neutrophils are present and the latter can be as high as 70 per cent of the total. In 90 per cent of the patients the white cell count is less than 500/µl. Rarely, the cell count exceeds 1000/µl. The CSF glucose concentration of the initial CSF sample is low in about 90 per cent of the patients. Although non-specific, this finding is of great practical use, because it is a simple test that differentiates TBM presumptively from most cases of viral meningitis. Indeed, TBM must be strongly suspected in any patient who presents with lymphocytic meningitis and a low CSF glucose concentration. The CSF protein concentration is usually raised, and ranges from normal to 5 g/l. Levels of more than 5 g/l suggests a spinal block. Success in detecting tubercle bacilli in CSF by Ziehl–Neelson staining can, in some hands, be increased from the usual average of 10 to 20 per cent by centrifuging a large volume of CSF (10–20 ml) and carefully examining the sediment under a microscope. Repeated lumbar punctures increase the chance of finding tubercle bacilli and of observing the characteristic changes in CSF composition. Marked neutrophil pleocytosis of the CSF may be seen transiently in association with abrupt deterioration of the headache, increased neck stiffness, and fever, suggesting bacterial meningitis. The phenomenon is self-limited, and is thought to be the result of a rupture of a microtubercle into the subarachnoid space. Culture of mycobacteria is successful in 40 to 60 per cent of cases. Specimens other than CSF (for example, sputum, gastric washings in children, urine, etc.) should also be cultured. Since it can take up to 2 months or longer for the mycobacteria to grow in the standard cultures, a number of methods for the rapid diagnosis of TBM have therefore been developed. The bromide partition test is not of practical use, because it lacks specificity and is abnormal in other types of meningitis and even in cerebral malaria. It is no more useful than the CSF glucose concentration. Tests for detecting membrane antigen of tubercle bacilli in CSF by enzyme immunoassay and latex-particle agglutination are disappointing because they are not reproducible and do not have sufficient sensitivity and specificity to be of clinical use. Detection of tuberculostearic acid (a lipid component of the mycobacterial cell wall) in the CSF by gas chromatography and mass spectroscopy is highly specific and sensitive, but the apparatus is very expensive and technically too complicated for clinical use. Detection of the genome of *M. tuberculosis* in the CSF by PCR can be specific and sensitive in the rapid diagnosis of TBM. Recent studies in centres of excellence suggest a sensitivity of 75 per cent and a specificity of 94 per cent; however, further work on larger sample sets are still required to establish the utility, reproducibility, and cost-effectiveness of this approach. Cell-mediated immunity should be assessed. The tuberculin test is positive in 50 to 95 per cent of patients with TBM. Reactivity is suppressed in debilitated or immunosuppressed patients. Serological tests for HIV infection and a CD4 cell count should, if possible, be performed in every case. Immunological assays based on the production of g-interferon following stimulation with *M. tuberculosis*-specific antigens (ESAT6 and CFP10) (ELI-SPOT TEST) have shown promise as a diagnostic tool among contacts of patients with TB. Their potential role in TB meningitis has not yet been established. A search for evidence of tuberculosis elsewhere in the body is useful. Chest radiographs are normal in about half of the patients, and miliary mottling is seen in only a minority.

The advent of computed tomography (**CT**) scanning and magnetic resonance imaging (**MRI**) has provided insight into disease progression, and gives prognostic and

diagnostic information. Both CT and MRI of the brain will reveal hydrocephalus, basilar meningeal thickening, infarcts, oedema, and tuberculomas (Fig. 7 and Fig. 8).

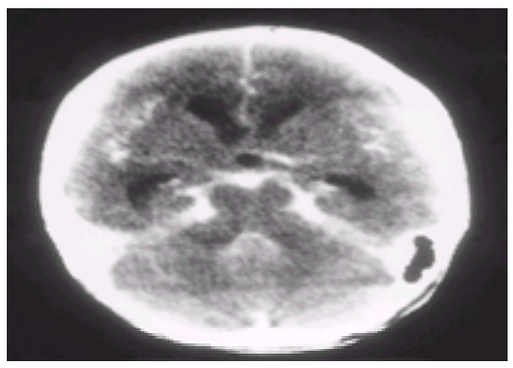

Fig. 7 CT scan with enhancement showing thick basal exudates and hydrocephalus. (Copyright the late Prida Phuapradit.)

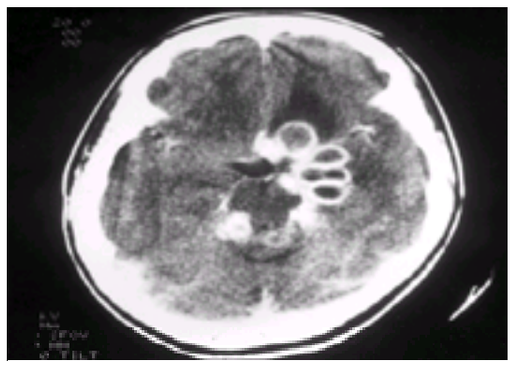

Fig. 8 CT scan with enhancement of a patient with TBM showing multiple tuberculomas developing near the basal cisterns (Copyright the late Prida Phuapradit.)

In a CT study of 60 cases of TBM in adults and children, only three had normal brain scans. Hydrocephalus was reported in 87 per cent of children and 12 per cent of adults. The incidence of hydrocephalus is greater in the young, and increases with duration of the illness. In children, hydrocephalus is invariably present after 6 weeks of illness. Infarcts are seen on CT scanning in 28 per cent, with 83 per cent occurring in the middle cerebral artery territory. The basal ganglia are the most commonly affected region. Poor prognosis has been associated with enhancing basal exudates and periventricular lucency.

MRI has increased sensitivity in detecting the distribution of meningeal inflammatory exudate. Gadolinium-enhanced, *T*1-weighted images highlight the exudate, and reveal parenchymal infarcts as hyperintense areas. MRI may provide more diagnostic information than CT when assessing space-occupying lesions. Cerebral miliary TB, with multiple small intraparenchymal granulomas, produces moderate perilesional oedema and contrast enhancement. Larger tuberculomas are initially non-enhancing, but later demonstrate marked enhancement.

CT and MRI are sensitive for the changes of TBM, particularly hydrocephalus and basal meningeal exudates, but they lack specificity. The radiological differential diagnosis includes cryptococcal meningitis, cyto-megalovirus encephalitis, sarcoidosis, meningeal metastases, and lymphoma. The major role of neuroradiology has been in the management and, in particular, in the diagnosis and follow-up of those complications requiring neurosurgery.

Differential diagnosis

Although a few patients with TBM present acutely, the majority show a subacute or chronic progression. Clinically, the differential diagnosis should include cryptococcal meningitis and various subacute or chronic meningitides, including partially treated bacterial meningitis, parameningeal infections, neoplastic and granulomatous infiltrations of the meninges (for example, carcinomas, leukaemias, lymphomas, sarcoidosis), and cerebral tumours. Fungal meningitides (with *Cryptococcus* spp., Coccidioides, *Histoplasma* spp., *Candida* spp.) may present like TBM. Other conditions that have caused confusion in particular clinical or geographical settings are meningovascular syphilis, toxoplasma meningitis in immunosuppressed patients (notably in those with AIDS), cysticercosis, amoebic meningoencephalitis, African trypanosomiasis, and schistosomal myelopathy. In most of these cases, CSF examination, including cytology, an India-ink preparation, immunodiagnostic tests (for example, cryptococcal latex agglutination), serological tests, and microbial cultures will allow differentiation.

Treatment

The untreated mortality of TBM is close to 100 per cent. Full treatment must be started when the diagnosis is suspected on clinical grounds, immediately after adequate samples have been taken for microscopy, culture, and immunodiagnosis. The choice of antituberculosis drugs has been based mainly on their pharmacokinetic and antibacterial properties. Isoniazid, pyrazinamide, ethionamide, and cycloserine freely distribute into the CSF. Penetration is limited, but still adequate during the first few months of the meningitis, in the case of rifampicin, ethambutol, and streptomycin. *p*-Aminosalicylic acid should not be used because it does not enter the CSF. At least two drugs to which the organism is sensitive should be used. During the first 2 months, however, intensive chemotherapy with three or four antituberculosis drugs should be given: the impairment of the blood–brain barrier during the active stage of meningitis allows most antituberculosis drugs to enter the CSF in amounts sufficient to kill the organism, and offers a good chance of eliminating mycobacteria from the CSF after a short period of treatment. The combination of isoniazid and rifampicin for 12 months, with pyrazinamide and streptomycin during the first 2 months, is an effective regimen that has been widely used. In adults, daily single doses of 300 mg of isoniazid, 600 mg of rifampicin, and 1500 mg of pyrazinamide provide adequate levels in the sera and CSF of patients with active TBM. Higher doses of these drugs are unnecessary and may result in a higher incidence of hepatotoxicity. The incidence of adverse reactions of antituberculosis drugs in TBM is acceptable and is similar to that encountered in the treatment of pulmonary tuberculosis.

In countries where rifampicin cannot be afforded, triple therapy with isoniazid, pyrazinamide, and streptomycin should be tried. TBM in HIV-infected patients should be similarly treated as the meningitis in those not infected. Responses to treatment and the outcome of TBM are similar in the two groups. Drug-resistant isolates of *M. tuberculosis,* which have been found increasingly, poses problems in the treatment now and in the future. Ethionamide, kanamycin or amikacin, and cycloserine should be considered in this situation. Development of new effective antituberculosis drugs is urgently needed.

Response to antituberculosis chemotherapy is slow, particularly in patients who are not given corticosteroids. There may be an increase in temperature and CSF protein concentration as well as a transient neutrophil pleocytosis during the first 2 months after starting optimal chemotherapy. However, some signs of clinical improvement are usually seen within the first few weeks. Early clinical evidence of response is an improvement of the headache, sense of general well being, and a decrease in the elevated intracranial pressure. A rapid return to normal in CSF composition within a few days virtually excludes the diagnosis of TBM, in which case antituberculosis treatment should be stopped. Usually it would take at least a few weeks to a few months for the cells, CSF glucose, and protein levels to return to normal. However, the high protein concentration persists in some patients.

'Trial' of chemotherapy is justified when there is clinical suspicion of TBM, particularly when diagnostic facilities are limited. Treatment should be continued for 12 months unless there is rapid improvement in the patient's condition and CSF composition, suggesting another cause for aseptic meningitis. In some severely ill patients who present acutely with features of acute bacterial meningitis (for example, neutrophil pleocytosis) but in whom initial laboratory results are unhelpful, it may be necessary to initiate 'blind' treatment for acute bacterial and TBM simultaneously. In these, fortunately rare cases, isoniazid, rifampicin, and streptomycin or ethambutol, together with penicillin or a third-generation cephalosporin, can be given.

There is conflicting evidence regarding the length of treatment. The current United Kingdom guidelines recommend 12 months in uncomplicated cases of TBM (including cerebral tuberculoma without meningitis), extending to 18 months should pyrazinamide be omitted. No guidelines exist for the components and duration of treatment in the case of multidrug-resistant TBM. Treatment for 12 months is probably a conservative estimate of the time required for bacterial cure. Different regimes, incomparable patient groups, and the variable use of adjuvant steroid therapy, makes meta-analysis from the trials impossible. Some suggest that TBM should be treated for a minimum of 2 years. Evidence from 781 cases of TBM treated for 2 years revealed that 35 patients had a recrudescence; however, nearly all patients with relapse had received less than 6 months' therapy, indicating that therapy should continue in excess of this period. In South Africa, 95 children were treated for 6 months with a combination of isoniazid 20 mg/kg, rifampicin 20 mg/kg, pyrazinamide 40 mg/kg, and ethionamide 20 mg/kg. Some 96 per cent of these cases presented in either stage II or III TBM. The doses of both isoniazid and rifampicin used were considerably higher than those recommended in the United Kingdom, but no serious adverse reactions were reported. The study provides good evidence for the adequacy of short-course intensive chemotherapy, but the lack of a control group does not allow conclusions to be drawn regarding the optimal dosages. Studies using 9 months' chemotherapy (2 months' isoniazid, rifampicin, pyrazinamide, streptomycin, followed by 7 months' rifampicin and isoniazid) at lower doses produced similar outcomes.

Treatment of complications

The complications of TBM are common, some of which are often serious enough to cause severe morbidity and death in spite of active treatment with antituberculosis drugs. Increased intracranial pressure, found in about 90 per cent of the patients and often associated with communicating hydrocephalus, is usually caused by the basal arachnoiditis. Less commonly, it is caused by diffuse cerebral oedema which compresses the small lateral ventricles. In these patients, conservative treatment by repeated lumbar punctures in combination with acetazolamide, with or without furosemide (frusemide), and corticosteroids should be tried. Within the first 4 to 6 weeks of treatment, the CSF pressures in the majority of the patients return to normal and the transependymal oedema (periventricular lucency on the CT scan) disappears. However, the sizes of the ventricles usually remain unchanged during the first 4 to 6 weeks of treatment. This is a state of arrested hydrocephalus. Usually, it would take up to 6 months for the ventricular size to return to normal. In a few centres, intrathecal hyaluronidase, which might resolve the basal exudates, has been shown to be beneficial in the treatment of communicating hydrocephalus and spinal arachnoiditis. If these conservative measures fail, surgical treatment will be needed for the hydrocephalus. Patients with communicating hydrocephalus who are very ill with impairment of consciousness should receive early temporary external ventricular shunting. Shunt surgery, as a first-line treatment, should be reserved for patients with non-communicating hydrocephalus.

Corticosteroids might be expected to reduce the inflammatory reaction and the fibrotic organization of exudate in the brain and spinal cord. A recent Cochrane review analysed six trials comprising a total of 595 patients. Steroids were associated with fewer deaths (relative risk (**RR**) 0.79; 95 per cent confidence interval (**CI**) 0.65 to 0.97) and a reduced incidence of death and severe residual disability (RR, 0.58; 95 per cent CI, 0.38 to 0.88). Subgroup analysis suggested an effect on mortality in children (RR, 0.77; 95 per cent CI, 0.62 to 0.96), but the results in a smaller number of adults were inconclusive (RR, 0.96; 95 per cent CI, 0.50 to 1.84). There is little evidence that the severity of disease influences the effects of steroids on mortality. The conclusion of the Cochrane reviewers was that adjunctive steroids might be of benefit in patients with TBM. However, existing studies were small, and publication bias may account for the positive results. The data are stronger for the use of steroids in children than in adults. No data are available on the use of steroids in HIV-positive patients. The usual regimen is intramuscular dexamethasone (16 mg/day in adults and 0.5 mg/kg per day in children) in divided doses, or oral prednisolone 60 mg/day for adults, 2 mg/kg per day for children, given in a tapering course over 3 to 6 weeks. There is no evidence that corticosteroids interfere with the penetration of antituberculosis drugs into the CSF. Intrathecal injection of corticosteroids is unnecessary.

Fluid, electrolyte, and acid–base disturbances are common, the result of vomiting, inadequate fluid intake, and SIADH. Progressive loss of vision caused by fibrosing exudate around the optic chiasma may respond to surgical decompression. Cerebral tuberculomas may occasionally develop during the course of the treatment of TBM. Characteristically, the lesions are thick-walled nodules of small or moderate size in clusters, and develop in the surface of the brain near the basal cisterns, such as the interpeduncular cistern and cistern of the optic chiasm (Fig. 8). They should be treated conservatively and the response to antituberculosis treatment assessed by CT scan. Biopsy or surgical intervention is unnecessary and may be harmful. Tuberculomas usually respond very slowly to antituberculosis drugs and it usually takes at least 24 months or longer for the lesions to disappear. Nursing care is very important during the acute illness, when there are the usual problems presented by unconscious patients, and during the prolonged phase of convalescence and rehabilitation. Anticonvulsants are often needed, especially in children.

Prognosis and sequelae

In Western industrialized countries, the mortality from TBM is still high, at about 15 to 30 per cent, and in developing countries it remains between 30 and 50 per cent. The prognosis is worst and the risk of sequelae highest in those admitted in coma with signs of brainstem damage, in the very young and very old, pregnant women, and those with malnutrition or other diseases. The outcome of TBM in HIV-infected patients is similar to that in patients without HIV infection. There are permanent sequelae in 10 to 30 per cent of survivors. Intellectual impairment is especially common in infants and young children. As many as 60 per cent of patients who have seizures during the illness will suffer recurrences. Up to 25 per cent of survivors will have cranial nerve deficits, including blindness, deafness, and squints. Some 10 to 25 per cent of survivors have some residual weakness after hemiparesis or paraparesis. About 10 per cent of patients develop CSF spinal block at some stage of the illness, but this will recover completely in at least half of them. Occasionally neurological deficit may progress or appear months after the illness as the subarachnoid exudate becomes fibrotic and calcified.

Prevention (see also Chapter 7.11.22)

BCG vaccination at birth reduces the risk of infection by at least 80 per cent, but this seems to vary in different countries. It is recommended for all infants born into communities where tuberculosis is prevalent, including Asians living in Britain and expatriates living in tropical countries. To prevent the development of TBM in household contacts of newly diagnosed cases of pulmonary tuberculosis, prophylaxis with isoniazid 10 mg/kg daily for 6 to 12 months is recommended for all Mantoux-positive children under the age of 5 years.

24.14.2 Viral infections of the central nervous system

*D. A. Warrell and J. J. Farrar**

Viruses invade and damage the central nervous system in two ways: directly, by infecting the leptomeninges, brain, and spinal cord; and, indirectly, by inducing an immunological reaction resulting in para- and postinfectious diseases. In both cases, the terms 'meningitis', 'encephalitis', and 'myelitis' are used alone or in combination. Meningitis implies inflammation of the meninges without alteration of consciousness, convulsions, or the production of focal neurological abnormalities; in encephalitis there is impairment of cerebral function, usually with an altered state of consciousness and often with convulsions and focal neurological signs; while myelitis indicates involvement of the spinal cord. Retroviral and prion diseases of the central nervous system are dealt with elsewhere (see Chapter 7.10.21, Chapter 7.10.22, Chapter 7.10.23 and Chapter 24.13.9).

Virology

There is considerable geographical and seasonal variation in the kinds of viruses causing meningitis, myelitis, and encephalitis. However, compared with bacterial infections of the central nervous system, there is less variation with age and immunocompetence.

Enteroviruses are responsible for 80 to 90 per cent of diagnosed cases of viral meningitis. Almost all the serotypes have been implicated in sporadic cases, and outbreaks have been associated with coxsackieviruses A7 and 9, all the coxsackie B types, and many of the echoviruses, especially 4, 6, 9, 11, 14, 16, and 30. Recently, echovirus 13, a rare type, has caused cases in the United States, Australia, and Europe and there has been an increase in echovirus 30 cases. Mumps is responsible for about 10 to 20 per cent of cases of viral meningitis. Other less common causes include herpes zoster, herpes simplex virus (predominantly type 2, HSV-2), measles, adenoviruses, Epstein–Barr virus and, in the United States, togaviruses, such as St Louis, eastern and western equine encephalitis, and West Nile and bunyaviruses, such as California (La Crosse) encephalitis viruses.

Poliovirus has long been considered the major cause of viral 'paralytic' myelitis throughout the world, but has now been virtually eliminated from the Americas. A confusingly similar syndrome of acute flaccid paralysis caused by Japanese encephalitis (**JE**) has now been reported from Vietnam. Coxsackie A7 (AB IV) has caused occasional small outbreaks, and other coxsackie A and B viruses, echoviruses, enterovirus 70, and flaviruses (tick-borne encephalitis) have all been implicated as causes of flaccid paralysis. Herpes zoster, paralytic rabies, Epstein–Barr, and *Herpes simiae* B viruses can cause myelitis or ascending paralysis, and HSV-2 can cause lumbosacral myeloradiculitis.

Viruses causing encephalitis vary from country to country. JE virus is the most widespread human togavirus infection in the world and is the major cause of encephalitis throughout Asia. There are at least 50 000 cases of JE with 15 000 deaths annually. The virus is transmitted by Culex mosquitoes and is endemic across much of southern Asia and the Indian subcontinent. It is spreading through the Pacific rim to New Guinea, Torres Strait Islands, and Cape York Peninsula, in northern Australia. Dengue viruses have been implicated as a cause of encephalitis in South-East Asia.

In 1999 an outbreak of an encephalitic illness among pig farm and abattoir workers was reported from Singapore and Malaysia. There were 258 cases of encephalitis, with a case fatality rate of almost 40 per cent. The causative agent was a new paramyxovirus, Nipah virus, closely related to the Hendra and Manangle viruses described in Australia. Nipah virus encephalitis is a zoonosis infecting pigs and flying foxes (*Pteropus* spp.). Almost all patients infected in this outbreak had direct contact with pigs. Hendra virus has caused a few cases of equine and human encephalitis (Chapter 7.10.6.1).

In North America, herpes simplex virus is the most common cause of sporadic fatal viral encephalitis, followed by the California encephalitis group, St Louis encephalitis virus, herpes zoster, enteroviruses, mumps, measles, and, most recently, the West Nile virus. In the United States, herpes simplex encephalitis has an estimated incidence of 2.3 per million population each year; HSV-1 accounts for 95 per cent of cases; HSV-2 causes encephalitis mainly in neonates and those who are immunosuppressed, such as transplant patients and those with human immunodeficiency virus (**HIV**) infection. In 1999 there was an outbreak of West Nile infection in the eastern United States with a cluster of cases of encephalitis in New York and, since then, 16 human deaths. West Nile virus is a mosquito-borne flavivirus closely related JE. It has been known to cause encephalitis in Africa, the Middle East, and southern and eastern Europe, but this was the first appearance of this virus in the New World. In endemic areas, infection with West Nile virus is usually asymptomatic or associated with a mild 'flu-like' illness. Only occasionally does it cause encephalitis, with a case fatality rate for patients admitted to hospital in New York of 12 per cent. The virus has now become established in migrant bird populations along the Atlantic coast of the United States and has killed hundreds of thousands of crows.

In the United Kingdom, mumps is the most frequently diagnosed viral encephalitis, followed by echoviruses, coxsackieviruses, measles, herpes simplex virus, herpes zoster virus, Epstein–Barr virus, and adenoviruses (especially adenovirus 7). Louping ill is the only indigenous arthropod (tick)-borne encephalitis in Britain. In Central and Eastern Europe and Scandinavia, tick-borne encephalitis virus and Russian spring–summer encephalitis viruses are endemic. Usutu, a flavivirus, has been isolated in birds in Austria. In many developing countries rabies is an important cause of viral encephalitis. Other regional causes are Rift Valley fever virus in Africa and the Middle East, arenaviruses (Junin, Guanarito, Sabiá, Lassa, and Machupo) in Latin America and Africa, Marburg and Ebola viruses in Africa, Colorado tick fever virus in North America, and Murray Valley encephalitis virus in Australia.

Postinfectious encephalomyelitis most commonly follows measles, vaccinia, varicella, rubella, mumps, and influenza. Guillain-Barré syndrome, a sensorimotor polyneuropathy (see Chapter 24.19), has been associated with infections by Epstein–Barr virus, cytomegalovirus, coxsackie B, and herpes zoster virus. Nervous-tissue vaccine against rabies may give rise to postvaccinal encephalitis (see below), while vaccination against influenza, rabies, hepatitis B, measles, and

poliomyelitis has been complicated by Guillain-Barré syndrome.

Immunodeficient patients are particularly vulnerable to some viral infections. Those with depressed cell-mediated immunity (Hodgkin's disease) may develop herpes zoster encephalitis, and cytomegalovirus may cause a subacute encephalitis in patients with acquired immunodeficiency syndrome (**AIDS**). In children or adults with hypogammaglobulinaemia, enteroviruses, including live-attenuated polio vaccine, may produce a progressive and fatal meningoencephalitis. Progressive multifocal leucoencephalopathy, a chronic and fatal papovavirus infection in patients with impaired cell-mediated immunity, is described below. HIV infection of the brain and meninges may be responsible for acute meningoencephalitis at the time of seroconversion and for subacute chronic encephalopathies and dementia in patients with AIDS (see Chapter 7.10.23 and Chapter 24.14.4).

Epidemiology

Many viral infections of the central nervous system occur in seasonal peaks or as epidemics, while others, such as herpes simplex encephalitis, are sporadic. Epidemics of Japanese encephalitis occur in the summer or rainy season in northern India, Nepal, northern Thailand, Korea, Taiwan, and China. However, in southern Vietnam, Indonesia, Malaysia, southern India, and the Philippines the disease can occur all the year round, although the peak is at the start of the rainy season. This variation in the incidence of disease is an important consideration when recommending vaccination. In endemic areas it is mostly a disease of children, but as the disease spreads to new regions, or non-immune travellers visit endemic regions, non-immune adults are also affected. The major vector is *Culex tritaeniorhynchus* mosquitoes which have been infected by first feeding on the bird (cattle egrets, herons) or mammal reservoir species. Indigenous children and non-immune (immigrant) adults are most susceptible. Tick-borne encephalitides occur in spring and early summer when the ticks are most active. Mumps encephalitis is commonest in the late winter or early spring, while enterovirus infections occur most often in the summer and early autumn. Rodent-related encephalitides, such as the arenaviruses, are most common when the rodent population is at its peak, either in the fields (Machupo and Junin viruses) or in the home (lymphocytic choriomeningitis virus). Zoonotic viral infections, such as Rift Valley Fever, survive periods of cold weather, during which the invertebrate–vertebrate cycle is suspended by 'overwintering' in their arthropod vectors (for example, in the bottom of dried-up ponds) or hibernating vertebrate reservoirs.

Invasion of the central nervous system seems to be a rare event in most viral infections. In the case of some togavirus infections, such as JE, there may be only one case of encephalitis for every 500 to 1000 asymptomatic infections. Eastern equine encephalitis virus produces a much higher proportion of encephalitic cases than other togaviruses.

Infections by many neurotropic viruses are most frequent and severe in children and the elderly. Herpes simplex encephalitis affects all age groups but shows peaks of incidence in those aged between 5 and 30 years and over 50 years. When HSV-2 invades the central nervous system it is likely to cause a benign lymphocytic meningitis in adults, but in neonates it usually produces a severe encephalitis. Among mosquito-borne epidemic encephalitides, California encephalitis and JE are most common in children, St Louis and West Nile encephalitis in the elderly, while eastern and western equine encephalitis affect both the very young and the elderly. Postinfectious encephalitis is most frequent in children, for it complicates the common childhood exanthematous viral infections. It is the most common demyelinating disease in the world.

Pathogenesis

Most viral infections reach the central nervous system from the primary site of infection and multiplication via the bloodstream, but the rabies virus enters peripheral nerves through acetylcholine and other receptors and travels to the CNS in axoplasm, employing the microtubular dynein motor system. Viruses inoculated through the skin include those transmitted by arthropods, rabies virus, herpes simplex virus, *Herpes simiae* B, and lymphocytic choriomeningitis virus. Arthropod-borne viruses are presumed to replicate in local lymph nodes, vascular endothelium, and circulating fixed macrophages, in order to sustain viraemia. Rabies virus may multiply locally in the cytoplasm of muscle cells before entering peripheral nerves. Viruses that enter through the respiratory tract (for example, measles, mumps, varicella) or gut (enteroviruses) multiply in local lymphoid tissue before entering the bloodstream. Viraemia is a feature of most viral infections, yet invasion of the central nervous system is rare in most cases. The explanation for this is not known, but the CNS contains a number of intrinsic physical barriers to infectious agents such as viruses. These include the blood–brain barrier with its 'tight junctions', virus-resistant cells, and the absence of lymphatic drainage. Non-specific mechanisms at or near the site of virus entry, such as gastric acidity and cilia in the respiratory tract, also play a protective role. In the case of rabies, herpes simplex, and herpes zoster viruses, the virus enters the central nervous system through the peripheral nerves. Although the subarachnoid space surrounding the olfactory nerves projects through the cribriform plate and is directly beneath the nasal mucosa, this route of infection seems to be extremely rare in humans and has been proven only in a few cases of inhaled rabies virus infection and herpes simplex encephalitis. Viruses have been inoculated directly into the central nervous system by infected corneal transplant grafts (rabies) and prions through infected brain-surface electrodes (Creutzfeldt–Jakob disease). Herpes simplex encephalitis may complicate primary herpes simplex virus infection in children and young adults, but in most cases of herpes simplex encephalitis the cause is thought to be reactivation of latent virus (HSV-1) in the trigeminal nerve, autonomic nerve roots, or brain.

Some viruses, such as the enteroviruses and mumps, usually infect the meninges rather than the parenchyma of the central nervous system, whereas others, such as the togaviruses, usually cause encephalitis. Different neural cells are selectively vulnerable to different neurotropic viruses. Examples are the predilection of polioviruses for motor neurones of the anterior horns of the spinal cord, and of rabies for neurones of the limbic system and cerebellar Purkinje cells. The pathological effects of viral infections on the central nervous system include:

1. the destruction and phagocytosis of neurones (neuronophagia) as a result of either viral invasion *per se* or immune lysis;
2. demyelination;
3. inflammatory oedema with the compressive effects of raised intracranial pressure; and, in some cases,
4. vascular lesions.

In rabies, a universally fatal encephalitis, neuronolysis is relatively mild. However, rabies virus may interfere with neurotransmission at central and peripheral synapses. It also produces severe systemic effects, following its centrifugal spread (for example, myocarditis and cardiac arrhythmias) or its focal effects on vasomotor and respiratory centres in the brainstem and in the temporal (lobes and amygdala (cf. Klüver–Bucy syndrome) (Chapter 7.10.9).

Postinfectious encephalitis and the Guillain-Barré syndrome are thought to result from sensitization to central and peripheral myelin, respectively. The animal model for the former is experimental allergic encephalomyelitis, which can be produced in a variety of animals following immunization with myelin basic protein. A similar animal model for Guillain-Barré syndrome is known as experimental allergic neuritis. It is uncertain how the preceding viral infection induces this autoimmune response. In the case of postvaccinal encephalomyelitis resulting from old-fashioned nervous tissue antirabies vaccines containing homogenized animal brain, the mechanism is still not clear. The anti-myelin basic protein is not always present and is probably not the direct cause of demyelination.

The host's immune responses to viruses play a crucial role in combating infection. They may be directed against either the virus particle or the virus-infected cell, and may be humoral- or cell-mediated. An important local immune response at infected surfaces is provided by IgA antibody, which is present in secretions in the gut, saliva, and respiratory tract. This is important, for example, in the early stages of poliovirus infection where the antibody neutralizes the virus by combining with viral surface proteins. The systemic viral infection may also be limited by means of circulating IgG and IgM antibodies, which can neutralize the virus in a variety of different ways. Immune responses may also occur locally within the CNS, where local synthesis of immunoglobulins in response to virus infection, sometimes in an oligoclonal pattern, may be evident. Such antibody elevations may be of considerable diagnostic value (see below). Under certain conditions immune responses to viruses may themselves set in train immunopathological processes leading to disease. This may occur in a number of different ways, such as through the deposition in blood vessels of immune complexes formed between an antiviral antibody and viral antigen. In other cases, such as lymphocytic choriomeningitis virus infection, the induction of virus-specific cytotoxic T lymphocytes is itself responsible for the production of encephalitis.

Pathology

Meningitis

The basal leptomeninges, ependyma, and choroid plexus are infiltrated with mononuclear cells but the parenchyma is normal. In mumps meningitis there may be exfoliation of ependymal cells.

Poliomyelitis

Virus is distributed widely throughout the brain and spinal cord, possibly even in non-paralytic cases, but usually the only cells to suffer chromatolysis and phagocytosis are motor neurones in the anterior horns of the spinal cord, medulla, and grey matter of the precentral gyrus.

Encephalitis

Most viral encephalitides are characterized by lymphocytic infiltration of the meninges and perivascular cuffing (in Virchow–Robin spaces) in the cortex and underlying white matter, by lymphocytes, plasma cells, histiocytes, and some neutrophils, and proliferation of microglia with the formation of glial nodules. Neuronolysis and demyelination are variable in their degree and location. Infected neurones may show characteristic inclusion bodies in their nuclei (measles, herpes simplex virus, and adenoviruses) or cytoplasm (Negri bodies in rabies). Microhaemorrhages and foci of necrosis may be found.

Herpes simplex encephalitis

Characteristic features of this condition are gross cerebral oedema and severe haemorrhagic and necrotizing encephalitis, which is often asymmetrically localized to the inferior and medial parts of the temporal lobe, the insula, and the orbital part of the frontal lobe. Histological sections show eosinophilic Cowdry type A intranuclear inclusions with margination of chromatin in neurones, oligodendrocytes, and astrocytes, inflammatory and haemorrhagic perivascular reactions, but no demyelination. Cowdry type A inclusions are also found in herpes zoster virus and cytomegalovirus encephalitides. The unique cerebral localization of herpes simplex encephalitis has not been satisfactorily explained, but is probably the result of viral spread along specific neural pathways rather than a differential susceptibility of particular cell populations. A popular idea is that herpes simplex virus spreads along olfactory pathways to the base of the brain and temporal lobes, but it is also possible that virus may spread from the trigeminal ganglia through sensory fibres innervating the dura near these regions. This latter mechanism is consistent with the discovery of latent HSV-1 in the trigeminal, superior cervical, and vagal ganglia in a high proportion of normal individuals, irrespective of whether they have a history of mucocutaneous herpes infections ('cold sores'). Latent HSV-1 might be reactivated by a variety of stimuli, such as sunlight, fever, trauma, and stress; however, the actual mechanisms underlying its latency and reactivation in the nervous system are not yet fully understood. If herpes simplex encephalitis is caused by the reactivation of latent virus, its rarity, despite ubiquitous asymptomatic infection in humans, is hard to explain.

Japanese encephalitis

Microscopical appearances are typical of other viral encephalitides: there is oedema, congestion, and focal haemorrhages of the brain and meninges, and perivascular cuffing, neuronophagia, and glial nodules of the brain parenchyma. Neuronolysis and neuronophagia are unusually widespread in the thalamus, basal ganglia, brainstem, cerebellum (where there is marked destruction of Purkinje cells), and the spinal cord. Viral antigen is localized to neurones, especially in the brainstem and thalamus.

Nipah virus encephalitis

Pathological studies on the brains of fatal cases demonstrated that the endothelium of small blood vessels in the central nervous system was particularly susceptible to infection. This led to disseminated endothelial damage and syncytium formation, vasculitis, thrombosis, ischaemia, and microinfarction. There was also evidence of neuronal infection by the virus that may have contributed to neurological dysfunction.

West Nile virus encephalitis

Pathological studies from the outbreak of this encephalitis in New York showed varying degrees of neuronal necrosis in the grey matter, with infiltrates of microglia and polymorphonuclear leucocytes, perivascular cuffing, neuronal degeneration, and neuronophagia. Viral antigens were demonstrated in neurones and in areas of necrosis. No antigen was detected in other major organs, including lung, liver, spleen, and kidney. The major pathological lesions were seen in the brainstem and spinal cord.

Enterovirus 71

Pathological studies of patients who died of enterovirus 71 infection showed severe perivascular cuffing, parenchymal inflammation, and neuronophagia in the spinal cord, brainstem, and diencephalon, and in focal areas in the cerebellum and cerebrum. Although no viral inclusions were detected, immunohistochemistry showed viral antigen in the neuronal cytoplasm. Inflammation was often more extensive than neuronal infection, suggesting that other indirect factors may be involved in tissue damage in addition to the effects of direct viral invasion.

Postinfectious encephalomyelitis

This is a perivenous microglial encephalitis with demyelination. Fibrinoid necrosis of arterioles is an associated lesion in a more severe form designated 'acute haemorrhagic leucoencephalitis'.

Clinical features

Meningitis

A prodromal influenza-like illness, followed by a brief remission of symptoms, is typical of lymphocytic choriomeningitis viral infection and some outbreaks of enteroviral meningitis (for example, echovirus 9), but in most cases of viral meningitis, symptoms start suddenly. As with bacterial meningitis, there is fever, headache, a stiff neck, and vomiting, especially in children. Compared with bacterial meningitis, headache is less severe and tends to be frontal or retrobulbar (eye movements may be painful) and neck stiffness is less marked. Nausea, anorexia, abdominal pain, myalgias, and sore throat are particularly common in enteroviral meningitis. Myalgia is particularly severe with coxsackie B infections. As in acute bacterial meningitis, infants usually present with vague irritability and a tense fontanelle, and young children with fever and irritability or lethargy. Conjunctival injection, pharyngitis, and cervical lymphadenopathy may be found. Macular or petechial exanthems or enanthems are seen with coxsackie A and B and echovirus infections (especially echovirus 9). Vesicles on the hands, feet, and mouth have been reported with coxsackie A16 and enterovirus 71 infections. By definition, the level of consciousness is normal in simple meningitis. Neurological features include vertigo, nystagmus, cerebellar ataxia, facial spasms, and involuntary movements.

The specific cause of viral meningitis may be suggested by characteristic signs outside the nervous system, such as genital or rectal vesicles in the sexually active age group (HSV-2), herpes zoster skin lesions, swelling in the parotid region (mumps, and occasionally coxsackie, lymphocytic choriomeningitis, and Epstein–Barr viruses), orchitis (mumps and lymphocytic choriomeningitis virus), and arthritis (lymphocytic choriomeningitis virus). However, potentially helpful features, such as gastrointestinal symptoms associated with enteroviral infections and parotitis associated with mumps, may be completely absent in patients with meningitis.

Paralytic poliomyelitis

The infection (see Chapter 7.10.7) is acquired by droplet spread from the respiratory tract or by the faecal–oral route. The 'minor illness', coinciding with viraemia, is a non-specific episode of influenza-like symptoms—fever, headache, sore throat, malaise, and mild gastrointestinal symptoms—which resolves in a few days. Most of those infected have no further symptoms but, in a minority, the 'major illness' follows, sometimes after a few days' remission of symptoms. The features are those of viral meningitis: muscle pain, spasms, and sensory disturbances may precede or accompany the development of lower motor neurone (flaccid) paralysis. Any combination of motor unit deficits may be seen (Fig. 1). It is most unusual for paralysis to extend after the first 3 days or after the temperature has fallen (Fig. 2). Respiratory and bulbar paralysis is life-threatening. Encephalitis is rare. The commonest causes of death are aspiration and airway obstruction, resulting from bulbar paralysis, and paralysis of respiratory muscles. Disturbances of respiratory and cardiac rhythm, thought to be the result of damage to medullary vasomotor and respiratory centres, are extremely uncommon. Other complications include impaired control of body temperature and blood pressure, gastrointestinal haemorrhage, aspiration pneumonia, and paralysis of the bladder and bowel.

Mechanisms of infection with polio viruses. In *Cellular biology, nucleic acids, and viruses*. New York Academy of Sciences, by permission.)

Encephalitis

Most patients with viral encephalitis present with the symptoms of meningitis (fever, headache, neck stiffness, vomiting) followed by altered consciousness, convulsions, and sometimes focal neurological signs, signs of raised intracranial pressure, or psychiatric symptoms.

Herpes simplex encephalitis

This relatively common sporadic encephalitis may occur in any age group. In neonates, it is caused by HSV-2.

As well as the usual clinical features of a severe viral encephalitis, patients with herpes simplex encephalitis have symptoms related to the focal nature of the encephalitis (frontal and temporal cortex and limbic system). These include behavioural abnormalities, olfactory and gustatory hallucinations, anosmia, amnesia, expressive aphasia, and temporal lobe seizures. Herpetic skin or mucosal lesions are rarely found, except in the case of acute genital HSV-2 infection, or proctitis, and a past history of 'cold sores' does not affect the chances of the infection being due to herpes simplex virus. Effects of cerebral oedema are unusually severe. Patients usually lapse into coma towards the end of the first week and most deaths occur within the first 2 weeks. This condition is also discussed in Chapter 7.10.2.

Japanese encephalitis

After an incubation period of 7 to 14 days, patients develop non-specific prodromal symptoms (fever, headache, malaise, and nausea) lasting 2 to 3 days. Neurological symptoms begin suddenly, with increasing headache, deteriorating level of consciousness, and generalized convulsions, which may result in status epilepticus. There is meningism and mask-like facies, with upper motor neurone signs or a myelitic pattern, cranial nerve lesions (for example, lower motor neurone VII), flaccid paralysis, ataxia, involuntary movements (Fig. 3), and, in severe cases, prolonged coma, hemi- or quadriparesis, decerebrate rigidity, and respiratory failure. Fever persists for 6 to 7 days and, in survivors, neurological symptoms may persist for several weeks. Parkinsonian and extrapyramidal features occur frequently and choreoathetoid movement disorders or severe dystonias can last for many months. The case fatality rate is 30 per cent in those admitted to hospital. Most deaths occur in the first 7 to 10 days from respiratory failure, aspiration pneumonias, intracranial hypertension, and uncontrolled seizures. Up to 50 per cent of survivors suffer from intellectual impairment, psychiatric problems, persistent epilepsy, or a vegetative state with spastic quadriparesis and evidence of basal ganglia involvement, such as dystonia of the limbs and trunk, rigidity, and tremor (Fig. 3).

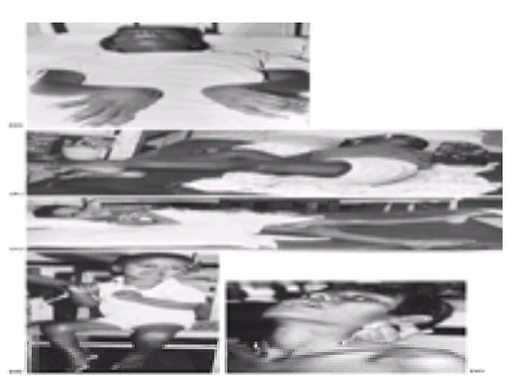

Fig. 3 Japanese encephalitis in Anuradhapura, Sri Lanka. (a) Comatose female patient showing symmetrical chorioathetotic movements of the upper limbs. (b) Comatose child showing dystonic movements of the upper and lower limbs. (c) Convalescent child, conscious but with residual dystonia of all four limbs. (d) Convalescent child with floppy head and involuntary movements of all four limbs. (e) Convalescent boy with residual weakness of the neck flexors. (All figures by courtesy of Dr D.T.D.J. Abeysekera.)

Nipah virus encephalitis

The main clinical features of Nipah virus encephalitis are fever, headache, dizziness, reduced consciousness, and prominent brainstem dysfunction. Distinctive signs included myoclonus, areflexia, hypotonia, hypertension, and tachycardia, suggesting extensive brainstem and spinal cord involvement. MRI imaging during the acute illness shows widespread focal lesions in subcortical and deep white matter and, to a lesser extent, in grey matter on T_2-weighted sequences (Fig. 4).

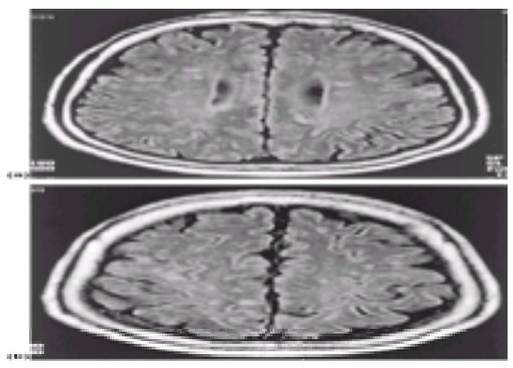

Fig. 4 (a) and (b) Acute Nipah virus encephalitis. MR brain images in a 57-year-old pig farmer showing multiple focal lesions in the grey–white matter junction. These are areas of infarction secondary to vasculitis. (By courtesy of Drs B.J. Abdullah and Sazilah Sarji, Kuala Lumpur.)

West Nile virus encephalitis

The most common clinical features are encephalitis, meningitis, fever, weakness, and headache following an incubation period of 3 to 15 days. Infection usually results in an acute febrile episode with no CNS involvement. In unusual cases or, as in the United States, when the virus is introduced into a naïve population, the incidence of encephalitis rises particularly in the elderly. An erythematous rash of the neck, trunk, and limbs is present in 20 per cent of cases. Patients over 50 years of age were most at risk of developing encephalitis during the New York outbreak, but all age groups are affected in endemic areas. Muscle weakness, areflexia, and diffuse flaccid paralysis in association with an axonal polyneuropathy was also reported. MRI imaging of the brain demonstrated enhancement of the meninges and periventricular areas. There is no specific treatment.

Enterovirus 71

As the goal of poliomyelitis eradication appears more achievable, another enterovirus is emerging as a significant cause of acute neurological disease in Asia. Enterovirus 71 (**EV71**) was first recognized in 1969 and is responsible for a variety of clinical manifestations, including: hand, foot, and mouth disease; aseptic meningitis; meningoencephalitis; and acute flaccid paralysis. In an outbreak of hand, foot, and mouth disease in Malaysia; a number of young children developed fatal encephalomyelitis, dying within a few hours of presentation with cardiovascular instability and severe pulmonary oedema. Postmortem examination in four cases revealed major involvement of the brainstem and spinal cord, with EV71 being isolated from brain tissue in all cases; there was no apparent cardiac pathology and virus was not isolated from the myocardium. Molecular characterization of these four viruses and others isolated concurrently suggest that at least two potentially virulent EV71 strains were circulating during the outbreak. An adenovirus was also thought to have complicated the infection in 60 per cent of the children dying with a similar clinical picture. It is possible that co-infection with the two viruses may have resulted in severe disease.

Postinfectious encephalomyelitis

Sudden convulsions, coma, fever, or pareses appear 10 to 14 days after the start of vaccination (vaccinia or nervous tissue rabies vaccine) or after infection with measles, varicella, rubella, mumps, or influenza. In the case of measles, varicella, and rubella, encephalitic symptoms develop 2 to 12 days after the rash has appeared, and in mumps before or after parotid swelling. Involuntary movements, cranial nerve lesions (VII, III), pupillary abnormalities, nystagmus, ataxia, and upper motor neurone signs are common

Diagnosis

Clinical and epidemiological details

The time of year, known current epidemics, the patient's age, occupation, animal contacts, and countries or states visited recently may help to narrow down the possibilities. A specific diagnosis may be suggested by distinctive clinical features of the encephalitis itself (for example, hydrophobia in rabies, temporal lobe features in herpes simplex encephalitis) or of the associated infection (for example, mumps parotitis; measles rash; skin and mucosal lesions of herpes viruses; and gastrointestinal symptoms associated with enteroviral infections).

Laboratory investigations

These should aim to demonstrate a specific viral agent (particularly important for the potentially treatable herpesvirus infections) or exclude potentially treatable non-viral causes of meningitis or encephalomyelitis (Table 1). The most important investigation is examination of the cerebrospinal fluid (**CSF**). Contraindications to lumbar puncture are the same as for acute bacterial meningitis (Chapter 24.7 and Chapter 24.14.1). If there are lateralizing neurological signs or evidence of raised intracranial pressure, a computed tomography (**CT**) or magnetic resonance imaging (**MRI**) scan should be performed to exclude an intracranial mass lesion before contemplating a lumbar puncture. CSF pressure is especially increased in herpes simplex encephalitis, where there is intense cerebral oedema. Pleocytosis ranges from tens to thousands of cells/µl. Lymphocytes and other mononuclear cells predominate, except in the early stages of some infections (for example, enteroviruses, herpes simplex encephalitis). The CSF contains erythrocytes or is xanthochromic in haemorrhagic encephalitides such as herpes simplex encephalitis and acute necrotic leucoencephalitis. Protein concentration is usually increased in the range of 50 to 150 mg/dl with an increasing proportion of IgG as the disease progresses. Leakage of serum IgG into the CSF and intrathecal IgG synthesis, indicated by a monoclonal band, are responsible. CSF glucose concentration is usually normal or increased towards the level in a blood sample taken simultaneously, but low levels are occasionally reported, especially in mumps and lymphocytic choriomeningitis virus infections. Measurement of lactate, C-reactive protein, lactic dehydrogenase, creatine kinase (CK-BB), muramidase, and various cytokines in the CSF have not proved helpful in distinguishing viral from other infections. CSF examination may be misleading if it is normal: as it is at the first examination in 10 to 15 per cent of patients with herpes simplex encephalitis; if there is a predominantly neutrophil pleocytosis; or if the glucose concentration is low. Myelin basic protein may be found in the CSF of patients with postinfectious encephalomyelitides.

Virology

Full laboratory resources allow a specific virus to be implicated in 70 to 75 per cent of cases of lymphocytic meningitis and in 30 to 40 per cent of patients with meningoencephalitis (Table 2). At appropriate stages of the illness, a rapid diagnosis by direct immunofluorescence may be made of herpes simplex virus (skin and brain), herpes zoster virus (skin lesion scrapings), rabies (skin sections and brain), measles (nasopharyngeal aspirate), and some non-viral causes such as Rocky Mountain spotted fever (skin). Electron microscopy of skin lesions will identify a herpesvirus. Some viruses can be isolated from the CSF (for example, mumps, enteroviruses, lymphocytic choriomeningitis virus, Central European encephalitides, Louping ill, and HIV). Virus cultured from a distant site may help with the diagnosis (for example, polio and other enteroviruses from stool, or arthropod-borne viruses from blood culture), but they may not be related to the neurological symptoms (for example, cytomegalovirus from the pharynx or urine, herpes simplex virus from skin or mucosa or adenovirus seen in stool by electron microscopy). Specific viral IgM can be detected in serum for mumps, Epstein–Barr virus, cytomegalovirus, or measles, or, using a µ-capture technique, in the CSF for JE virus. This method is being used increasingly to detect IgM to other viruses. The viraemia associated with JE is very brief and isolation from CSF difficult. Virus can occasionally be isolated from postmortem material. A viral diagnosis is often delayed until a rising convalescent antibody titre is found by an appropriate technique. This is usually the case for mumps, coxsackieviruses, and most arthropod-borne viruses.

An important diagnostic advance has been the introduction of polymerase chain reaction (**PCR**) technology for the routine diagnosis of a viral infection of the CNS. PCR greatly amplifies the amount of viral nucleic acid in the test sample, enabling the identification of herpes simplex virus in the CSF of suspected cases of herpes simplex encephalitis within a short time of the onset of symptoms. PCR is now the investigation of choice for the rapid diagnosis of HSV encephalitis, having a sensitivity of 95 per cent and a specificity of 100 per cent. The application of microchip and real-time PCR technology may further aid the rapid diagnosis of encephalitis. It is hoped that molecular techniques may aid the early diagnosis of a greater variety of CNS viral infections in the future (Table 2).

Brain biopsy

For the rapid diagnosis of viral encephalitides such as progressive multifocal leucoencephalopathy there is still no substitute for brain biopsy, but few would regard this inherently risky procedure as being justified. Electroencephalography, CT or MRI scans, angiography, or technetium scans can help to direct the surgeon towards the affected area of brain.

Imaging of the brain and spinal cord

CT and MRI scans of the brain and spinal cord can be extremely useful for the diagnosis of the site, nature, and extent of mass lesions and associated oedema, sub- and epidural empyemas, meningitis, cerebritis, and ventriculitis, the presence of intracranial hypertension, hydrocephalus, cerebral and brainstem herniation, demyelination, and other anatomical abnormalities (see Chapter 24.5).

CT scans are superior for bony details and calcifications, are quicker to perform, and are less dependent on the patient being able to lie motionless for prolonged periods. The resolution of MRI is greater for parenchymal lesions, but MRI cannot be performed in patients with pacemakers and may be dangerous in those with metal clips in cerebral blood vessels. Some viral encephalitides do have characteristic lesions on MRI. Some 94 per cent of patients with HSV have high-signal T_2-hyperintense lesions in the medial and inferior temporal regions, and JE is associated with characteristic lesions in the basal ganglia. More discrete high-signal intensity 2- to 7-mm lesions, particularly in the subcortical and deep white matter of the cerebral hemispheres, have been associated with the recently described Nipah virus infection (Fig. 4). However, these classical descriptions often overlap and the general features of oedema, infarction, and high signal on the T_2-weighted images are commonly seen in a variety of viral infections of the CNS.

Differential diagnosis

Viral infections of the CNS must be distinguished from the many other conditions that produce similar clinical features and CSF abnormalities (Table 1). The differential diagnosis of viral meningitis includes the other causes of aseptic meningitis, such as partially treated bacterial meningitis, tuberculous meningitis, spirochaetal infections (leptospirosis, borreliosis, Lyme disease, and syphilis), fungal, amoebic, neoplastic, granulomatous, and idiopathic meningitides. Viral myelitides must be distinguished from other causes of transverse myelitis and the Brown–Séquard syndrome. These include spinal compression by tumours, abscesses, helminths or their ova, or vertebral disease.

The differential diagnosis of paralytic poliomyelitis includes: postinfectious and other immunopathic polyneuroradiculopathies, such as Guillain-Barré syndrome and Landry's ascending paralysis; metabolic neuropathies such as acute porphyria; paralytic rabies; neoplastic polyradiculopathies; and rarities, such as tick paralysis and *Herpes simiae* B virus infection. The lack of objective sensory loss in poliomyelitis usually distinguishes it from these other entities.

The differential diagnosis of viral encephalitis includes other infective encephalopathies: bacterial, fungal, protozoal, and parasitic; intracranial abscesses and neoplasms; toxic and metabolic encephalopathies; and heat stroke. The diagnosis of 'viral encephalitis' should not be made too hastily, as it may condemn the patient with concealed cerebral malaria or some other curable encephalopathy to delayed treatment or even death.

Treatment

Antiviral chemotherapy

Aciclovir and, to a lesser extent, vidarabine (cytosine arabinoside) have proved effective in treating herpes simplex encephalitis. This subject is also discussed in Chapter 7.10.2. The nucleoside analogue acycloguanosine (that is, aciclovir) is only taken up by cells infected by herpes simplex virus and is therefore non-toxic to normal, uninfected cells. In view of this remarkable lack of serious toxicity, treatment can be started as soon as herpes simplex encephalitis is suspected clinically. Although there is still some controversy in the United States regarding the role of brain biopsy in herpes simplex encephalitis, virtually all clinicians in the United Kingdom now start therapy with aciclovir immediately on suspicion of encephalitis without attempting to confirm the diagnosis by brain biopsy. Aciclovir has also been used to treat herpes zoster virus encephalitis, but there is no convincing evidence for its efficacy in cytomegalovirus infections of the CNS. The rare, but very dangerous, encephalomyelitis caused by *Herpes simiae* B virus should be treated with aciclovir. Ribavirin is effective against some RNA viruses, such as those causing Lassa fever, haemorrhagic fever with renal syndrome, and possibly Argentine haemorrhagic fever, Rift Valley fever, and Congo Crimean haemorrhagic fever.

Interferons have been used by intravenous, intrathecal, or intraventricular routes in the treatment of rabies, herpes zoster virus, and other herpesvirus encephalitides, but have not proved effective. Although initial pilot studies of the use of interferon in JE were encouraging, the efficacy of this expensive treatment is awaited from randomized controlled trials.

Hyperimmune plasma given within 8 days of the start of symptoms has reduced the mortality of Argentine haemorrhagic fever (Junin virus) from between 20 and 30 to 1 and 3 per cent. Hyperimmune human globulin has also proved effective in the treatment of Congo Crimean haemorrhagic fever.

Supportive treatment

Corticosteroids have been used in the treatment of most of the viral encephalomyelitides, both in an attempt to combat cerebral oedema (especially in herpes simplex encephalitis) and for their other anti-inflammatory effects. Convincing evidence of benefit from controlled trials is lacking, but the immunosuppressive effects of corticosteroids have not led to obvious clinical deterioration, except perhaps in some cases of diffuse myelitis. Corticosteroids or ACTH have also been used for postinfectious and postvaccinal encephalomyelitides, but the evidence for their efficacy is not convincing and, since they may exacerbate latent rabies in experimental animals, should be used only in life-threatening cases of rabies postvaccinal encephalomyelitis. Severe intracranial hypertension should be treated with intravenous mannitol or mechanical hyperventilation. Nursing and general care are the same as for acute bacterial meningitis (Chapter 24.14.1) and tuberculous meningitis. Seizures must be controlled with phenytoin or phenobarbital, fever lowered by cooling, respiratory failure treated by mechanical ventilation, and attention given to fluid, electrolyte, and acid–base balance. Hyponatraemia is attributable to inappropriate secretion of antidiuretic hormone in some cases.

Paralytic poliomyelitis

Most authorities recommend rest and even mild sedation during the preparalytic stage of the 'major illness', because of the suspicion that exercise increases paralysis. The severe muscle pains and spasms reported in patients in some parts of the world are treated with mild analgesics, such as salicylate, and with hot-water bottles. During the phase of developing paralysis, patients must be observed closely and, if possible, assessed objectively for the development of life-threatening bulbar and respiratory paralysis. Those with weakness of swallowing should be nursed on their sides to prevent aspiration. The need for a cuffed tracheostomy tube may be avoided by careful positioning, frequent observations, and suction. Indications for mechanical ventilation are a progressive decline in ventilatory capacity to less than 30 to 50 per cent of normal, hypoxaemia, or gross disturbances of respiratory rhythm (Cheyne–Stokes respiration, long apnoeic intervals, etc.) suggesting damage to the respiratory centres. Respiratory weakness without bulbar paralysis may be treated in a tank respirator or rocking bed, which do not require tracheostomy. However, patients with severe or rapidly progressing respiratory paralysis need urgent tracheostomy and intermittent positive-pressure ventilation. Overventilation must be avoided. Assisted ventilation may be required for long periods. In the Copenhagen epidemic of the 1940s, this was achieved by manual ventilation. Attempts should be made to wean patients off the ventilator as soon as their condition becomes stable. Severe fluctuations in body temperature and blood pressure, reminiscent of those in severe tetanus and rabies, may require intensive care. The paralysed patient may have to lie in bed for many months and will develop complications from this prolonged immobilization. These include bed sores, osteomalacia, hypercalciuria leading to renal calculi, recurrent urinary tract infections resulting from chronic urethral catheterization, respiratory infections, and contractures of muscles and tendons leading to severe musculoskeletal deformities that will require orthopaedic correction. Some of these can be prevented by passive movement of the joints and splinting. Physiotherapy and psychological support are needed during the prolonged phase of rehabilitation.

Prognosis and sequelae

Viral meningitis has an excellent prognosis, but some patients with HSV-2 infection have recurrent attacks with spinal cord or nerve root involvement. Case fatality rates of some viral encephalomyelitides are as follows: rabies, 100 per cent; herpes simplex encephalitis (untreated), 40 to more than 75 per cent (highest in neonates

and those over 30 years old); eastern equine encephalitis, 50 per cent; Japanese encephalitis, 10 to 40 per cent; measles, 10 to 20 per cent; varicella, 10 to 30 per cent; western equine encephalitis, 8 per cent; St Louis encephalitis, 3 per cent; California encephalitis, Venezuelan encephalitis, and mumps, less than 1 per cent. The mortality of paralytic poliomyelitis increases from 5 per cent in young children to more than 20 per cent in adults. Postinfectious and postvaccinal encephalomyelitides carry case fatalities of 15 to 40 per cent.

Neurological sequelae are found in 5 to 75 per cent of survivors of Japanese encephalitis and herpes simplex encephalitis, and are especially common in infants. They include mental retardation, loss of memory, speech abnormalities (including subtle expressive aphasias), hemiparesis, ataxia, dystonic brainstem and cranial nerve lesions, recurrent convulsions, and various behavioural and personality disturbances. Sequelae are common with postinfectious encephalomyelitis. An unusual sequel to paralytic poliomyelitis developing after an interval of many years is a condition characterized by progressive muscle weakness and wasting, attributable to depletion of anterior horn cells, which has some similarities to motor neurone disease.

Prevention

Prophylactic vaccination against poliomyelitis and measles has virtually eradicated encephalitides caused by these viruses in many communities. Postexposure rabies vaccination has also proved effective in preventing rabies encephalitis, and tissue-culture rabies vaccines are used increasingly for pre-exposure prophylaxis. A formalin-inactivated, adult mouse-brain vaccine is manufactured in Osaka for JE. It is effective and carries a very low risk of objective neurological complications (one in a million courses). An alternative live-attenuated vaccine has been developed in China, and has been shown to be both safe and effective in over 100 million Chinese children. Promising future vaccine candidates are currently being evaluated in non-human primate models, including a chimeric live-attenuated JEV/yellow fever virus combination and two poxvirus-vectored recombinant JE vaccines. Travellers to endemic regions should be vaccinated.

Since the outbreak of West Nile infection in the United States, several vaccine candidates have already been identified and immune protection against infection demonstrated in several animal models: human trials have been planned. There have been no reports of such success against Nipah virus. Vaccines for use in humans have been prepared against a number of other arthropod-borne viruses (for example, European tick-borne encephalitis).

Hyperimmune immunoglobulin has been used for prophylaxis (and in some cases attempted treatment) of measles, herpes zoster virus, HSV-2, vaccinia, rabies, and some other infections in high-risk groups. Immunocompromised patients, such as those with leukaemia, who are household contacts of a case of herpes zoster virus infection, should be given prophylactic hyperimmune globulin and, if they develop skin lesions, they should be treated with aciclovir to prevent the development of severe disease.

Interferons have been used with some success to prevent herpesvirus infections, for example cytomegalovirus in high-risk groups such as renal transplant recipients. However, the evidence does not yet justify their recommendation.

Caesarean section before rupture of the membranes in a full-term pregnant woman with genital herpes may prevent HSV-2 encephalitis in the neonate. If the herpetic lesions are discovered during or after vaginal delivery, topical aciclovir should be applied to the eyes of the neonate, as they are the most likely portal of entry.

Arthropod-borne viral encephalitides can be prevented by avoiding or controlling the arthropod vectors (for example, by the use of mosquito nets, insect repellents, insecticides, etc.), by attempting to control the numbers of wild vertebrate reservoir species, or by immunizing domestic animals, such as horses (eastern and western equine encephalitides) and pigs (JE). To control rabies, the principal wild mammalian vectors can be immunized (for example, wild foxes, racoons, and black-backed jackals have been immunized by distributing oral vaccine in bait). Domestic dogs and cats should be vaccinated. To prevent the viral encephalitides transmissible from laboratory animals (for example, lymphocytic choriomeningitis from mice and rats, *Herpes simiae* B from monkeys) their screening, quarantine, handling, and housing should be strictly controlled.

Reye's syndrome

Reye's syndrome is an acute encephalopathy affecting children between the ages of 2 and 16 years. It is rapidly fatal in 10 to 40 per cent of cases. The defining characteristics are sudden impairment of consciousness, increase in serum aminotransferase concentrations (or, if a biopsy is done, a fatty liver), and the exclusion of other diseases. Symptoms develop a few days after varicella or an upper respiratory tract or gastrointestinal illness. Clusters of cases (median age 11 years) have been associated with influenza B epidemics, while sporadic cases (median age 6 years) have followed varicella, coxsackie, dengue, and other viral infections. Studies in the United States have demonstrated an association between Reye's syndrome and the use of salicylates, but not of paracetamol, during the preceding viral illness. This has led the United Kingdom Committee on Safety of Medicines to recommend that aspirin should not be given to children under 12 years of age, unless specifically indicated for childhood rheumatic conditions. Aflatoxin has been implicated in Thailand. In the United States, the annual incidence of Reye's syndrome in those under 18 years old is 0.42 per 100 000 urban dwellers and 1.8 per 100 000 rural and suburban dwellers.

The child is nauseated and retches or vomits for 1 or 2 days before becoming confused or comatose and requiring admission to hospital. Most are afebrile and have hepatosplenomegaly but no jaundice at presentation. Fever develops later. The CSF is usually normal or contains a few mononuclear cells. Irritability, extreme agitation, aggression, and delirium are succeeded by coma and death in 2 to 3 days. Decorticate and decerebrate posturing and convulsions may be partly attributable to hypoglycaemia, which occurs in the majority of cases. There is rapid neurological deterioration with loss of pupillary and oculovestibular reflexes, evidence of increased intracranial pressure, deepening coma, and death. Neurological sequelae are common in survivors. Blood ammonia is increased above the normal limit of 48 µg/dl in almost all cases. The characteristic histological abnormality is fatty droplets in the liver cells. Mitochondrial abnormalities, but no inflammatory changes, have also been seen in neurones and hepatocytes.

The differential diagnosis includes acute hepatic encephalopathy, especially associated with poisoning, infective encephalopathies such as cerebral malaria (usually distinguishable by a positive blood smear) or bacterial, viral, and fungal meningoencephalitides (distinguished by characteristic CSF abnormalities).

There is no specific treatment, but mortality can be reduced by treating hypoglycaemia, cerebral oedema, respiratory failure, fluid and electrolyte disturbances, and other complications. These measures are also considered in Chapter 24.14.1.

Other viral infections or disorders in which viruses play a role in the pathogenesis of neurological disease

Subacute sclerosing panencephalitis

This disorder (see also Chapter 7.10.6) is a form of subacute encephalitis affecting children and young adults due to persistent infection with the measles virus. The cumbersome title, usually abbreviated to **SSPE**, is derived from the conditions formerly known as subacute sclerosing leucoencephalitis and inclusion-body encephalitis, now known to be the same disease.

Aetiology

An infective cause was long suspected and there is now conclusive evidence to incriminate the measles virus. Measles virus antibody titres are extremely high in the blood and CSF, measles antigen has been demonstrated in the brain, and the virus has sometimes been isolated, but only with difficulty. Most affected children have had measles at an unusually early age and there is a mean interval of some 6 years between infection and the onset of encephalitis. The disease can occur in children vaccinated with live measles virus, but the risk is much lower than that following the natural disease.

The measles virus in subacute sclerosing panencephalitis appears to be incomplete, as the matrix (**M**) protein required to attach the nucleocapsid to the cytoplasmic membrane prior to budding is deficient or absent. It is not known whether the absence of M protein from the brain is the result of an abnormality of the virus or of the host, and, if the latter, whether inborn or acquired. Current thought is that during the long symptom-free interval between infection and appearance of disease, viral material accumulates, eventually leading to cell damage. The paradox of high antimeasles antibodies, except against M protein, and persistent virus has not been explained. The comparatively early age of clinical measles in affected children, often below the age of 2 years, suggests that the immature immune system permits entry and persistence of the virus in the brain.

Pathology

As its name implies, both grey and white matter show the changes of encephalitis, with perivascular cuffing and more diffuse cellular infiltration, neuronal loss and myelin destruction, with variable glial scarring or sclerosis. Acidophilic nuclear inclusion bodies are never profuse and may not be detected. No visceral lesions are found.

Clinical features

In the great majority, the onset is in the first two decades, but young adults may also be affected. The disease is twice as common in boys as in girls. Incidence has fallen sharply in countries where measles vaccination is at a high level; the annual incidence in England and Wales has fallen from 20 to around 5. Subacute sclerosing panencephalitis remains relatively common in parts of eastern Europe, Egypt, and the Lebanon. No convincing predisposing factors have been identified and, in particular, immunosuppressed children are not at special risk but they may occasionally develop acute measles inclusion-body encephalitis.

The speed of onset is extremely variable, but there is usually a prolonged period of altered behaviour, mild intellectual deterioration, and loss of energy and interest, often misinterpreted as sloth or neurosis. After some weeks or months increasing clumsiness or the appearance of focal neurological symptoms draws attention to the organic nature of the disease. Periodic involuntary movements then appear, the commonest form being myoclonus, consisting of a stereotyped jerk or lapse of posture involving the limbs, often asymmetrically, occurring every 3 to 6 s. The myoclonus may result in sudden falls, which are occasionally the presenting symptom. Visual signs may be prominent, with papilloedema, retinitis, optic atrophy, or cortical blindness. Choroidoretinal scarring is present in 30 per cent of cases. In other cases the onset is relatively abrupt with no recognizable prodromal stage. There is no fever or other evidence of systemic infection.

Further progression is marked by intellectual deterioration, rigidity and spasticity, and increasing helplessness. Some 40 per cent of patients die within a year, but a similar proportion survive for more than 2 years. A period of apparent arrest is common and in some patients, particularly at the upper end of the age range, substantial remission and prolonged survival occur. Even in such cases there may be radiological evidence of continued cerebral damage and it is probable that the disease is always eventually fatal.

Investigation

There is no significant pleocytosis in the cerebrospinal fluid and total protein is not increased, but there is evidence of intrathecal synthesis of immunoglobulin and oligoclonal bands of IgG. Although the measles antibody titres in blood and CSF are usually raised to high levels, occasionally they overlap control values. In established disease, the electroencephalogram (**EEG**) shows highly characteristic periodic discharges, synchronous with the myoclonus, but persisting in the absence of the movements. The CT scan shows low-density, white-matter lesions and cerebral atrophy.

Treatment

There is no effective treatment for subacute sclerosing panencephalitis. Inosiplex, 100 mg/kg daily by mouth in divided doses, possibly prolongs survival, particularly in older patients with disease of slow onset, but adequately controlled trials are naturally difficult to mount. Interferon given by intraventricular catheter has been reported to induce partial remission.

Progressive multifocal leucoencephalopathy (see also Chapter 24.14.4)

This disease is caused by opportunistic infection by papovaviruses, most commonly JC virus and the simian virus SV40. A high proportion of normal adults have antibodies to the former and the agent appears to be ubiquitous. The reservoir of SV40 is in monkeys and the agent was apparently transmitted in early types of poliomyelitis vaccine, without evident ill-effects. These viruses are potentially oncogenic, but are non-pathogenic for humans unless the immune system has been compromised.

Progressive multifocal leucoencephalopathy thus occurs in patients already affected by such conditions as lympho- or myeloproliferative diseases, sarcoidosis, and other chronic granulomatous diseases, or, more recently, AIDS, and also in those therapeutically immunosuppressed. Most patients are over 50 years old but, with the spread of AIDS, younger people are being affected, with a male preponderance, and the disease is no longer rare.

Pathology

The virus particularly invades the nuclei of the oligodendroglia and, as a result, there is demyelination of the white matter of the cerebral hemisphere, spreading from numerous foci. The cerebellum and brainstem are less often involved and the spinal cord is spared. Abnormal giant forms of oligodendrocytes with eosinophilic inclusions are seen microscopically, and arrays of intranuclear virus particles can often be identified by electron microscopy. JC virus antigen can be identified by immunofluorescence or immunohistochemistry. DNA probing has revealed unintegrated virus in oligodendrocytes, astrocytes, endothelial cells, and in extraneural organs such as kidney, liver, lung, spleen, and lymph nodes.

Clinical features

The onset is usually with progressive signs of a focal lesion of one cerebral hemisphere; limb weakness, aphasia, or visual field defect such as homonymous hemianopia. More widespread signs gradually develop, leading to personality changes, intellectual deterioration, dysarthria or fluent aphasia, and bilateral weakness. Fits are rare. There is no systemic evidence of infection. Spontaneous temporary arrest or partial remission are common but eventual progression causes death in 6 to 12 months, although much more chronic cases are on record, with survival, exceptionally, to 5 years.

Investigation

The CSF is normal apart from occasionally a mild elevation of protein and slight pleocytosis, and is not under increased pressure. The EEG shows a bilateral excess of slow activity. The CT scan may at first show little abnormality, but eventually large, non-enhancing, low-density lesions appear in the cerebral white matter. MRI is more sensitive. Serum antibodies are of no diagnostic help but the response in the CSF has not been fully evaluated. The diagnosis can be confirmed only by cerebral biopsy, but it is essential that white matter is included in the specimen. This may be important to distinguish lymphoma and, rarely, herpes simplex encephalitis involving white matter.

Treatment

No treatment is of proven value, but cytosine arabinoside has sometimes appeared to induce partial remission.

Progressive rubella panencephalitis

This extremely rare disorder (see also Chapter 7.10.12) may follow congenital rubella or rubella in early childhood. It evolves insidiously some 10 years after the original illness and is characterized by progressive mental retardation with behaviour changes, fits, ataxia, spasticity, optic atrophy, and macular degeneration. Pathological changes are those of encephalitis with perivascular infiltration. The CSF may show a slight rise in white cell and protein content, elevation of gammaglobulin and of antirubella antibodies to an extent greater than the rise in the serum level, suggesting local production of antibody within the CNS. The EEG may show changes similar to those seen in subacute sclerosing panencephalitis due to measles virus. The mechanism responsible for the appearance of this disorder is unknown and there is no effective treatment.

Vogt–Koyanagi–Harada syndrome

The cause of this rare syndrome is thought to be an inflammatory autoimmune reaction to an unidentified viral infection. The disorder affects tissues having a common embryological origin, the uvea and leptomeninges and the melanoblasts, ocular pigments and auditory labyrinth pigments originating from the neural crest. The

dermatological features consist of patchy whitening of eyelashes, eyebrows, and scalp hair, alopecia, and vitiligo. Neurological manifestations include meningoencephalitis, raised intracranial pressure, neurosensory deafness, tinnitus, nystagmus, ataxia, ocular palsies, and focal cerebral deficits. Ocular features are those of uveitis with pain and photophobia, more generalized inflammation of the eye, retinopathy, and impaired visual acuity. The condition tends to be self-limiting but may result in serious permanent ocular and neurological deficits. Steroids and immunosuppressive drugs have been used and are said to arrest the progression of at least some features of the disorder.

Viral causes of psychiatric illness

Mental changes are common in patients with encephalitis. Influenza, infectious mononucleosis, and infectious hepatitis are sometimes followed by psychiatric sequelae, in particular a depressive reaction. Psychosis following encephalitis lethargica has been reported on occasions.

Other possible virus infections in which the nervous system is involved

Acute disseminated encephalomyelitis is considered in Chapter 24.16. Reye's syndrome is discussed above and Behçet's syndrome in Chapter 18.10.5. Mollaret's meningitis is discussed in Chapter 24.14.1.

24.14.3 Intracranial abscess

P. J. Teddy

Intracranial abscesses may occur within the extradural or subdural space, or may be intracerebral. Occasionally, abscesses exist in more than one tissue plane. Intracerebral and subdural abscesses may rupture into the subarachnoid space and be accompanied by meningitis; intracerebral pus may rupture into the ventricular system and produce ventriculitis.

Aetiology

Extradural abscesses are usually related to focal osteomyelitis of the skull, mastoiditis and nasal sinusitis, penetrating injuries of the skull, and are a rare complication of craniotomy.

Subdural empyema is related most commonly to infection of the paranasal sinuses and middle ear. Other causes include septicaemia related to cyanotic congenital heart disease, lung abscess, trauma, and intracranial surgery.

The most common intracranial abscess is found within the intracerebral compartment, with about 60 per cent related to middle-ear infection and 20 per cent to frontal sinusitis. Other established causes are septicaemia related to congenital heart disease with a right-to-left shunt, lung abscess, bronchiectasis, penetrating injuries of the head, and bacteraemia following tooth extraction. In about 10 per cent of cases no primary source of infection can be identified. Owing to their strong connection with sinus and middle-ear disease, most intracerebral abscesses are found within the frontal or temporal lobes, or within the cerebellum. Infection disseminated through the bloodstream from more distant sites may result in multiple abscesses in any part of the brain.

Microbiology

The most common organisms associated with subdural empyema are aerobic, anaerobic, and micro-aerophilic streptococci, *Staphylococcus aureus*, and *Bacteroides* spp.

Cerebral abscesses associated with otitis media, mastoiditis, and nasal sinusitis usually show a mixed growth of anaerobes and aerobic organisms including anaerobic and micro-aerophilic streptococci and *Bacteroides*. *Streptococcus viridans and Staph. aureus* are frequently seen. *Listeria* spp. tend to produce areas of focal cerebritis rather than true abscess.

Pathology

Infection within an accessory air sinus or the petrous bone may cause an area of localized osteitis just above the dura, which can then spread intracranially. Initially it may be entirely confined to the extradural space, but will eventually penetrate the dura and spread subdurally or, if the adjacent arachnoid is stuck to the inflamed patch of dura, then it will spread into the subarachnoid space to give meningitis. If the subarachnoid space has been obliterated, it may penetrate the brain to produce initially a focal cerebritis. Usually after about 10 days the area of cerebritis becomes enclosed within an area of gliotic brain, and after about 3 weeks a firm capsule forms around the pus. Large intracerebral abscesses may rupture into the ventricular system, producing a ventriculitis.

Cerebral abscesses are usually surrounded by areas of oedematous brain, which may exert a considerable mass effect.

Clinical features

These will depend upon the site, size, and number of lesions, and the involvement of neighbouring structures such as the cerebral ventricles and the venous sinuses. The signs are therefore legion, but the diagnosis should be considered in any case where there is an obvious primary source of infection associated with evidence of raised intracranial pressure, focal neurological signs, epileptic seizures or meningeal irritation, or any combination of these.

Extradural abscess may be difficult to detect clinically, but is sometimes manifest by severe, unremitting, localized headache in association with sinusitis or mastoiditis. Patients with subdural empyema frequently appear toxic, with a swinging pyrexia, severe headache, a depressed level of consciousness, contralateral hemiparesis, papilloedema, meningeal irritation, and seizures. There is usually an accompanying frontal sinusitis with tenderness of the forehead and redness and swelling of the eyelids, or mastoiditis or scalp infection.

Diagnosis

If a brain abscess is suspected, predisposing sources of infection, including possible distant sites, should be carefully sought, as intracranial abscesses derived by haematogenous spread are often more fulminating in their course than those associated with local cranial disease. If CT is available, scans of the skull base, including views of the mastoids and other skull sinuses, should be performed. Otherwise, skull radiography with sinus views is necessary. Chest radiographs should be obtained.

The investigations of choice for all forms of suspected intracranial abscess are either CT scanning, with and without contrast, or MRI. CT will normally demonstrate both extradural and subdural empyema, may demonstrate diffuse cerebritis in early cases, and will normally show intracerebral abscesses as ring-enhancing lesions with low-attenuation centres (see Fig. 1). Nevertheless, there are pitfalls, particularly in the early stages both of subdural empyema and of cerebral abscess. Subdural empyema may initially be fairly thinly spread over the cerebral cortex, producing relatively little midline shift, and may be virtually isodense with brain on CT. Under such circumstances, contrast-enhanced MRI (particularly with coronal views) is of great value.

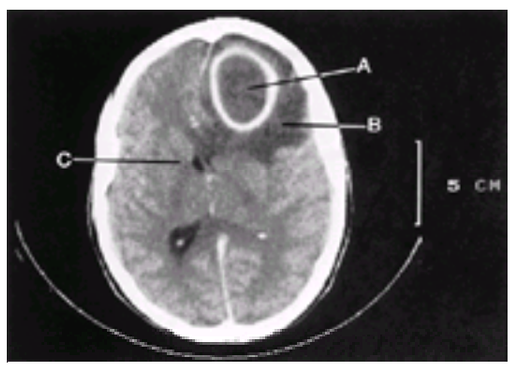

Fig. 1 Contrast CT scan showing large right frontal cerebral abscess (A) with surrounding oedema (B) and ventricular compression (C).

The principal differential diagnoses in an intracranial abscess are meningitis, subdural haematoma, and intracranial tumour. It is not always possible to differentiate between intracerebral abscess and tumour on CT scan, particularly when there is an appearance of ring enhancement, and it is largely for this reason that the biopsy of suspected cerebral tumour is advocated in nearly all such cases. MRI, however, tends to show a low-signal capsule on T_2-weighted images and may be helpful in making this differentiation.

One obvious concern is to differentiate between bacterial meningitis and intracerebral abscess. Both may present with pyrexia, neck stiffness, and with some focal signs, but if there is any evidence whatsoever of raised intracranial pressure, or any other supportive evidence of cerebral abscess, a lumbar puncture should be strictly avoided until a neurosurgical opinion has been sought. Lumbar puncture in the presence of cerebral abscess can lead to tonsillar or tentorial herniation, and in any event, the cerebrospinal fluid can be entirely normal.

Management

Except in a few cases of multiple or inaccessible abscess, and the occasional patient whose general medical condition is such that surgery is precluded, treatment of the intracranial infection requires evacuation of pus and high-dose intravenous antibiotic therapy.

The single, main factor in securing a good outcome is early diagnosis. Early management includes taking specimens for blood culture and culture of any extracranial infective lesion, setting up an intravenous infusion, administration of anticonvulsant agents, and, in cases of grossly depressed level of consciousness and massive cerebral oedema seen on CT scan, giving intravenous dexamethasone.

Pus from the suspected primary site of infection should be collected immediately and both aerobic and anaerobic cultures obtained. The intracranial pus must be similarly cultured. Antimicrobial treatment, using massive intravenous doses, should be commenced immediately without waiting for the culture report, and subsequently changed in the light of the sensitivity findings. The antimicrobial regimen should include penicillin (4 mega units 4-hourly), metronidazole, ampicillin, and either gentamicin or chloramphenicol depending on the likely source of infection and the infective agent. Intravenous antimicrobials should be continued for at least 1 week before reverting to oral medication.

Most supratentorial abscesses can be sterilized by aspiration through a burr hole, and the direct instillation of antibiotics is sometimes employed. Aspiration must usually be repeated several times, but in about 30 per cent of cases a single aspiration will suffice. Once the abscess is sterile, the capsule will shrink and finally form an irregular gliotic scar within the brain. Shrinkage of the abscess must be checked by serial CT scan. Subdural empyema should be evacuated through a craniotomy rather than burr holes, as very often the pus can spread widely, and particularly alongside the falx cerebri. Extradural empyema is evacuated through a burr hole, or through a craniotomy for larger collections.

Cerebellar abscess, when diagnosed early, may be aspirated through a burr hole, but immediate total excision is often recommended because the small volume of the posterior cranial fossa leaves little latitude in terms of tonsillar herniation and death.

Prognosis

The mortality is around 10 per cent, but the main problems remain those of late diagnosis and resistant bacteria. Even with an otherwise good outcome, epilepsy may continue in about 30 per cent of cases, particularly in patients with temporal-lobe abscess and subdural empyema.

24.14.4 Neurosyphilis and neuroAIDS

Hadi Manji

Neurosyphilis

Introduction

Syphilis remains a public health problem in certain areas of the United States, Eastern Europe, and in the developing world. The incidence of primary and secondary syphilis in the United Kingdom (excluding Scotland) increased from 109 cases in 1995 to 259 cases in 2000 – an increase of 138 per cent. Since syphilis, like other ulcerating genital infections such as herpes and chancroid, is an independent risk factor for the acquisition and transmission of infection with the human immunodeficiency virus (**HIV**), the disease has once again come under scrutiny. In addition, there are recent anecdotal reports of *Treponema pallidum* being more neurovirulent and with a greater risk of treatment failure in those dually infected with HIV.

Invasion of the central nervous system occurs early in the course of syphilis infection. *T. pallidum* has been isolated from the cerebrospinal fluid of up to 40 per cent of neurologically asymptomatic patients with untreated primary and secondary syphilis. Despite this, cohort studies of untreated patients suggest that symptomatic late syphilis (neurosyphilis, cardiovascular syphilis, and gummas) occurs in 15 to 40 per cent of such individuals; the Oslo study documented an incidence of clinical neurosyphilis in 9.4 per cent. Thus, it would seem as if, at least in the immunocompetent patient, *T. pallidum* has a low virulence for the central nervous system.

Clinical features (see Table 1)

Acquired syphilis is divided into an early, potentially infectious stage (primary, secondary, and early latent where less than 2 years have lapsed since infection) and a late, non-infectious stage (late latent where more than 2 years have lapsed, gummatous, cardiovascular, and neurosyphilitis). Although there is a rough time course to the development of the various neurological syndromes, there is considerable overlap; these syndromes are, in reality, part of a spectrum of disease.

Neurosyphilis may include meningitis (acute and chronic), a myeloradiculopathy due to a pachymeningitis and granulomatous lesions (gummas) that present as space-occupying lesions within the brain, the spinal cord, or the epidural space causing compression. Meningovascular syphilis involves the small- and medium-sized arteries, typically causing an endarteritis (Heubner's endarteritis obliterans) resulting in infarction. The so-called late manifestations of neurosyphilis result from a low-grade meningoencephalitis. In patients with general paralysis (also called general paralysis of the insane or dementia paralytica) the focus is on the frontotemporal cortex. Therefore, during the early stages, vague symptoms may include personality and mood changes, with impaired faculties of concentration and attention being the presenting features; memory difficulties develop later.

In tabes dorsalis (taboparesis), which may coexist with general paralysis, the clinical presentation results from involvement of the dorsal roots and ganglia as well as the posterior columns within the spinal cord, with the resultant emphasis on a sensory ataxia. Diabetes may produce a similar clinical picture with a neuropathy and pupillary abnormalities (diabetic pseudotabes).

The optic nerve may be involved with or without other evidence of neurosyphilis, but must always be treated as if it were part of a systemic infection. A uveitis, chorioretinitis, optic neuritis, papillitis, and optic atrophy have all been reported at different stages of the disease. Extraocular presentations include nerve palsies involving the eye muscles and a superior orbital fissure syndrome. Although the Argyll Robertson pupil may occur in any form of the disease, it is generally encountered in tabes dorsalis. The pupils are small and irregular, being unreactive to light, but constrict normally to accommodation and convergence. Unilateral involvement is rare. The light/near dissociation is the result of gliosis in the periaqueductal grey midbrain tegmentum, which may also account for the bilateral ptosis seen in some individuals.

Diagnosis

Neurosyphilis has a myriad of neurological manifestations and therefore the diagnosis enters the differential of most neurological conditions (Table 1). Treatment in the early stages of the disease (that is, of the meningitic and meningovascular syndromes) may well result in recovery, whereas the late forms—with general paralysis and tabes dorsalis—may only respond partially, if at all. These common neurological presentations include stroke, especially in younger patients, chorioretinitis, optic neuropathy of unknown cause, and single or multiple cranial neuropathies, particularly those involving the VIIIth nerve with vertigo and sensorineural deafness. Syphilis serology should be routinely performed in patients with dementia and psychiatric illnesses.

The serum reaginic tests, Venereal Diseases Research Laboratory test (**VDRL**) and rapid plasma reagin test (**RPR**), are usually positive in secondary syphilis when the first neurological complications may be encountered. However, a false-negative result may occur due to the prozone phenomenon if undiluted serum is used. This occurs in 1 to 2 per cent of cases of secondary syphilis and is due to blockage of agglutination caused by the saturation of antigenic sites by excess antibody. The specific serological tests (*Treponema pallidum* haemagglutination test (**TPHA**), *T. pallidum* particle agglutination test (**TPPA**), fluorescent treponemal antibody absorption test (**FTA-abs**), and the treponemal enzyme immunoassay (**EIA**)) are invariably positive.

In late syphilis (meningovascular syphilis, gummatous, general paralysis, and tabes dorsalis), the serum VDRL/RPR tests are negative in 30 per cent of untreated cases. All the specific tests have a sensitivity approaching 100 per cent, so that a negative treponemal antigen test has an extremely high predictive value for excluding neurosyphilis.

It is recommended that all patients with positive syphilis serology who have ocular and or neurological symptoms and signs should undergo cerebrospinal fluid (**CSF**) examination, as should patients with latent infection of unknown duration. In order for these tests to be correctly interpreted it is important that the CSF is not significantly (macroscopically) contaminated with blood.

In patients with neurosyphilis there is usually a lymphocytic pleocytosis (>5 cells/µl), with an elevated protein (>0.4 g/l). In the late stages, particularly in tabes, the CSF may be quiescent. A reactive CSF-VDRL establishes the diagnosis of active neurosyphilis, but a non-reactive test does not exclude it. The sensitivity of the CSF–VDRL is 50 per cent, with a specificity of 100 per cent. A non-reactive CSF-FTA-abs or TPHA excludes the diagnosis. However, a reactive CSF-FTA-abs or TPHA does not establish the diagnosis because the presence of treponemal antibodies in the CSF could result from the passive transfer from the blood, or may result from a previous episode of treated syphilis. The sensitivity for the CSF-FTA-abs is 100 per cent, with a specificity of 30 per cent.

The role of the polymerase chain reaction (**PCR**) in the diagnosis of neurosyphilis is unclear at present, for technique cannot discriminate between viable and non-viable organisms. *T. pallidum* DNA has been detected in CSF up to 3 years after intravenous treatment with penicillin.

Treatment

In patients with symptomatic neurosyphilis or ocular disease, the World Health Organization/United Nations Programme on HIV/AIDS (**WHO/UNAIDS**) as well as the Centers for Disease Control (**CDC**) recommend treatment with penicillin G (2–4 mU intravenously every 4 h for 14 days). In the United Kingdom the preference is for procaine penicillin (1.8–2.4 million IU intramuscularly once daily, plus probenecid 500 mg by mouth four times daily, for 17–21 days). The alternative is intravenous benzyl penicillin (3–4 million units intravenously every 4 h for 17–21 days). In patients with a history of penicillin allergy one option is to perform skin testing to confirm the allergy and to then consider desensitization. The other is to treat with doxycycline 200 mg by mouth four times daily for 28 days.

Following treatment of neurosyphilis, a repeat lumbar puncture should be performed at 6-month intervals until the cell count is normal. This should be decreased by 6 months and be entirely normal by 2 years. The CSF-VDRL may take years to become non-reactive.

Syphilis in the era of HIV

Since the onset of the AIDS epidemic there have been numerous reports of an accelerated course of syphilis and of treatment failures in patients who are dually infected. Compared to non-immunosuppressed individuals there certainly does seem to be a higher than expected rate of cases of syphilitic meningitis and meningovascular syphilis. To date, however, there are no denominator data. Since cell-mediated immunity, which is necessary to eradicate *T. pallidum*, may be impaired in HIV infection this seems plausible.

As a result of altered B-cell function there has been concern regarding serological tests. However, these are usually positive or may show a delayed response in the occasional case.

There is still debate as to whether or not patients with HIV and early syphilis who are neurologically asymptomatic should have a CSF examination. Any CSF cytochemical abnormalities could be either be due to HIV or syphilis. In view of the treatment failures reported with benzathine penicillin some authorities suggest that all HIV patients with early syphilis should be treated with neurosyphilis treatment regimens.

NeuroAIDS (or neurological complications of HIV infection)

Introduction

Soon after the onset of the AIDS epidemic in 1981, it became clear that the nervous system was frequently involved. However, opportunistic infections such as toxoplasmosis and cryptococcal meningitis as well as neoplasms (such as primary central nervous system lymphoma (**PCNSL**)) accounted for only 30 per cent of the neurological problems encountered. It also became evident that in the later stages of the AIDS illness, patients developed neurological complications due to the human immunodeficiency virus itself. This included a progressive decline in cognitive function in association with motor abnormalities—the HIV–dementia complex.

Neurological disorders are the AIDS-defining illness in up to 20 per cent of cases. Over the course of the illness the prevalence of neurological complications increases up to 70 per cent. These include other opportunistic infections and tumours, as well as the HIV-related problems of dementia, vacuolar myelopathy, and distal sensory peripheral neuropathy.

At postmortem more than 90 per cent of the brains from patients dying of AIDS show evidence of HIV encephalitis and of one of the opportunistic infections such as cytomegalovirus (**CMV**) and tumours.

During the last 5 years, with the introduction of the highly active antiretroviral therapies (**HAART**), there has been a dramatic decline in the incidence of neurological opportunistic infections as well as HIV related disorders such as HIV dementia. However, these are expensive drugs and are out of reach of the majority of HIV-infected individuals worldwide.

Clinical approach

All areas of the neuraxis are vulnerable in individuals infected with HIV. Not infrequently do differing pathological processes occur simultaneously in various parts of the nervous system. Thus, Occam's Razor—the principle of diagnostic parsimony, often used in medicine—does not always apply. Another aspect is the possibility of simultaneous infection with more than one organism: for example, meningitis due to *Mycobacterium tuberculosis* and *Cryptococcus neoformans*. Mass lesions in the brain, with some not responding to antitoxoplasma therapy, could be due to lymphoma or another infective cause such as a tuberculoma.

The nervous system is involved early in the course of infection, as evidenced by neurological seroconversion illnesses such as an aseptic meningitis, encephalitis, and the Guillain–Barré syndrome. Furthermore, during the asymptomatic phase of the illness (that is, when patients are well) the cerebrospinal fluid shows abnormalities in up to 60 per cent of cases. This may be a lymphocytic pleocytosis of up to 50 cells/mm ^{3}, an elevated protein, or the presence of oligoclonal bands. The CSF glucose level is usually normal. Therefore, these cytobiochemical markers are unhelpful in making a diagnosis of a meningitic or an encephalitic illness. Reliance is therefore placed on specific markers such as the cryptococcal antigen or antibody tests like the CSF-VDRL or TPHA.

As a result of the impaired immune response, a rise in antibody titres to specific infections may not occur, especially during the later stages of HIV infection. Furthermore, the typical clinical picture—the presentation of which, at least in some infections like meningitis, are due to a brisk inflammatory response such as fever—may not occur. In cryptococcal meningitis, only one-third of patients exhibit the classical signs of meningism: namely, neck stiffness, photophobia, and a positive Kernig's sign.

The specific type of opportunistic complications encountered is dependent on a number of factors, including the degree of immunosuppression. During the early stages when subjects are relatively immunocompetent, with CD4 counts above 500/µl, autoimmune disorders such as demyelinating neuropathies may occur. Between CD4 counts of 200 and 500/µl multidermatomal herpes zoster infections may present. Once the level declines below 200/µl, patients are vulnerable to all the major opportunistic infections and the complications due to HIV itself. Symptomatic infection with cytomegalovirus tends to occur at very low levels below 50/µl.

In different parts of the world, some infections may be more prevalent than others. The incidence of toxoplasmosis in France is significantly higher than in the United Kingdom because of a higher background seroprevalence, due to differing dietary habits and the greater prevalence of raw meat consumption.

Opportunistic infections

Toxoplasmosis

Toxoplasma gondii, whose definitive host includes members of the cat family with humans the intermediate hosts, is an obligate intracellular protozoan. Human infection occurs through the ingestion of tissue cysts in undercooked meat. Variations in dietary habits therefore explains the differing seroprevalence rates worldwide—90 per cent in French adults compared to 50 per cent of residents in the United Kingdom. Symptomatic toxoplasmosis is usually due to a reactivation of latent infection in individuals with HIV. The risk of an HIV-infected patient who is seropositive for IgG *T. gondii* antibody developing toxoplasmosis is around 25 per cent.

Toxoplasmosis is the most common cause of mass lesions in the brains of patients with HIV infection. The clinical presentation is variable, but headache, confusion, seizures, and focal neurological deficits such as hemiplegia, dysphasia, and visual field defects are the most common. Other presentations described include: a variety of movement disorders (choreoathetosis, dystonia, and hemiparkinsonism); psychiatric illness such as depression; brainstem syndromes; and a rapidly progressive diffuse encephalitis. Rarely, the spinal cord may be involved with a myelitis or a cauda equina syndrome.

A definitive diagnosis of toxoplasma encephalitis can only be made by brain biopsy. With increasing experience and pragmatism, it is now standard practice to treat any HIV-infected individual who has a low CD4 count and multiple lesions on imaging with antitoxoplasma therapy (Fig. 1). A response, clinically and radiologically, confirms the diagnosis. Although a negative blood toxoplasma serology result makes the diagnosis less likely, it may occur in up to 17 per cent of cases. This loss of

seropositivity may be the result of impaired antibody synthesis with increasing immunosuppression. It is useful therefore to document an individual's toxoplasma serostatus on first diagnosis of HIV-positivity. For similar reasons, the expected rise in IgM and IgG levels does not occur. A single lesion on magnetic resonance imaging (**MRI**) is most likely to be due to lymphoma. A single lesion on computed tomography (**CT**) scanning should, if possible, be followed by MRI, which is a more sensitive method of detecting lesions particularly in the posterior fossa (Fig. 2).

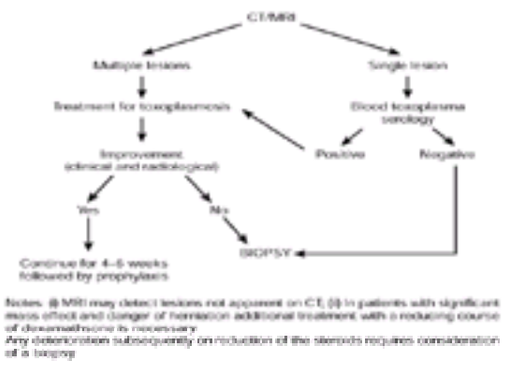

Fig. 1 Management of mass lesions in AIDS

Fig. 2 Cranial CT—multiple lesions with mass effect and cerebral oedema due to toxoplasmosis.

The main differential diagnosis is that of primary CNS lymphoma, which presents at similar CD4 counts and with a similar presentation both clinically and on imaging studies (Table 2).

A response is seen in 90 per cent of patients by the second week of treatment (Table 3). It is necessary to reimage 2 weeks after treatment even if there is clinical evidence of improvement, since it is not uncommon for some lesions to improve but others due to, for example *Mycobacterium tuberculosis*, to enlarge which then makes it necessary to consider a biopsy. The radiological improvement generally lags behind the clinical improvement.

Patients infected with HIV who are seropositive for IgG against *T. gondii* should be offered primary prophylaxis with 980 mg of co-trimoxazole (trimethoprim and sulfamethoxazole) when their CD4 count falls below 100/mm^3. This will confer cross-protection against *Pneumocystis carinii* pneumonia.

Cryptococcus neoformans

This encapsulated yeast is a ubiquitous organism in the environment acquired by humans through inhalation. Although disseminated infection can involve the skin, bones, lungs, eyes, and prostate, symptomatic infection with *C. neoformans* most often presents as a meningitis.

Cryptococcal infection is the most common infectious cause of meningitis in patients with AIDS (Table 4). The presentation may be acute, but it is usually subacute with symptoms of malaise, headache, fever, and vomiting. The classical signs of meningism—neck stiffness, photophobia, and Kernig's sign—are present in only one-third of patients. Other, less common symptoms include altered mental status, seizures, and focal neurological signs. The latter are due to parenchymal cryptococcal abscesses.

Brain imaging is usually normal, although the basal meningitis may result in hydrocephalus or sometimes, particularly on MRI, small abscesses—cryptococcomas—may be visualized.

Cerebrospinal fluid examination is essential for the diagnosis, with culture of the fungus being the 'gold standard'. The cytochemical markers in the CSF may be normal. India-ink staining of the CSF will reveal the fungal hyphae in 70 to 80 per cent of cases and cryptococcal antigen is detected in over 90 per cent. Cryptococcal antigen is also detected in the blood in over 90 per cent of patients, and should be measured in conjunction with the CSF level since in occasionally reported cases of fulminant cryptococcal meningitis the CSF may be negative and the blood positive. The blood antigen measurement may be used as a screening test in patients presenting with symptoms of early infection such as headache. However, it should be appreciated that a negative result does not completely exclude the diagnosis of cryptococcal meningitis.

Treatment with amphotericin B remains the drug of choice for the treatment of severe cases of cryptococcal meningitis. The mortality rate still remains around 10 per cent. Features that have been identified with a poor outcome include a relapse infection, abnormal mental status, CSF cryptoccal antigen titre over 1:1024, CSF white cell count <20 cells/mm^3, positive India-ink staining, hyponatraemia, and positive culture from an extrameningeal site. A CSF opening pressure of greater than 250 mmH_2O is also a marker of poor prognosis. In milder cases, where none of these features are present, oral fluconazole may be used. Although combination with 5-flucytosine has been shown to improve outcome in non-AIDS patients, this has not been confirmed in patients with AIDS. However, the combination should be considered in fulminant cases.

A specific complication that requires close monitoring is the development of raised intracranial pressure due to obstruction of the arachnoid villi and cerebral oedema. This should be managed with repeated lumbar puncture or, if necessary, by the insertion of a lumbar or ventricular drain.

Maintenance therapy is essential, with relapse rates approaching 100 per cent if secondary prophylaxis with oral fluconazole is not adhered to. The serum cryptococcal antigen titre is not useful in predicting relapse.

JC (Jamestown canyon) virus

Progressive multifocal leucoencephalopathy (**PML**) is caused by the reactivation of latent JC virus, which is acquired by the majority of the population during childhood as a banal upper respiratory infection. Prior to the AIDS epidemic, PML was a rare condition encountered in patients immunosuppressed as a result of haematological malignancies, drugs used in the treatment of post-transplant patients, autoimmune disorders such as systemic lupus erythematosus (**SLE**), and granulomatous disorders such as sarcoidosis. Nowadays, underlying HIV infection accounts for 85 per cent of cases.

Prior to the introduction of HAART, the incidence of PML was 4 per cent. The clinical presentation is subacute, with progressive focal neurological deficits such as a hemiparesis, visual field defects, and a cerebellar syndrome. The disorder is not restricted to the white matter since patients may also develop dysphasia and

seizures. Occasional patients may present with a progressive dementia with focal neurological signs.

MRI characteristically shows multiple areas of high signal on T_1-weighted images and a low signal on T_2-weighted ones (Fig. 3). There is little or no enhancement, with no mass effect or oedema around the lesions. Blood serological testing is unhelpful since 80 per cent of the general population is seropositive. Recently it has become possible to confirm the diagnosis of PML by isolating JC-viral DNA in cerebrospinal fluid by PCR techniques. This has a sensitivity of 75 per cent with a specificity of 95 per cent. In PCR-negative cases it may be necessary to either repeat the CSF examination or to perform a brain biopsy. The typical histological features show areas of focal demyelination, bizarre enlarged astrocytes, and abnormal oligodendrocytes with inclusion bodies that stain for JC viral antigens.

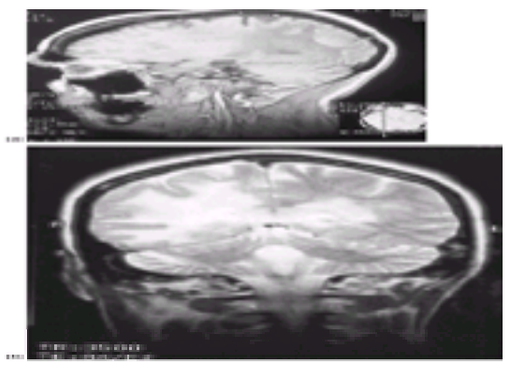

Fig. 3 (a) T_2 weighted and (b) T_1 weighted MRI in a patient with PML.

There is, to date, no specific treatment. Cytosine arabinoside, both intravenous and intrathecal, has been shown to be ineffective. Trials are underway to examine the efficacy of cidofovir, an anti-CMV drug, and interferon-a. However, improving immune function with HAART has been shown to improve survival times from a median survival of 10 weeks to 40 weeks.

Cytomegalovirus (CMV)

The neurological complications from this herpesvirus results from reactivation in severely immunocompromised patients. Almost all patients infected with HIV are seropositive for cytomegalovirus. Postmortem studies of the brains of patients who died from AIDS show evidence of CMV in 25 per cent of cases. However, clinical CMV disease, apart from CMV retinitis, is rare.

CMV retinitis is the most common manifestation of CMV disease and can affect up to 20 per cent of patients with AIDS. The slowly progressive necrotizing retinitis results in characteristic white irregular lesions with central necrosis and haemorrhages—the cheese and tomato ketchup appearance. Retinal detachment may occur in patients with extensive retinal involvement. The retinitis presents with symptoms of reduced visual acuity, floaters, and loss of peripheral vision. Since the condition may be asymptomatic in the early stages, regular ophthalmological screening is recommended for high-risk patients with CD4 counts below 50 cells/μl.

A necrotizing ventriculoencephalitis has been described, usually in patients with evidence of CMV disease elsewhere (Table 5). The onset is subacute over a period of days or weeks with confusion, seizures, and brainstem signs such as internuclear ophthalmoplegia, ataxia, and cranial nerve palsies. Imaging studies typically show periventricular enhancement.

CMV polyradiculopathy presents over a period of days with back pain, leg weakness, sensory impairment, and sphincter disturbance. The differential diagnosis includes syphilitic polyradiculopathy and infiltration with metastatic lymphoma. The cerebrospinal fluid reveals a polymorphonuclear leucocytosis which is unusual for a viral infection. Early recognition and treatment is necessary to stabilize and, in some cases, improve the neurological impairment.

Drugs licensed for the treatment of CMV disease include ganciclovir, cidofovir, and foscarnet. Oral ganciclovir is prescribed for secondary prophylaxis.

Opportunistic tumours

Primary CNS lymphoma (**PCNSL**) is the second most common cause of mass lesions after toxoplasmosis in adults, and the most common in paediatric patients with AIDS. Histologically, this a high-grade, non-Hodgkin's, B-cell lymphoma. Recent evidence suggests that the Epstein–Barr virus is causally linked to PCNSL, with the identification of the viral DNA incorporated into that of the neoplastic cells.

The common presenting symptoms are those of headache with focal neurological deficits, altered level of consciousness, and seizures.

Brain imaging reveals enhancing mass lesions with surrounding oedema and mass effect. These are similar to those found in toxoplasmosis. PCNSL is more likely to present as a single mass lesion than toxoplasmosis and is also more likely to invade the ventricular walls. Recent studies using thallium-201 single-photon emission computed tomography (**SPECT**) suggest that it may be possible to differentiate between an abscess and a tumour, with the former having little uptake compared with the high uptake of the mitotically active lymphoma.

There is no effective treatment for PCNSL. Whole brain radiotherapy provides, at best, only a modest benefit, with most patients succumbing within 2 months.

HIV-associated neurological disorders

HIV–dementia complex

Before the introduction of HAART (and in areas of the world where they are still unavailable) approximately 15 to 20 per cent of individuals infected with HIV developed a variably progressive dementia with associated motor deficits. In children, a similar HIV-1 associated progressive encephalopathy occurs more frequently than with opportunistic infections. This usually occurs within the context of severe immunosuppression in those with a CD4 count of less than 200/mm ^{3}. In around 3 per cent of cases, HIV-dementia is the AIDS-defining illness. Large cohort studies, using clinical, MRI, and neuropsychological methods, have largely discounted the early reports of evidence of cognitive changes in asymptomatic HIV-positive patients.

The clinical presentation in the early stages is with vague symptoms of apathy, mood changes, and difficulty with memory and concentration. These are features of a subcortical dementia with no features of cortical involvement such as language, visuospatial or calculation difficulties. This picture may be mimicked by depression, metabolic encephalopathy, and drugs, both therapeutic and recreational. At this stage, there may be few physical signs apart from brisk reflexes, impaired fine finger movements, and unsteady gait.

Later, the memory impairments are obvious, as is the psychomotor retardation—which may progress to frank mutism and a global dementia. Some patients develop seizures. The motor signs due to the associated vacuolar myelopathy with a spastic paraparesis and sphincter disturbances are also present in a significant number of patients (Table 6). In addition, some patients will have the HIV-related distal sensory peripheral neuropathy. Thus, this group will have absent ankle jerks and extensor plantar responses.

The diagnosis of the HIV–dementia complex is made by clinical assessment—there are usually no focal signs and the tempo of the disorder is an insidious one. Investigations are performed to exclude other infection or neoplastic pathologies, and therefore necessitate imaging, preferably with MRI, and a CSF examination. MRI may show evidence of cerebral atrophy with compensatory ventricular dilatation, a diffuse white-matter high signal on T_2-weighted images with no enhancement. A CSF examination may be non-specifically abnormal with a pleocytosis, elevated protein level, and oligoclonal bands. It important to exclude cryptococcal and tuberculous meningitis as well as neurosyphilis. The HIV RNA-viral load in cerebrospinal fluid correlates with the severity of clinical dementia, but there is too much

overlap between non-demented and demented subjects for the measurement to be of use as a diagnostic aid. There is no correlation between the plasma HIV RNA-viral load and dementia. Electroencephalography (**EEG**) may be normal in the early stages, with non-specific diffuse slowing being shown later.

The pathology of the HIV–dementia complex is a spectrum ranging from diffuse myelin pallor, microglial nodules—which are non-specific and may be found in CMV encephalitis—to multinucleated giant cells that are indicative of productive brain infection and cortical neuronal loss. There is no clear correlation between the clinical and pathological findings.

The mechanisms of disease in the HIV–dementia complex are still unclear. It is, however, evident that HIV predominantly infects the microglial and astrocytic cells rather than neurones or oligodendrocytes. One hypothesis for the entry of the virus into the CNS is the 'Trojan horse' theory, with invasion occurring by infected peripheral blood monocytes penetrating a blood–brain barrier that has been disrupted by damage to the capillary endothelial cells. Neuronal damage is subsequently caused by virotoxins (for example, Gp120) and cytokines (for example, tumour necrosis factor-a) released from activated macrophages.

After the introduction of zidovudine in 1987, there was a dramatic reduction in the incidence of HIV-associated dementia. One clinical study looking specifically at the effect of zidovudine on cognitive function confirmed its beneficial effect, albeit at dosages much higher than those currently used. With the introduction of the newer antiretroviral drugs—the majority of which have poor penetration into the CSF and presumably the brain—there is concern that, despite the reduction of plasma HIV viral loads, the CNS may develop into a safe sanctuary for the virus from which reinfection could occur. However, recently published studies do suggest that these newer therapies improve cognitive function and it seems prudent, until further data become available, to use drugs that best penetrate the CSF to treat HIV dementia complex.

Since macrophage activation resulting in the release of neurotoxic factors also has a role in the pathophysiological mechanism, trials are underway to assess the therapeutic benefits of drugs such as the **PAF** (platelet-activating factor) antagonist, lexipafant, and the **NMDA** (*N*-methyl-D-aspartate) antagonist, memantine.

HIV-associated neuropathy

The most common neurological complication encountered in patients infected with HIV is distal sensory polyneuropathy (**DSPN**), which may occur in 30 per cent of those with AIDS (Table 7). It is a significant cause of morbidity.

Typically, patients complain of numbness of the soles of the feet together with shooting pains and parasthesias developing over a period of months. There is little or no weakness. The hands are infrequently involved. The ankle jerks are depressed or absent. Sensory testing reveals impaired pain and temperature perception as well as vibration.

Further investigations are usually unnecessary in a patient with a CD4 count below 200 and showing the typical clinical picture, but it is always worth checking the blood sugar, vitamin B_{12} level, and syphilis serology. It is important to enquire about alcohol intake and the possibility of an excess intake of vitamin B_{6}.

Neurophysiological and pathological studies suggest this to be a length-dependent axonal neuropathy. Productive HIV infection has not been found in pathological specimens and the underlying mechanisms, like those for HIV dementia, are linked to macrophage activation products.

Since antiretroviral therapy has no benefit, treatment is symptomatic with the use of tricyclic antidepressants and anticonvulsant drugs such as gabapentin.

The nucleoside analogues didanosine (**ddI**), zalcitabine (**ddC**), and stavudine (**d4T**) cause a dose-dependent sensory neuropathy that may be indistinguishable from distal sensory polyneuropathy. Clues to this drug-induced neuropathy include the shorter history of weeks rather than months, and the improvement on stopping the offending drug. However, there may be a continued worsening of symptoms for a period of 4 to 8 weeks after stopping—the phenomenon of 'coasting'. The underlying mechanism appears to be the impairment of mitochondrial protein synthesis.

24.15 Metabolic disorders and the nervous system

*Neil Scolding and C. D. Marsden**

In general, the term metabolic diseases of the nervous system covers the neurological consequences of systemic disorders of metabolism. This alone is an enormous field, ranging from common disorders, such as diabetes, chronic and acute alcohol poisoning, and renal disease, to less common but no less important disorders such as pontine myelinolysis and critical illness polyneuropathy.

Metabolic complications of major organ disease

Cardiovascular disease/anoxia

Cerebral anoxia may be due to insufficient cerebral blood flow, reduced oxygen availability, reduced oxygen carriage by the blood, metabolic interference with the utilization of oxygen, or combinations of these events. Thus, acute cardiovascular insufficiency as a consequence of cardiac arrest is a relatively common cause of severe global cerebral anoxia; others as diverse as suffocation, anaesthetic catastrophes, drowning, or acute carbon monoxide poisoning can produce similar results.

A brief period of global ischaemic anoxia causes syncope. If the episode is prolonged, myoclonic jerks or tonic–clonic seizures may occur. Still more protracted insults may precipitate a period of confusion and residual amnesia.

Persisting acute severe anoxia rapidly leads to loss of consciousness, generalized fits, dilated pupils, and bilateral extensor plantar responses. Periods of anoxia up to perhaps 5 min may cause transient coma with recovery of consciousness. A delayed postanoxic encephalopathy, characterized pathologically by demyelination in the hemispheres and in the basal ganglia, may follow within 1 to 2 weeks, often commencing with increasing irritability, apathy, and confusion. Frank dementia may emerge, or an amnesic syndrome in less severe cases, and there may also be pseudobulbar palsy and other pyramidal signs, gait ataxia, and incontinence, and/or an akinetic–rigid syndrome with or without dystonia. Some patients may be severely disabled by action myoclonus—dramatic muscle jerking on attempted movement. The residual deficits following prolonged cerebral anoxia with survival may be permanent; in other patients they gradually recover, often to a very considerable degree, although over months or years. In yet other patients, the condition may progress over a matter of some weeks or months.

If oxygen deprivation lasts longer than a few minutes, permanent or prolonged but reversible brain damage occurs. Irreversible coma is accompanied by flaccidity and loss of all reflex function except heart beat and tendon jerks. The pupils remain fixed and dilated and the electroencephalogram is flat on repeated examination. (Drugs and hypothermia may cause a flat electroencephalogram, but recovery is possible.) Such patients may be said to have suffered irreversible brain death if all signs of brainstem function are absent on repeated examination over 12 to 24 h. Other, less severely affected patients show partial recovery of brainstem reflex function, such as pupillary responses, reflex eye movements, and muscle tone, and may breathe spontaneously. However, no sign of consciousness or intelligent response to the external world occurs, and they may remain in such a 'persistent vegetative state' for months or years.

Subacute or gradual anoxia may occur in severe anaemia, heart failure, pulmonary disease, or exposure to high altitude ('mountain sickness'). It produces inattentiveness, fatigue, headache, and intellectual deterioration, followed by memory difficulties and ataxia.

Cerebral anoxia is also the main cause of neurological symptoms in a number of other systemic conditions. Disseminated intravascular coagulation (see Section 22), resulting from platelet aggregation and fibrin formation, can be produced by a number of illnesses, including sepsis and malignancy. Patients complain of headache and difficulty in concentration, vertigo, blurred vision, and speech difficulties. Such confusion and disorientation may progress to stupor and coma with focal or generalized signs of brain disturbance. Spontaneous bleeding is common, in the form of petechiae in the skin or optic fundus, purpura, and even intracranial haemorrhage. Cerebral malaria (see Chapter 7.13.2) should always be borne in mind as a cause of unexplained coma in patients recently returning from an infective area. Most patients describe chills and fever for a few days prior to the onset of lethargy, stupor, and finally coma. The diagnosis is established by finding the parasite in fixed smears of the blood.

Fat embolism follows severe trauma, particularly to the limbs, but may also be a complication of burns and other severe system disturbance. Multiple pulmonary microemboli of fat may lead to progressive hypoxia and respiratory failure. Multiple cerebral microemboli produce confusion, lethargy, stupor, and finally coma. Symptoms often begin hours to days after the original injury, and are accompanied by fever and hyperventilation. A characteristic petechial rash usually develops over the upper half of the body on the second to third day after injury. There may also be fundal haemorrhages. The respiratory features range from the appearance of linear streaks radiating from the hilar region or patchy opacities on the chest to the fully developed adult distress syndrome (see Section 16). Clotting abnormalities range from mild thrombocytopenia to acute disseminated intravascular coagulation (see Section 22). Management consists of correcting hypoxia, in severe cases with positive end-expiratory pressure (PEEP) ventilation, and correction of the coagulation disorder (see Section 16). Cardiac surgery, at least in the earlier days of bypass pump oxygenation, produced frequent transient neurological damage in many patients. Improvements in technique, such as the introduction of filters in blood perfusion lines to remove debris, have greatly reduced neurological complications of the procedure. However, some patients still emerge from the anaesthetic with signs of diffuse or focal brain damage. If they survive the acute episode, the prognosis usually is good.

Hepatic failure

Patients with liver disease of whatever cause (see Section 14) may develop acute hepatic coma or a more chronic form of hepatic encephalopathy with behavioural disturbance and other neurological symptoms.

Acute hepatic coma

This occurs with massive liver necrosis due to severe hepatitis or poisons such as paracetamol. In other patients, who may have relatively well-preserved liver function but extensive portosystemic shunts, coma may be precipitated by a sudden intake of nitrogenous substances as occurs with gastrointestinal bleeding, infections, or high-protein diets. Personality and cognitive changes proceed if unchecked to confusion, apathy, and lack of concentration, or occasionally excitement requiring sedation, and are rapidly followed by stupor and coma in a matter of a few hours or days. Characteristic findings are asterixis ('liver flap'), in which the outstretched hands show postural lapses or negative myoclonus, and hepatic fetor. Chorea and pyramidal signs may appear as the patient lapses into coma. Decerebrate posturing is common at this stage, and focal deficits such as hemiplegia may occur. Nystagmus, conjugate deviation of the eyes, skew deviation, and even disconjugate eye movements may be evident, but reflex eye movements and pupillary responses are preserved, until the patient becomes totally unresponsive and dies. Paroxysmal and later persistent high-voltage triphasic slow waves are present in the electroencephalogram until death is imminent.

Many metabolic abnormalities may contribute to the cause of hepatic coma, including hyperammonaemia (more than 145 µmol/l or 200 mg/dl), which results from the products of intestinal digestion bypassing the urea-synthesizing mechanisms of the liver. However, hypoglycaemia and hyperventilation producing a respiratory alkalosis are also nearly always present. Altered amino acids and neurotransmitters (especially a-aminobutyric acid), formation of toxic amines such as octopamine, and short-chain fatty acids have also been incriminated. Intravascular coagulation occurs, as do other coagulation defects, leading to secondary vascular damage to the brain; cerebral oedema can raise intracranial pressure seriously or even fatally.

Hepatic coma carries a high mortality, but if the patient can be kept alive, liver regeneration and recovery may occur. Treatment includes correcting where possible the precipitant, sterilizing the bowel, correction of metabolic and bleeding abnormalities, the administration of lactulose, and haemoperfusion or other techniques to remove toxins (see Chapter 14.21.3). The benzodiazepine antagonist flumazenil may have a useful role. Intracranial pressure monitoring is fraught with hazards, not least the coagulopathy, but mannitol (though not dexamethasone) is of proven benefit in lowering intracranial pressure in this context.

Chronic hepatic encephalopathy

This refers to the development of changes in intellect, cognitive function, and consciousness, often accompanied by other neurological signs (such as tremor or chorea, an akinetic–rigid syndrome, ataxia, or even spastic paraparesis) occurring in those with chronic liver failure, and particularly in those with extensive portosystemic anastomoses. (For Wilson's disease see Chapter 11.7.2.) The exact nature of the substances responsible for chronic hepatic encephalopathy has not been established. Characteristically, the disorder fluctuates, with episodes of marked confusion, excitement, or frank hepatic coma. In addition, intellectual changes, parkinsonism, ataxia, or spasticity may gradually progress. Treatment consists of a low-protein diet and antibiotics to sterilize the gut, and the administration of lactulose.

Respiratory disease

Hyperventilation causes hyocarbia and alkalosis, resulting in parasthesias, especially perioral, light-headedness and unsteadiness, visual disturbances, and occasionally carpopedal spasm; syncope may follow.

More seriously, chronic respiratory failure causes what is essentially a low-grade chronic hypoxia and hypercarbic encephalopathy, with the defining features of confusion and headache accompanied by a myoclonic or asterictic tremor and papilloedema. Mechanical devices for delivering domiciliary oxygen have transformed the management of this disorder, and the quality of life of its sufferers.

Obstructive sleep apnoea is characterized by conspicuous snoring and an often obese habitus. Early morning headache and inattentiveness or irritability with excessive daytime sleepiness should suggest this disorder.

Critical illness polyneuropathy

This disorder develops subacutely but often asymptomatically in (often anaesthetized) patients on intensive care units receiving intensive support for multiorgan failure and/or sepsis, only revealing itself as they otherwise improve. It is axonal in nature, but of still unknown aetiology. The prognosis is variable; it may slowly improve in patients whose underlying disease allows sufficient time for recovery.

Renal failure

Renal failure (see Section 20) is associated with a variety of neurological complications. Uraemic encephalopathy was common before the use of dialysis. Patients become progressively drowsy, stuporose, and finally lapse into coma. Hyperventilation, multifocal myoclonus, tremor, asterixis, tetany, and generalized fits are common. Eye movements and pupillary reactions are not affected. Uraemia, metabolic acidosis, hyperkalaemia, disorders of calcium, sodium, and water balance, and hypertensive encephalopathy all contribute to the clinical picture. Dialysis rapidly reverses the metabolic abnormalities of uraemia, but the encephalopathy may take days to clear. Other complications of chronic renal failure include myopathy due to chronic hypocalcaemia, and a symmetrical sensorimotor polyneuropathy, often subacutely progressive and disabling. It may be resistant to dialysis, but renal transplantation has been associated with a slow and sustained improvement.

Iatrogenic disease in renal failure

Some patients develop the dialysis disequilibrium syndrome during correction of their uraemic abnormalities. Rapid correction of the metabolic changes, possibly through osmotic shifts, leads to the emergence of asterixis, myoclonus, delirium, generalized convulsions, stupor, and even coma. Raised intracranial pressure with papilloedema may occur. Chronic dialysis—perhaps 3 to 7 years—may precipitate dialysis dementia if dialysate with a high aluminium content has been used. Such patients begin to develop speech hesitancy and arrest, then intellectual and cognitive abnormalities, convulsions, myoclonus, and sometimes focal neurological abnormalities. Death follows with a year.

Wernicke's encephalopathy (see below) can occur, due to chronic dialysis without thiamine supplements.

Patients with renal disease are particularly prone to develop toxic complications of drugs normally excreted in the urine—peripheral neuropathy due to nitrofurantoin, labyrinthine damage due to streptomycin, or optic atrophy due to ethambutol.

Metabolic disorders due to endocrine disease (seeSection 12)

Adrenal disease

Phaeochromocytoma

Phaeochromocytoma causes paroxysms of anxiety, tremor, headache, and palpitations, together with the consequences of malignant hypertension. Fits may occur. The associations with von Hippel–Lindau disease, multiple endocrine neoplasia syndromes, ataxia telangiectasia, and Sturge–Weber syndrome should not be overlooked.

Cushing's syndrome

Endogenous Cushing's syndrome in two-thirds of cases is due to a pituitary ACTH-secreting adenoma—conventionally termed Cushing's disease. Ectopic

ACTH-secreting malignant neoplasms and ACTH-independent adrenal tumours represent the other principal causes of endogenous disease; iatrogenic hyperadrenalism produces similar neurological symptoms. The systemic features are described in Chapter 12.7.1. Neurological complications include: (i) proximal myopathy, which can be severe and painful; (ii) psychiatric disorders, ranging from mild mood disturbance through moderate depression (common) to severe psychosis; (iii) a benign intracranial hypertension-like picture; and (iv) direct consequences of a pituitary tumour, particularly optic chiasmal compression.

Adrenal insufficiency

Hypoadrenalism due to primary adrenal failure (Addison's disease) or ACTH deficiency (from pituitary disease or chronic steroid treatment) causes weakness, lassitude, nausea and diarrhoea, and stupor or coma may be precipitated by surgical procedures or other acute illness. Hypotension (especially postural), hyponatraemia, hyperkalaemia, and often hypoglycaemia (see Chapter 12.11.1) occur: each may be symptomatic—indeed, attacks of hyperkalaemic periodic paralysis may occur. Amnesic deficits, depression, and impaired concentration progressing to confusion are relatively common. Addisonian crises may be accompanied by generalized convulsions, which are attributed to hyponatraemia and water intoxication. Benign intracranial hypertension with papilloedema and a proximal myopathy may also occur.

X-linked adrenoleukodystrophy is discussed in Section 12.7.

Thyroid disease

Thyroid disease carries one set of neurological complications directly related to abnormal thyroxine levels; another sharing the same autoimmune origin (and eponyms)—Hashimoto's encephalopathy and Grave's ophthalmopathy. Here only the former will be considered.

Thyrotoxicosis

The features of hyperthyroidism include anxiety, tremor, tachycardia, and insomnia. Chorea or mania may occur. A severe proximal myopathy is not uncommon, and rarely myasthenia gravis is seen. Thyroxine-responsive hypokalaemic periodic paralysis is well reported.

Myxoedema

Hypothyroidism may present with lethargy, even progressing to a toxic confusional state or a subacute hypothermic, hypotensive coma. The latter (which may be provoked by infection, trauma, exposure to cold, or sedation), together with the occasionally seen psychosis or dementing illness ('myxoedema madness') responds to (judicious) thyroxine hormone replacement. Ataxia occurs in 5 to 10 per cent of patients with hypothyroidism, and improves with thyroxine replacement.

Hypothyroid myopathy is characterized by proximal weakness with stiffness, aching, and cramps, and pseudomyotonic delayed muscle relaxation evident on tapping tendons or muscle bellies (with percussion-induced muscle ridging). Muscle hypertrophy (Hoffmann's syndrome) is rare. The carpal tunnel syndrome may occur due to deposits of myxoedematous tissue around the median nerve of the wrist, and rarely this may cause a diffuse peripheral neuropathy.

Diabetes mellitus

Diabetes mellitus (Chapter 12.11.1) causes a wide variety of neurological disturbances. Centrally, stupor or coma may be produced by hyperosmolality, ketoacidosis, lactic acidosis, spontaneous (prediabetic) or iatrogenic hypoglycaemia, uraemia, or hypertensive encephalopathy. Transient ischaemic attacks and stroke due to cerebral arteriosclerosis and hypertension are common in patients with diabetes.

Peripherally, nerve damage may occur in patients with established diabetes, or may be the presenting feature of the illness; it is described in more detail in Chapter 24.19. The following syndromes are recognized.

1. Single painful nerve lesions (mononeuritis) such as isolated ocular nerve palsies, Bell's palsy, a lateral popliteal nerve palsy, or an intercostal neuropathy are common and may result from haemorrhage or infarction of the nerve.
2. Carpal tunnel syndrome, an ulnar nerve palsy, or other compression neuropathies may result from the undue susceptibility of peripheral nerves in diabetes to pressure.
3. Mononeuritis multiplex may occur, with a microvascular basis.
4. Diabetic amyotrophy refers to a proximal motor neuropathy causing the subacute weakness and wasting, often with pain, affecting quadriceps muscles, usually asymmetrically. It is probably due to ischaemia or haemorrhage in the femoral nerve or lumbosacral plexus.
5. A distal symmetrical peripheral neuropathy in diabetes may take the form of a mild asymptomatic sensory neuropathy with loss of vibration sense in the feet and absent ankle jerks. Less commonly, there is severe and progressive sensorimotor neuropathy affecting the legs before the arms.
6. Autonomic neuropathy is common, producing impotence, diarrhoea, loss of sweating, and abnormal pupils. The last may be irregular, and unreactive to light, mimicking Argyll Robertson pupils. Autonomic neuropathy causes orthostatic hypotension, syncope, and sometimes abrupt cardiac arrest in patients with diabetes.

It should be recalled that diabetes may occur as a feature of a number of genetically determined neurological diseases, including Friedreich's ataxia, X-linked spinomuscular atrophy, mitochondrial cytopathies, myotonic dystrophy, and the Wolfram syndrome; it is also associated with the stiff man syndrome.

Hypoglycaemia

Hypoglycaemic coma can be difficult to diagnose and dangerous. In any case of coma, stupor, or confusion of unknown cause, and often in newly presenting status epilepticus, blood should be drawn for glucose analysis and insulin levels, and then 25 g of glucose (with thiamine) should be administered intravenously. Such an injection can do no harm and may save life.

The commonest cause of hypoglycaemia is insulin overdose, or excessive hypoglycaemic drug intake. Hyperinsulinism due to an adenoma of the islets of Langerhans in the pancreas is uncommon, as is hypoglycaemia due to prediabetes or a retroperitoneal sarcoma. Hypoglycaemia may also occur in alcoholism and liver disease, after gastric surgery, and in a variety of rare metabolic conditions.

Hypoglycaemia presents in four ways: (i) as an organic toxic confusional state, sleepy confusion, bizarre behaviour, or mania; (ii) as unexplained coma with brainstem dysfunction, including decerebrate spasms and neurogenic hyperventilation, but with preserved oculocephalic reflexes and pupillary responses; (iii) as a stroke-like illness with focal deficit; and (iv) as epilepsy. Hyperinsulinism, very rarely, also causes predominantly motor peripheral neuropathy.

Hypoglycaemia is established by measurement of the blood glucose concentration, and by clinical response to intravenous glucose replacement. Hyperinsulinism is difficult to diagnose on occasion, but can be established by satisfying the criteria for Whipple's triad, namely symptoms of hypoglycaemia, associated with a low blood sugar and a disproportionately high serum insulin, and clinical response to glucose replacement. A 72-h fast, measuring morning blood sugar and insulin levels, will detect nearly all pancreatic islet cell adenomas (see Chapter 12.10).

Metabolic disorders due to ionic or acid–base abnormalities

Hyponatraemia or 'water intoxication'

Sodium is the most abundant serum cation, so that hyponatraemia is almost always the cause of hypo-osmolality. Serum osmolality is approximately equal to double the serum sodium concentration plus 10, provided glucose and urea levels are normal. Normal serum osmolality is 290 ± 5 mosmol/kg; serum osmolality below about 260 or above about 330 mosmol/kg is likely to produce cerebral changes. Hyponatraemia means that body water is increased relative to solute, resulting in water excess in the brain. Rapid changes in serum sodium osmolality produce much greater neurological effects than does slowly developing chronic hyponatraemia. Hyponatraemia occurs in renal disease, as a result of excessive intravenous water infusions, due to excessive diarrhoea, vomiting, or sweating, or may result from the inappropriate secretion of antidiuretic hormone that occurs in bronchial carcinoma, focal hypothalamic damage due to neoplasm or infection, or diffuse acute brain

disease resulting from head injury, meningitis, or encephalitis, or subarachnoid haemorrhage. (It is, however, noteworthy that in the latter acute situations, salt-wasting may also cause hyponatraemia, in which circumstances fluid restriction exacerbates the problem: hypovolaemia distinguishes salt-wasting from the eu- or hypervolaemia of vasopressin excess.) Patients with hyponatraemia become confused and restless, and develop asterixis, multifocal myoclonus, generalized convulsions, stupor, and coma. Symptoms may appear when the plasma sodium drops below about 120 mmol/l, and fits and coma usually are associated with plasma sodium values below 110 mmol/l. A few patients with chronic hyponatraemia may develop the syndrome of central pontine myelinolysis (see below). Treatment is by water restriction; infusions of hypertonic saline are not advised.

Central pontine myelinolysis

This is a rare disease, often associated with hyponatraemia, and in particular with rapid attempts to correct serum sodium by parenteral hypertonic fluids: elevation by no more than 0.55 mmol/l per hour is allegedly safe. It is also seen in alcoholics, in severe liver and renal disease, and other metabolic disturbances. The disease is characterized by a rapidly progressive flaccid or spastic quadriplegia, with involvement of bulbar muscles producing dysarthria and dysphagia. Consciousness and eye movement may remain intact. At worst the patient may be unable to speak or swallow, or to move any muscle except those of the eyes. Death is common but remarkable recovery may occur.

Hypernatraemia

The common cause of hyperosmolality is diabetes, producing severe hyperglycaemia. Hyperosmolality due to hypernatraemia is rare, except in those who dehydrate in hot climates. Chronic uncompensated water loss in untreated diabetes insipidus may result in mild hypernatraemia, but such patients only develop severe hypernatraemia if they fail to drink. Patients with simple diabetes insipidus usually maintain thirst, but if intercurrent illness leads to excessive water loss and restricted water intake, they may become dehydrated, drowsy, stuporose, and unconscious. Simple diabetes insipidus may be due to pituitary surgery, trauma, or pituitary tumours. If pathology extends into the hypothalamic region, not only may secretion of vasopressin be deficient, but thirst regulation may also be abolished. Hypothalamic damage causing severe hypernatraemia may occur in large pituitary tumours, craniopharyngiomas, hypothalamic tumours, sarcoidosis, or Hand–Schüller–Christian disease. Loss of thirst in such patients often precipitates hypernatraemic coma with serum sodium rising above 160 to 170 mmol/l. Hypernatraemia may also occur as a result of severe water depletion, particularly in children with intense diarrhoea.

Hypercalcaemia (see Chapter 12.6)

A high serum calcium concentration may be due to primary hyperparathyroidism, immobilization, sarcoidosis, vitamin D intoxication, or multiple bony metastases. Symptoms include anorexia, nausea, vomiting, intense thirst, polyuria, and polydipsia. Muscle weakness, lassitude, and a mild encephalopathy are common. The latter may produce delusions and changes in mood so that many such patients are initially treated for a psychiatric condition. A toxic confusional state with lethargy and stupor, sometimes with generalized or focal seizures and papilloedema, also may occur. A more severe syndrome with pyramidal signs, ataxia, and an internuclear ophthalmoplegia is also described.

Hypocalcaemia (see Chapter 12.6)

Reduced serum calcium concentration may be caused by parathyroid or thyroid surgery, chronic renal failure, or chronic anticonvulsant drug treatment. It also occurs in primary idiopathic hypoparathyroidism (when the serum parathormone level is low), and in pseudohypoparathyroidism (in which the serum parathormone level is normal or high, and there is no response to parathyroid hormone; skeletal deformities and dysmorphism also are present). Pseudopseudohypoparathyroidism is a syndrome with similar skeletal and dysmorphic abnormalities but normal serum calcium and parathormone levels. Hypocalcaemia causes neuromuscular irritability, tetany with a positive Chvostek's sign, and a mild encephalopathy. Severe degrees of hypocalcaemia produce generalized convulsions, psychotic behavioural disturbances, stupor, and coma. Raised intracranial pressure with papilloedema may occur in hypoparathyroidism. Hypocalcaemia is commonly misdiagnosed as mental retardation, dementia, or epilepsy. Skin changes and cataracts are characteristic. Calcification in basal ganglia on skull radiograph or CT scan may be evident. Rarely, basal ganglia calcification may be associated with extrapyramidal disorders.

Magnesium

Renal disease may impair the ability to excrete magnesium, which is cardiotoxic. Hypomagnesaemia, due to inadequate intake or excessive renal or gastrointestinal loss, causes secondary hypocalcaemia; the former rarely occurs without the latter, and the neurological complications often attributed to low magnesium are precisely those of hypocalcaemia. Hypermagnesaemia may cause an encephalopathy with decreased or absent tendon jerks; the latter may progress to a flaccid paralysis.

Potassium

Hypokalaemia, not uncommonly caused by diuretics, is associated with myalgia and a proximal myopathy; if severe, rhabdomyolysis can occur. Hyperkalaemia can precipitate an areflexic flaccid paralysis, which may be fully reversible with correction of the serum potassium. The periodic paralyses are discussed in Chapter 24.22.5.

Acid–base disturbances

Systemic acidosis and alkalosis (see Section 11) occur in many diseases causing metabolic coma, but of the four disorders of acid–base balance (respiratory or metabolic acidosis or alkalosis), only respiratory acidosis acts as a direct cause of stupor and coma. Hypoxia associated with respiratory acidosis may be important in producing neurological abnormalities. Metabolic acidosis, by itself, usually only causes delirium or, at most, drowsiness. The reason why even severe disorders of systemic acid–base balance usually do not interfere with the function of the brain is that it possesses powerful mechanisms for protecting its own acid–base balance, including respiratory compensation, changes in cerebral blood flow, and cellular buffering in nervous tissue. Coma in metabolic acidosis due to diabetic ketosis or hyperosmolality, lactic acidosis, uraemia, alcohol poisoning, or intake of ethylene glycol, methyl alcohol, or paraldehyde is usually due to associated metabolic abnormalities or direct effects of other toxins in these conditions. Severe respiratory acidosis produces a reduction in alertness parallel to the degree of acidosis. Respiratory alkalosis, although constricting cerebral arterioles and decreasing cerebral blood flow, rarely interferes with cerebral function. A patient in coma with respiratory alkalosis due to hyperventilation has some other condition such as sepsis, hepatic disease, pulmonary infarction, or salicylate overdose. Even severe metabolic alkalosis only produces a confusional state rather than stupor or coma.

Alcohol and the nervous system

Alcohol damages the nervous system in many ways. Some are the result of acute or chronic poisoning, while others are a consequence of associated vitamin deficiency. This section will mainly address the neurological consequences of chronic, excessive alcohol intake, not the acute transient effects of alcohol.

Delirium tremens

This develops several days after ethanol abstinence in chronic abusers. Usually rapid in onset, there is an agitated confused state, with signs of sympathetic overactivity. Circulatory collapse may contribute to the 5 to 10 per cent mortality. It is generally distinguished from the less severe alcohol withdrawal syndrome, characterized by broadly similar symptoms that occur sooner—within hours of withdrawal—and are usually self-limiting. Ethanol withdrawal seizures represent a not uncommon cause of late-onset fits. Benzodiazepines have transformed the management of delirium tremens and the alcohol withdrawal syndrome, and significantly reduced its mortality.

The Wernicke–Korsakoff syndrome

Aetiology

Inadequate intake of thiamine, of whatever cause, may lead to foci of marked hyperaemia with multiple small haemorrhages affecting particularly the upper brainstem, hypothalamus, and thalamus adjacent to the third ventricle, and the mamillary bodies. Histologically there is a proliferation of dilated capillaries with perivascular

haemorrhage in these areas. There may be associated alcohol-induced damage to the cerebral cortex, cerebellum, and peripheral nerves.

Such pathology can be produced in animals by a diet deficient in thiamine. Thiamine deficiency can be demonstrated in patients with the Wernicke–Korsakoff syndrome, and administration of thiamine can reverse many of the symptoms and signs of this syndrome. (Wernicke's and Korsakoff's syndromes probably represent the acute and chronic consequences of the same pathological process.) Thiamine and its pyrophosphate are cofactors to at least four enzymes—pyruvate decarboxylase, a-ketoglutarate dehydrogenase, the branched-chain ketoacid decarboxylase system, and transketolase. Thiamine deficiency results in reduced conversion of pyruvate to acetyl coenzyme A, causing elevated plasma and tissue pyruvate levels, with decreased flux through the Krebs cycle, reducing ATP production, and impairing energy supply. In addition, there is a shortage of one-carbon groups for biosynthetic pathways.

Alcoholism with an inadequate diet is the most frequent cause of the Wernicke–Korsakoff syndrome today. Malnutrition in prisoners of war, or at times of famine, may also be responsible. Chronic vomiting, for example during pregnancy or due to gastrointestinal disease, systemic malignancy, prolonged intravenous feeding, and anorexia nervosa are rarer causes.

Clinical features

The onset may be insidious or subacute with increasing lethargy and inattentiveness, which develops into a typical confusional state with disorientation in time and place, loss of memory, and altered consciousness. Ophthalmoplegia develops with diplopia. The most common eye signs are nystagmus on lateral or vertical gaze, sixth-nerve palsies, or defects of conjugate gaze. Retinal haemorrhages may occur. Most patients who are alcoholics will also have signs of a peripheral neuropathy, and many exhibit ataxia—the third classically described feature. Hypothermia may appear. Wernicke's encephalopathy is a medical emergency: untreated, the patient lapses into stupor and then coma, and dies—the mortality untreated is 20 per cent.

In less acute cases, or in those recovering from the acute confusional phase, the characteristic features of the Korsakoff psychosis or amnesic syndrome will appear. The patient has an often very severe gross defect of memory for recent events, such that new information cannot be retained for more than a matter of minutes or hours. The patient is disorientated in time and place, but alert. Despite the severe defect of recent memory, he or she can recall events in the remote past. Gaps in memory are filled by giving imaginary and often graphic accounts of events (confabulation).

Diagnosis

Diagnosis is essentially clinical. The cerebrospinal fluid is usually normal, although the protein may be slightly raised. Brain scanning can be normal, although patients who are alcoholic (who fall often) may have subdural haematomas. Demonstration of reduced red cell transketolase activity, or of raised plasma pyruvate levels, is often invalidated by intake of food as soon as the patient comes under supervision.

Treatment

The Wernicke–Korsakoff syndrome must be considered in any individual with unexplained confusion, stupor, or coma, particularly in the presence of eye signs, a peripheral neuropathy, or a history of alcoholism or excessive vomiting. Thiamine should be given to all such patients. High-potency vitamin injections should be given daily until oral vitamin B complex preparations can be taken.

A particular problem arises commonly in the emergency department when patients exhibiting stupor or coma of unknown cause are admitted. All such patients should be given high-dose thiamine and glucose parenterally—if glucose is given without thiamine to a patient with Wernicke–Korsakoff syndrome, rapid deterioration and death can follow. Those who are thiamine deficient cannot handle the glucose load.

Effective treatment will restore consciousness and reverse eye signs, the latter usually within hours, but unfortunately the Korsakoff amnesia syndrome frequently does not resolve. The earlier the treatment, the better the chances of recovery, so suspicion or possibility of this diagnosis represents a medical emergency.

Alcoholic peripheral neuropathy (see also Chapter 24.17)

Aetiology

Although thiamine deficiency has long been held responsible for the peripheral neuropathy associated with chronic alcoholism, a direct toxic effect has more recently been proposed. Pathologically the picture of peripheral nerve damage is very similar to that seen in beriberi. There is predominantly axonal neuropathy of the 'dying back' type, affecting the somatic and sometimes the autonomic nerves.

Clinical features

Alcoholic peripheral neuropathy predominantly involves sensory nerves, producing distal parasthesias in the feet, followed by the hands, and characteristic pain. The last may be intense and agonizing. Squeezing the calves or scratching the soles of the feet may cause severe discomfort. At a later stage, weakness and wasting of the distal limb muscles follows. Tendon reflexes are lost. Evidence of autonomic neuropathy may be seen in abnormal pupillary reactions and tachycardia, although postural hypotension is rare and the sphincters are usually spared.

Treatment

Alcohol must be proscribed and high-potency vitamin B given parenterally for some 10 days and then orally. The prognosis depends on how early treatment is initiated. Symptoms may take weeks to subside and in more severe cases recovery may take many months or may be incomplete.

Alcoholic cerebellar degeneration

Some patients who are alcoholic may develop a relatively pure syndrome of midline cerebellar ataxia, with a progressive unsteadiness of gait and of leg movements, and little or no involvement of the arms. Speech is not affected, and nystagmus is not present. Many such patients also have evidence of alcoholic peripheral neuropathy. Pathologically there is degeneration of the cerebellar cortex, particularly of the Purkinje cells, and also of the olivary nuclei. Changes in the cerebellum characteristically affect the anterior and superior parts of the vermis and hemispheres. This complication of alcoholism does not seem to be due to thiamine deficiency. However, withdrawal of alcohol and vitamin replacement can lead to recovery.

Alcoholic dementia (see Section 26)

In the past, there has been much debate over whether alcoholism produces dementia. However, it is now clear that a large proportion of those who habitually take excessive alcohol develop cognitive deficits. These can vary from mild changes to severe diffuse global dementia, and are associated with atrophy of the cerebral cortex and enlargement of the cerebral ventricles.

The dementia has the usual features of personality change, loss of memory, impairment of intellect, and emotional instability. Patients who are alcoholic commonly fail at work or in personal relationships. The gradual drift into destitution is well described in the literature and all too familiar on the streets. Head injuries in alcoholic bouts and epilepsy may occur and contribute to the overall final picture. The fully developed case of the 'down and out' is an antisocial demented individual, with dysarthric speech, tremor, an ataxic gait, and a peripheral neuropathy, who still forlornly or aggressively clutches the bottle and a bag of residual belongings.

The dementia of alcoholism is not directly related to thiamine deficiency alone. Treatment by withdrawal of alcohol, if possible, and vitamin replacement can lead to improvement. Indeed, some degree of reversal of evidence of cerebral atrophy on CT brain scan can be seen after 'drying out'. However, the prognosis is generally poor, not least because of the difficulties of persuading those addicted to alcoholic to stop drinking.

Marchiafava–Bignami disease

This rare disease was first described in Italian drinkers of crude red wine, but occurs in other patients who are alcoholic. It presents as a subacute dementing illness, which progresses rapidly to fits, spasticity or rigidity, and paralysis, culminating in coma and death within a few months. Pathologically there is widespread demyelination and axonal damage in the corpus callosum and the central white matter of the cerebral hemispheres, as well as in the optic chiasma and middle cerebellar peduncles. Abstinence stabilizes but rarely reverses the syndrome.

Alcoholic myopathy

Acute alcohol poisoning can produce a dramatic toxic myopathy. There is severe pain, muscle tenderness, oedema, and weakness, which may be associated with myoglobinuria, renal damage, and hyperkalaemia. Arrhythmias may occur. The syndrome is reversible if the necessary intensive support is available. A subacute painless myopathy resolving after withdrawal of alcohol has also been described. Chronic alcoholism is associated commonly with a painless myopathy, occasionally with coexistent cardiomyopathy; again abstinence can cure the disorder.

Tobacco–alcohol amblyopia

Another uncommon complication of alcohol occurs in combination with strong tobacco. The patient develops sudden or subacute bilateral visual failure, associated with bilateral centrocaecal scotomas. The condition has been attributed to cyanide in tobacco causing a disorder of vitamin B_{12} metabolism. Visual failure and optic atrophy may occur in patients with pernicious anaemia, particularly those who smoke. A related condition is tropical amblyopia, occurring in Africa. This has been related to excessive consumption of cassava root containing cyanide. Treatment of these conditions is with hydroxycobalamine injections.

Superficial siderosis of the central nervous system

Superficial siderosis is an unusual disorder of the nervous system that has been recognized only recently. The four principal clinical manifestations are: progressive ataxia; cranial polyneuropathy, particularly sensorineural deafness; myelopathy causing a spastic tetraparesis; and progressive dementia. Headaches occasionally feature. Cerebrospinal fluid examination reveals xanthochromia which, importantly, persists with repeated examination. MRI is diagnostic, with low signal intensity on T_2-weighted images apparent at the surface of the cerebellum, cranial nerves, brainstem, spinal cord, and more deeply on the borders of the dentate and basal ganglia. Iron deposition can be shown by high-strength MRI, corresponding to pathological descriptions of siderotic deposits in the meninges. Repeated subarachnoid haemorrhage, cerebral tumours, or past surgery are recognized causes of this syndrome, but often none is historically evident; repeated subclinical haemorrhage is postulated but not proven. No treatments are of proven benefit.

Porphyria

Porphyrias affect predominantly the liver (acute intermittent porphyria (AIP), variegate porphyria, hereditary coproporphyria, and porphyria cutanea tarda) or the blood (for example erythropoietic protoporphyria). AIP spares the skin. Certain drugs (sulphonamides, barbiturates, oral contraceptive pill), starvation, alcohol, and other insults can precipitate 'crises' in AIP, hereditary coproporphyria, and variegate porphyria characterized by: (i) a predominantly motor, often proximal areflexic peripheral neuropathy, occasionally mimicking the Guillain–Barré syndrome; (ii) abdominal pain and cardiovascular instability caused by autonomic involvement; and (iii) confusion or psychosis. Fits may occur and acute attacks are commonly accompanied by progressive severe hyponatraemia due to inappropriate secretion of vasopressin. Increased urine and faecal porphyrins lead to the diagnosis. Acute attacks are treated largely symptomatically with benzodiazepines or opiates and major tranquillizers, and cardiorespiratory support. Carbohydrate loading may be beneficial.

24.16 Demyelinating disorders of the central nervous system

Alastair Compston

Clinicians suspect demyelination when episodes reflecting damage to white matter tracts within the central nervous system occur in young adults. The diagnosis of multiple sclerosis becomes probable when these symptoms and signs recur, affecting different parts of the brain and spinal cord. Demyelination also underlies many postinfectious neurological conditions affecting the central nervous system.

Neurobiology of demyelination

Glial development and myelination

Glial progenitors migrate from germinal zones around the lateral ventricles, the fourth ventricle, and in the ventral spinal cord, and differentiate either into astrocytes or oligodendrocytes. Oligodendrocyte precursors can be recovered from the adult nervous system. These behave as stem cells, dividing asymmetrically (at least *in vitro*) to produce one daughter precursor cell and one oligodendrocyte—providing a potential pool of new oligodendrocytes.

Growth, differentiation, and survival of glial progenitors and their progeny are orchestrated by growth factors. These are produced by neurones, astrocytes, and microglia. Those factors involved in rodent development (where most is currently known: glial-derived nerve growth factor, fibroblast growth factor 2, platelet-derived growth factor, insulin-like growth factors 1 and 2, nerve growth factor, neurotrophin 3, ciliary neurotrophic factor, retinoic acid, glial growth factor, interleukin 6, and leukaemia inhibitory factor) are not yet shown to be relevant in development of the human central nervous system.

Myelination occurs when the membraneous processes of mature oligodendrocytes contact and ensheathe axons and compact to form the myelin lamellae needed for saltatory axonal conduction. The number of surviving oligodendrocytes is matched to local axon density. Compact myelin consists of a condensed membrane, mainly composed of lipid (cholesterol, phospholipid, and galactolipid) with some protein, wrapped spirally many times around axons to form a segmented sheath. The glycoproteins are galactocerebroside, myelin-associated glycoprotein, and myelin oligodendrocyte glycoprotein (**MOG**). The two major proteins are proteolipid protein (**PLP**) and myelin basic protein (**MBP**). A further structural component is the myelin-specific enzyme 2',3'-cyclic nucleotide 3'-phosphohydrolase (CNP-ase). It is periodically interrupted along the course of the axon at the (unmyelinated) nodes of Ranvier, where electrical resistance is low due to the high concentration of sodium channels, and depolarization thereby facilitated. In myelinated axons, the action potential generates electrical currents which preferentially trigger depolarization at the next node of Ranvier. This saltatory conduction is considerably more rapid than continuous propagation of the nerve impulse.

Pathophysiology of demyelination

Myelin injury blocks saltatory conduction through myelinated pathways in the central nervous system. Although function may be preserved by redundancy in individual systems or tracts, strategically placed pathways lose their safety factor for conduction resulting in neurological symptoms and signs. Most clinical manifestations of demyelination merely reflect abnormalities to be expected from any process that disrupts physiological performance at that site. However, saltatory conduction may be compromised by partial demyelination in ways which account for specific features of multiple sclerosis and related disorders.

Partially demyelinated axons cannot transmit fast trains of impulse. This may explain symptoms that reflect physiological fatigue. Depolarization may traverse the lesion but at reduced velocity. This accounts for the characteristic delay in arrival of potentials evoked by sensory stimuli and recorded over appropriate cortical receptor zones. Partially demyelinated axons may discharge spontaneously. This explains distortions of sensation reported by a high proportion of patients. Increased mechanical sensitivity manifests as movement-induced symptoms including flashes of light on eye movement, and the electric sensation that spreads down the spine, limbs, or anterior chest wall after neck flexion—Lhermitte's symptom and sign. Increased temperature sensitivity, with a reduction in the safety factor for conduction in partially demyelinated axons, explains the temporary increase in severity of pre-existing symptoms experienced by many patients after exercise or immersion in hot water. Cold may improve performance—some patients adopting complicated water-cooled systems and others reporting that, for example, vision improves after eating ice cream. Ephaptic transmission occurs between neighbouring and partially demyelinated axons giving rise to paroxysmal symptoms of demyelination usually manifesting as trigeminal neuralgia, ataxia, and dysarthria, or tonic brainstem seizures. These are often triggered by touch or movement.

There are several mechanisms of symptom recovery early in the course of multiple sclerosis. These include the resolution of conduction block in nerve fibres which were never demyelinated, re-establishment of conduction in persistently demyelinated axons, functional reorganization of surviving pathways, and remyelination. Onset and recovery of conduction block and clinical impairments match the phase of acute inflammation. Transient symptoms depend on reversible conduction block caused by direct action of cytokines and inflammatory mediators (especially nitric oxide) on normal or hypomyelinated axons (Fig. 1). Function may be restored after demyelination by rearrangement of sodium channels providing a variety of alternative patterns of ordered or partially disordered conduction. There is probably also a contribution from the remyelination seen in acute lesions. Experimentally, remyelinated axons restore conduction of the nerve impulse and motor function.

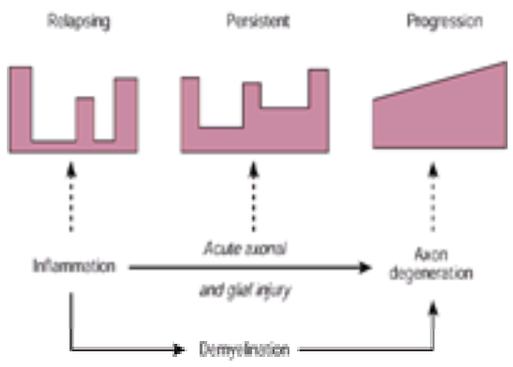

Fig. 1 Inflammatory mediators cause reversible symptoms in multiple sclerosis. Inflammation drives demyelination, which explains persistent symptoms. Progression depends mainly on axon degeneration, which causes acute axonal inury and continues throughout the course, but is conditioned by the amount of early inflammation.

Inflammation and the brain

Demyelinating disease includes conditions in which myelin fails to develop (leucodystrophies) or is lost through inflammatory (multiple sclerosis and related conditions) and metabolic (central pontine myelinolysis) mechanisms. Outstandingly the most common group is inflammatory demyelination. In all but the most severe forms, perivascular inflammation evolves through stages of acute axonal injury, demyelination, oligodendrocyte depletion, remyelination, astrocytosis, and axon chronic degeneration. The order and relationship of these separate components is still debated. The resulting plaques are widely distributed but concentrated around venous networks, the ventricles, and in the corpus callosum, the optic nerve, brainstem, and cervical cord.

Conditions required for inflammatory cell penetration of cerebral vessels include slowing of the circulation and the establishment of electrostatic force which allows adhesion between circulating and lining cells. Endothelial cells extend microvillar processes in response to injury and these entangle inflammatory cells as they pass along the vessel wall. Infiltrating lymphocytes which are not activated against brain antigen either return to the circulation or (in common with immune cells that have outlived their purpose elsewhere) die by apoptosis. Activated T cells that encounter antigen persist within the nervous system.

Outward migration of cells from the inflammatory nidus is promoted by local production of chemokines interacting with specific receptors on migrating cells, and by metalloproteases which degrade tissue barriers. Proinflammatory cytokines (especially interferon-g) amplify the immune response. Microglia are activated, leading to the release of yet more T-cell derived interferon-g, and the recruitment of additional naive microglia. Contact is established between activated microglia and the oligodendrocyte–myelin unit if the latter is opsonized with ligands for (Fc and complement) receptors activated on the surface of microglia. Demyelinated axons are coated with anti-MOG antibody in the lesions of acute multiple sclerosis. This may be a key antigen in attracting degradation of the oligodendrocyte–myelin unit by activated microglia. Adherent activated microglia deliver their lethal signal to the target oligodendrocyte using tumour necrosis factor-a bound to the cell surface. Together, these inflammatory processes lead to disruption of the myelin membrane with increased spacing, vesicular disruption, splitting, vacuolation, and fragmentation of the lamellae.

Much emphasis has been placed on the role of axon degeneration as a pathological feature. In hyperacute multiple sclerosis, large confluent zones of demyelination are associated with extensive axonal loss and surrounding oedema but little inflammation. In many other lesions, immunohistochemical staining for the amyloid precursor protein shows that axonal injury is initiated as part of the acute demyelinating episode. However, it is not certain when axons actually die. Acute damage to axons with transection appears early and the circumstantial evidence suggests vulnerability of recently demyelinated axons to the inflammatory environment of acute lesions; but there is also a chronic attrition which may be degenerative and secondary to loss of trophic support normally provided by myelin.

Acute lesions sometimes show an increase in the number of oligodendrocytes indicating microglia-associated loss of healthy oligodendrocytes and recruitment of new progenitors which then undergo differentiation. Axons are remyelinated in acute shadow plaques. Remyelination is associated with inflammation and reactive astrocytes which deliver cytokines and growth factors. The morphological criteria for remyelination are inappropriately thin myelin lamellae for the corresponding axon, with a short internode and myelin embedded in a satellite cell. Experimentally, remyelination can restore structure, conduction of the nerve impulse, and function, but—in a clinical context—new myelin may not survive repeated injury. The source of remyelinating cells is presumed to be the oligodendrocyte progenitor which is found in the lesions of multiple sclerosis.

Isolated demyelinating syndromes

The clinical expression of demyelination may be focal and monophasic even when imaging shows multiple lesions. The distinction between multiple sclerosis and isolated demyelinating disorders can therefore reliably only be made when more than one episode has occurred, affecting two or more sites, and not merely on the basis of anatomical dissemination of lesions.

Acute disseminated encephalomyelitis

Typically, acute disseminated encephalomyelitis develops within days or a few weeks after an infectious illness. It is usually but not invariably a disease of children. Formerly, acute disseminated encephalomyelitis affected 1 in 1000 children with exanthematous illnesses, the risk being slightly lower following pertussis and scarlet fever than measles and rubella, but these childhood illnesses, and hence their complications, are now less prevalent. A greater variety of causative organisms has been implicated in adult-onset acute disseminated encephalomyelitis, but in both groups a presumptive diagnosis often has to be made in the absence of an identifiable preceding infection.

The disorder is usually diffuse, and with a cerebral flavour, but the clinical manifestations may be restricted to the brainstem, optic nerves, or spinal cord. About 50 per cent of cases occurring after varicella infection present with a pure cerebellar syndrome. Headache, drowsiness, meningeal irritation, signs of systemic infection, focal or generalized fits, and combinations of lesions indicating damage to the cerebrum, optic nerves, brainstem, or spinal cord evolve over the course of a few days. The cerebrospinal fluid contains a mixture of polymorphonuclear cells and lymphocytes with raised protein and slight reduction in glucose; oligoclonal bands may be present. Whilst there is an appreciable mortality, the majority of patients survive, sometimes with persistent neurological deficits. Magnetic resonance imaging shows changes similar to those occurring in multiple sclerosis but the lesions are more extensive and symmetrical; they persist long after recovery of the clinical illness.

The hyperacute form of acute disseminated encephalomyelitis (Hurst's disease) starts with headache and progresses over hours to disorientation, confusion, drowsiness, and coma; events move quickly and the illness often proves fatal before the diagnosis has been established. The combination of pyrexia and a marked cerebrospinal fluid pleocytosis with a predominantly neutrophil response mimics pyogenic infection of the central nervous system, but the course is not influenced by antimicrobial treatment. Occasionally, the clinical and pathological features of acute haemorrhagic leucoencephalitis are focal and suggest a rapidly expanding tumour or herpes simplex encephalitis.

The outcome in acute disseminated encephalomyelitis is probably influenced by early use of high-dose intravenous steroids, but anecdotally, there may be a more favourable response to intravenous immunoglobulin. A proportion of patients recovering from the initial attack subsequently relapse. In some, although the illness remains monophasic, separate sites are involved sequentially over several weeks but the disorder does not recur. In others, the illness is subsequently shown to be the encephalopathic presentation of multiple sclerosis, which then follows the typical relapsing–remitting course. The nosological status of multiphasic disseminated encephalomyelitis—based on a history of episodes and atypical imaging appearances for multiple sclerosis—has not gained general acceptance.

Postvaccinial encephalomyelitis has become a rare disorder and the definitive series were collected several decades ago when vaccination against smallpox was necessary. The illness develops within 2 to 3 weeks of vaccination with a skin rash and systemic symptoms, followed by cerebral or myelitic signs which usually recover spontaneously, in due course.

Optic neuritis

Optic neuritis presents with pain on eye movement, followed by blurred vision which evolves over hours or days, sometimes to complete blindness; patients may be aware of selective loss of colour vision and flashes of light (phosphenes) on eye movement. The pain disappears within a few days; vision improves in 90 per cent of patients over months, but defects of colour perception frequently persist. Optic neuritis may present with progressive visual failure in one or both eyes, but in these situations care must be taken to exclude compression of the anterior visual pathway. Transient visual loss, mimicking optic neuritis, also occurs in ischaemic optic neuropathy, sarcoidosis, or Eales' disease and a family history should be taken since the presentation of visual failure in Leber's hereditary optic neuropathy is similar to bilateral sequential optic neuritis in men. The lesion responsible for optic neuritis can be imaged *in vivo*; inflammation within the intracanalicular portion of the nerve and long lesions are associated with delayed or incomplete recovery of vision. Correlations between imaging, symptoms, and neurophysiological changes indicate that the visual deficits in optic neuritis arise at the time of altered blood–brain barrier permeability. They are associated with conduction block and precede demyelination or axonal degeneration.

The frequency with which the optic nerve is involved leads to anxiety in the informed patient that an episode of optic neuritis is likely to be the first manifestation of multiple sclerosis. The risk is highest in the first 5 years, but the proportion of cases having recurrent demyelination continues to rise thereafter and life-table analysis suggests that up to 80 per cent eventually convert. In children, optic neuritis is commonly bilateral and recurrent demyelination affecting other parts of the nervous system rarely occurs. Bilateral simultaneous optic neuritis in adults, although less common than in children, also carries a low risk of multiple sclerosis. Recurrent optic neuritis is associated with an increased risk and this is marginally higher in females than males. MRI abnormalities in the periventricular white matter are found in more than 60 per cent of patients with optic neuritis, and the risk of developing multiple sclerosis is substantially increased for those having two or more such lesions at presentation; conversely, the absence of cerebral lesions is a good prognostic sign. The presence of oligoclonal bands on cerebrospinal fluid electrophoresis during the acute phase is also a significant risk factor.

Transverse myelitis

The spinal cord is vulnerable to postinfectious inflammatory damage, but as with acute disseminated encephalomyelitis in adults, the precipitating cause is often not identified. Transverse myelitis presents with pain at the site of the lesion, followed by weakness in the legs, sensory symptoms, and sphincter involvement. The weakness increases and the clinical picture is that of spinal shock—features rarely seen in acute cord lesions due to multiple sclerosis. Sphincter control is lost, but unlike patients with multiple sclerosis, there is usually difficulty in emptying rather than filling the bladder. The need to exclude a structural abnormality in patients with transverse myelitis means that many patients undergo radiological investigation which may demonstrate cord swelling. The spinal fluid shows an increased mononuclear cell count, numerically intermediate between the marked pleocytosis of acute necrotizing myelitis and the marginal abnormalities seen in multiple sclerosis; total protein is raised and oligoclonal bands may be present on electrophoresis, but the glucose is usually normal. Transverse myelitis is more common in adults than children; there is a high frequency of persistent disability, but a much lower conversion to multiple sclerosis than following optic neuritis.

Acute necrotizing myelitis causes rapidly progressive flaccid areflexic paraplegia with anaesthesia and loss of sphincter control. The intensity of inflammation results in severe pain with meningism, pyrexia, and systemic symptoms. The condition mimics cord compression; the cerebrospinal fluid changes resemble pyogenic or tuberculous infection of the central nervous system. For these reasons, treatment with high-dose intravenous steroids, which may usefully influence mortality and limit long-term disability, is often withheld. Acute necrotizing myelitis has been described in association with herpes virus infection, and as a complication of acute lymphocytic leukaemias, lymphoma, carcinoma, and acquired immune deficiency syndrome.

Devic's disease (neuromyelitis optica)

Devic's disease is characterized by massive confluent demyelination in the anterior visual pathway together with equally severe spinal cord damage, occurring simultaneously or sequentially and in either order, the episodes usually separated by weeks or months. Cellular reaction in the cerebrospinal fluid more usually involves polymorphonuclear cells than lymphocytes, but often lacks oligoclonal bands. Cerebral white matter abnormalities tend to be frontotemporal and the spinal lesion is long, extending over several segments, in contrast to the several short lesions which characterize spinal MRI in multiple sclerosis.

The distinction from multiple sclerosis is partly confused by definitions. Demyelinating disease often follows the Devic pattern in Japanese and African patients, where multiple sclerosis is otherwise rare. Cases are described complicating pulmonary tuberculosis, especially in African patients. European patients with bilateral simultaneous optic neuritis and transverse myelitis often show manifestations of widespread demyelination and multiple events occur in due course. There is a better prognosis for recovery when the optic nerves and spinal cord are affected in rapid sequence, but the outcome is generally poor with an appreciable mortality, especially in relapsing patients with more than two episodes.

Isolated brainstem syndromes

The clinical symptoms and signs of isolated brainstem syndromes typically consist of disequilibrium, disturbed eye movements, facial numbness, and dysarthria, but there may be severe headache which rightly leads to early investigation in order to exclude a structural lesion. The majority of patients progress to clinically definite multiple sclerosis; as with other isolated demyelinating syndromes, abnormal MRI outside the affected site at presentation is a poor prognostic sign for clinical conversion.

Multiple sclerosis

Aetiology

The aetiology of multiple sclerosis involves an interplay between genes and the environment. It is a disease of northern European people and occurs less frequently in other racial groups. The familial recurrence rate is approximately 15 per cent. Meta-analysis amongst relatives of probands from three population-based series shows that the age-adjusted risk is highest for siblings (3 per cent), then parents and children (2 per cent), with lower rates in second- and third-degree relatives. Recurrence in monozygotic twins is around 35 per cent. Conversely, the frequency of multiple sclerosis in adoptees is similar to the population risk for Europeans. The age-adjusted risk for half-siblings is intermediate between social and biological relatives. Recurrence is higher in the children of conjugal pairs with multiple sclerosis (age-adjusted 20 per cent) than the offspring of single affecteds (2 per cent) (Fig. 2).

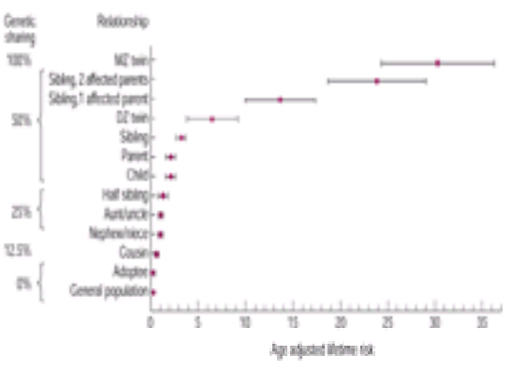

Fig. 2 Lifetime risk for multiple sclerosis amongst European people and in biological and social relatives of affected individuals. The increased risk with relatedness implicates genetic factors whereas the incomplete concordance in identical twins reflects the contribution made by environmental conditions.

Population studies demonstrate an association between the class II MHC alleles (DR15 and DQ6) and their corresponding genotypes. A specifically different association in seen in Mediterranean populations (DR4). Extensive searches, using association and linkage studies over many years, have yielded very few additional candidates for susceptibility. To date, eight genome screens have failed to identify a major susceptibility locus using identity by descent analysis in sibling pairs and enough markers to provide around a 10 centiMorgan map. The possible reasons are that no such gene exists, it has been missed, or heterogeneity has obscured the picture. Whole genome association screens dependent on linkage disequilibirum are in progress. Genetic analyses assume that multiple sclerosis is one disease, but

this may not be true. Mutations of mitochondrial DNA are responsible for a multiple sclerosis-like illness characterized by disproportionate involvement of the anterior visual pathway, although mitochondrial genes do not contribute generally to susceptibility in multiple sclerosis. Conditioning the United Kingdom genome screens for DR15 shows clustering of regions of interest within subsets of families. A major part of future studies in the genetics of multiple sclerosis will be to resolve the question of disease heterogeneity.

The distribution of multiple sclerosis cannot be explained only on the basis of population genetics. In white South African people and in Australia, prevalence rates are half those documented for many parts of northern Europe. There is a gradient in frequency, both in Australia and in New Zealand, which does not follow genetic clines. The risk is higher for English-speaking white people migrating into South Africa as adults than in childhood. Multiple sclerosis occurs at a low frequency in the Caribbean poulation, but the risk increases substantially in their first-generation descendants raised in the United Kingdom. Over and above the effect of racial predisposition, migration influences distribution of the disease. Surveys of multiple sclerosis have prompted speculation on the occurrence of post-Second World War epidemics in Iceland, the Orkney and Shetland Islands, and the Faroes, but others prefer the interpretation that these merely reflect improved case recognition.

The risk of developing multiple sclerosis is increased for individuals exposed to measles, mumps, rubella, and Epstein–Barr virus infection relatively late in childhood or adolescence. These studies suggest that an age-linked period of susceptibility to viral exposure exists in those who are constitutionally at risk of developing the disease. Attempts to implicate specific environmental agents are frustrating. Putative candidates of current interest are human herpes virus 6 and *Chlamydia pneumoniae*.

Clinical symptomatology

Special senses

Visual involvement is almost invariable and most commonly affects the optic nerve (see above). The post-chiasmal visual pathway is occasionally involved resulting in hemianopic field defects. Deafness occurs in multiple sclerosis, sometimes at presentation. Feelings of unsteadiness are common. Acute brainstem demyelination causes severe positional vertigo, vomiting, ataxia, and headache. Taste may be subjectively abnormal but ageusia is rarely described. Anosmia is reported in a high proportion of asymptomatic patients examined with more than usual thoroughness.

Motor symptoms and signs

Impaired mobility affects the majority of patients with multiple sclerosis usually as a result of spinal disease. Movements are slow, weakness differentially affecting extensors in the arms and flexors in the legs, and there are the expected signs of upper motor neurone lesions. Spasticity may be more problematic than weakness and all aspects of immobility are frequently complicated by fatigue. Cerebellar involvement causes incoordination of speech, bulbar control, eye movements, the individual limbs, or balance, usually in combination with corticospinal damage. Damage to the superior cerebellar peduncle or red nucleus produces a disabling proximal wild flinging tremor, and many other movement disorders have been described. Lower motor neurone signs occur when there is extensive demyelination adjacent to the dorsal root entry zone.

Sensory symptoms and signs

Altered sensation occurs at some stage in nearly every patient with multiple sclerosis. Damage to the posterior columns in the cervical cord produces tight, burning, twisting, tearing, or pulling sensations, which are usually unpleasant. Associated loss of proprioception severely compromises function. Spinothalamic tract involvement leads to loss of thermal and pain sensation. Non-specific tingling without accompanying signs is often described and the commonest physical sign found in the absence of symptoms is impaired vibration sense in the legs.

Demyelination of the dorsal or lumbar segments of the spinal cord produces paraesthesias and numbness in the legs, ascending to the trunk, and sometimes associated with sacral sparing, although a characteristic sensory syndrome seen in patients with multiple sclerosis is numbness of the perineum and genitalia with disturbed sphincter function.

Autonomic involvement

Autonomic symptoms occur in most patients with multiple sclerosis. Bladder symptoms are most common in women, whereas impotence occurs frequently in males. Loss of inhibition of reflex bladder emptying, normally mediated by cholinergic neurones that contract the detrusor and relax the internal sphincter, results in urgency and frequency with incontinence when combined with immobility. With conus lesions, the problem is impaired bladder emptying. Failure to fill and empty may coexist, resulting in detrusor contractions against a closed sphincter.

Impaired control of the rectal sphincter is much less of a problem than failure of emptying. Some impotent males with multiple sclerosis retain reflex erections, in which case psychogenic factors are often invoked; others have erectile failure due to spinal cord disease. Mechanical difficulties, spasticity, altered sensation, skin excoriation, and in-dwelling catheters affect sexual performance in both sexes. Other autonomic features in multiple sclerosis include: loss of thermoregulation leading to inappropriate sweating, fever, and hypothermia; Horner's syndrome; abnormalities of cardiac rhythm and vascular responses with acute pulmonary oedema; weight loss; and inappropriate secretion of vasopressin.

Eye movements

Abnormalities of eye movement are routine in multiple sclerosis. They are often asymptomatic but may manifest as double vision and oscillopsia. The commonest sign is first-degree symmetrical horizontal jerking nystagmus. Weakness of the lateral rectus is more common than isolated third and fourth nerve palsy. Internuclear ophthalmoplegia is often bilateral and may coexist with gaze paresis to produce the 'one and one half' syndrome.

Vertical up-beating nystagmus is always associated with bilateral internuclear ophthalmoplegia. Down-beating nystagmus has other important causes which can be confused with multiple sclerosis. Ocular flutter consists of horizontal saccadic oscillations without an intersaccadic interval. Opsoclonus, in which the movements occur in all directions, is equally disabling. Ocular bobbing describes an initial rapid downward eye movement followed by slow return to the neutral position and denotes cerebellar involvement. Abrupt displacement from the primary position during central fixation (square wave jerks) occurs with severe cerebellar deficits.

Other brainstem manifestations

Facial weakness, indistinguishable from Bell's palsy, occurs in patients with multiple sclerosis, alone or in association with other signs of brainstem disease including hemifacial spasm and diffuse rippling of muscle fibres (myokymia). Exceptionally, there may be unilateral involvement of the hypoglossal and recurrent laryngeal nerves. Extensive brainstem demyelination may produce disturbances of consciousness and respiratory failure distinct from the narcolepsy syndrome which is seen more frequently in patients with multiple sclerosis than expected by chance—an observation of immunogenetic interest in view of their shared HLA DR2 association. Occasional manifestations include the locked-in state, persistent hiccup, and the lateral medullary syndrome.

Paroxysmal symptoms are invariably brief but repetitive and last a few months before remitting. Symptomatic trigeminal neuralgia may begin in the first division or bilaterally, at a younger age than the idiopathic condition, and with associated signs of trigeminal involvement including motor weakness and sensory loss. It is usually associated with demyelinating lesions of the dorsal root entry zone, but may coexist with compression of the fifth cranial nerve by ectatic vessels. Other than trigeminal neuralgia, isolated involvement of the fifth nerve is rare. Paroxysmal dysarthria and ataxia with a clumsy arm, complex disturbances of sensation, and painful tetanic posturing of the limbs lasting 1 or 2 min are often triggered by movement and preceded by positive sensory symptoms on the side opposite to the muscular spasm. These are easily recognized and treated. Bursts of pain and paraesthesias, sensory distortion, itching, cough and hiccup, painful extensor spasm, akinesia, kinesogenic choreoathetosis, and complex gaze palsies—any of which may respond to anticonvulsants, especially carbamazepine—also appear to be paroxysmal manifestations of multiple sclerosis.

Cognitive and affective symptoms

Defects of visual and auditory attention occur in multiple sclerosis, sometimes at an early stage, and these are also detectable in patients with isolated demyelinating

lesions. An overall impairment in intelligence quotient relates more to duration of disease, and onset of the progressive phase, affecting memory rather than language skills. Specific cognitive deficits due to hypothalamic involvement including the Korsakoff state and the syndrome of bulimia, lack of social restraint, mental interia, and mutism are sometimes seen. Psychotic behaviour is rare, but depression occurs more frequently than in patients with comparable neurological disability; hypomania is occasionally seen but should not be confused with pathological laughter and crying, arising from loss of central inhibition of facial and bulbar reflexes in association with extensive brainstem disease.

Rare manifestations of multiple sclerosis

The list of rare clinical manifestations (some already described) includes massive cerebral lesions, aphasia, headache, fever, movement disorders, epilepsy, hypothalamic and pituitary symptoms, respiratory failure, and peripheral neuropathy. Narcolepsy, Sjögren's syndrome, ankylosing spondylitis, type I neurofibromatosis, and autoimmune thyroid disease have periodically been associated with multiple sclerosis.

Childhood multiple sclerosis

In retrospect, symptoms attributable to recurrent demyelination often affect individuals with multiple sclerosis as teenagers, but onset in the first decade also occurs; 2 per cent of patients with multiple sclerosis present before the age of 10, and 5 per cent before 16 years. Children with multiple sclerosis are usually girls. The individual episodes are often severe but the long-term prognosis surprisingly good. Fever and meningism, impaired conscious level due to cerebral oedema with swollen optic discs, and seizures are regular features and the distinction from acute disseminated encephalomyelitis can often only be made by the later occurrence of remission and relapse.

Clinical course and prognosis

The majority (80 per cent) of patients present with relapsing–remitting disease. Typically, the illness passes through the three phases of relapse with full recovery, relapse with persistent deficits, and secondary progression. One patient may spend several years or even a few decades in each, whereas another moves rapidly to a condition of fixed progressive disability. About 25 per cent of patients have multiple sclerosis in a form which is not disabling. In 5 per cent, relapses occur frequently and do not recover, leading rapidly to disability and early death from respiratory failure when the medulla is affected and from massive cerebral or spinal demyelination. Up to 15 per cent become severely disabled within a short time.

Episodes occur at random frequency but initially average about 1.5 per year and decrease steadily thereafter. Recovery from each attack is invariably slower than onset and may be incomplete. Self-evidently, secondary progressive multiple sclerosis tends to affect whichever system has previously been involved. Progression may follow directly upon a severe relapse and be interrupted by further episodes. In 20 per cent, multiple sclerosis is progressive from onset. The spinal cord bears the brunt of progressive multiple sclerosis, but optic nerve, cerebral, and brainstem disease may also advance slowly. Primary progressive spinal disease is the usual mode of presentation when multiple sclerosis develops beyond the fifth decade. Life expectancy is at least 25 years, and a high proportion of patients die from unrelated causes.

The prognosis is relatively good when sensory or visual symptoms dominate the illness and there is complete recovery from individual episodes; this pattern in most common in young females. Conversely, motor involvement, especially when co-ordination or balance are disturbed, has a less good prognosis. The outlook is also poor in later-onset patients and these are often males. Frequent, prolonged relapses with incomplete recovery and a short interval between the initial episode and first relapse carry a worse prognosis, but the main determinant of disability is onset of the progressive phase.

Prospective studies show that 9 per cent of upper respiratory (adenovirus) and gastrointestinal infections occurring in patients with multiple sclerosis are followed by relapse and 27 per cent of new episodes are related to infection. The emerging evidence suggests that disease activity is not increased by vaccination. Relapse rate is affected by pregnancy. There is a reduction in the prepregnancy relapse rate for each trimester with approximately a threefold higher risk in the puerperium, and the attacks may be more severe. The clinical course is uninfluenced by breast feeding or epidural anaesthesia. There is no evidence that trauma ever triggers the first or recurrent clinical manifestations of multiple sclerosis in someone who has the underlying disease process, or alters the course in individuals who have already experienced symptoms. A study of 170 patients studied prospectively for 8 years showed that (with the possible exception of electric shock) all forms of trauma are negatively correlated both with clinical exacerbations and disease progression.

Laboratory investigations

Investigations are used for four purposes in patients with multiple sclerosis: to demonstrate the anatomical dissemination of lesions; to provide evidence for intrathecal inflammation; to demonstrate that conduction is altered in a form consistent with demyelination; and to exclude conditions that mimic demyelinating disease. That said, the diagnosis can often reliably be made using clinical criteria and without laboratory support.

Electrophysiology

Demyelination can be detected in clinically unaffected pathways using visual, auditory, somatosensory, central motor, and event-related potentials; their latencies are characteristically delayed whereas, except in acute lesions, the amplitude is unaffected. Evoked potentials add little in situations where the pathway under investigation is clinically affected. Since they provide qualitatively different information, evoked potentials remain useful as an adjunct to diagnosis despite the advent of imaging techniques.

Magnetic resonance imaging

Low-density lesions, corresponding to areas of demyelination, may be seen using contrast-enhanced computed tomography and these occasionally have the appearances of cerebral tumour or abscess, but this technique is insensitive compared with MRI. More than 95 per cent of patients with clinically definite multiple sclerosis have periventricular lesions and more than 90 per cent also show discrete white matter abnormalities. Focal demyelination can be imaged in the optic nerve, brainstem, and spinal cord.

Variations in the imaging protocol are beginning to distinguish separate components of the underlying pathological process. Imaging can distinguish inflammation (gadolinium–DTPA enhancement of T_1-weighted lesions, indicating that the lesion is of recent origin), demyelination (magnetization transfer ratio), astrocytosis (T_2-weighted lesions, the signal arising from increased water content), and axonal damage (reduction in diffusion tensor imaging anisotropy and *N*-acetyl-aspartate spectra with chemical shift imaging, or the presence of focal atrophy and T_1-weighted black holes). The evolving lesion starts with increased blood–brain barrier permeability which lasts for up to 4 weeks and precedes the onset of T_2-weighted magnetic resonance changes. These lesions may disappear but reactivation is sometimes seen, the cycles lasting about 8 weeks. The periventricular lesions, which best characterize multiple sclerosis, correlate with areas of persistent demyelination and astrocytosis. A mixture of new, evolving, and recovering lesions may be seen in an individual patient at any one time. Magnetic resonance lesions occur about 15 times more frequently than new clinical events. Eventually, there is a reduction in the frequency of new lesions as patients switch from the relapsing to progressive phases of the disease and evidence for atrophy is then more apparent. The number or volume of lesions correlates poorly—if at all—with disease severity or course, but there is less cerebral involvement in patients who present with primary progressive disease compared with those having similar disability from secondary progression. The imaging abnormalities of multiple sclerosis are not specific and similar changes occur with inflammatory or vascular lesions and with advancing age (Fig. 3).

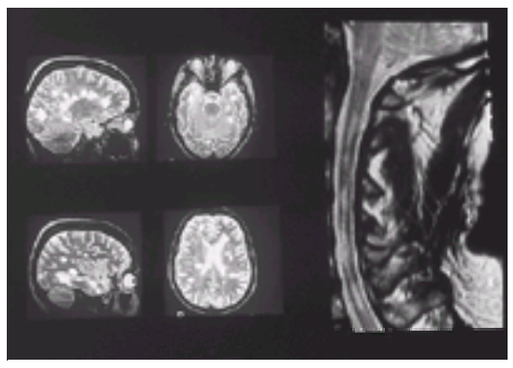

Fig. 3 T_2-weighted MRI abnormalities diffusely affecting the cerebrum and spinal cord in multiple sclerosis.

Imaging is not always necessary for diagnostic purposes in patients with a history of relapsing disease affecting multiple sites within the central nervous system. The major practical use is in the investigation of individuals with isolated demyelinating lesions, recurrent episodes at a single site, or progressive disease affecting the spinal cord. In all these situations the first requirement is to exclude a structural lesion, especially since these can present with relapsing symptoms. Imaging any region of the nervous system, clinically affected in isolation, will reliably exclude a structural lesion that might mimic multiple sclerosis and may show changes consistent with focal demyelination, but will not distinguish the syndromes of isolated demyelination from multiple sclerosis. Once the clinically affected part has proved negative for a structural lesion, the diagnosis of multiple sclerosis also requires the demonstration of anatomically separate lesions, ideally with enhancement to identify recent lesions, or the accumulation of new imaging abnormalities over time even if these are not expressed clinically.

Cerebrospinal fluid

Cerebrospinal fluid analysis provides information which is complementary to imaging abnormalities and specifically useful in elderly patients suspected of having multiple sclerosis. The cell count rarely exceeds 50 lymphocytes/ml, even during periods of clinical activity, and is normal in more than 50 per cent of patients. There is a rise in total protein with a specific increase in the immunoglobulin concentration and the presence of oligoclonal bands on protein electrophoresis in more than 90 per cent of cases, after correction for leakage of serum proteins through the blood–brain barrier, providing evidence for synthesis of immunoglobulin within the central nervous system. As with the imaging abnormalities, these are sensitive but not specific. Although some antibodies are directed against components of the oligodendrocyte or its myelin membranes, and others recognize extrinsic antigens including viruses, collectively these specificities only account for a minority of the bands. In each clinical situation a number of additional investigations will be required to exclude conditions which mimic multiple sclerosis.

Differential diagnosis

The commonest error in clinical practice is to make the diagnosis of multiple sclerosis in patients with progressive spinal disease in whom a structural lesion has not been adequately excluded. Rarely, spinal tumours present with intermittent symptoms creating difficulties for the unwary; it is just not safe to assume the diagnosis of multiple sclerosis in patients with symptoms and signs restricted to a single site whatever the clinical course. Lesions at the foramen magnum are particularly well placed to cause confusion through appearing to produce evidence for independent spinal and brainstem lesions. Errors also arise with progressive and relapsing manifestations of brainstem or spinal arteriovenous malformations.

Care must be taken in the diagnosis of multiple sclerosis when several members are affected within one family. Hereditary spastic paraplegia mimics familial multiple sclerosis and this should also be considered in isolated cases of progressive spastic paraplegia when pyramidal manifestations occur in isolation and with disproportionate spasticity. Other familial disorders confused with multiple sclerosis include the hereditary ataxias, adult-onset leucodystrophies, and vasculopathies (CADASIL). Pedigrees with affected males and maternal inheritance may be examples of X-linked adrenoleucodystrophy and individuals with the phenotype of multiple sclerosis occur in families with the clinical and genetic features of Leber's hereditary optic atrophy (Harding's disease).

Clinical, immunological, and imaging abnormalities indistinguishable from multiple sclerosis occur with granulomatous and vasculitic diseases of the brain, especially the cerebral variant of systemic lupus erythematosus which often occurs in the absence of systemic manifestations or informative serology. Sarcoidosis may present with clinical involvement of the central nervous system, typical magnetic resonance and cerebrospinal fluid abnormalities, and without pulmonary or cutaneous manifestations; uveitis also occurs in multiple sclerosis and so is not necessarily a useful discriminator. Orogenital ulceration in a patient with the clinical manifestations of multiple sclerosis suggests the diagnosis of Behçet's disease.

Alternative diagnoses need to be considered when multiple sclerosis is diagnosed in African or Asian people in whom progressive spinal disease, sometimes with visual involvement, is more probably due to HTLV1-associated tropical spastic paraplegia or neuromyelitis optica (see above). Infections of the nervous system can mimic the isolated demyelinating syndromes and multiple sclerosis. These include tuberculous and other chronic meningitides, and the neurological manifestations of acquired immunodeficiency syndrome and Lyme disease; borreliosis can also cause a chronic or relapsing disorder of the central nervous system, but this is usually preceded by the characteristic painful polyradiculitis and facial palsy that epitomizes Lyme disease. Similarities between multiple sclerosis and neurosyphilis should not be forgotten in the context of opportunistic infection complicating HIV infection. The age distribution and clinical manifestations usually make it easy to distinguish subacute combined degeneration of the spinal cord from multiple sclerosis, but focal spinal lesions, accompanied by Lhermitte's sign, occur in vitamin B_{12} deficiency.

The high public profile which multiple sclerosis currently enjoys leads many individuals with vague sensory symptoms or dizziness to consider the diagnosis for themselves. Many are easily reassured when these transient symptoms are unaccompanied by physical signs; these understandable anxieties differ from the syndromes fabricated by individuals seeking the dignity of a neurological diagnosis in the setting of psychiatric disease, which are much more difficult to manage.

Treatment of demyelinating disease

Management of the acute episode

Corticosteroids are effective in abbreviating acute episodes in multiple sclerosis. There is no difference in early or eventual response to treatment using high-dose oral or intravenous regimens. Most neurologists prefer the intravenous route despite the practical advantage of oral therapy. There may be a role for intravenous immunoglobulin in patients with severe acute deficits which do not respond to corticosteroids, although this strategy has not been assessed in clinical trials. Plasma exchange given up to 1 month after onset in the context of failed response to intravenous corticosteroids may reduce persistent deficits, although this does not prevent subsequent disease activity.

The treatment of symptoms

Several manifestations of multiple sclerosis can be improved symptomatically. Urgency or frequency of micturition respond to drugs with anticholinergic activity (oxybutinin or propantheline). A simple means for intermittently reducing urine volume, and hence the desire to micturate, is to use intranasal desmopressin spray. When detrusor and sphincter function become uncoupled, causing impaired bladder emptying with failure to fill, the preferred treatment is self-intermittent catheterization, which is easily adopted by motivated patients with adequate vision and arm function and ensures complete bladder emptying often with unimagined advantages to social activities and sleep. Other options include subtrigonal injections to reduce bladder sensation, a suprapubic catheter with closure of the lower urinary tract, urinary diversion through an ileal conduit, insertion of an artificial mechanical sphincter, or electrical stimulation of the spinal nerve roots in an attempt to synchronize sphincter contraction and relaxation. These may be preferable to an indwelling urethral catheter or, worse still, constant dribbling incontinence, which usually leads to skin excoriation.

Constipation in multiple sclerosis is managed by dietary alteration and the use of bulk laxatives, avoiding agents that act directly on the bowel wall. Loperamide may be useful where the predominant complaint is rectal urge incontinence. Psychological factors contribute to impotence in males with multiple sclerosis, but in most cases the complaint is a direct consequence of spinal demyelination. Trends in management have shifted from the use of semirigid prostheses and vacuum pump-induced tumescence, and self-administered cavernous injection of papaverine or prostaglandin E_1 applied through the urethra, to oral treatment with sildenafil

(Viagra)—a phosphodiesterase inhibitor which acts by increasing local production of nitric oxide in response to sexual stimulation.

The mainstay of pharmacological treatment for tremor is b-blockers; alternatives include anticonvulsants, isoniazid, ondansetron, and hyoscine. Physical restraint is rarely successful. Stereotactic procedures involving stimulation of the ventrolateral nucleus produce results comparable to destructive procedures, but the dividend is small. Unsteadiness arising from altered vestibular input may improve with the use of a vestibular sedative.

Fatigue may improve with amantadine or modetanil. Use of the aminopyridines in this and other contexts is limited by adverse effects including the risk of convulsions, although they can improve vision and muscle strength. Baclofen is still the most widely used effective antispastic agent. Benzodiazepines also reduce spasticity by increasing presynaptic spinal inhibition. Dantrolene sodium acts by uncoupling excitation–contraction mechanisms in individual muscle fibres. It is claimed that Tizanidine reduces spasticity without increasing weakness. Patients report that spasticity and pain improve with the use of cannabis and this is now formally being evaluated. Intrathecal baclofen carries the potential advantage of selectively reducing muscle tone in affected muscles whilst leaving others intact. It is mainly appropriate for patients with advanced disease and does not seem to have any additional adverse effects compared with systemic administration. Another approach is to use local injection of botulinum toxin. There may be a role for surgical interruption of the reflex pathways or tenotomy and peripheral nerve block with phenol or alcohol.

The paroxysmal manifestations of multiple sclerosis usually stop abruptly with the use of carbamazepine; this and other anticonvulsants, especially gabapentin, may also relieve trigeminal neuralgia or the more refractory forms of pain arising from spinal demyelination. Nerve block and chemical or surgical destruction of nerve fibres are sometimes an acceptable method for reducing pain in multiple sclerosis. All these sensations are coped with less well in the context of impaired mood and can respond usefully to antidepressants.

For those who develop significant disabilities and impairments, comprehensive care includes access to physical and occupational therapists, social workers, and other health-care staff with expertise in the management of chronic neurological illness. Complications are best prevented by awareness and anticipation since they usually develop quickly yet take months to resolve. Minimizing handicap by attention to social, vocational, marital, sexual, and psychological aspects of the illness remains more important to most patients than drug treatment. In situations where the natural history has already led to loss of mobility, the early use of mechanical aids and home adaptations should be encouraged despite the associated stigma.

Immunological treatment in multiple sclerosis

The use of non-specific agents in multiple sclerosis proved the concept that immunosuppression is a valid approach to treatment even if the magnitude of the effect often failed to establish a role for any one drug. The modern era began with meta-analysis of trials evaluating azathioprine showing a reduction in relapse rate but with a more modest effect on disability. The conclusion that the effect was of doubtful value to the individual patient and potentially posed serious long-term risks, meant that azathioprine was never routinely used to treat patients with multiple sclerosis. More recently introduced drugs appear to offer better adverse effects profiles but only achieve comparable efficacy. Some have already disappeared because of a poor showing in initial or confirmatory phase III trials, and due to unexpected toxicity. Casualties include linomide, cladribine, methotrexate, anti-CD4 monoclonal antibody, anti-TNFa antibody, oral myelin, altered myelin basic protein peptide, T cell vaccination, sulfasalazine, and intravenous imunoglobulin. For example, despite the apparent therapeutic rationale, a fusion protein linked to the soluble TNFa receptor produces a dose-dependent increased relapse rate, reduced time to relapse, and longer and more severe episodes—results which presumably have their explanation in the complex interacting networks of pro- and anti-inflammatory cytokines. Only a minority of patients receiving one or more well tolerated courses of a chimeric anti-CD4 antibody, sufficient partially to suppress the CD4 count, demonstrated clinical and imaging effects. Thus, the available anti-CD4 monoclonals used in isolation appear not to have a therapeutic future in multiple sclerosis. The two trials of altered myelin basic protein peptide ligand therapy in multiple sclerosis, designed to tolerize against auto-aggressive myelin basic protein-reactive T cells, either promoted relapses of multiple sclerosis or caused intolerable allergic adverse effects.

Several drugs, however, are now licensed in Europe and the United States for use in defined groups of patients with multiple sclerosis. Mitoxantrone achieves a higher conversion to disease inactivity (clinical and enhanced magnetic resonance imaging) in patients with active disease receiving monthly injections of methyl prednisolone—at least in the short term—but treatment is limited by the cumulative potential for cardiotoxicity. Glatiramer acetate (Copaxone) has been used in multiple sclerosis on the basis that disease activity can be suppressed by mimicking the antigenic challenge initiating brain inflammation. There is a reduction in relapse rate, more relapse free patients, and a delay in time to relapse but a less clear-cut effect on disability. Copaxone is associated with a change in cytokine production from a pro-inflammatory Th-1 to an anti-inflammatory Th-2/3 profile.

The therapeutic rationale for use of the b-interferons rests on the argument that IFN-b may limit inflammation by inhibiting antigen presentation, promoting a Th-2 immune phenotype, restricting migration of cells across the blood-brain barrier, reducing parenchymal cytokine production, and enhancing growth factor protection of axons; but it seems intrinsically unlikely that so many desirable properties, many characterized *in vitro* using experimental systems, are all relevant *in vivo*. BetaferonTM (IFN-b1b) is given by alternate day subcutaneous injection (8 million international units [miu]); AvonexTM (IFN-b1a) by weekly intramuscular injection (30 µg); and RebifTM (IFN-b1a) by alternate day subcutaneous injection (12 or 30 miu). IFN-b1a and IFN-b1b both reduce relapse rate by about one third and significantly reduce the accumulation of lesion load on magnetic resonance imaging in relapsing-remitting multiple sclerosis. The main adverse effects of IFN-b1b and IFN-b1a are local injection site reactions, flu-like symptoms and hyperthermia; contraindications include the use of IFN-b in pregnancy, and in patients with epilepsy or depression. Complications are not necessarily immediate and may occur 2 to 3 years after starting treatment. Between 15 and 40 per cent of patients receiving IFN-b develop neutralizing activity. Antibodies to IFN-b1a and IFN-b1b are immunologically and biologically cross-reactive. Subsequent attention has turned to whether there are dose response effects, a role for patients already in the progressive phase, and clinically useful delays in conversion to multiple sclerosis when IFN-b is given after a first episode of demyelination.

Comparisons of the licensed regimens do not show obvious dose effects or superiorities but some would rank high-dose Rebif above Betaseron and then Avonex for efficacy; whereas Avonex may have the edge over the other products for convenience and adverse effects. Although IFN-b1b was shown to delay progression in patients with secondary progressive multiple sclerosis, it seems likely that this mainly reflects suppression of superimposed new inflammatory lesions rather than an effect on other components of the pathogenesis contributing to secondary progression – and trials of the other products have shown no benefit; at best, IFN-b is only indicated in patients with secondary progressive multiple sclerosis also having frequent and clinically significant relapses. As predicted from the initial demonstrations of reduced relapse rate, IFN-b increases the time to a second and hence defining episode for multiple sclerosis in patients with isolated episodes of demyelination but this does not mean that these drugs have been shown to prevent multiple sclerosis.

Much effort has gone into the design of humanized monoclonal antibody and small molecule treatments for multiple sclerosis which either remove lymphocytes from the systemic circulation or prevent their migration into the central nervous system. Pulsed anti-a4 integrin antibody treatment in relapsing-remitting or progressive disease reduces active magnetic resonance lesions in the short term and is being studied in phase III trials. The humanized anti-CDw52 (CAMPATH-1H) antibody was originally shown to suppress radiological markers of cerebral inflammation by more than 90 per cent after a 1-week course and for at least 18 months during which relapses also stopped. However, 50 per cent of patients became progressively disabled from deficits acquired prior to treatment; these showed brain atrophy with evidence for axon degeneration on magnetic resonance spectroscopy. Clinical progression and atrophy correlated with the amount of brain inflammation in the pretreatment phase but occur in the absence of ongoing disease activity. The reduction in brain inflammation was associated with alteration in the immune response from a Th-1 pattern of cytokine release but, unexpectedly, this exposed autoimmune thyroid disease in one-third of patients. This drug is in phase II trials.

These observations support the hypothesis that inflammation is necessary for new lesion formation and conditions axon degeneration. The implication is that immunological therapies will best prevent progression of disability if given early in the course and before the cascade of events leading to axon degeneration is irretrievably established. This may explain the present limitations of immunotherapy in patients with secondary progressive multiple sclerosis but raises the dilemma of exposing individuals who may never develop disabilities from multiple sclerosis to the unpredictable hazards of prolonged immunosuppression.

Central pontine myelinolysis

Central pontine myelinolysis is associated with metabolic disturbances induced by alcohol with and without Wernicke's encephalopathy, non-alcoholic cirrhosis, Wilson's disease, following hepatic transplantation, as a complication of uraemia and haemodialysis, after prolonged vomiting, and in the context of diuretic therapy. In each of these situations, affected individuals have usually been hyponatraemic before the onset of neurological symptoms. Central pontine myelinolysis seems to result from overzealous correction of a low (and occasionally also a high) serum sodium. Demyelination correlates both with the degree of hyponatraemia and rate at which this is corrected; starting levels of less than 110 mmol/l or rates of correction of more than 2 mmol/l per hour substantially increase the risk of central pontine

myelinolysis. Rapid changes in sodium are better tolerated in acute than chronic hyponatraemia.

The illness affects central pontine pathways and spreads centrifugally. The fully evolved clinical picture is of flaccid paralysis with facial and bulbar weakness, disordered eye movements, loss of balance, and altered consciousness. Features of hyponatraemia, such as epilepsy, are not usually present since pontine demyelination follows correction of the serum sodium. The recent literature emphasizes the extrapontine manifestations including movement disorders and other features of extrapyramidal disease. The clinical features are distinctive and present no diagnostic difficulties unless the reduction in serum sodium has been overlooked; the acute changes of central pontine myelinolysis can be imaged and abnormalities persist after clinical recovery. Prognosis depends on the underlying metabolic disorder. With stabilization of the serum sodium and management of bulbar failure, neurological recovery is often complete and the condition does not recur spontaneously.

Childhood and adult-onset leucodystrophies

The leucodystrophies are characterized by non-inflammatory demyelination. They include a heterogeneous group of conditions. Increasingly, these are being shown to result from mutations affecting genes which determine the synthesis, maintenance, and structure of myelin. Although rare even in paediatric practice, these need to be considered in young adults with atypical syndromes combining physical and intellectual deficits, sometimes with peripheral nerve involvement, in whom imaging shows confluent lesions confined to white matter.

Diffuse sclerosis (Schilder's disease)

The term diffuse cerebral sclerosis was originally used to identify a heterogeneous group of diseases affecting cerebral white matter. Of the diseases previously classified under this heading, familial sudanophilic diffuse sclerosis, Pelizaeus–Merzbacher disease, Krabbe's diffuse sclerosis (globoid cell leucodystrophy), Canavan's diffuse sclerosis (spongy degeneration of the white matter), Alexander's disease, and metachromatic leucodystrophy are dysmyelinating leucodystrophies. Conversely, Binswager's subcortical encephalopathy is now considered a consequence of diffuse cerebral arteriosclerosis—although some cases may have been examples of CADASIL; and Balo's concentric sclerosis is now considered within the spectrum of multiple sclerosis. Many male patients previously classified as having diffuse sclerosis were probably suffering from adrenoleucodystrophy. Some of the relapsing disorders were probably Leigh's disease associated with mutations of mitochondrial DNA. But even after separating these newly recognized conditions, the nosological status of diffuse sclerosis remains uncertain and some consider that, between them, acute childhood multiple sclerosis and adrenoleucodystrophy account for all the cases.

Krabbe's disease

Globoid cell leucodystrophy usually presents as an early infantile disorder. Late-onset globoid cell leucodystrophy is uncommon—almost all patients becoming symptomatic before the age of 5 years and so almost never leading to confusion with childhood multiple sclerosis. The clinical picture is dominated by behavioural changes with startle, progressive intellectual and motor deterioration, epilepsy, visual failure, and peripheral neuropathy leading to severe disabilities; pyrexia and other autonomic features usher in the onset of a vegetative state. Visual evoked potentials are delayed and the spinal fluid has a raised protein level but does not contain oligoclonal bands. MRI shows periventricular lesions subsequently extending into extensive white matter changes. The deficiency of a-galactocerebrosidase, best demonstrated in peripheral blood leucocytes or skin fibroblasts, leads to the accumulation of galactocerebroside, the neurotoxic molecule psychosine, and the myelin-laden macrophages or globoid cells.

Adrenoleucodystrophy

An important group of disorders is characterized by deposition of saturated fatty acids in the brain and other lipid-containing tissues as a result of defective very-long-chain fatty acyl-CoA synthetase activity in peroxisomes. The molecular defect may result from failure of the adrenoleucodystrophy gene product to anchor very-long-chain fatty acids into the peroxisomal membrane or translocate these into peroxisomes.

Four related syndromes share this biochemical abnormality: childhood adrenoleucodystrophy and adult-onset adrenomyeloneuropathy are X linked; neonatal adrenoleucodystrophy and Zellweger's syndrome are autosomal recessive disorders.

X-linked childhood adrenoleucodystrophy presents with behavioural disturbance, dementia, and epilepsy followed by involvement of special senses and motor systems. Although a significant proportion of children later develop adrenal insufficiency, Addison's disease may precede the neurological manifestations by several years. Treatment has been proposed with a dietary supplement containing a 4:1 mixture of glyceryl trioleate and trieructate, popularly known as Lorenzo's oil. This lowers the plasma levels of very-long-chain fatty acids, but does not appear to influence the phenotype in individuals with established neurological disease, although there may be a prophylactic role. Bone marrow transplantation is successful in early symptomatic cases and, in view of the inflammatory reaction, trials of immunosuppression are in progress.

Adrenomyeloneuropathy presents in adult men with spastic paraparesis and sensory loss in the legs; attention is drawn to an unusual cause for this otherwise common neurological problem by the associated peripheral neuropathy, but the diagnosis is frequently overlooked if adrenal insufficiency is not obvious at presentation. Identification of the peroxisomal defect in easily sampled body tissues has led to the description of cases with obscure clinical manifestations; these include focal cerebral lesions, Kluver–Bucy syndrome, dementia, and spinocerebellar degeneration. Mild spastic paraparesis with sphincter involvement and peripheral neuropathy may occur in obligate heterozygote female carriers with elevated very-long-chain fatty acids. The gene has been mapped to Xq28, close to that for glucose-6-phosphate dehydrogenase deficiency and colour blindness.

Autosomal recessive adrenoleucodystrophy presents in infancy with seizures, hypotonia, retardation, retinal degeneration, and hepatic involvement; females are more commonly affected than males. Although the clinical manifestations and mode of inheritance are similar in neonatal adrenoleucodystrophy and Zellweger's syndrome, these are thought to be separate disorders.

The sensitivity and specificity of routine assays for very-long-chain fatty acids show that the level of hexasanoic acid and its ratios to tetrasanoic and docosanoic acids are fully discriminating in homozygote males, irrespective of the clinical phenotype, from the day of birth if dietary supplements have not been given, providing an opportunity for mass screening; there is a false-negative rate of 15 per cent for heterozygotes.

Metachromatic leucodystrophy

The separation of metachromatic leucodystrophy from the heterogeneous group of diffuse sclerosis occurred when metachromatic material was first detected in urinary deposits. It subsequently became clear that the diagnosis can be confirmed by demonstrating increased urinary sulphatide excretion with a deficiency of arylsulphatase A in urine, peripheral blood leucocytes, and skin fibroblasts, or showing metachromatic material in peripheral nerve biopsies having segmental demyelination and remyelination. There is diffuse white matter involvement due to non-inflammatory demyelination with loss of oligodendrocytes, axon preservation, and reactive astrocytes which, together with macrophages, contain the metachromatic material, especially in the most extensively demyelinated areas.

The clinical phenotype varies with the amount of surviving arylsulphatase A depending on heterozygosity of the mutant allele; pseudodeficiency refers to those individuals with low levels of arylsulphatase A that are sufficiently high not to display a clinical phenotype. Some affected individuals have a genetic defect of the arylsulphatase A activator and this is associated with a more complex pattern of sphingomyelin storage, biochemically and in terms of the tissue distribution.

The most common form of metachromatic leucodystrophy develops in late infancy with delayed walking due to the neuropathy, which may be painful. There are also features of brainstem involvement and the emergence of diffuse upper motor neurone signs with reduced intellectual development, optic atrophy, and death within about 5 years from presentation. In later-onset childhood cases, after several years normal development, there are behavioural changes with poor school performance, anticipating cerebellar and upper motor neurone disability which then follows much the same course as in younger patients, although with less evidence for neuropathy. The early adult form of metachromatic leucodystrophy is rare, or perhaps seldom diagnosed, and tends to present with intellectual or emotional abnormalities. Onset with dementia and behavioural disorders is usual with ataxia, paralysis, and optic atrophy only developing at late stages; the presentation is occasionally with paraparesis or cerebellar ataxia and the condition can then more easily be mistaken for multiple sclerosis. Clinical evidence for peripheral neuropathy may be revealed by slowed nerve conduction. Treatments have included dietary manipulation with reduced vitamin A and sulphur-containing substances, and bone marrow transplantation, but the successes are limited.

Multiple sulphatase deficiency combines the features of metachromatic leucodystrophy with mucopolysaccharidosis. It also has neonatal, early childhood, and juvenile forms. The pattern of combined motor and mental regression or lack of development reflecting widespread dysmyelination with peripheral neuropathy is associated with dysmorphic features and organomegaly. The more severe phenotype also reflects extensive neuronal loss due to the combination of stored sulphatide, sulphated steroids, and mucopolysaccharides. The enzyme defects are complex involving many sulphatases including arylsulphatase A.

Pelizaeus–Merzbacher disease

The three phenotypes of X-linked Pelizaeus–Merzbacher disease usually present in childhood. The clinical features which may distinguish the otherwise ubiquitous motor and developmental delay with epilepsy are abnormal eye movements, dystonia and choreoathetosis, and laryngeal paralysis. Affected individuals often stabilize with severe disabilities and live into early adult life. Some cases do not manifest until early adult life, but here the blur with specifically different disorders becomes more apparent. MRI either fails to show myelin or depicts myelin which is immature with an atrophic brain.

The molecular defect is a mutation of the gene for proteolipid protein (encoded on X-q21.2). Proteolipid protein is normally involved in stabilizing the lamellar structure of central myelin. Over 30 mutations have been described resulting in expression of truncated forms of proteolipid protein sufficient to cause extensive oligodendrocyte loss and failure of myelination. The pedigree is not always X linked in the early-onset connatal form and, in these situations, a genetic defect other than proteolipid protein mutation is presumably involved.

Adult-onset dominant leucodystrophies

Forms of dominantly inherited leucodystrophy also occur exclusively in adults and may closely resemble chronic progressive multiple sclerosis. MRI shows diffuse, non-discrete, white matter disease and there are no oligoclonal bands in the spinal fluid. It remains uncertain whether all the adult-onset dominant leucodystrophies are one and the same disorder, and many are difficult to distinguish from the heterogeneous group of hereditary spastic paraplegias. The various phenotypes are gradually being classified as their biochemical and genetic defects are characterized. A family with spastic paraparesis, ataxia, and mild dementia presenting in adulthood, but with onset in childhood, has been described; diffuse white matter abnormalities were present on cerebral magnetic resonance, whereas pathognomic features of the other leucodystrophies were absent. The most recent addition to this group involves two siblings with behavioural abnormalities progressing to dementia with extensive white matter abnormalities on MRI in whom brain biopsy showed glycolipid inclusions in macrophages unlike any other lysosomal storage disease.

24.17 Disorders of the neuromuscular junction

David Hilton-Jones and Jackie Palace

Introduction

Two fundamentally different pathological processes are associated with disease at the neuromuscular junction. First, acquired disorders in which autoantibodies are directed against nerve or muscle ion channels. Second, and much rarer, inherited conditions in which the defect may be pre- or postsynaptic. These acquired and inherited conditions share some symptomatology. The most important are the autoimmune diseases: myasthenia gravis, the Lambert–Eaton myasthenic syndrome, and acquired neuromyotonia—disorders for which therapy is available.

The pharmacological and neurophysiological complexities of the neuromuscular junction can be simplified to a level that permits ready understanding of the pathogenesis and treatment of these various conditions and will reduce the frequency of misdiagnosis and/or mismanagement.

Neuromuscular transmission

Anatomically there are three main components to the neuromuscular junction (Fig. 1). The presynaptic component is the motor nerve terminal, which contains packages (quanta) of acetylcholine, each of which contains several thousand molecules of acetylcholine. This is separated from the postsynaptic acetylcholine receptors, which sit atop the terminal expansions of the junctional folds of the muscle fibre membrane, by the synaptic space. The nerve fibre membrane contains voltage-gated sodium, potassium, and calcium channels. Voltage-gated sodium channels are also present postsynaptically, at the base of the clefts of the junctional folds.

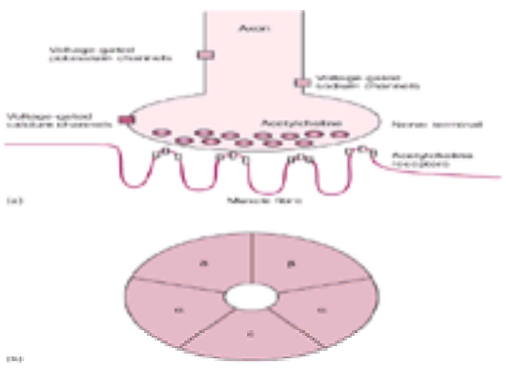

Fig. 1 (a) VGNC, voltage-gated sodium channel; VGCC, voltage-gated calcium channel; VGKC, voltage-gated potassium channel; ACh, acetylcholine. (b) Cartoon of the organization of the subunits of the nicotinic acetylcholine receptor (see text).

The nicotinic acetylcholine receptor is a pentameric structure composed of four different subunits—a, b, g, and † in fetal muscle, and a, b, e, and † in adult muscle. It is configured to produce a central ion channel. Structurally and functionally there are similarities to voltage-gated ion channels, but the acetylcholine receptor is a ligand-gated channel, the ligand being acetylcholine.

Depolarization of the motor nerve terminal is dependent upon voltage-gated sodium channels. Repolarization is the result of inactivation of these sodium channels and opening of voltage-gated potassium channels. During depolarization, voltage-gated calcium channels open—the influx of calcium ions into the nerve terminal triggers release (by exocytosis) of quanta of acetylcholine.

The acetylcholine binds to the a-subunits of the acetylcholine receptors. This alters the conformation of the channel allowing cations (mainly sodium) to enter the muscle fibre. This influx generates the end-plate potential, which in turn activates voltage-gated sodium channels. These trigger the action potential which is propagated through the muscle fibre and initiates contraction. Spontaneous release of individual quanta of acetylcholine, as opposed to mass release triggered by a nerve action potential, gives rise to miniature end-plate potentials, which can be recorded by microelectrode. These are of insufficient amplitude to trigger an action potential in the muscle fibre membrane.

The action of acetylcholine on acetylcholine receptors is terminated by the hydrolysis of acetylcholine by the enzyme acetylcholinesterase, which is anchored to the basal lamina by a collagen-like molecule, ColQ.

The acquired myasthenic disorders are associated with antibodies directed against one of the ion channels (Table 1). That there are three autoimmune disorders known to affect such a small region may be explained by the fact that the neuromuscular junction, unlike the peripheral nerves, is not contained within the blood–nerve barrier, which stops just short of the nerve terminal, and is thus potentially exposed to immune-mediated attack. The inherited disorders may affect presynaptic processes (acetylcholine resynthesis, packaging, or release), acetylcholinesterase binding, or postsynaptic function (point mutations in acetylcholine

receptor subunits). Pathogenetic mechanisms are considered in more detail when discussing individual disorders.

Myasthenia gravis

This is by far the most common of the conditions to be discussed in this section and responds favourably to treatment. In general, over 90 per cent of patients can be returned to normal function, although in most this represents a pharmacological remission and the patient remains dependent on treatment.

Epidemiology

All ethnic groups are affected. The annual incidence is about 4 per million population, and the prevalence about 8 per 100 000. All ages may be affected. Overall, women are more frequently affected, in a ratio of about 3:2. The female bias is even more marked in younger-onset cases, whereas over the age of 50 years male cases predominate. A rather different pattern is seen in people of Asian origin; prepubertal onset is very common, the disease is often purely ocular, and there is a strong association with HLA DRw9.

Pathogenesis

The fundamental disorder in myasthenia gravis is loss of functional acetylcholine receptors consequent upon binding of anti-acetylcholine receptor (**anti-AChR**) antibodies. IgG class antibodies can be detected, by the standard assay used for diagnostic purposes, in 85 per cent of patients with generalized myasthenia and about one-half of those with purely ocular myasthenia (so-called seropositive cases). Antibodies mostly bind to the main immunogenic region of the a-subunits of the acetylcholine receptor. Patients who do not have antibodies detected by this assay are called seronegative. However, there is overwhelming evidence even in these patients that their disease is immune mediated, possibly by IgG antibodies that bind to other regions within the end-plate area or to other IgM class antibodies; their clinical characteristics are similar to seropositive patients, they respond to plasma exchange and immunosuppressant therapy, their plasma can induce neuromuscular transmission dysfunction when injected into animals, and the infants of such mothers may be born with neonatal myasthenia (see below) indicating transplacental transfer of a humoral component.

Loss of functional acetylcholine receptors by antibody binding is due to complement-mediated lysis, acceleration of internalization and degradation, and blocking of acetylcholine binding. Morphological consequences include widening of the synaptic cleft and a marked reduction of the postsynaptic folds of the muscle fibre membrane.

Although the efferent limb of the immune response, described above, has been reasonably well characterized, numerous questions remain to be answered about the afferent limb. Susceptibility to myasthenia gravis is associated with particular immune response genes, with correlation to different haplotypes relating to the age of onset of the disease. These observations are not of immediate relevance to routine clinical practice. In contrast, knowledge about involvement of the thymus is relevant to classification and management.

In early-onset, seropositive patients there is hyperplasia of the thymic medulla, with germinal centres surrounded by a T-cell zone. The acetylcholine receptor is expressed on thymic myoid cells and there is enrichment of acetylcholine receptor-specific T cells. In addition, the thymus has a key role in the process of inducing immune tolerance, by removal of self-antigen T-cell clones. On the basis of these observations, and the beneficial response to thymectomy, there seems little doubt that the thymus is involved in the pathogenesis of myasthenia gravis, but exactly how has yet to be elucidated. Identification of the mechanism may well be important in developing immune-specific treatment.

In late-onset cases and seronegative patients, the thymus is typically normal or atrophic, although some pathological changes have been noted.

Thymomas occur in about 10 per cent of cases. They are locally invasive (notably affecting the pleura and pericardium) and may seed within the pleural cavity. These patients are almost invariably seropositive. Surgical excision is required because of local tumour invasiveness, but in contrast to those patients with thymic hyperplasia, this does not usually ameliorate the myasthenic symptoms.

Based on the presence or absence of antibodies detected by the routine clinical assay and the state of the thymus gland, four main subgroups of patients can be identified (Table 2). Penicillamine-induced myasthenia, which generally recovers following drug withdrawal, is clinically similar to the idiopathic disease and the patients are seropositive.

Clinical features

Myasthenia gravis causes skeletal muscle weakness but the most characteristic feature is fatiguability. The term fatigue causes some confusion because it may have different meanings to a clinician, physiologist, and lay person. Thus, the fatigue of chronic fatigue syndrome is quite different from that of myasthenia. Simply, fatigue in myasthenia gravis manifests itself by increasing, demonstrable weakness precipitated by repeated or sustained muscular activity. Symptoms fluctuate from day to day and week to week, which may in part explain the common delay in diagnosis and suspicions as to its genuineness. Other factors which can exacerbate the weakness include heat, emotional factors, menstruation, intercurrent infections, and drugs that interfere with neuromuscular transmission (aminoglycoside antibiotics, quinine, quinidine, b-blockers, procainamide, and neuromuscular-blocking drugs related to anaesthesia).

In over one-half of patients the presenting symptoms relate to extraocular muscle weakness (diplopia and ptosis); these muscles will be involved in over 90 per cent of patients at some stage during the disease. The next most frequent presentation is with limb-girdle weakness. Typically, as the disease worsens, the weakness spreads from the extraocular muscles to the lower facial and bulbar muscles (causing dysarthria and dysphagia), to the neck, and then to the limbs. However, there are many variations on this theme. A relatively common presentation in older patients, typically men, is with selective weakness of neck extension—as they walk their head drops forwards and they arrive in the clinic holding up their head with a hand under the chin. Relatively selective weakness of finger extension and abduction is common.

On examination, weakness may or may not be evident—fatigue can be demonstrated in limb muscles, but is often most striking around the eyes and with respect to bulbar muscles. Fatiguable ptosis is a striking sign (Fig. 2). As the patients give their history, the fatigue of bulbar muscles may be revealed by increasing dysarthria. A potentially misleading sign is 'pseudo-internuclear ophthalmoplegia', which may be bilateral—failure of adduction due to weakness of the medial recti. Eye movements may show striking fatigue. With increasing severity, the weakness at rest may be so marked that it is difficult to demonstrate fatigue. Respiratory muscle weakness may be out of proportion to limb weakness—it is best assessed by measuring the vital capacity (not peak flow), and the effects of it by monitoring oxygen saturation. Muscle wasting is only seen in undertreated patients with long-established disease. The tendon reflexes are normal, and indeed often rather brisk. There are no abnormal sensory signs.

Fig. 2 Fatiguable ptosis in myasthenia gravis.

There is an increased incidence of other autoimmune diseases, particularly thyroid disease (about 3 per cent of patients) and less frequently rheumatoid arthritis, systemic lupus erythematosus, polymyositis, Lambert–Eaton myasthenic syndrome, and acquired neuromyotonia.

Natural course

This is very variable. In some patients the disorder remains confined to the extraocular muscles (ocular myasthenia gravis). If that is the case for more than 2 years, and particularly if the patient is seronegative, the development of generalized disease is unlikely. Older studies, before the introduction of immunosuppressive therapies, suggest that the disease reaches maximum severity within 7 years. In one study, the interval between onset and the first episode of maximal weakness ('myasthenic crisis') was less than 36 months in over 80 per cent of patients. Permanent, spontaneous remission occurs, but is rare—in the order of 1 per cent per annum. On the other hand, particularly early in the course of the disease, there may be protracted periods of spontaneous remission, sometimes lasting several years.

Diagnosis

This is based on the clinical picture, supported by appropriate laboratory results. For practical purposes, the presence of anti-AChR antibodies is confirmatory and no further diagnostic investigations are required. In seronegative patients, electromyography and the intravenous edrophonium (Tensilon®) test are helpful. Although the edrophonium test has a long pedigree and sound pharmacological basis (it is a short-acting cholinesterase inhibitor), there are concerns about its use, particularly by the inexperienced. The patient is given 600 µg of atropine intravenously—this blocks the potentially unpleasant muscarinic effects of the edrophonium and also acts as a single-blind placebo for the patient. The test dose of 2 mg of edrophonium follows, which in some patients is sufficient to give a diagnostic response. If not, a further 8 mg of edrophonium is given. There must be an easily assessable measure of improvement—most commonly degree of ptosis. The test is therefore likely to be of most use in patients with purely ocular symptoms and signs. Rarely, cardiorespiratory collapse may occur. False-negative and false-positive results are not uncommon.

The conventional electromyographic measure for diagnosing myasthenia gravis is the demonstration of a decremental response of the compound muscle action potential in response to repetitive nerve stimulation at 3 Hz. More sensitive, but not specific and only available in specialist centres, is the presence of increased jitter and blocking, as assessed by single-fibre electromyography.

The presence of a thymoma is best assessed by computed tomography or magnetic resonance imaging of the thorax.

Differential diagnosis

There are few difficulties in the presence of extraocular muscle involvement and readily demonstrable fatigue, although there can be confusion with the Lambert–Eaton myasthenic syndrome and the congenital myasthenic syndromes. Diagnostic difficulties can occur when, as occasionally happens, eye signs and fatigue are absent. Amyotrophic lateral sclerosis with little wasting may be suspected. Conversely, in long-established myasthenia, muscle wasting may be misleading. More difficult is seronegative, purely ocular myasthenia—the most important differential diagnosis is mitochondrial cytopathy, in which increased jitter may also occur. Other diagnoses to consider include oculopharyngeal muscular dystrophy and thyroid ophthalmopathy.

Botulism, caused by food poisoning, an infected wound, or clostridial overgrowth in the gastrointestinal tract in infants, may need to be considered. Features of autonomic malfunction are usually present.

Treatment

As noted, thymomas require excision, but this in itself will not improve the myasthenia. Management of patients with thymic tumours follows the same guidelines given below.

Anticholinesterase drugs, by reducing acetylcholine breakdown, give symptomatic improvement in most patients, and may be sufficient in those with very mild disease. Pyridostigmine is the drug of choice, given orally four or five times daily, starting at 30 mg per dose and increasing if required to 60 mg. Abdominal cramping is a common side-effect, relating to muscarinic overstimulation, and responds to propantheline, ideally taken 30 min before each dose of pyridostigmine. If an adequate response is not obtained at this dose, then further increases should not be made and other forms of therapy should be considered. The management of ocular myasthenia differs somewhat from the generalized form of the disease, the latter also depending upon age of onset and antibody status.

Ocular myasthenia

If anticholinesterase drugs have given an inadequate response, alternate-day prednisolone therapy should be introduced. A suitable starting daily dose is 5 mg, increasing by 5 mg every fourth dose (or weekly) until an adequate response has been obtained (often, for an adult, a dose of around 30 mg) or a maximum acceptable dose (around 0.75 mg/kg body weight) has been reached. Once remission has been achieved, the pyridostigmine can be withdrawn, and then the prednisolone reduced slowly— initially by 5 mg per month, but when down to 20 mg by as little as 1 mg, each month). Azathioprine may be added if there is an inadequate response or the minimal effective dose of prednisolone is deemed to be unacceptably high. Ocular muscle surgery can be beneficial if there is a poor or incomplete response to treatment and if the defect appears to be fixed.

Early-onset, seropositive myasthenia

Many, but not all, of these patients benefit from thymectomy. Up to one-third enter remission, and a further one-half improve. These benefits are occasionally rapid, but more typically develop over the following 1 to 2 years, possibly longer. The conventional approach is through a sternal split. There is concern that less invasive surgical procedures risk leaving behind thymic remnants which will negate the benefits of the operation. Thymectomy should be performed in centres experienced in such surgery and with the support of appropriately trained anaesthetists and neurologists.

For those patients who do not respond adequately to anticholinesterase drugs and thymectomy, immunosuppression with prednisolone and azathioprine is indicated. A controlled trial has shown the benefits of the addition of azathioprine (2.5 mg/kg body weight per day)—the starting dose is 25 or 50 mg daily, increased by 25 or 50 mg daily, each week (or more rapidly as an in-patient) until the target dose is reached. During introduction, weekly tests of full blood count and liver function are required. When established, testing can be reduced gradually to 3-monthly. Introduction of prednisolone may exacerbate myasthenic weakness and should generally be done in hospital. The starting dose is 10 mg on alternate days, increasing by 10 mg per dose until the patient reaches the target dose of 1 to 1.5 mg/kg body weight per dose. When remission has been achieved the dose is slowly reduced, as for ocular myasthenia, until the minimal effective dose has been established.

For those who do not respond to, or are intolerant of, prednisolone and/or azathioprine, other immunosuppressant drugs such as cyclosporin, methotrexate, or cyclophosphamide may be used.

Late-onset and seronegative myasthenia

Although not formally assessed, it appears that these patients do not benefit significantly from thymectomy. Most respond to the immunosuppressant regime described above.

Myasthenic crisis

Intubation and assisted ventilation may be required. Plasma exchange and intravenous immunoglobulin may both lead to a rapid improvement (within 1 to 2 weeks) in strength, but the beneficial effects start to wear off within about 8 weeks. However, this gives useful time in which to establish an immunosuppressant regime, as discussed above.

Plasma exchange and intravenous immunoglobulin are also useful in preparing myasthenic patients for thymectomy and may reduce the likelihood of deterioration

consequent upon the introduction of prednisolone.

Osteoporosis is an important concern in patients receiving long-term, high-dose prednisolone. A bone density determination should be carried out before starting such therapy, and repeated periodically, as appropriate. Local guidelines should be followed—these will advise on general physical measures, assess dietary calcium intake, and indicate the need to introduce calcium/vitamin D or a bisphosphonate, and the place of hormone replacement therapy for postmenopausal women.

Prognosis

The outlook for most patients with myasthenia is good, with over 90 per cent achieving near-normal functional recovery. Death is most likely to occur during a myasthenic crisis early in the course of the disease. The response to thymectomy has been noted. Unwanted effects relating to the immunosuppressant drugs may have an important influence on the outcome.

Myasthenia in pregnancy

Pregnancy has no significant long-term effect on myasthenia, but relapse may be more common in the puerperium. Some 10 per cent of infants born to myasthenic mothers have transient neonatal myasthenia due to transplacental passage of maternal anti-AChR antibodies. Symptoms include feeding and respiratory difficulties, generalized weakness, and less commonly, ptosis. They resolve within a few weeks.

Immunosuppressive treatment should be maintained during pregnancy to ensure good control of the mother's myasthenia and to reduce the likelihood of neonatal weakness.

Much more rarely, the infant is born with arthrogryposis multiplex congenita, secondary to profound intrauterine weakness and lack of movement. This relates to maternal antibodies which target the fetal form of the acetylcholine receptor (see above— Neuromuscular transmission) and in some cases the mother herself has been asymptomatic.

Future research

This may provide a better understanding of the immune processes involved, and thus lead to the development of selective treatments that avoid generalized immune suppression or other unwanted effects of the currently available drugs.

Lambert–Eaton myasthenic syndrome (LEMS)

This is a presynaptic disorder, characterized by limb-girdle weakness and symptoms of autonomic dysfunction, which is often associated with small-cell lung cancer. Delayed diagnosis is common. Symptomatic and immunosuppressant therapies are available.

Epidemiology

Some 60 per cent of patients have cancer-associated LEMS, caused by small-cell lung cancer and the peak presentation is in the fourth to sixth decades. The other 40 per cent have non-cancer-associated LEMS and may present from childhood onwards. It is estimated that 3 per cent of patients with small-cell lung cancer develop LEMS, but that the diagnosis is frequently not made. The weakness is often attributed to non-specific cachectic effects and the disorder is not either suspected or investigated. LEMS may predate the appearance of the cancer by as much as 5 years.

Pathogenesis

Both forms are associated with IgG class antibodies, which reduce the number of functional presynaptic P/Q-type voltage-gated calcium channels by cross-linking adjacent channels. This causes reduced calcium influx and therefore reduced quantal release of acetylcholine. As in myasthenia, patients with LEMS have an increased incidence of other forms of autoimmune disease, including a rare association with acquired myasthenia gravis.

Small-cell lung cancers express voltage-gated calcium channels and it is proposed that the tumour triggers an antibody response to those channels, the antibodies then cross-react with the calcium channels at the neuromuscular junction, causing LEMS.

Clinical features

Most patients present with an abnormality of gait and complain that their legs feel heavy or weak. Symptomatic upper limb weakness tends to present later. Autonomic dysfunction is common, but infrequently volunteered, and includes dryness of the mouth and constipation. In males, impotence may predate limb weakness. Compared with myasthenia gravis, ocular symptoms are rarely severe or particularly troublesome, and bulbar weakness is rare.

On examination, mild ptosis and diplopia may be evident. The abnormality of gait is often more striking than demonstrable weakness when testing on the examination couch. Partly this is because of the phenomenon of postexertional potentiation. Physiologically, with sustained effort there is mobilization of nerve calcium stores and consequently increased quantal release of acetylcholine. Clinically, this augmentation is apparent in two ways. First, strength increases after a few seconds of maximal effort. Second, the tendon reflexes, which are reduced or absent, increase or appear following 10 to 15 s of maximal contraction of the relevant muscle. Sensory testing is normal.

Diagnosis

Single-fibre electromyography, as in myasthenia gravis, shows increased jitter and blocking, and repetitive nerve stimulation studies show decrement at certain frequencies. However, the characteristic neurophysiological finding, which reflects the clinical observations made above, is of a small-amplitude compound muscle action potential which shows potentiation, sometimes enormous, 15 s after voluntary maximal contraction. Diagnosis is confirmed by demonstrating the presence of antivoltage-gated calcium channel antibodies, which are detectable in 95 per cent of cases.

Treatment

Pyridostigmine may offer some symptomatic benefit, but 3,4-diaminopyridine is more effective and the drug of choice (but is only available from specialist centres). 3,4-Diaminopyridine blocks the voltage-gated potassium channels (see Fig. 1), thereby prolonging the duration of the nerve action potential and allows a greater influx of calcium. The maximum dose of 3,4-diaminopyridine is 100 mg daily.

When an associated cancer is unlikely (young patients, non-smokers, more than 5 years since onset and no cancer apparent), treatment with alternate-day prednisolone (up to 1.5 mg/kg body weight per dose) and azathioprine (2.5 mg/kg body weight per day), as in myasthenia gravis, can be highly effective.

In a smoker in whom a cancer is not identified at presentation, it is prudent to repeat chest imaging (CT or MRI) yearly for 5 years.

In cancer-associated LEMS, removal of the tumour often leads to symptomatic improvement. Although there is some reluctance to use immunosuppression in patients with known cancer, alternate-day prednisolone may be used if there has been an inadequate symptomatic response to 3,4-diaminopyridine.

Plasma exchange and intravenous immunoglobulin both give short-term benefit and can be used in cancer-associated and non-cancer-associated LEMS.

Prognosis

In cancer-associated LEMS the prognosis is largely determined by the tumour. In non-cancer-associated LEMS many patients can be rendered symptom free, but

some prove very resistant to treatment.

Congenital myasthenic syndromes

This is a rare group of conditions with an overall prevalence in the order of 1 in 200 000 population. They are genetically determined (usually autosomal recessive—so a history of consanguinity is common), non-autoimmune disorders. Major clinical features include onset in infancy, fatiguable weakness, a decremental response to repetitive nerve stimulation, and absence of anti-AChR antibodies. A significant exception to this generalization is the classic slow-channel syndrome, which may present in infancy or adult life, and is inherited as an autosomal dominant trait. The syndromes may be classified on the basis of the site of the defect of neuromuscular transmission, but this is not always certain. A revised classification is likely to evolve as the molecular basis of each is identified. Diagnosis depends upon electrophysiological tests, morphological studies of the end-plate region in muscle biopsy specimens, and increasingly on identification of the specific genetic defect.

Presynaptic disorders

These are the least well characterized of the myasthenic disorders. They include disorders of acetylcholine resynthesis or packaging (previously known as familial infantile myasthenia, now called congenital myasthenic syndrome with episodic apnoea), and a recently described condition with paucity of synaptic vesicles with reduced quantal release. Symptoms respond to anticholinesterase drugs. The episodic apnoea syndrome has recently been shown to be caused by choline acetyltranasferase mutations.

H4>End-plate acetylcholinesterase deficiency

Fatiguable weakness is usually evident from birth. A single nerve stimulus may give rise to a repetitive compound muscle action potential response. The molecular basis is a mutation within the ColQ polypeptide gene. ColQ anchors acetylcholinesterase to the basal lamina. In the absence of the enzyme the acetylcholine receptors have a prolonged exposure to acetylcholine. Anticholinesterase drugs, not surprisingly, are ineffective. No specific treatments are available.

Postsynaptic disorders

These disorders are associated with mutations in the genes that encode the acetylcholine receptor subunits. They may affect the number of receptors or the kinetic properties of the central ion channel.

The most common in the United Kingdom is acetylcholine receptor deficiency, which is most frequently caused by mutations in the e-subunit gene. Presentation is at birth or within the first few years of life. There is generalized weakness, delayed motor milestones, feeding difficulties, and extraocular muscle involvement. There is a good response to anticholinesterase drugs and 3,4-diaminopyridine.

The low-affinity, fast-channel syndrome is phenotypically similar to acetylcholine receptor deficiency and may be associated with a-, †-, or e-subunit mutations. The mechanism is altered kinetics of the receptor ion channel.

The slow-channel syndrome is also a kinetic disorder, associated with mutations in different subunits and in different domains within those subunits. It is an autosomal dominant disorder with variable penetrance that may not become symptomatic until adult life or may remain subclinical. It tends to be progressive and characteristically produces weakness of periscapular muscles and of finger extensors. As in end-plate acetylcholinesterase deficiency, electromyography may show a repetitive response to a single nerve stimulus. Anticholinesterase drugs are unhelpful, but quinidine may be beneficial.

Neuromyotonia

This term describes a condition in which peripheral nerve overactivity leads to spontaneous muscle activity. It is thus quite different from classic myotonia, which relates to an abnormality of muscle fibre membrane activity. Neuromyotonia may be seen in association with a variety of inherited disorders (notably neuropathies and spinal muscular atrophy), but the commonest form is acquired. The acquired form may be idiopathic, but recognized associations include tumour (thymoma—sometimes also in association with myasthenia gravis; bronchial carcinoma) and acquired demyelinating polyneuropathies. Most acquired cases are autoimmune in origin and relate to the presence of antibodies directed against voltage-gated potassium channels in the peripheral nerve (Fig. 1), for which an assay is now available. As noted above, activation of these channels is an important factor in nerve repolarization—the symptoms of neuromyotonia can be understood in terms of prolonged depolarization and excessive release of acetylcholine.

The main clinical features are muscle stiffness, cramps, and twitching (myokymia), which may be localized or generalized. Voluntary muscle contraction may precipitate or exacerbate the abnormal activity. The myokymia persists during sleep and general anaesthesia. Additional symptoms include peripheral paraesthesias and excess sweating, and rarely, mood change, disturbed sleep, and hallucinations.

Apart from the muscle twitching (which may be confused with the fasciculation of denervation), physical examination may be normal. Mild weakness may be evident, proximally or distally. In long-standing cases, muscle hypertrophy (simply a form of work hypertrophy) may be present. Tendon reflexes may be reduced.

Electromyography shows highly characteristic, and diagnostic, doublet, triplet, or multiplet motor unit discharges, or periods of continuous motor unit discharge, with a high (up to 300 Hz) intraburst frequency. Fibrillation and fasciculation potentials may also be seen. Further confirmation of the diagnosis comes from antivoltage-gated potassium channel antibody assay, which is positive in about 50 per cent of cases using the currently available assay. Chest imaging should be considered to exclude thymoma and bronchial carcinoma.

Most patients gain symptomatic relief from carbamazepine, phenytoin, or lamotrigine. If the benefit is insufficient, immunosuppression with prednisolone and azathioprine is often helpful. Intractable cases may respond to plasma exchange and intravenous immunoglobulin.

24.18 Paraneoplastic syndromes

Jerome B. Posner

Introduction

The term paraneoplastic syndrome refers to disorders of an organ or tissue caused by cancer but occurring at a site distant from the tumour or its metastases. Organs or tissues commonly involved include the skin (for example paraneoplastic pemphigus), the endocrine system (for example paraneoplastic hypercalcaemia or paraneoplastic Cushing's syndrome), and the central and peripheral nervous system. The nervous system can be damaged directly or the damage may be indirect, such as when paraneoplastic hypercalcaemia or paraneoplastic Cushing's syndrome causes secondary nervous system dysfunction. Table 1 lists paraneoplastic syndromes involving the central and peripheral nervous system. Only the direct paraneoplastic syndromes are discussed here. More extensive reviews of paraneoplastic syndromes and other effects of systemic cancer on the nervous system can be found in the further reading section.

Incidence

Neurological examination of patients with cancer often reveals mild abnormalities such as proximal leg weakness or diminished Achilles reflexes. Most of these mild, usually subclinical, abnormalities result from metabolic or nutritional disturbances associated with advanced cancer. These disorders are not usually classified as paraneoplastic syndromes. In fact, most paraneoplastic syndromes occur in patients not known to have cancer at the time the neurological symptoms develop. Furthermore, most paraneoplastic syndromes are significantly disabling. If one limits oneself to 'true paraneoplastic syndromes' as indicated in Table 1, the disorders are rare. In one series of almost 1500 patients, only 3 had paraneoplastic cerebellar degeneration, and none had subacute sensory neuronopathy. With the exception of the Lambert–Eaton myasthenic syndrome (**LEMS**), a disorder that affects about 3 per cent of patients with small-cell lung cancer, paraneoplastic syndromes probably affect fewer than 1 per cent of patients with cancer.

Despite their low incidence, paraneoplastic syndromes are important for several reasons.

1. They usually develop before the cancer has been identified and so their presence may lead to the detection of small and potentially curable cancers.
2. Certain paraneoplastic syndromes characterized by specific autoantibodies suggest a specific cancer site.
3. The paraneoplastic syndrome is often more disabling than the cancer and may, in some instances, be the cause of death.
4. A paraneoplastic syndrome or an antibody associated with a paraneoplastic syndrome (see below) may predict an indolent course for the cancer.
5. The presence of specific antibodies in the serum of patients with a paraneoplastic syndrome identifies the neurological disorder as paraneoplastic and, as indicated above, sometimes strongly suggests the location of the underlying tumour.
6. Paraneoplastic antibodies identify proteins normally restricted to neurones that are of importance in the development and maintenance of neurones.

Pathogenesis

Current evidence suggests that paraneoplastic syndromes affecting the nervous system result from an autoimmune reaction to the tumour: protein antigens that are normally restricted to the nervous system are expressed in some cancers. The immune system recognizes the antigen in the cancer as foreign and some patients mount an immune response. The immune response has the dual effect of retarding the growth of the tumour but damaging those portions of the nervous system that express the antigen. A few of these so-called paraneoplastic antigens are normally expressed not only in the nervous system but also in the testis which, like the nervous system, is an immunologically privileged site. The best evidence for an immune-mediated mechanism comes from studies of the LEMS. Voltage-gated calcium channel proteins are found in all small-cell lung cancers. Some patients develop antibodies against these proteins. The antibodies react with voltage-gated calcium channels found in the presynaptic neuromuscular junction to prevent calcium from entering the junction, which in turn prevents the release of acetylcholine. The decreased release of acetylcholine causes the weakness that characterizes the syndrome. If one removes the antibody from the patient by plasma exchange, the patient's symptoms improve. If one injects experimental animals with the antibody from the patient, the syndrome is reproduced.

Evidence of immune-mediated mechanisms in most other paraneoplastic syndromes is less firm. However, several lines of evidence suggest that immune-mediated mechanisms are also pathogenetic in syndromes involving the central nervous system.

1. In some but not all patients with a paraneoplastic syndrome, the serum and cerebrospinal fluid contain high titres of autoantibodies that react with both tumour and those portions of the nervous system damaged by the paraneoplastic syndrome.
2. The titre of the antibody relative to total IgG is higher in cerebrospinal fluid than in serum.
3. In some patients, T-cell infiltrates of limited T-cell receptor families are found in the tumour and the nervous system.
4. One report describes intracellular IgG in the brain of patients who die of a paraneoplastic syndrome.

Several different autoantibodies have been found in the serum of patients with different paraneoplastic syndromes. The antibodies often identify patients with a specific clinical syndrome and with a specific underlying tumour (Table 2). For example, the anti-Yo antibody, which reacts with Purkinje cells of the cerebellum and some ovarian and breast cancers, is almost always associated with the syndrome of paraneoplastic cerebellar degeneration and with breast, ovarian, or other gynaecological cancers. In a few patients, the antibody and the paraneoplastic syndrome have been associated with other cancers, including cancers in men. Conversely, most patients with paraneoplastic cerebellar degeneration associated with non-gynaecological cancers either demonstrate other antibodies that react with Purkinje cells or do not have antibodies identifiable by current techniques. For example, some patients with paraneoplastic cerebellar degeneration express the anti-Hu antibody, an antibody usually associated with small-cell lung cancer and paraneoplastic encephalomyelitis or sensory neuronopathy.

Some autoantibodies are associated with specific tumours but widely varying paraneoplastic syndromes. For example, the anti-Hu antibody is almost always associated with small-cell lung cancer (occasionally neuroblastoma, prostate cancer, or mesenchymal chondrosarcoma), but may be associated with several different clinical syndromes usually encompassed by the term encephalomyelitis. The clinical abnormalities include limbic encephalitis (see below), paraneoplastic cerebellar degeneration, brainstem encephalitis, sensory neuronopathy, and autonomic failure. Some or all of these clinical abnormalities may be found in the same patient.

In some patients with paraneoplastic syndromes no antibodies are found. A good example is opsoclonus/myoclonus associated with neuroblastoma in children. Most observers believe that this paraneoplastic disorder is immune-mediated, articularly because it responds to ACTH. The failure to find an antibody does not mean that one is not present, only that current techniques cannot identify it. Another good example is LEMS. Standard histochemical and immunoblotting techniques cannot identify an antibody; only by the special techniques of electron microscopic histochemistry or immune precipitation can the P/Q type calcium channel antibodies be identified. These findings give some hope that by using better techniques, antibodies may be found in some currently antibody-negative paraneoplastic syndromes.

Diagnosis

Certain clinical clues suggest to the physician that a patient with a neurological disorder may be suffering from a paraneoplastic syndrome. These are summarized in

the following paragraphs.

Most paraneoplastic syndromes evolve subacutely. The disorder usually becomes apparent to the patient within a few days and often within several weeks has reached its peak. A few patients develop symptoms overnight. Occasional patients have a more protracted course, slowly evolving over several months. However, disorders that evolve slowly over many months to years are unlikely to be paraneoplastic.

Most paraneoplastic syndromes stabilize after weeks to months. As indicated above, symptoms usually progress rapidly but the progression usually ceases within several months.

The neurological disorders are usually severe. Most patients have substantial disability by the time they first consult a physician. Mild or waxing and waning neurological disorders are usually not paraneoplastic. For example, the patient with paraneoplastic cerebellar degeneration is usually unable to walk, unable to write, and sometimes because of the oscillopsia associated with nystagmus, unable to read or watch television. Many patients cannot sit unsupported.

The neurological findings are often characteristic. Those disorders are listed in Table 1. A subacutely developing pancerebellar disorder, the rapid development of opsoclonus (see below), or the development of LEMS strongly suggests cancer as the underlying cause. However, none of the syndromes, even the most characteristic, is invariably associated with cancer. Thus, only about two-thirds of patients with LEMS have cancer and only about 15 per cent of patients with myasthenia gravis have a tumour (almost always thymoma). Probably about half of patients with subacute cerebellar degeneration have cancer.

Paraneoplastic syndromes involving the central nervous system are often accompanied by cerebrospinal fluid pleocytosis, elevated protein, increased IgG, and oligoclonal bands. The spinal fluid findings are more likely to be abnormal early in the course of disease and revert to more normal values later on. In particular, the pleocytosis, rarely more than 30 to 40 cells, may be gone within a few weeks of the onset of disease. The immunoglobulin abnormalities usually persist.

Paraneoplastic syndromes often affect one particular portion of the nervous system with additional subtle or minor findings suggesting dysfunction in other areas. For example, paraneoplastic cerebellar degeneration selectively affects Purkinje cells of the cerebellum, causing pancerebellar neurological symptoms. Some patients will also be found to be mildly demented and demonstrate extensor plantar reflexes or sensory changes. These widespread changes have led to the term encephalomyelitis when the central nervous system is involved and neuromyopathy when the peripheral nerves and muscles are involved.

The physician encounters the patient with a paraneoplastic syndrome in one of two settings. In the first, the patient is known to have or have had cancer and then develops a neurological disorder. The cancer may be under active treatment, may have recurred after a remission, or may be assumed to have been cured in the remote past. Because paraneoplastic syndromes are the least common of the neurological complications of systemic cancer (Table 3), the physician must rule out all of the other causes before considering the disorder to be paraneoplastic. Unless a paraneoplastic antibody is found in the serum, the diagnosis is one of exclusion.

In the second setting, the patient is not known to have cancer. The physician must consider if the clinical findings fit a paraneoplastic syndrome (Table 1) and order the appropriate antibody studies (Table 2). Although the presence of a paraneoplastic antibody usually establishes the diagnosis, its absence does not. If an antibody is present and the search for an underlying cancer is negative, the physician is obligated to follow the patient carefully, searching periodically for a cancer.

Treatment

Some paraneoplastic syndromes, such as LEMS, respond to immunosuppression or to treatment of the underlying cancer (Table 4). Some syndromes, such as opsoclonus/myoclonus, may remit spontaneously, but for most paraneoplastic syndromes, treatment is unrewarding and most patients remain with severe neurological disability even if the cancer is cured. Most treatment has involved immunosuppression, particularly for those syndromes associated with autoantibodies. It is possible that the rapid onset of the syndromes does not allow sufficient time for accurate early diagnosis and for treatment to begin before irreversible neural damage has occurred. With earlier diagnosis, therapy may be more successful.

Specific syndromes

Brain and cranial nerves (Table 5)

Paraneoplastic cerebellar degeneration

The disorder may complicate any malignant tumour but is most common with lung cancer (especially small-cell), gynaecological neoplasms, and Hodgkin's disease. Males and females are both affected and the age incidence reflects the age distribution of the cancer. Neurological manifestations precede detection of the associated tumour in over one-half of patients, rarely by up to 4 years. Alternatively, paraneoplastic cerebellar degeneration may develop after diagnosis of the neoplasm. In some instances, the tumour is not found until autopsy. Typically, the disorder begins as gait ataxia that over a few days to months progresses to severe truncal and appendicular ataxia with dysarthria and often nystagmus. The nystagmus is frequently downbeating. Vertigo with or without nausea and vomiting is common and many patients complain of diplopia. The cerebellar signs are bilateral but may be asymmetrical. A more rapid onset within a few hours or days or a slower progression sometimes occurs. The cerebellar deficit usually stabilizes but, by then, the patient is often incapacitated. Spontaneous improvement sometimes occurs, particularly when associated with Hodgkin's disease.

The cerebrospinal fluid may be normal, but early in the illness usually shows a mild pleocytosis. Oligoclonal bands may be present. Cytological examination of the cerebrospinal fluid and contrast-enhanced MRI of the neuraxis rule out leptomeningeal metastases. MR scans typically are normal early, but later show signs of progressive cerebellar atrophy with prominent cerebellar folia and a dilated fourth ventricle.

The pathological hallmark of paraneoplastic cerebellar degeneration is loss of Purkinje cells, affecting all parts of the cerebellum. Less striking changes in the cerebellar cortex may include thinning of the molecular layer with microglial proliferation and astrocytic gliosis, proliferation of Bergmann astrocytes, and slight thinning of the granular layer with decreased numbers of granule cells.

When typical, the clinical picture of paraneoplastic cerebellar degeneration is almost pathognomonic. When atypical, the disorder must be distinguished from a cerebellar tumour (primary or metastatic) and from leptomeningeal metastases (by MRI and cerebrospinal fluid examination, respectively), from late-onset, non-paraneoplastic cerebellar degenerative disorders, cerebellar haemorrhage and infarction, abscess, prion diseases, cerebellar ataxia related to 5-fluorouracil or high-dose cytarabine, and metabolic disorders, especially alcoholic cerebellar degeneration. In alcoholic cerebellar degeneration, the ataxia predominantly involves the lower extremities; dysarthria and nystagmus are unusual.

There have been occasional reports of a partial or near-complete remission of paraneoplastic cerebellar degeneration following treatment of the primary tumour. The presence of ocular flutter or opsoclonus indicates a better chance of improvement, but this may be a different paraneoplastic syndrome (see below). Only rarely is immunosuppression beneficial and most patients do not respond. It is possible that if begun early in the illness, before Purkinje cells are irreversibly damaged, plasmapheresis and immunosuppressive drugs might have a beneficial effect. Symptomatic improvement in the ataxia occurs in a few patients using clonazepam in doses varying from 0.5 to 1.5 mg daily. Buspirone may also give modest relief.

Opsoclonus/myoclonus

Opsoclonus, a disorder of eye movements consisting of almost continuous arrhythmic, multidirectional, involuntary, high-amplitude conjugate saccades that are often accompanied by synchronous blinking of the lids, is a paraneoplastic syndrome complicating neuroblastoma in children and a variety of tumours in adults. Opsoclonus may be an isolated neurological sign, but is often accompanied by myoclonus of the trunk, limbs, head, diaphragm, larynx, pharynx, and palate, and ataxia. When opsoclonus is a paraneoplastic syndrome of adults it may be accompanied by paraneoplastic cerebellar degeneration. Opsoclonus/myoclonus is also associated with viral infections, postinfectious encephalitis, trauma, intracranial tumours, hydrocephalus, thalamic haemorrhage, and toxic encephalopathies from thallium or lithium, amitriptyline overdose, and diabetic hyperosmolar coma. Opsoclonus occurs in about 2 per cent of children with neuroblastomas. Neurological symptoms precede identification of the neuroblastoma at least 50 per cent of the time and the tumour often is not obvious on examination; thus, recognition of the neurological syndrome is an important clue to the presence of a neuroblastoma. When a neuroblastoma is associated with opsoclonus/myoclonus, there is a higher than expected incidence of intrathoracic tumours and of tumours with a benign histology. The prognosis of the neuroblastoma is better if opsoclonus/myoclonus is associated than when there

is no neurological complication, an observation not explained by earlier diagnosis when neurological symptoms are present. The neurological disorder responds to ACTH and to intravenous immunoglobulin but not to prednisone. However, most patients suffer residual neurological damage, usually cognitive.

Opsoclonus/myoclonus is less common in adults. Nevertheless, about 20 per cent of adult patients reported with opsoclonus/myoclonus have an underlying cancer. The neurological symptoms usually precede diagnosis of the tumour and commonly progress over several weeks, although more rapid or slower progression may be observed. Opsoclonus often is associated with truncal ataxia, dysarthria, myoclonus, vertigo, and encephalopathy. The cerebrospinal fluid may show a mild pleocytosis and a mildly elevated protein. The MRI is usually normal, but brainstem abnormalities have been reported.

Neuropathological findings have been variable. In some patients there are no identifiable abnormalities. In others, the changes resembled those of paraneoplastic cerebellar degeneration with a loss of Purkinje cells, inflammatory infiltrates in the brainstem, Bergmann gliosis, and loss of cells from the granular layer of the cerebellum.

The prognosis for recovery or partial remission of the neurological disorder is better for paraneoplastic opsoclonus/myoclonus than it is for paraneoplastic cerebellar degeneration. Improvement may follow treatment of the underlying tumour, and spontaneous partial remissions occur. Remissions have been reported to follow treatment of the tumour or immunosuppressive treatment including immunoadsorptive therapy using a protein A column.

Limbic encephalitis

Limbic encephalitis may occur as an isolated finding or as a more extensive encephalomyelitis. The neurological symptoms often precede diagnosis of the tumour by up to 2 years; sometimes the cancer is not detected until autopsy. Symptoms usually progress over several weeks but the course may be more insidious. Anxiety and depression are common early symptoms, but the most striking feature is a severe impairment of recent memory. Other manifestations include agitation, confusion, hallucinations, partial or generalized seizures, and hypersomnia. Progressive dementia usually occurs, but occasionally there may be a spontaneous remission. The cerebrospinal fluid commonly shows a pleocytosis and an elevated protein concentration. MR scans are usually normal but medial temporal abnormalities have been reported.

Inflammatory pathological changes affect the grey matter of the hippocampus, cingulate gyrus, pyriform cortex, orbital surfaces of the frontal lobes, insula, and the amygdaloid nuclei.

No treatment has proved uniformly beneficial although spontaneous remissions have been reported and some patients have improved after treatment of the underlying tumour.

Brainstem encephalitis

Paraneoplastic brainstem encephalitis is often associated with clinical and pathological evidence of encephalomyelitis elsewhere within the central and peripheral nervous systems, but may occur as the dominant or an isolated clinical finding. It is commonly associated with small-cell lung cancer, but an identical clinicopathological syndrome may be seen in the absence of a malignancy.

The clinical features vary according to the brainstem structures involved in the pathological process. Common manifestations include vertigo, ataxia, nystagmus, vomiting, bulbar palsy, oculomotor disorders, and corticospinal tract dysfunction. Less common clinical features include deafness, myoclonus of the branchial musculature, hypoventilation, and movement disorders including chorea or Parkinson's syndrome.

Neurological symptoms may develop before or after discovery of the malignancy. The pathological changes are identical to those observed in other forms of paraneoplastic encephalomyelitis.

Visual loss

Paraneoplastic syndromes can affect retinal photoreceptors, either rods or cones or both. They can cause a retinal vasculitis or optic neuropathy. Paraneoplastic retinal degeneration, also called cancer-associated retinopathy, usually occurs in association with small-cell cancer of the lung, melanoma, and gynaecological tumours. Typically, the visual symptoms include episodic visual obscurations, night blindness, light-induced glare, photosensitivity, and impaired colour vision. Visual symptoms usually precede the diagnosis of cancer. The symptoms progress to painless visual loss. They may begin unilaterally but usually become bilateral. Visual testing demonstrates peripheral and ring scotomas and loss of acuity. Funduscopic examination may reveal arteriolar narrowing and abnormal mottling of the retinal pigment epithelium. The electroretinogram is abnormal. Cerebrospinal fluid is typically normal, although elevated immunoglobulin levels have been reported. Inflammatory cells are sometimes seen in the vitreous by slit-lamp examination.

Pathologically, a loss of photoreceptors and ganglion cells with inflammatory infiltrates and macrophages is usually noted. The other parts of the optic pathway are preserved, although a loss of myelin and lymphocytic infiltration of the optic nerve may occur.

Treatment of cancer-associated retinopathy is usually unsuccessful although a recent report describes improvement in some patients with the use of intravenous immunoglobulin.

Spinal cord and dorsal root ganglia (Table 6)

Necrotizing myelopathy

This is an extremely rare remote effect of cancer. The initial symptoms of muscle weakness and sensory loss in the arms and legs may be asymmetrical, but eventually signs become bilateral and symmetrical. Back or radicular pain may precede other neurological signs. Cerebrospinal fluid abnormalities may include an elevated level of protein and a mild pleocytosis. Swelling of the spinal cord may be apparent on MRI. Typically, the neurological deficit progresses rapidly over days or a few weeks, ultimately leading to respiratory failure and death. There is no effective treatment.

Pathologically, there is widespread necrosis of the spinal cord, often most marked in the thoracic segments. The necrosis involves all components of the spinal cord with white matter usually more affected than grey matter.

Motor neurone disease (amyotrophic lateral sclerosis)

Paraneoplastic syndromes include: (i) amyotrophic lateral sclerosis with both upper and lower motor neurone dysfunction; (ii) progressive muscular atrophy, a pure lower motor neurone syndrome that is sometimes reversible and also associated with lymphoproliferative disorders; and (iii) primary lateral sclerosis, a pure upper motor neurone syndrome associated with solid tumours as well as lymphoproliferative disorders. The clinical and pathological characteristics differ little from non-paraneoplastic motor neurone disease save for the fact that the paraneoplastic disorders are often more rapid in onset and evolution, sometimes reverse spontaneously, and, at autopsy, may be more inflammatory than non-paraneoplastic disorders.

Myelitis

Paraneoplastic myelitis is usually a part of the encephalomyelitis syndrome with inflammatory lesions elsewhere in the brain and dorsal root ganglia as well as the spinal cord. The clinical picture is characterized by patchy wasting and weakness of muscles, sometimes combined with fasciculations. The upper extremities are often more severely affected than the legs, reflecting predominant involvement of the cervical spinal cord. There may be striking weakness of neck and intercostal muscles, resulting in respiratory failure. Sensory symptoms may be present. Autonomic dysfunction results from involvement of autonomic neurones.

Sensory neuronopathy

In contrast to the common axonal or demyelinating sensory neuropathies, paraneoplastic sensory neuronopathy where the dorsal root ganglion is the site of pathology

is a rare syndrome. At least two-thirds of the patients have small-cell lung cancer. Symptoms typically begin before the cancer is identified, with dysaesthetic pain and numbness in the distal extremities or occasionally in the arm(s), face, or trunk. The symptoms may be asymmetrical at onset but progress over days to several weeks to involve the limbs, trunk, and sometimes the face, causing a severe sensory ataxia. All sensory modalities are affected, distinguishing this disorder from cisplatin neuropathy, in which pin and temperature sensation are spared. Deep tendon reflexes are lost but motor function is preserved. The cerebrospinal fluid is typically inflammatory.

Early pathological changes are limited mostly to the dorsal root ganglia, in which both a loss of neurones and the presence of lymphocytic inflammatory infiltrates are noted. About 50 per cent of patients with paraneoplastic sensory neuronopathy have pathological changes that may be clinically inapparent in other regions of the nervous system.

In most patients, treating the underlying tumour or removal of the autoantibody by plasmapheresis or immunosuppressive therapy does not alter the course of the neurological disease, although there are isolated reports of responses to immunotherapy. Occasional patients have a mild and indolent neuropathy.

Peripheral nerves (Table 7)

Sensory and sensorimotor neuropathy

Peripheral neuropathies, particularly mild distal sensorimotor neuropathies, are quite common in patients with cancer. In one study of lung cancer the incidence was 16 per cent. The incidence is even higher if one defines the disorder by electrical evidence in clinically asymptomatic patients. However, many patients may have suffered from the metabolic or nutritional ravages of late cancer and would not be considered by the definitions here to have true paraneoplastic syndromes.

Some patients not known to have cancer, and who are not evidently systemically ill, present to the neurologist with a peripheral neuropathy which may be quite severe and disabling. It is estimated that in those patients whose initial evaluations do not reveal an obvious cause (such as vitamin deficiency, amyloidosis, diabetes), about 10 per cent will eventually prove to have cancer as the underlying reason for the peripheral neuropathy. Therefore, one should seriously consider a cancer diagnosis in such patients. Paraneoplastic peripheral neuropathy may take several clinical and pathological forms. The most common is the distal, symmetrical, subacutely developing, sensory neuropathy which may be either axonal or demyelinating. A relatively pure sensory neuropathy, a mononeuritis multiplex due to microvasculitis, and acute polyradiculopathy, a focal neuropathy such as brachial neuritis, or an autonomic neuropathy may also be paraneoplastic. Most of these neuropathies are not associated with autoantibodies and the diagnosis is often one of exclusion.

Neuromuscular junction and muscle (Table 8)

Paraneoplastic disorders of the neuromuscular junction include the Lambert–Eaton myasthenic syndrome and myasthenia gravis. These disorders have a common pathogenetic mechanism—they are caused by antibodies against ion channels and, whether paraneoplastic or not, they respond to immunological treatment. Another ion channel disorder included in this section is neuromyotonia, which is not confined to the neuromuscular junction. Finally, because of its similarity to neuromyotonia, the stiff person syndrome is also included in this section.

Lambert–Eaton myasthenic syndrome (LEMS)

LEMS results from a reduced release of acetylcholine at presynaptic nerve terminals. The same P/Q-type voltage-gated calcium channels are found in small-cell lung cancers. Interestingly, the richest source of P/Q-type voltage-gated calcium channels is the cerebellum, perhaps explaining the occasional relationship of paraneoplastic cerebellar degeneration and LEMS.

LEMS can be treated either by immune suppression or by treatment of the underlying cancer when present. Patients with small-cell lung cancer associated with LEMS have a better prognosis than patients with small-cell lung cancer who do not develop a paraneoplastic disorder.

Myasthenia gravis

Myasthenia gravis occurs in 30 per cent of patients with thymomas, and approximately 15 per cent of patients with myasthenia gravis are found to have a thymoma.

Polymyositis and dermatomyositis

Only a minority of patients suffering from these disorders have an underlying malignancy as the cause; elderly patients are more likely to have an underlying malignancy. Dermatomyositis with typical cutaneous changes is more likely than polymyositis to be paraneoplastic. Females and males are affected in approximately equal numbers. Symptoms of the muscle weakness generally precede identification of the cancer. The tumour may be at any site, but breast, lung, ovarian, and gastric malignancies are the most common. Hodgkin's disease and prostate and colon cancer are also reported offenders.

Corticosteroids, cyclosporine, and other immunosuppressants have been used successfully. Other reports suggest that high-dose intravenous immunoglobulin is useful in patients unresponsive to other forms of immunosuppression.

Neuromyotonia and stiff person syndrome

Muscle cramps are a common complication of cancer, sometimes related to electrolyte imbalance or induced by chemotherapy. A much rarer but clinically significant paraneoplastic disorder is acquired neuromyotonia. The disorder is characterized by muscle stiffness, cramps, and obviously rippling and twitching muscles, sometimes leading to sustained abnormal postures. Relaxation after voluntary contraction is delayed. Symptoms persist during sleep but are abolished by curare. Sudden prolonged bursts of high-frequency, involuntary, repetitive muscle action potentials are seen on electromyography.

The muscle spasms and rigidity are sometimes precipitated by activity, forcing patients to become sedentary. The disorder arises from peripheral nerves and is sometimes a part of the encephalomyelitis syndrome. The disorder is usually non-paraneoplastic, but may be associated with cancer including thymomas and small-cell lung cancer. Antibodies against voltage-gated potassium channels are often positive. Plasma exchange improves the patient's condition. Some patients respond to anticonvulsants. Injection of IgG from affected patients into experimental animals can reproduce the syndrome.

The stiff person syndrome may superficially resemble neuromyotonia, but has a central origin. The disorder is clinically characterized by stiffness and rigidity with episodic spasms of axial muscles. A variant of the syndrome affects the limbs. Painful reflex spasms can occur in response to tactile stimuli or startle. Muscle action potentials are normal on electromyography but the activity is continuous and excessive and increased by voluntary activity. The disorder is not usually associated with cancer, but in some patients the underlying syndrome is paraneoplastic.

24.19 Diseases of the peripheral nerves

P. K. Thomas

Pathophysiological considerations

The peripheral nerves consist of bundles (fascicles) of unmyelinated and myelinated axons that have their cell bodies in the anterior horns of the spinal cord, dorsal root ganglia, or autonomic ganglia. The fascicles are surrounded by a lamellated cellular sheath, the perineurium, which provides a diffusion barrier that separates the intrafascicular or endoneurial compartment from the extracellular tissues. Peripheral nerve trunks usually consist of several fascicles bound together by the mainly collagenous epineurial connective tissue. The nutrient vessels connect with a longitudinal anastomotic network of arterioles and venules in the epineurium. This in turn communicates through perforating vessels with a longitudinal intrafascicular capillary anastomotic network. This anastomotic system is extremely efficient: experimentally it is very difficult to produce ischaemia of nerve trunks by ligation of nutrient vessels. The occurrence of an ischaemic neuropathy, therefore, implies widespread vascular insufficiency. A blood–nerve barrier, comparable to the blood–brain barrier, exists in peripheral nerves (except in the sensory and autonomic ganglia). This, in conjunction with the diffusion barrier provided by the perineurium, probably regulates the composition of the endoneurial connective tissue fluid and thus the ionic environment of the nerve fibres.

All nerve fibres, whether myelinated or unmyelinated, are closely related to satellite cells, the cells of Schwann. There is evidence that they may provide metabolic support for the axons, which often extend for very considerable distances from their perikarya. In myelinated fibres the myelin segments are derived by the spiralling of Schwann cell surface membrane around the axons. The axon is exposed at the nodes of Ranvier, which represent the gaps between adjacent myelin segments. Conduction in unmyelinated axons takes place by the spread of a continuous wave of depolarization, the action potential, that migrates along the axolemma. In myelinated fibres, because of the high electrical resistance of the lipid in the myelin lamellae, the generation of the action potential is restricted to the region of the nodes of Ranvier. Conduction is therefore saltatory, jumping from one node to the next by local currents that traverse the axon and the extracellular tissue fluid. By this means, conduction velocity is increased from about 1 m/s in unmyelinated axons to 60 to 70 m/s in the largest myelinated fibres in human nerves.

The majority of the synthetic mechanisms in neurones are sited in the cell bodies. Synthesized materials are then transported down the axons to the termination of the fibres by an active transport system. This involves a fast system with a rate of about 400 mm/day, and a slow system, in which the structural proteins travel at 1 to 2 mm/day. The system is bidirectional: apart from the two anterograde fluxes, there is a retrograde system transporting materials, including neurotrophic factors, back from the periphery to the cell body. The retrograde system may be involved in the regulation of protein synthesis in the cell body and probably carries the signal for chromatolysis which ensues on transection.

Disorders of peripheral nerve function can be categorized in terms of the site of the primary disturbance. Conditions that lead to the death of the neurone as a whole, with the loss of the cell body and the axon, are categorized as neuronopathies. Conditions that have a selective effect on axons are termed axonopathies. A selective effect on axonal conduction is seen in poisoning with tetrodotoxin, which blocks the sodium channels at the nodes. Axonopathies may be focal or generalized. Focal axonopathies occur as a result of insults such as trauma or ischaemia. Axonal interruption leads to wallerian-type degeneration below the site of the injury. Recovery has to take place by axonal regeneration which is a slow process: the rate of axonal regeneration is about 1 to 2 mm/day.

Generalized axonopathies often lead to a selective degeneration of the distal portion of the fibres which then extends proximally. The axons are said to 'die back' towards the cell bodies. This pattern is seen in many toxic neuropathies and neuropathies due to nutritional deficiency. It has been suggested that in these conditions the axonal breakdown may result either from interference with enzymes involved in glycolysis which provide the metabolic energy for axonal transport mechanisms, or from cofactor deficiency or inactivation. As the enzymes are synthesized in the cell bodies and then transported down the axons, the further the distance from the cell body the greater will be the likelihood of the occurrence of metabolic insufficiency. This probably accounts for the distal distribution of many such neuropathies, as longer axons will be more vulnerable. Recovery again has to take place by axonal regeneration. In many distal axonopathies that involve the peripheral nervous system, not only does the degeneration affect the distal parts of the motor and sensory axons in the periphery, but the terminal parts of the centrally directed axons derived from the dorsal root ganglion cells also degenerate. Thus degeneration may be found in the rostral portions of the posterior columns. This process has been referred to as central–peripheral distal axonopathy. Neuropathy from iminodipropionitrile blocks the slow axonal transport system and leads to large swellings in the proximal parts of the axons that contain aggregations of neurofilaments (proximal axonopathy).

Other neuropathies primarily affect the myelin, either directly, or through an interference with Schwann cell function. The consequence is a selective demyelination with relative preservation of axonal integrity. This may be restricted to the region of the nodes of Ranvier (paranodal demyelination) or involve whole internodal segments (segmental demyelination) with consequent conduction block. The selective myelin damage may occur, for example, as the result of a cell-mediated attack on myelin by sensitized mononuclear cells, which is the likely explanation of the Guillain–Barré syndrome. Another instance is in diphtheritic neuropathy where the demyelination is considered to be secondary to an interference with Schwann cell protein metabolism. Local compression by a tourniquet also gives rise to selective damage to myelin through mechanical effects, although more severe pressure also causes axonal interruption. In diffuse demyelinating neuropathies, the distribution of the clinical effects, as for distal axonopathies, is often maximal peripherally. Presumably, this is a statistical effect: the longer the nerve fibre, the more likely it is to develop a region of demyelinating conduction block.

Recovery after paranodal or segmental demyelination occurs by remyelination. Initially, the newly formed myelin is thin, which results in an abnormally slow conduction velocity. Such reductions in conduction velocity may be focal, for example in relation to localized myelin damage in entrapment neuropathies, or widespread as in the Guillain–Barré syndrome or the inherited demyelinating neuropathies. In the latter, motor nerve conduction velocity is sometimes reduced to 10 m/s or less.

Finally, in other neuropathies the nerve fibres may be secondarily damaged by processes that primarily affect the connective tissues of nerve or the vasa nervorum. Usually a combination of demyelination and axonal loss occurs.

Clinical categories of neuropathy

Mononeuropathy, multifocal neuropathy, and polyneuropathy

Peripheral neuropathies may be divided into two broad categories depending upon the distribution of the involvement. The first category comprises lesions of isolated peripheral nerves or nerve roots termed mononeuropathy or multiple isolated lesions termed multifocal neuropathy (multiple mononeuropathy or 'mononeuritis multiplex'). The lesions in a widespread multifocal neuropathy may summate to produce a symmetrical disturbance, but the history or a careful examination may indicate the involvement of individual nerves. Isolated or multiple isolated peripheral nerve lesions arise from conditions that produce localized damage, such as mechanical injury, nerve entrapment, thermal, electrical, or radiation injury, vascular causes, granulomatous, neoplastic, or other infiltrations, and nerve tumours.

Secondly, there may be a diffuse and bilaterally symmetrical disturbance of function which can be designated polyneuropathy. When such a process affects the spinal roots, or affects the roots and the peripheral nerve trunks, the terms polyradiculopathy and polyradiculoneuropathy are sometimes employed. In general terms, polyneuropathies result from causes that act diffusely on the peripheral nervous system, such as metabolic disturbances, toxic agents, deficiency states, and certain instances of immune reaction. Isolated nerve lesions may sometimes be superimposed upon a symmetrical polyneuropathy, as a consequence, for example, of pressure lesions in a patient confined to bed. In certain polyneuropathies, there is an abnormal susceptibility to pressure lesions.

Symptomatology

Weakness or paralysis may be due either to conduction block in the motor nerve fibres or to axonal degeneration. Conduction block is related to demyelination with preservation of axonal continuity (neurapraxia). Recovery may occur by remyelination and may be rapid and complete. This can be the situation in localized nerve lesions, for example 'Saturday night' paralysis of the radial nerve, or in more widespread polyneuropathies, such as in acute inflammatory demyelinating polyneuropathy (Guillain–Barré syndrome). If axonal interruption takes place, axonal degeneration occurs below the site of interruption. The muscle weakness is accompanied by denervation atrophy and electromyographic signs of denervation. In a reversible process, recovery has to take place by axonal regeneration which is often slow and incomplete. An important recovery mechanism in conditions in which muscles become partially denervated is reinnervation of denervated muscle fibres by collateral sprouting from the remaining intact axons.

In generalized symmetrical polyneuropathies, the muscle weakness and wasting are commonly peripheral in distribution with an onset in the lower limbs. This results in bilateral footdroop and a 'steppage' gait in which an affected individual lifts his feet to an abnormal extent to avoid catching his toes against the ground. Involvement of the upper limbs begins with weakness and wasting of the small hand muscles and usually weakness of the finger and wrist extensors before the forearm flexor muscles are affected. At times, a symmetrical involvement of the proximal musculature in the limbs occurs in polyneuropathies, for example in the Guillain–Barré syndrome or porphyric neuropathy. Fasciculation due to spontaneous contraction of isolated motor units is most often a feature of anterior horn cell disease but may be encountered in peripheral neuropathies, as may muscle cramps. Postural tremor, mainly affecting the upper limbs and resembling essential tremor, may be seen in patients with chronic demyelinating polyneuropathies with slow conduction velocity. This 'neuropathic tremor' is most often encountered in type I hereditary motor and sensory neuropathy, chronic inflammatory demyelinating polyneuropathy, and IgM paraproteinaemic neuropathy. A rare manifestation of peripheral neuropathy is the occurrence of continuous repetitive discharges in motor nerve fibres leading to generalized muscular rigidity or 'neuromyotonia' (Isaacs' syndrome, continuous motor unit activity syndrome).

Loss of the tendon reflexes is a frequent accompaniment of a peripheral neuropathy, and usually first affects the ankle jerks. In assessing the clinical findings, it is important to remember that the ankle jerks may be lost in later life, probably as a result of senile changes in the peripheral nerves.

Sensory symptoms and sensory loss in symmetrical polyneuropathies are usually distal in distribution, giving rise to the 'glove and stocking' pattern of involvement. Only rarely is a proximal pattern encountered. The sensory loss may affect all modalities or be restricted to certain forms of sensation. If the loss is restricted, two broad patterns are discernible. In the first, the impairment predominantly affects the sense of joint position and vibration and touch–pressure sensibility, corresponding to a predominant loss of function in the larger myelinated nerve fibres. Sensory ataxia is the salient manifestation in 'large fibre' sensory neuropathies. Loss of postural sensibility may lead to sensory ataxia in the limbs and to 'pseudoathetosis', that is, involuntary movements, most often of the fingers and hands, that occur, for example, when a patient holds their arms outstretched with their eyes closed. In the second pattern of selective sensory loss, pain and temperature sensibility are predominantly affected, often associated with loss of autonomic function, corresponding to a predominant loss of small myelinated and unmyelinated axons. 'Trophic changes' and pain may complicate such small fibre neuropathies. The most important factor in their genesis is the loss of the protective effect of pain sensation with the consequent development of persistent ulceration or more extensive tissue loss, most commonly in the feet, and neuropathic joint degeneration.

Paraesthesiae are a frequent feature in peripheral neuropathy. These are usually of a tingling nature ('pins and needles'), but, especially in 'small fibre' neuropathies, may involve thermal sensations, most often with a burning quality. The paraesthesiae may be aggravated by touching or stroking the skin. Stimuli that are normally not painful may acquire an unpleasant quality (allodynia) and painful stimuli may give rise to an excessive or hyperpathic response, in which the stimulus, for example a pinprick, is abnormally intense. With repeated stimulation at the same site, the pain that is felt may spread widely and reach an intolerable intensity. An unusual symptom encountered most often in uraemic neuropathy is that of 'restless legs' (Ekbom's syndrome). Affected individuals experience sensations in the feet and legs that they find difficult to describe but which are temporarily relieved by movement of the feet and legs. 'Ekbom's syndrome' may also occur in the absence of any detectable disease process.

Spontaneous pains of an aching or lancinating character may complicate a number of generalized polyneuropathies. Severe paroxysms of lancinating pain occur in trigeminal neuralgia, but here the responsible lesion may well lie within the central nervous system. Causalgia constitutes a particularly troublesome painful syndrome, most often following gunshot wounds injuring the median nerve, the lower trunk of the brachial plexus, or the tibial nerve. It is a severe persistent pain, often with a burning quality that is characteristically aggravated by emotional factors. Sympathectomy relieves a high proportion of such cases.

Disturbances of autonomic function are occasionally the salient abnormality in a peripheral neuropathy, as in the Riley–Day syndrome, or they may accompany other manifestations, and can be observed both with localized peripheral nerve lesions and in generalized neuropathies.

Diagnosis and investigation

The history and physical examination frequently indicate that the disturbance has affected the peripheral nerves. If confirmation is required, this may usually be obtained by nerve conduction studies. Conduction may be examined in motor and sensory nerve fibres, and can give evidence of both localized and generalized neuropathies. Severely reduced conduction velocity may occur as a result of segmental demyelination or because of conduction in regenerating axons of small calibre after axonal degeneration.

Examination of the cerebrospinal fluid is not commonly of value in the diagnosis of peripheral neuropathies, although the substantially elevated protein content that often occurs in the Guillain–Barré syndrome may be helpful, as may inflammatory changes in some neuropathies.

Nerve biopsy is rarely required in establishing the existence of a peripheral neuropathy, but may be of diagnostic value in establishing the cause of the neuropathy, particularly in conditions that affect the vasa nervorum or neural connective tissues, in some 'storage' disorders and in inflammatory demyelinating neuropathies.

Individual nerves

Phrenic nerve (C2–C4)

This nerve innervates the diaphragm. When the diaphragm is totally paralysed, the normal protrusion of the upper abdomen during inspiration is lost, or is replaced by retraction (paradoxical movement). Radiographically, paralysis may be detected by unilateral or bilateral elevation of the diaphragm in a chest radiograph and its failure to descend on inspiration. The phrenic nerve may be involved in its course through the neck or thorax by wounds or tumours such as bronchial carcinoma, and it is sometimes affected in idiopathic brachial plexus neuropathy (neuralgic amyotrophy).

Nerve to serratus anterior (C5–C7)

The serratus anterior acts as a fixator of the scapula, holding the scapula against the chest wall when forward pressure is exerted by the arm. It is involved in forward movement of the shoulder as in a rapier thrust and in elevation of the arm, when it rotates the scapula. When serratus anterior is paralysed in isolation, the position of the scapula is normal at rest but if the extended arm is pushed forwards against resistance, 'winging' of the scapula becomes evident. The vertebral border, particularly in its lower portion, stands away from the chest wall. The nerve to serratus anterior may be involved in penetrating wounds, but usually in association with damage to the brachial plexus. It may be injured by forcible depression of the shoulder. Serratus anterior weakness is a common component of idiopathic brachial plexus neuropathy (neuralgic amyotrophy) and it is not infrequently encountered as an isolated and unexplained lesion.

Brachial plexus

The brachial plexus may be affected by penetrating wounds of the neck, in fractures and dislocations of the shoulder and clavicle, as a result of traction on the arm, by pressure from an aneurysm or a cervical rib, and by neoplastic involvement.

Traction lesions

Traction on the arm may result in damage to the plexus itself or may lead to avulsion of the spinal roots from the cord. If the roots are avulsed, sensory nerve action potentials will be preserved if recorded from affected fingers despite total anaesthesia, and the histamine flare response will be preserved in anaesthetized skin. This follows from the fact that the nerve fibres are interrupted proximal to the dorsal root ganglia and therefore the peripheral sensory axons do not degenerate.

In severe traction lesions, commonly encountered in current medical practice as a result of motorcycle or aircraft accidents, the whole of the plexus may be damaged. With forcible downward displacement of the shoulder, as when someone is thrown forwards and the shoulder strikes against an obstacle, only the upper part of the plexus, involving the contribution from the fifth and sixth cervical nerve roots, may be damaged. This may also be encountered as a birth injury from traction on the head, or on the trunk in a breech presentation (Erb's palsy), and rarely in anaesthetized patients during operation or in individuals carrying heavy rucksacks. Selective injury to the lower part of the plexus involving the contributions from the eighth cervical and first thoracic nerve roots occurs as a result of traction with the arm extended, as when an individual falls from a height and tries to save himself by hanging on to a ledge. It may also occur as a birth injury following traction with the arm extended (Klumpke's paralysis), but is less common than upper plexus damage.

Selective damage to the upper portion of the plexus (C5 and C6 roots or upper trunk) results in paralysis of deltoid, biceps, brachialis, brachioradialis, and sometimes supraspinatus, infraspinatus, and subscapularis. If the roots are avulsed from the cord, the rhomboids, serratus anterior, levator scapulae, and the scalene muscles will be affected. The arm hangs at the side, internally rotated at the shoulder, with the elbow extended and the forearm pronated in the 'waiter's tip' position. Abduction at the shoulder and flexion at the elbow are not possible. The biceps and brachioradialis jerks are lost. Sensory loss affects the lateral aspect of the shoulder and upper arm and the radial border of the forearm. Selective paralysis of the lower brachial plexus (C8, T1) results in paralysis of all the intrinsic hand muscles and a consequent claw-hand deformity, weakness of the medial finger and wrist flexors, and sensory loss along the medial border of the forearm and hand and over the medial two fingers. Cervical sympathetic paralysis, giving rise to Horner's syndrome, is frequently associated.

When the spinal roots are avulsed from the cord, regeneration is impossible and intractable spontaneous pain may be a highly troublesome sequel. Where the injury is distal to the dorsal root ganglia, lesions of the upper portion of the brachial plexus recover more satisfactorily than lower plexus lesions. The value of surgical repair is still a controversial issue. In the Erb's form of birth injury, weakness of abduction at the shoulder and flexion at the elbow often persist, although there may be little residual sensory loss. Full recovery takes place in about a third of the cases. It is less likely to occur with lower plexus injuries or if the whole plexus is involved. Early recognition and the application of measures to reduce the risk of joint contractures are important. Surgical treatment is of limited value.

Thoracic outlet syndromes

The contribution of the eighth cervical and first thoracic roots to the brachial plexus may be damaged by angulation over an abnormal rib or, more usually, a fibrous band arising from the seventh cervical vertebra and attached to the first rib. Although local structures such as the tendon of scalenus anterior may be involved in the production of symptoms, the isolation of a separate 'scalenus anterior syndrome' or of 'costoclavicular compression' is not justified. The subclavian artery may be affected by cervical ribs giving rise to aneurysmal dilatation and vascular symptoms such as Raynaud's syndrome and embolic phenomena, but the simultaneous occurrence of both neural and vascular phenomena is rare.

Damage to the lower part of the brachial plexus leads to weakness and wasting of the small hand muscles, and of the medial forearm wrist and finger flexors. Occasionally, there is selective wasting of the thenar pad in the hand, mimicking to some extent the appearances of the carpal tunnel syndrome. Numbness, pain, and paraesthesiae occur along the inner border of the forearm and hand, extending into the medial two fingers. The pain tends to be provoked by carrying heavy articles with the hand on the affected side. Horner's syndrome may be a feature. Nerve conduction studies are helpful when there are difficulties in distinguishing a cervical rib syndrome from a lesion of the ulnar or median nerves on clinical grounds. Surgical removal of the rib or fibrous band often leads to abolition of the pain and paraesthesiae, but recovery of power in the small hand muscles is usually disappointing.

Neoplastic involvement

Tumours may arise locally in the brachial plexus, such as neurofibromata in von Recklinghausen's disease (type I neurofibromatosis) or a solitary neurinoma, or the plexus may be invaded by tumours arising in other structures. In the latter case the commonest situation is involvement of the lower part of the plexus by an apical carcinoma of the lung (Pancoast's syndrome), which gives rise to wasting and weakness of the small hand muscles and of the medial forearm wrist and finger flexors, pain and sensory loss affecting the medial border of the forearm and hand, and cervical sympathetic paralysis. Other tumours that may invade the brachial plexus include carcinoma of the breast and malignant lymphomas affecting the lymph glands in the root of the neck.

Neuralgic amyotrophy

This condition was not clearly differentiated from the other painful paralytic disorders of the shoulder and upper arm, such as root compression from disc prolapse, until the Second World War. It has been described in a variety of terms, including 'idiopathic brachial plexus neuropathy' and 'paralytic brachial neuritis'. It may follow immunizing procedures, in particular the administration of antitetanus serum or operations, or occur without recognizable antecedent event. It can occur on a genetic basis as an autosomal dominant disorder, hereditary neuralgic amyotrophy (HNA), with variable penetrance. This has been mapped to chromosome 17p.

The disorder develops acutely with intense pain in the shoulder region which may take some weeks before it subsides completely although generally it ceases after a few days. Paralysis of the muscles of the shoulder girdle becomes evident within a day or two of the onset of the pain, sometimes also of the arms or of the diaphragm. It may be unilateral or bilateral and may be associated with sensory loss. More distal upper limb muscles may at times be affected, as may the phrenic nerve, and, occasionally, the recurrent laryngeal nerve. The cerebrospinal fluid is consistently normal. The affected muscles show electromyographic evidence of denervation. Recovery is usually ultimately satisfactory. Not all cases recover fully and recurrences may occur. A comparable disorder can affect the lumbosacral plexus (idiopathic lumbosacral plexus neuritis).

The pattern of muscle involvement and sensory disturbances suggests that the neuralgic myotrophy affects the brachial plexus in a patchy manner. An immune reaction is assumed but not established. The condition takes the same course whether or not it follows an immunizing procedure. Corticosteroids do not influence

either the initial pain or the ultimate outcome.

Post-irradiation brachial plexus neuropathy

Brachial plexus damage may occur as a sequel to radiotherapy for breast carcinoma or tumours in the neck. The onset of symptoms is usually several years after treatment, but may be within months. It can be difficult to distinguish from tumour recurrence but is less likely to be painful. Magnetic resonance imaging may be helpful in diagnosis.

Radial nerve (C5–C8)

The long course of the radial nerve and its position in relation to the humerus make this nerve unusually susceptible to external compression. It is a continuation of the posterior cord of the brachial plexus. In the upper arm it supplies triceps and anconeus and the skin on the back of the arm just above the elbow through the posterior cutaneous nerve of the arm. The lateral aspect of the lower part of the upper arm is supplied by the lower lateral brachial cutaneous branch and the dorsal aspect of the forearm by the posterior cutaneous nerve of the forearm. Muscular branches of the radial nerve innervate brachioradialis and extensor carpi radialis longus and brevis. The superficial branch of the nerve is its continuation. It descends along the radial border of the forearm and supplies the skin over the dorsum of the hand and the thumb, index, and middle fingers. The deep branch posterior interosseus nerve winds around the lateral aspect of the radius, passes through supinator, which it supplies, and innervates extensor digitorum, extensor digiti minimi, extensor carpi ulnaris, and often extensor carpi radialis brevis, abductor pollicis longus, extensor pollicis longus and brevis, and extensor indicis.

The nerve may be injured in wounds of the axilla so that the paralysis includes triceps, resulting in loss of extension at the elbow. The most frequent type of injury is compression of the nerve in the middle third of the arm against the humerus. This is encountered as 'Saturday night paralysis' in which an individual falls asleep when intoxicated with their upper arm over the arm of a chair. Triceps is spared, but brachioradialis, supinator, and all the forearm extensor muscles are paralysed. Sensory impairment is limited to the dorsum of the hand. Commonly the lesion consists of a localized conduction block (neurapraxia) so that muscle wasting does not occur and a muscle response can be obtained on electrical stimulation of the nerve below the level of the lesion. Recovery is complete within a matter of weeks. A cock-up wrist splint may be helpful while recovery is awaited. At times, there is some associated axonal degeneration so that electromyographic evidence of denervation is detectable and full recovery is correspondingly delayed.

Many muscles not supplied by the radial nerve work at a disadvantage when the wrist and finger extensors are paralysed. These defects must not be mistaken for signs of injury to other nerves. Owing to the flexed position of the wrist, gripping is impaired, but if the power of the wrist and finger flexors is tested with the wrist extended, it can be shown to be normal. The action of the interossei in abducting and adducting the fingers is also feeble when the wrist is flexed, but full power is demonstrable if these muscles are tested with the hand resting flat on a table.

A lesion of the posterior interosseus nerve gives rise to weakness confined to abduction and extension of the thumb and extension of the index finger. Supinator is spared, together with brachioradialis and the radial wrist extensors, and there is no sensory loss. The nerve may be compressed under the arcade of Frohse or during its transit through supinator.

Axillary nerve (C5, C6)

This is a branch of the posterior cord of the brachial plexus. It supplies deltoid and teres minor and the skin over deltoid through the upper lateral brachial cutaneous nerve. It may be damaged in injuries to the shoulder and the chief symptom is an almost complete inability to raise the arm at the shoulder. In the past, it was sometimes injured by pressure from a crutch ('crutch palsy').

Musculocutaneous nerve (C5, C6)

This nerve is rarely damaged alone, but may be involved in injuries to the brachial plexus. It supplies coracobrachialis, biceps, and brachialis and the skin over the lateral aspect of the forearm through the lateral cutaneous nerve of the forearm. Flexion at the elbow is still possible by brachioradialis, but is weak, and sensation may be impaired along the radial border of the forearm.

Median nerve (C6–C8, T_1)

The median nerve arises from the medial and lateral cords of the brachial plexus and descends with the brachial artery through the upper arm, entering the forearm deep to the bicipital aponeurosis. It has no muscular branches above the elbow. It supplies all the muscles in the anterior aspect of the forearm except flexor carpi ulnaris and the medial half of flexor digitorum profundus. The main trunk of the nerve supplies pronator teres, flexor carpi radialis, palmaris longus, and flexor digitorum superficialis. Through the anterior interosseus branch, it also supplies the lateral aspect of flexor digitorum profundus, flexor pollicis longus, and pronator quadratus. The main trunk passes deep to the flexor retinaculum of the wrist and its recurrent muscular branch supplies abductor pollicis brevis, opponens pollicis, and contributes to the innervation of flexor pollicis brevis. It also supplies the lateral two lumbrical muscles and the skin of the lateral aspect of the palm and the lateral three and a half digits over their palmar aspects and terminal parts of their dorsal aspects.

Lesions in the forearm

The median nerve may be injured in the region of the elbow or compressed at the level of the pronator teres muscle. Entrapment neuropathies in the upper forearm, however, are uncommon. Occasionally the anterior interosseus branch is involved in isolation.

Complete lesions of the median nerve at the elbow give rise to paralysis of pronator teres, the radial flexor of the wrist, the long finger flexors except the ulnar half of the deep flexor, most of the muscles of the thenar eminence, and the two radial lumbricals. In brief, there is an inability to flex the index finger and the distal phalanx of the thumb, flexion of the middle finger is weak, and opposition of the thumb is defective. The appearance of the hand has been described as simian; it shows ulnar deviation, the index and middle fingers are more extended than normal, and the thumb lies in the same plane as the fingers.

In more detail, pronation is incomplete and defective. The patient attempts to overcome this by rotating the whole limb at the shoulder. Paralysis of the wrist flexors is evident when attempts are made to flex against resistance. The tendon of flexor carpi ulnaris stands out alone and the hand goes into ulnar deviation. Flexion of the fingers is good in the ulnar two fingers, although weaker than normal. The index finger cannot be flexed, and the middle finger only incompletely. Flexion at the metacarpophalangeal joints is possible in all fingers, including the index, and flexion at these joints with extension at the interphalangeal joints is accomplished by the interossei and lumbricals. If the proximal phalanx of the thumb is immobilized, it will be found that flexion of the terminal phalanx is abolished because of paralysis of flexor pollicis longus. Paralysis of the thenar muscles gives rise to defective abduction and opposition of the thumb. By means of the adductor, the thumb can be drawn into the palm, but as the radial fingers cannot be flexed or the thumb opposed, it is impossible to place the tip of the thumb on the fingers.

Sensory loss is evident over the lateral three and a half digits and the lateral aspect of the palm, although individual variations occur. There is almost complete anaesthesia over the two terminal phalanges of the index and middle fingers. This degree of sensory loss, combined with the motor deficit, renders the thumb and index fingers almost useless and makes paralysis of the median the most serious single nerve lesion in the upper limb.

Vasomotor and trophic changes often ensue. The skin in the distribution of the median nerve tends to become reddened, dry, and atrophic. The pulp of the affected fingers becomes atrophic and ulceration occasionally develops in the tip of the index finger. The nails may become white and atrophic.

After a total transection of the nerve in the region of the elbow, even with a satisfactory surgical repair, recovery is slow and rarely complete, particularly with respect to the innervation of the hand.

With partial lesions of the median nerve in the arm or forearm, causalgia may be a troublesome consequence. This most often follows gunshot wounds. The pain develops at any time from a few hours to 45 days after the injury. The pain is severe and unremitting, frequently of a burning or smarting quality. Upon this may be superimposed severe paroxysms of pain provoked by touching or jarring the limb or by emotional factors. Vasomotor and sudomotor changes may be associated. The skin usually becomes dry and scaly, but excessive sweating may be a feature. The patient adopts a protective attitude towards the limb, so that fixation of the joints of

the fingers and wrist may develop, together with atrophic changes in the skin and subcutaneous tissue. About 80 per cent of cases of true causalgia are relieved by sympathectomy. Untreated, the pain gradually subsides over months or years.

Lesions at the wrist

The superficial situation of the median nerve at the wrist renders it liable to injury in lacerations sustained by falling against a window with the hand outstretched or in suicidal attempts. It may also be damaged as an occupational hazard by individuals who exert repeated pressure on the butt of the hand.

Much the most common lesion at this site is the carpal tunnel syndrome, in which the median nerve is compressed as it passes deep to the flexor retinaculum. The usual presentation is with acroparaesthesiae. These consist of numbness, tingling, and burning sensations felt in the hand and fingers, the pain sometimes radiating up the forearm as far as the elbow or even as high as the shoulder or root of the neck. The paraesthesiae are sometimes restricted to the radial fingers, but may affect all the digits as some fibres from the median nerve are distributed to the fifth finger through a communication with the ulnar nerve in the palm. The attacks of pain and paraesthesiae are most common at night and often wake the patient from sleep. They are then relieved by shaking the hand. The hand tends to feel numb and useless on waking in the morning but recovers after it has been used for some minutes. The symptoms may recur during the day following use, or at times if the patient sits with the hands immobile. Such symptoms of acroparaesthesiae may persist for many years without the appearance of symptoms of median nerve damage. In other patients, weakness of the thenar muscles develops, particularly of abduction of the thumb, and is associated with atrophy of the lateral aspect of the thenar eminence (Fig. 1). Sensory loss may appear over the tips of the median innervated fingers. Occasionally patients present with symptoms of median nerve deficit in the hand without attacks of acroparaesthesiae having occurred, or motor and sensory signs may be discovered incidentally in the absence of symptoms, particularly in older individuals.

Fig. 1 Thenar wasting in a patient with the carpal tunnel syndrome.

The symptoms are usually characteristic. If confirmation is required in atypical cases, this can generally be obtained by nerve conduction studies. In patients who are experiencing frequent attacks of acroparaesthesiae, the symptoms may be reproduced by inflating a sphygmomanometer cuff around the arm above arterial pressure for 2 min. At times percussion over the carpal tunnel may elicit a Tinel's sign, or symptoms may be provoked by hyperextension of the wrist or sustained flexion (Phalen's sign).

The majority of cases occur in middle-aged and often obese housewives. In younger women it is commonly associated with excessive use of the hands, and it may develop in males after unaccustomed use of the hands, such as in house painting or fly fishing. In these instances, tenosynovitis of the flexor tendons is responsible. It may also be caused by tuberculous tenosynovitis at the wrist or involvement of the wrist joint in rheumatoid arthritis. It may develop as a consequence of osteoarthritis of the carpus, perhaps related to an old fracture. Other predisposing causes are pregnancy, myxoedema, acromegaly, and infiltration of the flexor retinaculum in primary and hereditary amyloidosis.

In cases in which muscle weakness and wasting, or sensory loss, are present when the patient is first seen, treatment should be decompression of the nerve by section of the flexor retinaculum. In patients with acroparaesthesiae alone and in which the cause is probably tenosynovitis at the wrist, reduction in the amount of activity engaged in with the hands may be sufficient to allow the symptoms to subside. Injection of the carpal tunnel with a long-acting corticosteroid preparation may give temporary relief. Splinting of the wrist to reduce movement during the day may also be useful. If the symptoms persist despite conservative measures, decompression is then advisable.

The majority of patients with acroparaesthesiae are relieved by decompression. In patients with sensory impairment and cutaneous hyperaesthesia, such symptoms may persist for prolonged periods despite decompression. If denervation of the thenar muscles has been present for a long time, full recovery may not occur.

Ulnar nerve (C7, C8, T1)

This nerve arises from the medial cord of the plexus, usually with a contribution from the lateral cord. It descends in the medial side of the upper arm, passes around the elbow in the ulnar groove, and enters the forearm under an aponeurotic band between the humeral and ulnar heads of flexor carpi ulnaris. It then runs superficial to flexor digitorum profundus to the wrist and enters the hand between the pisiform bone and the hook of the hamate, superficial to the flexor retinaculum. After penetrating the hypothenar muscles, its deep branch crosses the palm and ends in flexor pollicis brevis.

In the upper arm, branches arise that supply flexor carpi ulnaris and the medial part of flexor digitorum profundus. In the forearm, the dorsal branch arises that winds around the ulna and supplies the skin over the dorsal aspect of the hand and the medial one and a half fingers. In the hand, a superficial branch supplies palmaris brevis and the skin over the medial aspect of the palm and the medial one and half fingers. The deep branch, after supplying the hypothenar muscles, innervates the interossei, the third and fourth lumbricals, adductor pollicis, and part of flexor pollicis brevis.

Lesions at the elbow

Total paralysis from lesions at this level, including the branches to flexor carpi ulnaris and flexor digitorum profundus, gives rise to wasting along the medial side of the forearm flexor mass. There is weakness of flexion of the fourth and fifth fingers. If the proximal portions of these fingers are held immobilized, flexion of the terminal phalanges is not possible. When the hand is flexed to the ulnar side against resistance, the tendon of flexor carpi ulnaris is not palpable. Paralysis of the hypothenar muscles abolishes abduction of the fifth finger. Paralysis of the interossei and the medial two lumbricals gives rise to the 'claw hand' deformity (Fig. 2). The action of these muscles is to flex the fingers at the metacarpophalangeal joints with the fingers extended at the interphalangeal joints. In the claw hand, the posture of the fingers is opposite to this, namely, extension of the metacarpophalangeal joints with flexion at the interphalangeal joints. Although all the interossei are paralysed, the defect is seen mainly in the ulnar fingers since the radial lumbricals supplied by the median nerve are still active. The long extensors of the fingers, being unopposed, overextend the proximal joints, and the flexor digitorum superficialis flexes the proximal interphalangeal joints.

Fig. 2 'Claw hand' deformity in a patient with an ulnar nerve lesion.

In the hand, there is wasting of the hypothenar muscles, of the interossei, and of the medial part of the thenar eminence. Movements of abduction and adduction of the fingers are weak, as is adduction to the extended thumb against the palm. Sensory loss affects the dorsal and palmar aspects of the medial side of the hand and the medial one and a half fingers.

The ulnar nerve may be damaged by dislocations or fracture dislocations at the elbow and is sometimes compressed in individuals who habitually lean on their elbows. Entrapment may occur in the cubital tunnel as the nerve underlies the aponeurotic band between the two heads of the flexor carpi ulnaris. This is most likely to occur in those performing heavy manual work or if there is an excessive carrying angle at the elbow, as may occur following a previous malunited supracondylar fracture of the humerus ('tardy ulnar palsy'). The medial wall of the cubital tunnel is formed by the elbow joint; osteoarthritis of the elbow can lead to osteophytic encroachment on the tunnel and compression of the ulnar nerve. In the cubital tunnel syndrome, the ulnar nerve is often palpably enlarged in the ulnar groove and for a short distance proximally. Ulnar nerve lesions are not infrequent in leprosy. Here the enlargement of the nerve tends to be maximal at a little distance above the elbow.

When it is suspected that the nerve has been subjected to repeated compression at the elbow, surgical transposition to the front of the medial epicondyle should be considered. If the nerve is compressed in the cubital tunnel, decompression by slitting the aponeurosis may suffice.

Lesions at the wrist or in the hand

Damage to the nerve at the wrist will spare the dorsal branch, so that cutaneous sensation over the dorsum of the hand and fingers is spared. A lesion just proximal to the wrist will give rise to sensory impairment on the palmar aspect of the hand and fingers alone, and weakness of all the ulnar-innervated intrinsic hand muscles. A slightly more distal lesion spares the superficial branch of the nerve and therefore produces no sensory deficit. Finally, damage to the deep palmar branch spares the hypothenar muscles, but causes weakness of the other ulnar-innervated small hand muscles. Lesions at the wrist or in the hand are usually the result of compression by ganglia or by repeated occupational trauma. Damage to the deep palmar branch, for example, may be caused by firm pressure in the palm from a screwdriver or drill. If occupational pressure is the cause, recovery follows cessation of the precipitating cause. Should improvement fail to occur after an appropriate interval, surgical exploration to establish whether a ganglion is present is merited.

It is not always easy on clinical grounds to decide whether the lesion is at the elbow or the wrist. Compression of the nerve in the cubital tunnel, for example, may spare the branches to the flexor carpi ulnaris and flexor digitorum profundus. In these circumstances, nerve conduction studies may be helpful, as they may in distinguishing between lesions of the ulnar nerve and damage to the eighth cervical and first thoracic spinal roots.

Lumbosacral plexus

Lesions of the lumbosacral plexus are not common. The plexus may be involved in pelvic malignancy, such as from carcinoma of the uterine cervix, bladder, prostate, or rectum, or be the site of a local neural tumour. It may be compressed by a haematoma in patients receiving anticoagulant therapy or suffering from haemophilia, or be involved in fractures of the pelvis. The lumbosacral cord may be compressed against the rim of the pelvis by the fetal head during parturition, with consequent weakness of the anterior tibial and peroneal muscles, and sensory impairment in the distribution of the fourth and fifth lumbar dermatomes. The superior gluteal nerve may also be affected. Recovery is initially good but may not be complete. The plexus may be affected in diabetic amyotrophy. Rare instances of idiopathic lumbosacral plexus neuropathy are encountered, comparable to the corresponding disorder that affects the brachial plexus.

Femoral nerve (L2–L4)

This nerve arises from the lumbar plexus, crosses the iliac fossa between the psoas and iliacus muscles, and enters the thigh deep to the middle of the inguinal ligament. In the iliac fossa it supplies the iliacus, and in the thigh, pectineus, sartorius, and quadriceps femoris, and anterior cutaneous branches to the front of the thigh. The continuation of the femoral nerve is the saphenous which supplies the skin over the medial aspect of the lower leg as far as the medial malleolus.

Damage to the femoral nerve causes weakness of knee extension, wasting of quadriceps, loss of the knee jerk, and sensory impairment over the front of the thigh and in the distribution of the saphenous nerve. With a proximal lesion, there may also be weakness of hip flexion from paralysis of iliacus.

The femoral nerve may be injured in fractures of the pelvis or femur, in dislocations of the hip, and at times during operations on the hip. It may be involved by psoas abscesses, tumours, or implicated in wounds of the thigh. It is commonly involved in large psoas muscle haematomas in haemophiliacs (see Section 22) and in diabetic amyotrophy. Owing to the rapid dispersion of the branches in the thigh, partial lesions are common from wounds at this site. The nerve to quadriceps is most often injured. The resulting paralysis causes considerable difficulty in walking as the knee cannot be locked in extension and gives way, especially when descending stairs. The saphenous nerve is sometimes damaged in operations for the treatment of varicose veins.

Obturator nerve (L2–L4)

The nerve emerges from the lateral border of psoas, crosses the lateral wall of the pelvis, and enters the thigh through the obturator foramen where it supplies gracilis, adductor longus and brevis, adductor magnus, obturator externus, and sometimes also pectineus, and the skin over the lower medial aspect of the thigh.

Damage to the obturator nerve results in weakness of adduction and internal rotation at the hip, pain in the groin, and sensory impairment on the medial part of the thigh. The nerve may be involved in neoplastic infiltration in the pelvis and can be damaged by the fetal head or by forceps during parturition.

Lateral cutaneous nerve of the thigh (L2, L3)

This nerve arises from the lumbar plexus, passes obliquely across iliacus and enters the thigh under the lateral part of the inguinal ligament. It supplies the skin over the anterolateral aspect of the thigh.

Meralgia paraesthetica is an entrapment neuropathy resulting from compression of this nerve as it passes under the inguinal ligament. It is more common in men, who are often obese, and may be unilateral or bilateral. The symptoms consist of numbness in the territory of the nerve combined with tingling or burning paraesthesiae provoked by prolonged standing, or following excessive walking. Weight loss may be helpful, and in many instances the condition subsides spontaneously. Decompression of the nerve is rarely necessary.

Sciatic nerve (L4, L5, S1–S3)

The sciatic nerve enters the thigh through the sciatic notch. It is composed of the tibial and peroneal divisions which are usually bound together within a common sheath, the tibial division lying medially. It descends through the posterior aspect of the thigh, initially deep to gluteus maximus, and supplies semitendinosus, semimembranosus, and the long head of biceps through its peroneal division. It separates into the tibial and common peroneal nerves in the lower thigh, which supply all the muscles below the knee, and both nerves contribute to the formation of the sural nerve.

Total interruption of the sciatic nerve gives rise to foot drop. Walking is possible, but the patient cannot stand on the toes or the heel of the affected foot and the ankle is unstable. All movement below the knee is paralysed. If the injury is in the upper thigh, flexion of the knee is also weak. The skin is completely anaesthetized over the entire foot except for the medial border which is supplied by the saphenous nerve. Pressure sores may develop. The anaesthesia extends upwards on the posterolateral aspect of the calf in its lower two-thirds. The sense of joint position is abolished in the foot and toes. Beyond this area of complete anaesthesia, there is a wide zone in which sensibility may be diminished. Sweating is absent on the sole and dorsum of the foot, but is preserved on the medial side. The ankle jerk is lost

but the knee jerk is retained.

The sciatic nerve may be involved in pelvic tumours and can be injured by fractures of the pelvis or femur or during hip replacement operations. After the radial and ulnar, it is implicated in gunshot wounds more frequently than any other nerve. Partial injury of the tibial division may be followed by causalgia. Incomplete lesions of the nerve may be caused by pressure of the nerve against the hard edge of a chair in individuals who fall asleep while intoxicated. Similar lesions may occur in diabetic subjects, in whom the peripheral nerves are more susceptible to pressure neuropathy.

The syndrome of root pain and sciatica is considered in Chapter 24.3.11.

Tibial nerve (L4, L5, S1–S3)

After separating from the peroneal division of the sciatic nerve in the lower thigh, this nerve passes through the popliteal fossa and enters the calf deep to gastrocnemius through the fibrous arch of soleus. It descends through the calf to the medial side of the ankle, passes beneath the flexor retinaculum, and divides into the medial and lateral plantar nerves. It supplies popliteus, all the muscles of the calf, and, through the plantar nerves, the small muscles of the sole of the foot and sensation to the sole.

When the nerve is interrupted, the patient is unable to plantarflex or invert the foot, to flex the toes, or to stand on the ball of the foot. Paralysis of the interossei leads to a claw-like deformity of the toes. Sensation is lost over the sole. Causalgia may arise after partial lesions. Injury to the distal portion of the nerve by a penetrating injury or deep wound of the calf gives rise to paralysis of the intrinsic muscles of the foot but spares the muscles acting at the ankle. Sensation is lost on the sole of the foot and this may be accompanied by pain. If the injury is distal to the origin of the branches to flexor hallucis longus and flexor digitorum longus, the lesion may escape detection since paralysis of the small foot muscles and sensory loss over the sole may be overlooked.

The tibial nerve is occasionally compressed under the flexor retinaculum (tarsal tunnel syndrome), usually precipitated by osteoarthritis or post-traumatic deformities at the ankle or by tenosynovitis. Burning pain and tingling paraesthesiae occur in the sole, usually following prolonged standing or walking. The condition is generally unilateral. Careful examination may demonstrate wasting of the intrinsic muscles in the medial aspect of the foot, and sensory impairment over the sole. Nerve conduction studies may be helpful diagnostically. Treatment is by surgical section of the flexor retinaculum.

Painful neuromas sometimes develop on the digital branches of the plantar nerves. These give rise to the syndrome of Morton's metatarsalgia in which pain occurs in the anterior part of the foot on standing. A localized area of tenderness is detectable on palpation. The condition is relieved by excision of the neuroma.

Common peroneal nerve (L4, L5, S1, S2)

After separating from the tibial division of the sciatic nerve in the lower part of the thigh, this nerve descends through the popliteal fossa, winds around the neck of the fibula, and divides into its superficial and deep branches. The superficial peroneal nerve passes down in front of the fibula, supplies peroneus longus and brevis, and emerges in the lower leg, supplying the skin on the lateral aspect of the lower leg. It crosses the extensor retinaculum and supplies the skin on the dorsum of the foot and the second to the fifth toes. The deep peroneal branch continues to wind around the fibula, pierces the anterior intermuscular septum, and descends on the anterior interosseous membrane. It innervates tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius. It passes deep to the extensor retinaculum after which it supplies the extensor digitorum brevis and the skin of the adjacent sides of the first and second toes.

Damage to the common peroneal nerve is more frequent than injury to its two branches because of its vulnerable superficial position at the neck of the fibula. It gives rise to foot drop with paralysis of dorsiflexion and eversion at the ankle and of toe extension. Cutaneous sensation is impaired over the lateral aspect of the lower leg and ankle and on the dorsum of the foot.

The common peroneal nerve may be compressed at the neck of the fibula by habitual sitting with the legs crossed, prolonged squatting, pressure during sleep or while anaesthetized, and various other events. It can be damaged by traction caused by fractures of the tibia and fibula and is sometimes damaged by ischaemia in the anterior tibial compartment syndrome. Paralysis caused by external pressure frequently gives rise to a local conduction block (neurapraxia) with satisfactory recovery within a few weeks. If electromyography indicates that nerve degeneration has taken place a foot drop support should be provided while axonal regeneration is awaited.

Sural nerve (L5, S1–S2)

This arises from the sciatic nerve and descends to the back of the calf, winds around to the lateral side of the ankle, and reaches the lateral border of the foot. It supplies the skin in this distribution. Sensory impairment occasionally results from pressure on the nerve as it lies in a superficial situation in the back of the calf.

Generalized neuropathies

Neuropathies related to metabolic and endocrine disorders

Diabetes mellitus

A significant degree of peripheral neuropathy develops in about 15 per cent of patients with diabetes, although a substantially greater number either have minor symptoms without signs, or evidence of a subclinical neuropathy either on clinical examination or on the basis of abnormalities of nerve conduction. In general, the neuropathies that appear can be divided into symmetrical sensory and autonomic polyneuropathies on the one hand, and isolated peripheral nerve lesions or multifocal neuropathies on the other. Mixed syndromes are common.

The commonest form is a symmetrical sensory polyneuropathy, giving rise to numbness and tingling paraesthesiae in the toes and feet and less often in the fingers. Aching or lancinating pains in the feet and legs, particularly at night, may be a troublesome feature. Examination reveals loss of vibration sense in the feet, depression of the ankle jerks, and distal cutaneous sensory impairment. Neuropathic plantar ulcers and occasionally Charcot joints are an important complication. Loss of pain sense results in perforating ulcers on the feet and neuropathic joint degeneration, particularly in the toes and in the tarsal joints; impaired postural sense may give rise to an ataxic gait. An acute painful diabetic neuropathy also occurs that predominantly affects the lower limbs. The onset is often associated with poor diabetic control and precipitate weight loss ('diabetic neuropathic cachexia').

Autonomic neuropathy frequently accompanies the sensory neuropathy and may be the salient manifestation. It rarely occurs in isolation. Pupillary disturbances usually take the form of a reduced response to light. Gustatory facial sweating provoked by the smell and taste of food can be troublesome. Anhidrosis may occur distally in the limbs; if it is extensive and also affects the trunk, heat intolerance may result. Symptoms referable to the alimentary tract include dysphagia from oesophageal involvement, episodes of vomiting related to gastric atony, and episodic nocturnal diarrhoea, often alternating with periods of constipation. Those related to the genitourinary system include impotence, retrograde ejaculation, and bladder atony with difficulty in voiding and urinary retention with overflow. Vascular denervation sometimes results in orthostatic hypotension, and cardiac denervation may be demonstrable by an elevated resting heart rate and the absence of beat-to-beat variation with respiration. The risk of diabetic polyneuropathy is reduced by strict glycaemic control.

Isolated nerve lesions tend to occur more commonly in elderly diabetic subjects. At times they develop insidiously, at others they have an abrupt onset with pain. Of the cranial nerves, the nerves to the external ocular muscles, particularly the third and sixth, and also the facial nerve, are the most often affected. In contradistinction to the effects of compression of the third nerve by a carotid aneurysm, the pupillary innervation is often spared. In the limbs, the lesions tend to occur at the common sites of compression or entrapment. It seems likely that the nerves of diabetics exhibit an excessive vulnerability to damage from pressure.

Diabetic amyotrophy, or proximal diabetic neuropathy, represents a particular example of a multifocal neuropathy that develops usually in elderly obese diabetics. It consists of an asymmetric proximal motor syndrome that affects the anterior thigh muscles and hip flexors, and sometimes also the anterolateral muscles of the lower leg. Less commonly it is symmetric. Its onset may be acute or insidious and is often accompanied by pain, particularly at night. There is generally little or no associated sensory loss. The knee jerks are usually depressed or absent. Inflammatory lesions including vasculitis have recently been demonstrated in peripheral

nerves in proximal diabetic neuropathy, leading to trials of immunomodulatory therapy.

The causation of diabetic neuropathy is uncertain. It tends to occur more often in poorly controlled diabetics, but the correlation is not close. It may occur for the first time on initiation of treatment with insulin, or be the presenting symptom in maturity onset diabetes. There is evidence to suggest that diabetic microangiopathy is important in the genesis of isolated nerve lesions. Metabolic factors are probably more important in the origin of the symmetric polyneuropathies, but their nature is uncertain. An increased concentration of sorbitol in nerves secondary to hyperglycaemia may be involved in causing nerve fibre dysfunction.

Focal peripheral nerve lesions and diabetic amyotrophy, if of acute onset, often recover adequately, as does acute painful diabetic neuropathy when satisfactory glycaemic control is achieved. Symmetric sensory and autonomic neuropathy, once established, recovers less satisfactorily, even with good diabetic control. Correcting the hyperglycaemia by continuous subcutaneous insulin infusion or pancreatic transplantation will stabilize the neuropathy. Trials of aldose reductase inhibitors to reduce sorbitol accumulation have, so far, not given clear evidence of improvement in neuropathy.

Care of the feet is vitally important in diabetic sensory neuropathy, to prevent the development of chronic ulceration. Pain may sometimes be helped by carbamazepine, tricyclic antidepressants, phenothiazines, or mexiletine. Hypotension can be improved by raising the head of the bed at night or by support bandages to the legs; more severe cases may require treatment with fludrocortisone. Gastroparesis may respond to metoclopramide, domperidone, or erythromycin; persistent vomiting may necessitate a Roux-en-Y gastroenterostomy. Diabetic diarrhoea can be helped by low-dosage tetracycline or diphenoxylate, loperamide, or codeine phosphate. Diabetic cystopathy can be managed in the earlier stages by regular voiding and cholinergic treatment with bethanechol. Urinary tract infections should be treated promptly. Bladder neck resection can be useful in carefully selected cases. Penile papaverine injections can be employed for erectile impotence, and sildenafil (Viagra) may be helpful in early cases. Silicone implants should be avoided because of the risk of infection.

Amyloidosis

The various forms of amyloid disease are described in Section 11.12. The peripheral nerves may be involved in primary amyloidosis due to a benign plasma cell dyscrasia and in amyloidosis related to myeloma (light chain amyloidosis). There are also several dominantly inherited forms of amyloid neuropathy, the most important of which are due to mutations in the gene for transthyretin (*TTR*), including the Portuguese type (see later). Isolated lesions may occur from the infiltration of amyloid into nerves or from compression of the median nerve in the carpal tunnel because of deposits in the flexor retinaculum. More strikingly, a generalized neuropathy may develop. It begins with selective loss of pain and temperature sensation in the feet and later in the hands. Motor involvement, loss of tendon reflexes, and impairment of other sensory modalities occur later. Autonomic involvement is an early feature, causing impotence, orthostatic hypotension, bladder atony, and disturbances of alimentary function. Amyloid deposits are present in the peripheral nerve trunks, which may be enlarged, and in the dorsal root and sympathetic ganglia.

No treatment influences the progress of the neuropathy apart from liver transplantation in neuropathy due to *TTR* mutations (see Section 11). The use of stem cell transplantation is being explored in amyloidosis related to malignant plasma cell dyscrasias. The spontaneous pains are sometimes improved by carbamazepine or tricyclic antidepressant drugs. Care must be taken to prevent damage to the anaesthetic feet, lower legs, and hands. Autonomic symptoms may require treatment as described for diabetic neuropathy.

Carpal tunnel syndrome is frequent in patients on long-term haemodialysis related to deposition of amyloid in the flexor retinaculum derived from retained b_2-microglobulin.

Uraemia

Uraemic neuropathy did not become a clinical problem until the advent of treatment of endstage renal failure by haemodialysis. It occurs in patients with severe chronic renal failure. It was most often seen in patients under treatment with periodic haemodialysis but is now much less frequently a problem. The symptoms are usually predominantly sensory, with numbness and tingling paraesthesiae in the feet. 'Restless legs' (Ekbom's syndrome) are often a conspicuous feature (see Section 24.22). A distal motor neuropathy may be associated and occasional cases are purely motor. The condition is improved by increased haemodialysis and more effectively by renal transplantation. A retained metabolite is assumed to be the cause, but this has not so far been identified.

Myxoedema

Compression of the median nerve in the carpal tunnel in myxoedema has already been discussed. Rarely a generalized mixed motor and sensory neuropathy develops. This improves on treatment of the hypothyroidism.

The slow contraction and relaxation observed in the tendon reflexes is not due to a disturbance of peripheral nerve function, but to an alteration in the contractile mechanism of the muscle fibres.

Acromegaly (see Section 12)

The occurrence of the carpal tunnel syndrome in acromegaly has also been mentioned. A rare manifestation of this condition is a sensorimotor polyneuropathy in which the peripheral nerves are thickened because of an overgrowth of the neural connective tissues. A similar neuropathy is occasionally observed in pituitary gigantism.

Critical illness polyneuropathy

A generalized polyneuropathy involving widespread axonal degeneration may be encountered in patients in intensive care units with sepsis and multiple organ failure. The neuropathy is discovered when attempts are made to wean them from the ventilator. The precise cause of this condition which has been termed critical illness polyneuropathy is unknown. Slow recovery occurs.

Other metabolic disorders

It has been claimed that a generalized peripheral neuropathy may be caused either by acute or chronic hepatic failure, but this is probably uncommon. A mild painful sensory neuropathy is occasionally encountered in primary biliary cirrhosis, sometimes related to xanthomatous deposits in the cutaneous nerve trunks. A motor neuropathy is a rare sequel to severe recurrent hypoglycaemia.

Toxic neuropathies

Industrial, environmental, and pharmaceutical substances

Acrylamide

This substance is widely employed industrially. The monomer is neurotoxic and causes peripheral neuropathy with mixed motor and sensory features. Ataxia is prominent and is possibly the result of concomitant cerebellar damage. Distal axonal degeneration occurs and slow recovery takes place on cessation of exposure.

Arsenic

Arsenical poisoning is occasionally seen as a result of accidental or homicidal ingestion of insecticides containing arsenic, or from indigenous medicines in India. Gastrointestinal symptoms develop after acute ingestion, followed by a mixed sensory and motor neuropathy after 1 to 3 weeks. Desquamation of the skin of the feet and hands takes place after about 6 weeks and white lines (Mees' lines) appear in the nails. With ingestion of smaller quantities on a chronic basis, gastrointestinal symptoms are less obtrusive and a slowly progressive neuropathy makes its appearance. The skin may become generally pigmented or show focal 'raindrop' pigmentation, and hyperkeratosis of the palms of the hands and soles of the feet may appear.

Slow recovery in the neuropathy occurs with removal from exposure. Chelating agents are of value in treating the non-neurological complications, but it is uncertain whether they are effective for the neuropathy.

Lead

Lead neuropathy is now a rare occurrence in Britain, although it was encountered as a consequence of the contamination of drinking water by lead pipes in old buildings. Subclinical neuropathy may be detectable in lead workers. It remains a hazard in certain parts of the world from the use of lead glazes in pottery. Lead neuropathy is predominantly motor, typically giving rise to wrist and foot drop. The 'lead colic' that may occur is probably a manifestation of autonomic involvement. Other features of lead poisoning that may be associated include a sideroblastic anaemia and a 'lead line' on carious teeth. The neuropathy improves on cessation of lead intake; the utility of treatment with BAL (dimercaprol), edetate, or penicillamine is uncertain.

Mercury

Exposure to inorganic mercury salts and to organic mercurial compounds may lead to neurological damage, as in 'Minamata disease' which was related to consumption of fish contaminated by organic mercury. Dementia, cortical blindness, and ataxia occur, together with sensory changes in the limbs attributed to a sensory neuropathy, although how far these have a peripheral origin is uncertain. Historically, a peripheral neuropathy was an important component of 'pink disease' which was caused by the administration of mercury-containing purgatives.

Thallium

This is present in certain pesticides and rodent poisons and was formerly used as a depilatory agent. Accidental or homicidal poisoning is occasionally encountered. Abdominal pain and diarrhoea are followed after 2 or 5 days by the development of a mixed motor and sensory neuropathy which is often painful. Evidence of central nervous system damage may be present with behaviour disorder, optic neuropathy, and choreiform movements. Alopecia develops later, after about 2 or 3 weeks, and renal damage may be produced. Diethyldithiocarbamate, which binds thallium, has been employed in treatment.

Triorthocresyl phosphate

This substance is used industrially as a high-temperature lubricant. Outbreaks of a sensorimotor neuropathy, often accompanied by evidence of damage to the central nervous system, occur periodically, usually as a consequence of the contamination of cooking ingredients or utensils. The original description was in relation to illegal liquor distillation (ginger jake paralysis) in the United States during the prohibition era. In more recent years, a large outbreak occurred in Morocco from the use of contaminated cooking oil. Recovery is slow and often incomplete.

Other industrial substances

Carbon disulphide, used in the manufacture of rayon, occasionally gives rise to a mild sensory neuropathy. Neuropathy may occur as a result of industrial exposure to the organic solvents *n*-hexane and methyl-*n*-butyl ketone. The former is also encountered as a consequence of solvent abuse; *n*-hexane, which has an intoxicant action, has been used as a solvent in certain glues. Other industrial agents causing neuropathy are ethylene oxide and methyl bromide. Trichlorethylene (or an impurity) has caused trigeminal neuropathy.

Iatrogenic

Cisplatin

This platinum derivative (*cis*-diaminedichloroplatinum) is used in the treatment of malignancy, including carcinoma of the ovary. A predominantly sensory neuropathy that recovers poorly may develop after the administration of several courses. Ototoxicity is more frequent, causing high-tone deafness and tinnitus.

Isoniazid

A mixed motor and sensory neuropathy may be produced by isoniazid and is more likely to occur in individuals who acetylate the drug slowly. The neuropathy is related to an interference with pyridoxine metabolism. Axonal degeneration occurs in the peripheral nerves. The neuropathy recovers slowly on cessation of administration of the drug and may be prevented by giving pyridoxine, which does not interfere with the antituberculous action of the isoniazid.

Nitrofurantoin

Excessively high blood levels of this preparation, as may occur in patients with reduced renal function, can cause a mixed motor and sensory neuropathy.

Vincristine

A neuropathy will occur in all subjects if sufficient amounts of this cytotoxic agent are administered. Mild sensory symptoms and the loss of tendon reflexes may have to be accepted if a satisfactory therapeutic effect of the drug is to be achieved. If the neuropathy advances, bilateral weakness of the extensors of the wrist and fingers develops, followed by more widespread weakness. The neuropathy improves satisfactorily if the drug is withdrawn or if the dosage is reduced.

Other substances

Less important drugs that may give rise to neuropathy are adriamycin, amiodarone, dapsone, disulfiram, gold, metronidazole, misonidazole, nitrous oxide (with a myelopathy), suramin, and zimeldine. A mild sensory neuropathy may develop after prolonged administration of phenytoin, and neuropathy was one of the complications produced by thalidomide. Pyridoxine, if taken in large doses, as 'megavitamin therapy', causes a sensory neuropathy.

Deficiency neuropathies

Beri beri neuropathy (see also Section 10)

This disorder is predominantly encountered in populations subsisting on diets composed largely of polished rice, but a similar neuropathy may be observed in other malnourished communities. Thiamine deficiency is probably involved, but a deficiency of other vitamins of the B group may also be implicated. A distal motor and sensory neuropathy develops which is frequently accompanied by spontaneous aching pain in the extremities, cutaneous hyperaesthesia, and tenderness of the soles of the feet and calves. Involvement of the recurrent laryngeal nerves may lead to hoarseness of the voice. The neuropathy may be associated with a cardiomyopathy ('wet beri beri'). Thiamine deficiency is established by the finding of reduced activity of erythrocyte transketolase. This enzyme requires thiamine as a cofactor.

Distal axonal degeneration occurs in the peripheral nerves and slow recovery ensues with vitamin replacement.

Strachan's syndrome

Strachan's syndrome, originally described in Jamaica but also observed in other parts of the world under conditions of nutritional deprivation, is characterized by the combination of a painful sensory neuropathy with amblyopia and at times deafness, in association with an orogenital dermatitis. It is assumed to be due to B vitamin deficiency, but the precise deficit has not been identified. It improves with B vitamin supplementation.

Alcoholic neuropathy

This always occurs on a background of nutritional deficiency. The dietary intake of the alcoholic is high in carbohydrates and low in vitamins. Moreover, alcoholics are known to have a reduced capacity to absorb thiamine. A direct toxic effect of alcohol on peripheral nerves may also be involved. The clinical features of alcoholic neuropathy are similar to those of beri beri. Other deficiency states may coexist, such as the Wernicke–Korsakoff syndrome. Improvement may take place with vitamin replacement and reduced alcohol intake, but it is beset with the usual difficulties met in treating alcoholic patients.

Pyridoxine deficiency

Attention has already been drawn to the fact that isoniazid neuropathy is related to an interference with pyridoxine metabolism. Pyridoxine deficiency may contribute to the neuropathy that occurs in nutritional deficiency states, and possibly accounts for the mild neuropathy of pellagra.

Pantothenic acid deficiency

Experimental deficiency of pantothenic acid in human volunteers is known to give rise to a sensory neuropathy, and the administration of pantothenic acid has been reported to alleviate the 'burning feet' syndrome which sometimes develops in deficiency states.

Vitamin B_{12} deficiency

Vitamin B_{12} deficiency, from whatever cause, may be responsible for the development of a distal sensory neuropathy, with 'glove and stocking' sensory loss and paraesthesiae, and areflexia, either in isolation or in association with a myelopathy or other central nervous system manifestations. Haematological changes are not always present. The peripheral neuropathy improves more satisfactorily with treatment than the central disturbances. This condition is considered in detail in Chapter 24.3.9.

A peripheral neuropathy is one component of Nigerian ataxic neuropathy, in which the other features are posterior column degeneration, sensorineural deafness, and optic atrophy. It has been suggested that an interference with vitamin B_{12} metabolism by cyanide derived from cassava in the diet, combined with nutritional deficiency, may be responsible.

Chronic severe vitamin E deficiency has recently been established as a cause for peripheral neuropathy in combination with a spinocerebellar degeneration. This may occur in abetalipoproteinaemia, and isolated vitamin E deficiency, both of autosomal recessive inheritance, and in congenital biliary atresia, cystic fibrosis, and occasional adults with chronic intestinal malabsorption.

Inflammatory and post-infective neuropathies

Leprous neuropathy

Peripheral nerve involvement in leprosy is considered in Chapter 7.11.24.

Guillain–Barré syndrome (acute idiopathic inflammatory polyneuropathy)

Guillain–Barré syndrome is characterized by a polyneuropathy that develops over the course of a few days up to maximum of 4 weeks. Cases that progress for up to 8 weeks (subacute Guillain–Barré syndrome) are probably distinct. An identifiable infection may precede the onset of the neuropathy by 1 to 3 weeks. This is commonly an upper respiratory tract infection or an infection with an enterovirus, Epstein–Barr virus, or mycoplasma. More recently *Campylobacter jejuni* has been recognized as an important cause, as has human immunodeficiency virus (**HIV**) infection. Other cases may follow surgical operations. In approximately 40 per cent of cases no antecedent event is identifiable.

The neuropathy may be ushered in by severe lumbar or interscapular pain. Motor involvement usually predominates over sensory loss and may be of a proximal, distal, or generalized distribution, and in severe cases affects the respiratory musculature. Distal paraesthesiae in the limbs are common and, if sensory loss occurs, it tends to affect tactile, vibratory, and postural sensibility. The cranial nerves may be affected, in particular the facial nerves, but bulbar involvement also occurs sometimes. A complete 'locked-in' state may develop. Autonomic disturbances may be associated, including bladder atony, ileus, hypertension (possibly the result of denervation of the carotid sinus), and orthostatic hypotension. Associated central nervous system involvement is occasionally encountered, particularly after infectious mononucleosis, and such cases are sometimes excluded from the Guillain–Barré syndrome as such. Papilloedema sometimes develops, possibly related to impaired resorption of cerebrospinal fluid because of the elevated protein content. Further variants are a combination of an external ophthalmoplegia, ataxia, and tendon areflexia (Miller Fisher syndrome), as possibly are instances of acute sensory neuropathy or pandysautonomia.

Nerve conduction studies reveal evidence of demyelination in most cases, but at times the findings indicate an axonopathy ('axonal' Guillain–Barré syndrome), as is seen in the acute motor axonal neuropathy or motor and sensory axonal neuropathy that occurs as an annual epidemic in children in northern China. Cerebrospinal fluid protein is usually raised, often to a substantial degree, but it may be normal, particularly in the early stages. The cell content is usually normal, but there may be a mild lymphocytic pleocytosis; this is more likely to occur in cases related to HIV infection or infectious mononucleosis. The Miller Fisher syndrome is frequently associated with circulating anti-GQ1b antibodies. Histologically, the abnormalities are maximal in the spinal roots but also occur diffusely throughout the peripheral nerves. In the demyelinating form, focal perivascular accumulations of inflammatory cells are associated with segmental demyelination of the nerve fibres and relative preservation of axonal continuity. Recovery occurs by remyelination. The disease probably represents a cell-mediated hypersensitivity reaction in which myelin is stripped off the axons by mononuclear cells. Whether antibody-mediated demyelination is also involved is not yet established. Severe axonal loss may be a 'bystander effect' or represent direct axonal damage in cases of axonal Guillain–Barré syndrome.

Most cases of Guillain–Barré syndrome recover satisfactorily within weeks or months. Severely affected patients, particularly those that require assisted respiration and in whom extensive axonal degeneration occurs, recover slowly and often show residual muscle weakness. Occasional patients have recurrences, which are sometimes multiple.

Although widely employed in the past, controlled trials of treatment with corticosteroids have shown no beneficial effects. Plasma exchange and high-dose intravenous human immunoglobulin have both been shown to improve the rate of recovery if given before the nadir of the disease. Because of significant morbidity, particularly with plasma exchange, and cost, these forms of treatment are best reserved for more severe cases. Severely affected patients may require extensive support in an intensive care unit because of respiratory failure and autonomic dysfunction.

Chronic inflammatory demyelinating polyneuropathy

Instances of peripheral neuropathy occur that resemble Guillain–Barré syndrome in that the neurological involvement is predominantly motor and the cerebrospinal fluid protein level is elevated, but which pursue either a chronic relapsing or chronic progressive course. They are also associated with widespread demyelination in the spinal roots and peripheral nerves and with inflammatory infiltrates. Nerve conduction velocity is usually markedly reduced and conduction block may be evident. Cases with a purely sensory ataxic neuropathy also occur, as do others with localized involvement, most often of the brachial plexus. Both the generalized and focal cases may respond to treatment with corticosteroids, plasma exchange, or high-dose intravenous human immunoglobulin. Cytotoxic drugs may be required in refractory cases. The response is less satisfactory in the chronic progressive cases.

Patients have recently been identified with a chronic multifocal motor neuropathy with persistent conduction block associated with GM1 ganglioside antibodies. They probably represent a variant of chronic inflammatory demyelinating polyneuropathy. They may respond to immunosuppressive therapy or plasma exchange.

Lyme borreliosis

Lyme borreliosis is a multisystem disease caused by a tick-borne spirochaete *Borrelia burgdorferi* (see Chapter 7.11.30). The peripheral nervous system is frequently affected both during the phase of early disseminated infection and during the late stage. Cranial neuropathies or an acute or subacute radiculoneuritis characterize involvement in the early stages, and a mild, predominantly distal, neuropathy characterizes the late stage. Nerve biopsies show perivasculitis and nerve fibre

degeneration, but spirochaetes are not identifiable. Laboratory diagnosis is based on the detection of specific antibodies to *B. burgdorferi* but seronegative cases occur, as may false positive reactions. Treatment, which is with doxycycline and amoxicillin, may therefore have to be given on clinical suspicion of the disease.

Human immunodeficiency virus infection (see Chapter 24.14.4)

A variety of neuropathies may be related to HIV-1 infection, particular types tending to occur in different phases of the disease. Characteristically, Guillain–Barré syndrome or chronic inflammatory demyelinating polyneuropathy occur at the time of seroconversion, when the patient is otherwise well, and a multifocal vasculitic neuropathy occurs in the early symptomatic stage. A distal, often predominantly sensory and painful neuropathy occurs mainly in the later AIDS phase, and an aggressive lumbosacral polyradiculoneuropathy from cytomegalovirus infection is encountered in advanced cases. Neuropathy may also occur in patients with human T-cell leukaemia virus (HTLV-I) infection. The treatment of HIV infection is discussed in Chapter 7.10.21.

Sarcoid neuropathy

Sarcoidosis (see Section 17) may give rise to a multifocal neuropathy with a particular tendency to involve the facial nerves, or to a generalized neuropathy. The neuropathy may be restricted to the cranial nerves (polyneuritis cranialis). Evidence of involvement of other systems is not always present and sarcoid tissue may or may not be detectable on biopsy.

Diphtheritic neuropathy

The neuropathy of diphtheria (Chapter 7.11.1) is caused by the exotoxin which produces segmental demyelination by interfering with Schwann cell function, probably by affecting protein synthesis. The nerves are not invaded by the bacteria.

Palatal weakness tends to develop after 2 to 3 weeks following pharyngeal diphtheria, and local muscle paralysis after a similar interval following cutaneous diphtheria. Paralysis of accommodation and sometimes of the external ocular muscles appears after an interval of 4 to 5 weeks. A generalized predominantly motor neuropathy of distal distribution may develop after 5 to 7 weeks. In severe cases the respiratory muscles are affected, but if death occurs it is usually as a result of an associated myocarditis.

Neuropathy in autoimmune connective tissue disorders

Peripheral nerve involvement may be encountered in a wide range of the 'collagen-vascular' disorders. Polyarteritis nodosa characteristically gives rise to a multifocal neuropathy, often with considerable pain. Wegener's granulomatosis may similarly be associated with a florid neuropathy and, in both instances, the peripheral nerve damage is related to necrotizing angiitis of the vasa nervorum. Such changes may also occur in rheumatoid arthritis in association with a florid multifocal neuropathy; at other times, a less aggressive neuropathy is observed, either in the form of a distal sensory neuropathy or one restricted to the digital nerves. Entrapment neuropathies also occur in rheumatoid arthritis, for example median nerve compression in the carpal tunnel, related to inflammatory changes in articular synovial tissues or tendon sheaths.

An ataxic sensory neuropathy related to a sensory ganglionitis can complicate the Sjögren sicca syndrome. A clinical constellation that combines a distal ensory neuropathy with a trigeminal sensory neuropathy, and myotonic pupils with the sicca syndrome is particularly characteristic. A multifocal neuropathy can also be seen in patients with Sjögren's syndrome.

The neuropathy of polyarteritis nodosa or rheumatoid arthritis may respond to corticosteroids or cyclophosphamide. The neuropathy of Sjögren's sicca syndrome is largely refractory to treatment.

Neoplastic and paraneoplastic neuropathy

Peripheral neuropathy may develop as a non-metastatic complication of carcinoma, most often bronchial or gastric, or lymphoreticular proliferative disorders. The precise mechanism of production of the neuropathy is uncertain. The neuropathy may antedate the discovery of the carcinoma by as much as 2 or 3 years. In relation to carcinoma of the bronchus, the neuropathy may be purely sensory, either subacute or chronic, often with troublesome distal dysaesthesiae, or mixed sensory and motor. The sensory neuropathy is associated with circulating antineuronal Purkinje cell and anti-Hu antibodies. Guillain–Barré syndrome may be encountered in Hodgkin's disease and in chronic lymphocytic leukaemia, and a subacute, mainly motor neuropathy in relation to lymphoma. Non-metastatic carcinomatous neuropathies may regress following removal of the underlying tumour, or may remain unaffected.

Direct invasion of cranial nerves or spinal roots may occur in cases of malignant infiltration of the meninges and of the cervical and lumbosacral plexuses from local malignancies. Infiltration of peripheral nerve trunks is seen most commonly from malignant lymphomas.

Paraproteinaemic neuropathy

A sensory or sensorimotor polyneuropathy related to benign monoclonal paraproteins (monoclonal gammopathies of undetermined significance) has emerged n recent years as an important cause of late onset neuropathy. The neuropathy is usually demyelinating, and in some with features similar or identical to chronic inflammatory demyelinating polyneuropathy. A postural upper limb tremor is often a prominent feature. The paraprotein is most commonly immunoglobulin M, less frequently immunoglobulins G or A. The immunoglobulin M paraproteins can be demonstrated on surviving myelin sheaths in nerve biopsies, where they are probably acting as demyelinating antibodies. Neuropathies associated with immunoglobulin G or A paraproteins may respond to corticosteroids, intravenous immunoglobulin, plasma exchange or immunosuppressive drugs; the response in immunoglobulin M paraproteinaemic neuropathy is disappointing. Although a distal sensorimotor and often painful axonal neuropathy may be associated with myeloma, a demyelinating neuropathy accompanied by a dermatoendocrine syndrome may be encountered, referred to as the Crow–Fukase or POEMS syndrome (**P**olyneuropathy, **O**rganomegaly, o**E**dema, **M** protein, **S**kin changes). A mixed sensorimotor neuropathy occurs which may be associated with papilloedema. The skin changes consist of excessive pigmentation and hypertrichosis. Peripheral oedema develops. Partial syndromes may occur in which all features of the syndrome are not present. The disorder is most often related to osteosclerotic myeloma.

Multifocal, predominantly lower limb, neuropathy may be caused by single or mixed cryoglobulins in myeloma, lymphoma, systemic lupus erythematosus, rheumatoid arthritis, or Waldenström's macroglobulinaemia. They may be the result of vasculitis produced by the deposition of immune complexes in the walls of the vasa nervorum, or to intravascular precipitation of cryoglobulin. These neuropathies occasionally respond to treatment either with immunosuppressive or cytotoxic drugs, or to repeated plasma exchange.

Genetic neuropathies

Porphyria (see also Section 11)

A predominantly motor neuropathy may complicate acute attacks in the autosomal dominant disorders of acute intermittent and variegate porphyria and hereditary coproporphyria, and in the recessively inherited †-aminolaevulinic acid dehydratase deficiency. It tends to affect the proximal muscles to a greater extent. There may be associated sensory loss which, although sometimes distal in distribution, can affect the trunk and the proximal portions of the limbs. The tendon reflexes are lost, with occasional paradoxical sparing of the ankle jerks. Accompanying autonomic features include abdominal pain and vomiting, tachycardia and hypertension; mental confusion, psychotic behaviour, and epilepsy.

The explanation of the neurological damage has not been established. Axonal degeneration occurs in the peripheral nerves so that recovery is slow and often incomplete.

Attacks may be provoked by a variety of drugs, including barbiturates, sulphonamides, and the contraceptive pill, and by alcohol, probably by enzyme induction in the liver (see Section 14).

Treatment with oral or intravenous glucose, or by infusions of laevulose or haematin, has been shown to reduce the urinary excretion of porphyrin precursors, but a

beneficial effect on the neurological disturbances has not been established.

Familial amyloid polyneuropathy

A number of inherited amyloid neuropathies have been recognized, the commonest being those related to point mutations in the gene for transthyretin, formerly known as prealbumin, which is on chromosome 18. The commonest is the Portuguese type where there is a substitution of valine for methionine in the transthyretin molecule. The neuropathy begins with the involvement of small nerve fibres, leading to a distal loss of pain and temperature sensation and autonomic failure. Spontaneous pain is often a feature and a mutilating acropathy frequently develops. The onset is commonly in the fourth or fifth decades and the disorder is slowly progressive, leading to death within about 10 years. Transthyretin is produced mainly in the liver and liver transplantation may halt the progression of the disease. In other types of hereditary amyloid neuropathy with differing clinical features, the amyloid is derived from a variant apolipoprotein A1 (Iowa form) or plasma gelsolin (Finnish form).

Hereditary motor and sensory neuropathy types I and II and X-linked (Charcot–Marie–Tooth disease, peroneal muscular atrophy); hereditary neuropathy with liability to pressure palsies

Hereditary motor and sensory neuropathies type I and II (or Charcot–Marie–Tooth 1, Charcot–Marie–Tooth 2) usually present during childhood or adolescence with difficulty in walking or because of foot deformity. The deformity is most commonly pes cavus associated with clawing of the toes and sometimes with an equinovarus position of the foot. Muscle weakness tends to affect the lower leg muscles and may give rise to bilateral foot drop with a 'steppage' gait. The muscle wasting is often restricted to below the knees, producing a 'stork leg' appearance (Fig. 3). Weakness and wasting of the small hand muscles may appear later. The tendon reflexes become depressed or lost, and there is a variable degree of distal sensory loss. This is the Charcot–Marie–Tooth phenotype. Progress of the disease is slow and cases with little disability or which are asymptomatic are common.

Fig. 3 Patient with type I hereditary motor and sensory neuropathy (Charcot–Marie–Tooth disease) showing symmetrical distal lower limb muscle wasting.

In the commoner type I families, there is a diffuse demyelinating neuropathy. The onset is most frequently in the first decade. Foot deformity and scoliosis occur more often than in the type II disease. Sensory loss and ataxia tend to be greater and generalized tendon areflexia is usual. Weakness in the hands appears earlier. The peripheral nerves may be thickened. Cases with ataxia and upper limb tremor are sometimes referred to as the Roussy–Lévy syndrome. The onset in the type II form, which is an axonal neuropathy, is most often in the second decade but it may be delayed until middle or even late adult life. Inheritance in both types I and II hereditary motor and sensory neuropathy is usually autosomal dominant. The disorder in type I hereditary motor and sensory neuropathy is most often caused by a segmental duplication on chromosome 17p11.2 (hereditary motor and sensory neuropathy HMSN Ia) which includes the gene for peripheral myelin protein 22 (*PMP22*). Other cases are related to mutations in the gene for myelin protein zero (hereditary motor and sensory neuropathy Ib). X-linked hereditary motor and sensory neuropathy is due to mutations in the gene for connexin 32. The clinical features resemble hereditary motor and sensory neuropathy I but female carriers are asymptomatic or only mildly affected. Several separate loci have so far been identified for hereditary motor and sensory neuropathy II but the gene products are not known.

Nerve conduction velocity is severely reduced in type I cases, moderately reduced in the X-linked form, and either normal or only slightly reduced in type II.

Affected individuals may be helped by the use of orthotic appliances and sometimes by surgical correction of foot deformity or tendon transfer.

Hereditary neuropathy with liability to pressure palsies is an autosomal dominant disorder in which affected individuals develop recurrent focal peripheral nerve or brachial plexus lesions produced by compression or stretch injury. It has been shown usually to be due to a segmental deletion on chromosome 17p11.2, i.e. it is the reciprocal of hereditary motor and sensory neuropathy Ia. Nerve fibres show focal regions of myelin thickening (tomacula).

Hereditary motor and sensory neuropathy type III (Dejerine–Sottas disease and congenital hypomyelination)

The Dejerine–Sottas phenotype consists of a severe slowly progressive mixed motor and sensory polyneuropathy with an onset in childhood. There is hypomyelination and extensive demyelination in the peripheral nerves, and there may be accompanying hypertrophic changes (concentric Schwann cell proliferation). Striking enlargement of the peripheral nerve trunks may be evident. These cases are most often due to de novo *PMP22* or P zero (*P0*) mutations. Some cases result from mutations in the early growth response gene 2 (*EGR2*). A severe congenital hypomyelination neuropathy can also result from *P0* or *EGR2* mutations.

Refsum's disease

This is a rare disorder inherited as an autosomal recessive trait that gives rise to a mixed motor and sensory polyneuropathy accompanied by a variety of other clinical features, including ataxia, anosmia, pigmentary retinal degeneration, pupillary abnormalities, deafness, cardiomyopathy, and ichthyosis. The presentation is usually during adolescence or early adult life and the course may be steadily progressive or relapsing. The peripheral nerves become thickened and display hypertrophic changes. Nerve conduction velocity is usually severely reduced.

The disorder is due to an inability to metabolize phytanic acid, a long-chain fatty acid, which accumulates in the blood and tissues. Phytanic acid is largely of dietary origin, and clinical improvement may be achieved with diets low in phytanic acid. Plasma exchange is effective for acute episodes of deterioration.

Hereditary sensory and autonomic neuropathies

Predominantly sensory neuropathies may occur with either an autosomal dominant or recessive inheritance. The symptoms in the latter instance are usually present from birth; in the former they generally develop during the second or third decades. In both, the sensory loss often leads to a mutilating acropathy, with neuropathic joint degeneration and chronic cutaneous ulceration, particularly of the feet (Fig. 4). Autonomic features are dominant in the recessive disorder of familial dysautonomia (Riley–Day syndrome). A further rare recessive neuropathy combines congenital insensitivity to pain and anhidrosis. Most cases of 'congenital insensitivity to pain' are probably examples of small-fibre neuropathies.

Fig. 4 Chronic foot ulceration and deformity in a case of hereditary sensory neuropathy.

Familial dysautonomia

Otherwise known as the Riley–Day syndrome, this recessively inherited disorder is encountered most often in Jewish populations. There is an aplasia of peripheral autonomic neurones that leads to a variety of symptoms, including absence of tears, unexplained pyrexia, cutaneous blotching, and episodic sweating attacks. These symptoms are present at birth and are accompanied by congenital insensitivity to pain related to an associated sensory neuropathy. In early infancy there is usually difficulty in feeding because of poor sucking, and repeated episodes of aspiration pneumonia. Later, stunted growth and often kyphoscoliosis become evident. The disorder has been mapped to chromosome 9.

Other hereditary neuropathies (see also Section 11)

Peripheral nerve involvement occurs in metachromatic and globoid cell leucodystrophy, adrenomyeloneuropathy, Fabry's disease, hereditary high-density lipoprotein deficiency (Tangier disease), hereditary abetalipoproteinaemia, and cholestanolosis. Giant axonal neuropathy is a rare autosomal recessive disorder with an onset in childhood, characterized by segmental axonal enlargements containing accumulations of neurofilaments. Affected children usually have abnormally curly hair and may have enlarged tangerine-coloured tonsils.

Cryptogenic neuropathy

Despite extensive investigation, the cause of a substantial number of peripheral neuropathies remains unknown. This applies in particular to examples of chronic progressive axonopathies, some of which may be instances of late onset type II hereditary motor and sensory neuropathy. A careful family history in such cases may reveal evidence of undetected neuropathy in relatives. Prolonged follow-up in other cases may disclose underlying malignancy.

24.20 Neurological complications of systemic autoimmune and inflammatory diseases

Neil Scolding

Introduction

The range and breadth of diseases of the nervous system caused by immunological, infective, or inflammatory disturbances is very large. It includes 'primary' or idiopathic neuroimmune disorders, which may affect any part of the neuraxis (for example multiple sclerosis and Guillain–Barré syndrome) and which are very familiar to neurologists. However, 'secondary' disorders, where the neurological disturbance reflects involvement of the nervous system in a systemic inflammatory disease, are often no less common than idiopathic immune disorders, but most neurologists are rather less familiar and possibly less comfortable with them.

Systemic lupus erythematosus

Systemic lupus erythematosus, like many autoimmune diseases, occurs more in women than men—perhaps 20 times more commonly. Black people are more commonly affected than white. The neurologist should not (but usually does) omit direct enquiry and focused systemic examination to exclude fever and general malaise, skin changes—classically, the malar butterfly rash and/or photosensitivity—and large and small joint arthritis. Glomerulonephritis, pleurisy and pneumonitis, pericarditis and (so-called) Libmann–Sachs endocarditis, and haematological disorders—anaemia, thrombocytopenia, leucocytopenia, and the generation of circulating anticoagulants—also occur. Other laboratory abnormalities include the presence of a variety of autoantibodies, including antinuclear antibodies and anti-native DNA antibodies. The diagnosis—particularly for research and therapeutic trial purposes—is now commonly based on the widely accepted revised diagnostic criteria suggested by the American College of Rheumatology. The presence of any four (or more) of the listed features, 'serially or simultaneously, during any interval of observation' are sufficient for the diagnosis, with an estimated specificity and sensitivity of 96 per cent.

Neurological complications

Neurological involvement in systemic lupus erythematosus is seen in perhaps 50 per cent of cases; neurological presentation, in perhaps 3 per cent of cases. Central nervous system disease is much more frequent than neuromuscular involvement, and is a poor prognostic sign, reducing the overall survival figures, and representing the third commonest cause of death (after renal involvement and iatrogenic causes).

An enormous variety of central nervous system disease complications can occur, reflecting two broad pathogenetic mechanisms—thromboembolic (triggered either by changes in endothelial surfaces or by coagulation disturbances, including lupus anticoagulant activity) and more direct autoimmune events affecting the target tissue—neurones or glia—in which soluble and cellular mediators are implicated.

Headache (including that associated with dural sinus thrombosis), acute or subacute encephalopathy, fits, myelitis, strokes and movement disorders (especially chorea), ataxia and brainstem abnormalities, and cranial and peripheral neuropathies are all seen in the context of systemic lupus erythematosus. Psychiatric and cognitive disturbances have also long been associated with lupus.

Stroke, the lupus anticoagulant, and the primary phospholipid syndrome

The thrombotic tendency in patients with systemic lupus erythematosus and lupus anticoagulant manifests itself principally in the form of stroke and recurrent spontaneous abortion. Intra-abdominal and deep venous thrombosis, and peripheral arterial thrombosis are also seen. Thrombocytopenia is a key additional feature. Importantly, Hughes also showed that a similar clinical picture was associated with the presence of anticardiolipin antibodies (ACA) and/or lupus anticoagulant in patients without serological or clinical evidence of lupus, and introduced the term 'antiphospholipid syndrome'.

ACAs represent an independent risk factor for stroke. Central nervous system thrombosis in patients with primary or secondary antiphospholipid syndrome takes the form of completed arterial stroke, repeated transient ischaemic attacks, multi-infarct dementia, and cerebral venous sinus thrombosis. Vascular visual problems, including amaurosis fugax and ischaemic retinopathy, also occur. Chorea too is associated with antiphospholipid antibodies; the putative link with migraine may be factitious.

A severe acute ischaemic encephalopathy is also described, with confusion, obtundation, and a hyperreflexic quadriparesis (usually asymmetrical), with or without systemic disturbances (dermatological and renal). Cerebrospinal fluid examination may show only a raised protein; a fatal outcome is common. The disorder may represent a focal variant of the recently described 'catastrophic antiphospholipid syndrome', in which there is severe multi-organ failure and a mortality of the order of 60 per cent.

There are both clinical and pathological similarities between microangiopathic complications of lupus and the syndrome of thrombotic thrombocytopenic purpura. In this latter uncommon disorder, multi-organ involvement is also seen, with hepatic and renal disease, and fever, together with thrombocytopenia and an associated purpuric rash and other haemorrhagic complications. Neurologically, an encephalopathy occurs, often with fits, with or without focal deficits. Pathologically, there are widespread microangiopathic changes in the brain and systemically. Plasma exchange is commonly recommended.

Diagnosis of central nervous system lupus

Cerebrospinal fluid examination may reveal a raised protein level and a neutrophil or lymphocyte pleocytosis. It is clearly vital in such cases to exclude infectious complications of immune suppressants or steroids, now a major cause of death in patients with lupus. Serological tests are discussed elsewhere. MRI changes are common, though neither invariable nor specific. Cerebrospinal fluid oligoclonal band analysis is positive in up to 50 per cent of patients with central nervous system lupus and, interestingly, these changes can resolve with successful immunotherapy. A skin biopsy can be extremely helpful in suspected lupus (see Chapter 18.10.2).

The management of neuropsychiatric lupus

Symptomatic therapies are important in patients with encephalopathies, epilepsy, and/or psychiatric ailments. Disease-modifying therapeutic efforts fall into two categories depending on the presumed underlying mechanisms: (i) stroke prevention in cerebral ischaemia, particularly that associated with ACA, probably best achieved with moderate- to high-dose warfarin, and (ii) immunotherapy of 'other' central nervous system complications. Here, intravenous methyl prednisolone followed by oral steroids is the mainstay of treatment. Cyclophosphamide may be given for severe or steroid-resistant disease, with azathioprine to maintain remission and spare steroids. Plasmapheresis synchronized with cyclophosphamide, and intravenous immunoglobulin, may prove useful.

Rheumatoid arthritis

An inflammatory peripheral neuropathy occurs in approximately 30 per cent of seropositive rheumatoid cases. A relatively benign mononeuritis is typical, but a more severe and aggressive axonal polyneuropathy or mononeuritis multiplex may be seen when rheumatoid arthritis is accompanied by a vasculitis. More common than either are entrapment neuropathies of conventional distribution, precipitated by synovial swelling. Pannus formation and cervical spine subluxation with resulting cord compression represent the commonest cause of central nervous system involvement. More rarely, rheumatoid vasculitis, or deposition of rheumatoid nodules, may involve the central nervous system; the former warrants treatment with cyclophosphamide and steroids.

Sjögren's syndrome

Sjögren's syndrome characteristically comprises a triad of: (i) keratoconjunctivitis sicca, and (ii) xerostomia, occurring in approximately 50 per cent of cases (iii) in the context of another connective tissue, usually rheumatoid arthritis. Speckled antinuclear antibodies of the anti-Ro (SS-A) or anti-La (SS-B) type are present in up to 75 to 80 per cent of patients. Conventionally, the principal neurological manifestations have been held to be peripheral, with descriptions of both a mainly sensory neuropathy and of myositis. Trigeminal sensory neuropathy is also classically described.

More recently, attention has been drawn to various central nervous system complications of the disorder, with seizures, focal stroke-like or brainstem neurological deficits, and encephalopathy with or without an aseptic meningitis, often with raised cerebrospinal fluid pressure, protein, and white cell count, together with oligoclonal immunoglobulin bands. Psychiatric abnormalities may occur; spinal cord involvement may take the form of an acute transverse myelitis, a chronic myelopathy, or intraspinal haemorrhage. Occasionally, the features resemble those of multiple sclerosis (optic neuropathy is particularly associated) although most such patients have additional features of peripheral neuropathy or myositis.

Steroids may be insufficient for the treatment of patients with central nervous system complications of Sjögren's syndrome; more powerful immunosuppressants are probably more useful, although, as is so often the case, their value is yet to be proved objectively.

Systemic sclerosis

Systemic sclerosis results from the excessive deposition of collagen in the skin and other affected tissues. The cutaneous manifestation, scleroderma, may exist in isolation, but in multisystem disease, it is accompanied by Raynaud's phenomenon, calcinosis and atrophy of subcutaneous tissues, telangiectasia, and oesophageal strictures. Neurological complications are not common. Peripheral nervous system disease predominates, particularly painful trigeminal neuropathy; myopathy with an elevated creatine phosphokinase also occurs. A myelopathy may be associated. No treatment is of proven benefit.

Mixed connective tissue disease

In this disorder, features of scleroderma, polymyositis, and systemic lupus erythematosus coincide, and high levels of antibodies directed against extractable nuclear antigens—ribonucleoproteins—are found. Rheumatoid factor is also often present. In common with both systemic sclerosis and Sjögren's syndrome, trigeminal neuralgia and/or sensory neuropathy are described.

Seronegative arthritides

Ankylosing spondylitis

Neurological disease in the setting of ankylosing spondylitis usually reflects advanced bony disease; a cauda equina syndrome is well reported, unexplained, and difficult to treat.

Reiter's disease

The clinical triad of seronegative arthropathy, non-specific urethritis, and conjunctivitis, usually following venereal or dysenteric infection, constitutes Reiter's syndrome. As many as 25 per cent of patients are reported to have neurological features. Peripherally, radiculitis and polyneuritis occur; central nervous system disorders include aseptic meningoencephalitis, seizures, and psychiatric disturbances, particularly paranoid psychosis. Cranial neuropathies, pyramidal signs, and myelopathy are also reported. A recent report suggests that cyclosporin may be of value in severe Reiter's disease.

Psoriasis

Included as the third seronegative arthropathy, the neurology of psoriasis is not extensive. Cord compression from cervical psoriatic spondylosis is described, but reports of a complicating polyneuritis have not been substantiated.

Vasculitis

The vasculitides are a heterogeneous group of disorders which share certain pathological features, particularly intramural inflammation and necrotic changes within the walls of blood vessels. Their classification is complex, with subdivisions into: (i) idiopathic vasculitic disorders, for example giant cell arteritis and Wegener's granulomatosis; (ii) vasculitis secondary to collagen diseases, malignancy, viral infection, and so on; and (iii) vasculitis according to pathological features, largely vessel size (see Section 18.10). Nervous system involvement can occur in any of the systemic vasculitides. Additionally, isolated vasculitis of the central or peripheral nervous system is recognized, where little or no inflammation is apparent outside the nervous system—primary central (or peripheral) nervous system angiitis. In both primary and secondary vasculitis of the nervous system, neurological features arise from inflammation and necrosis of the vasculature, principally through infarction.

The clinical features of vasculitis of the nervous system

The picture of peripheral nerve vasculitis is relatively straightforward: a mixed sensory and motor neuropathy, usually rapidly progressive, and often painful. About 50

per cent of patients present with mononeuritis multiplex, the remainder with a more diffuse asymmetrical polyneuropathy or a distal symmetric neuropathy.

Central nervous system disease is infinitely more varied; focal or multifocal infarction, or diffuse ischaemia, affecting any part of the brain, explaining the protean manifestations, wide variation in disease activity, course, and severity, and the absence of a pathognomic or even a typical clinical picture. Thus, in primary and secondary intracranial vasculitis, the following are seen: headache, focal and generalized seizures, stroke-like episodes causing hemispheric or brainstem deficits, acute and subacute encephalopathies, progressive cognitive changes, behavioural disturbances, chorea, myoclonus and other movement disorders, and optic and other cranial neuropathies. The course is commonly acute or subacute, but monophasic, chronic progressive, and spontaneously relapsing–remitting presentations all occur. Despite this range, three broad clinical categories of presentation may be delineated: (i) phenotypically resembling atypical multiple sclerosis ('MS-plus'), with a relapsing–remitting course, and features such as optic neuropathy and brainstem episodes accompanied by other features less common in multiple sclerosis—seizures, severe and persisting headaches, encephalopathic episodes, or hemispheric stroke-like episodes; (ii) acute or subacute encephalopathy, with headache with an acute confusional state, progressing to drowsiness and coma; and (iii) intracranial mass lesion—with headache, drowsiness, focal signs, and (often) raised intracranial pressure. This grouping carries neither pathological nor therapeutic implications, but may help improve recognition of the condition. Systemic features, such as fever and night sweats, livedo reticulares, or oligoarthropathy, may be present (although often only revealed on direct enquiry) even in so-called isolated central nervous system vasculitis.

Diagnosis and management

The diagnosis of cerebral vasculitis involves the exclusion of alternative possibilities (Table 1), the confirmation of intracranial vasculitis, and pursuit of the causes of vasculitis.

Confirming cerebral vasculitis

No single simple investigation is universally useful in confirming cerebral vasculitis. Serological markers, including antineutrophil cytoplasmic antibodies (**ANCA**), are important. Spinal fluid examination is, like the erythrocyte sedimentation test, often abnormal, but lacks specificity, with changes in cell count and/or protein in 65 to 80 per cent of cases; oligoclonal immunoglobulin bands may be present. Magnetic resonance imaging may disclose ischaemic areas, periventricular white matter lesions, haemorrhagic lesions, and parenchymal or meningeal enhancing areas, but lacks both specificity and sensitivity. Contrast angiography may show segmental (often multifocal) narrowing and areas of localized dilatation or beading, often with areas of occlusion, rarely also with aneurysms. Again, these changes are not specific, and angiography carries a false-negative rate of perhaps 50 per cent, and a risk of 10 per cent for transient neurological deficit, and 1 per cent for permanent deficit. Nuclear imaging of labelled leucocytes and examination of the ocular vasculature may be useful.

Histopathological confirmation, taking a biopsy of an abnormal area of brain where possible, or 'blind' biopsy, incorporating meninges and non-dominant temporal white and grey matter, is important. Biopsy may reveal an underlying process not otherwise suspected with profound therapeutic implications, such as infective or neoplastic (principally lymphomatous) vasculopathies, but is not a trivial procedure, carrying a risk of serious morbidity estimated at 0.5 to 2 per cent—although immune-suppressant treatment may have a higher morbidity than biopsy, emphasizing the rationale behind this procedure.

Once a vasculitic process has been confirmed, the specific defining characteristics of the primary and secondary vasculitides must be painstakingly sought.

Neurological vasculitis complicating systemic vasculitides

Wegener's granulomatosis predominantly affects the upper and lower respiratory tracts—the nose (often with destructive cartilaginous change causing saddle nose deformity), sinuses, larynx, trachea, and lungs. Ocular involvement may occur; renal disease is usual. cANCA is positive, with proteinase-3 specificity, and the biopsy is characteristic, with granulomatous vasculitis. Microscopic polyangiitis is a multisystem small-vessel vasculitis which can involve almost any organ, or may rarely be confined to a single organ. Renal involvement is almost invariable. The diagnosis usually rests upon a combination of renal biopsy and ANCA serology (commonly pANCA). Classic polyarteritis nodosa is now recognized as an unusual disorder which may have some overlap and coexist with microscopic polyangiitis, but often occurs alone. Medium-sized vessels are affected in polyarteritis nodosa, and the kidneys are again commonly involved; renal angiography may reveal microaneurysms. pANCA testing is also often positive in Churg–Strauss syndrome, a multisystem disease characterized pathologically by a granulomatous necrotizing vasculitis, and clinically by prominent asthma with an eosinophilia. Small-vessel vasculitis commonly affects postcapillary venules. The skin is most commonly involved, usually with purpura or urticaria; the common presence of an allergic precipitant has led historically to the term hypersensitivity vasculitis often being used synonymously in this context; cutaneous leucocytoclastic vasculitis is the currently preferred epithet.

In all these disorders, peripheral nervous system involvement, with mononeuritis multiplex, is considerably more common than central nervous system disease, ranging from up to 70 per cent in patients with classic polyarteritis nodosa and microscopic polyangiitis, to around 30 per cent in patients with Wegener's disease. Central nervous system disease can, however, also occur. Direct effects of the granulomatous process—either by contiguous invasive spread or from remote metastatic granulomas—represent a mode of neurological involvement unique to Wegener's disease.

Neurological vasculitis complicating non-vasculitic systemic disorders

Although the clinical picture of cerebral vasculitis may closely be mimicked by systemic lupus erythematosus, a non-inflammatory vasculopathy is far more commonly responsible, but rare instances of vasculitis are described. In contrast, seropositive rheumatoid disease is a well-recognized precipitant of vasculitic mononeuritis multiplex and of central nervous system vasculitis. There are rare reports of central nervous system vasculitis in the context of systemic sclerosis, Sjögren's syndrome, and mixed connective tissue disease. The clinical features of cryoglobulinaemia represent the combined consequences of hyperviscosity and of immune complex deposition-triggered vasculitis, particularly in mixed cryoglobulinaemia, when associated with hepatitis C infection. Skin disease, with purpura progressing to necrotic ulceration, and renal and joint involvement are common. However, the diagnosis will only be made if blood is collected into a plain tube, immediately placed in water in a vacuum flask at 37°C, taken to the laboratory, and tested immediately. Peripheral neuropathy occurs in a quarter of patients with essential cryoglobulinaemia; central nervous system involvement is rare. Peripheral nerve disease, and/or histologically and angiographically evident vasculitis of the central nervous system, usually in the context of granulomatous meningitis, may occur in sarcoidosis.

Drug-induced vasculitis

The issue of vasculitis and drugs is complex. The most compelling evidence of a direct association relates to amphetamines, with clinical and histological evidence of multisystem necrotizing vasculitis. The majority of strokes occurring with cocaine abuse are associated with arterial spasm, platelet aggregation, severe abrupt hypertension, or migrainous phenomena, not vasculitis, although histologically proven cerebral vasculitis does occur.

Infections

At least three mechanisms may underlie microbe-related vascular damage—direct invasion, immune complex formation and deposition, and (in part related to the second) secondary cryoglobulinaemia. Although the association of hepatitis C infection with cryoglobulinaemia and small-vessel vasculitis has been stressed above, other infections, including hepatitis B, Epstein–Barr virus, cytomegalovirus, Lyme disease, syphilis, malaria, and coccidiomycosis have also been linked to mixed cryoglobulinaemia.

Primary invasion of the vascular wall by the infectious agent is, however, the commonest precipitant of infection-associated vasculitis. *Histoplasma*, *Coccidioide*s, and *Aspergillus* spp. are among the fungal causes of this picture, usually confined to immune-suppressed patients—although this includes diabetes mellitus. In HIV infection, cytomegalovirus and *Toxoplasma* may precipitate vasculitis, and syphilitic cerebral vasculitis has re-emerged in the context of HIV. More general bacterial causes of meningeal or cerebral infection—mycobacteria, pneumococci, and *Haemophilus influenzae*—may also trigger intracranial vasculitis.

Herpes zoster can precipitate cerebral vasculitis in approximately 0.5 per cent of cases, usually causing a monophasic illness, with hemiparesis contralateral to the eye disease. However, more generalized necrotizing and granulomatous vasculitis can also occur.

Malignancy, lymphomatoid granulomatosis, and malignant angioendothelioma

Leucocytoclastic vasculitis (often dermatological) may occur in association with a variety of cancers as a paraneoplastic phenomenon. Central nervous system

disease in the context of Hodgkin's disease with a pathological picture indistinguishable from conventional isolated central nervous system angiitis is reported. Lymphomatoid granulomatosis is a lymphomatous disorder centred on the vascular wall, with destructive change and secondary inflammatory infiltration lending the appearance of true vasculitis; the infiltrating neoplastic cell is of T-lymphocyte derivation. Cutaneous and pulmonary involvement are common, with nodular cavitating lung infiltrates, and neurological manifestations occur in 25 to 30 per cent of cases; they are the presenting feature in approximately 20 per cent. Neoplastic or malignant angioendotheliosis is also a rare, nosologically separate disorder, wherein the neoplastic process is intravascular (within the lumen) and the lymphomatous cells are B-cell derived and characteristically do not invade the vascular wall. The neurological features of each disorder are similar, largely representing those of cerebral vasculitic disease; in malignant angioendotheliomatosis, lung involvement is not the rule; characteristic skin manifestations occur.

Treatment of cerebral vasculitis

Prospective controlled randomized trials remain conspicuous by their absence, but retrospective analyses support the use of cyclophosphamide with steroids in vasculitis. In proven cerebral vasculitis—as in lupus—a 3- to 4-month induction regime might comprise high-dose intravenous then oral steroids, with oral or pulsed intravenous cyclophosphamide; this is followed by a maintenance regime of alternate-day steroids with azathioprine. In resistant disease, methotrexate (10 to 25 mg once weekly; again, with steroids) or intravenous immunoglobulin may be useful.

Two eponymous primary disorders may involve the central nervous system. Cogan's syndrome is an unusual disorder, mostly affecting young adults, characterized by recurrent episodes of interstitial keratitis and/or scleritis with vestibuloauditory symptoms, which may be complicated by central or peripheral nervous system or systemic vasculitis. In Eale's disease, an isolated retinal vasculitis occurs, causing visual loss; again, neurological complications are well described.

Giant cell arteritis

Giant cell arteritis, the most common large-vessel vasculitis, rarely affects individuals under 55 years of age. It affects women twice as commonly as men, with an overall prevalence of 100/10 000. Generally it presents with uni- or bilateral scalp pain, often severe, with exquisite tenderness. Additional symptoms include jaw claudication and polymyalgia rheumatica, with stiffness and aching of the shoulder girdle, worse in the mornings, and occasionally general malaise. The affected temporal artery (-ies) may be thickened and cord-like, often non-pulsatile, and tender. A raised erythrocyte sedimentation rate, often accompanied by a normochromic normocytic anaemia, must be followed by temporal artery biopsy—a specimen of several centimetres in length is recommended to help avoid false-negative results, which may occur because of the focal or multifocal nature of the disorder.

Histopathological examination of the vessel reveals changes of vasculitis, with an inflammatory infiltrate comprising mononuclear and giant cells; the latter phagocytose the elastic laminae, causing characteristic fragmentation. Immunoglobulin and complement deposits are apparent in lesions, but activated T cells predominate in the inflammatory infiltrate, suggesting cell-mediated immune damage. Vasculitic changes may still be apparent in biopsies taken 14 days or more after the commencement of steroids.

Neurological complications

Blindness occurs in approximately one-sixth of treated patients with temporal arteritis, as a consequence of anterior ischaemic optic neuropathy following vasculitic involvement of the posterior ciliary arteries and/or the ophthalmic artery, from which they are derived. A typical picture comprises (locally) painless loss of acuity, commonly severe, often with an altitudinal field defect. The fundal appearances may be normal, although swelling (usually mild) may be seen. Intracranial involvement is much less common; vertebral artery involvement is typical.

Treatment

Oral steroids should be used immediately there is serious suspicion of the disease, and in high doses (60 to 80 mg a day) in view of the risk of permanent blindness. The dose is generally reduced slowly (5 mg decrements weekly) after 4 to 7 days to a maintenance dose of perhaps 10 mg daily; thereafter, some would suggest continuing for 12 to 24 months before closely monitored phased withdrawal. Such a duration of steroid therapy, particularly in this elderly population, should direct attention to the treatable or preventable long-term consequences of corticosteroids, particularly osteoporosis, diabetes, cataract, and peptic ulceration.

Behçet's disease

Behçet's disease is a chronic relapsing multisystem inflammatory disorder whose clinical manifestations vary. The classic triad of recurrent uveitis with oral and genital aphthous ulceration remains clinically useful, although formal diagnostic criteria have now been proposed and generally adopted. Recurrent oral ulceration (at least three times in one 12-month period) is an absolute criterion; any two of (i) recurrent genital ulceration, (ii) uveitis (anterior or posterior) or retinal vasculitis, (iii) skin lesions, including erythema nodosum, or acneform nodules, pseudofolliculitis, or papulopustular lesions, or (iv) a positive pathergy test (read at 24 to 48 h) are also required to confirm the diagnosis.

Approximately one-third of patients develop neurological involvement, although this includes the very common occurrence of benign headache. Cerebral venous sinus thrombosis is one of the more specific serious complications; others include sterile meningoencephalitis, encephalopathy, brainstem syndromes, cranial neuropathies, and cortical sensory and motor deficits. Psychiatric and progressive cognitive manifestations are reported. Investigation may reveal an active cerebrospinal fluid, and oligoclonal IgA and IgM bands—but apparently not IgG—may be present. Evoked potentials may be diagnostically useful. MRI abnormalities are non-specific.

Treatment of Behçet's disease

Recent retrospective studies indicate an improved survival in patients with Behçet's disease of the central nervous system treated with steroids and immunosuppressants. The place of thalidomide in steroid-unresponsive Behçet's disease is currently under review; chlorambucil is often advocated. Monitoring treatment is difficult—neither the erythrocyte sedimentation rate nor C-reactive protein levels are useful; MRI might have such a role.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disease of unknown aetiology commonly affecting the lungs and, in approximately 5 per cent of patients, the nervous system. Optic and other cranial neuropathies (especially involving the facial nerve), often due to meningeal infiltration, and brainstem and spinal cord disease are the commoner manifestations. Cognitive and neuropsychiatric abnormalities are reported. Peripheral nerve and muscle involvement is also well described.

The diagnosis can be difficult. Serum and cerebrospinal fluid ACE levels may be elevated; the cerebrospinal fluid may reveal more general abnormalities of protein or cell count and oligoclonal bands may be present. Whole-body gallium scanning remains a useful indicator of systemic disease. Cranial MRI may show multiple white matter lesions or meningeal enhancement. The diagnosis is confirmed where possible by biopsy, either of cerebral or meningeal tissue, or of lung or conjunctiva where appropriate.

The mainstay of medical treatment in neurosarcoidosis is corticosteroids, although response rates as low as 29 per cent have been reported. Methotrexate, azathioprine, hydroxychloroquine, and cyclophosphamide have been used in steroid-resistant cases.

Organ-specific autoimmune disease

Ulcerative colitis and Crohn's disease

While differences in the frequency and type of, for example, dermatological or articular complications may occur between ulcerative colitis and Crohn's disease, the neurological complications, seen in around 5 per cent of patients, are similar. Three types of central nervous system disease have been associated: cerebrovascular accidents, mostly precipitated by the hypercoagulable state, and including venous or arterial thromboembolism, cerebral sinus venous thrombosis, and (more rarely and less explicably) vasculitis; epileptic seizures, focal and generalized, and not always in connection with dehydration or sepsis; and, in some reports, a slowly progressive myelopathy.

Peripheral neuropathy is seen in 0.5 to 1.0 per cent of cases and an acute Guillain–Barré syndrome is the commonest phenotype. Lastly, myopathy, sometimes of metabolic origin but mostly inflammatory, is also reported.

Whipple's disease

Whipple's disease is an uncommon multisystem disorder characterized by arthropathy, respiratory symptoms, anaemia, fever, erythema nodosum, and severe wasting in addition to steatorrhoea and abdominal distension, caused by *Tropheryma whippelii*. Approximately 10 per cent of patients have neurological involvement; 5 per cent present in this way. A wide variety of features is seen (Table 2).

Diagnosis and management

Up to 20 per cent of cases of cerebral Whipple's disease occur in the absence of gastrointestinal or indeed other systemic symptoms. CT and MR scanning may be normal, although the latter can also reveal non-specific abnormalities—multiple high-signal intensity areas on T_2-weighted images, or more striking enhanced mass lesions warranting biopsy. Similarly, the cerebrospinal fluid may be normal, or show an elevated protein and/or raised cell count; widely varying ratios of monocytes and polymorphonucleocytes are reported. One-third of cerebrospinal fluid samples may reveal pathognomic periodic acid–Schiff-stained bacilli; repeat spinal fluid examination increases this yield. Approximately 30 per cent of cases have a non-informative small bowel biopsy, although electron microscopy increases the sensitivity. Lymph node biopsy can also be useful. Polymerase chain reaction analysis of blood, lymph node, spinal fluid, small bowel tissue, or brain is increasingly used.

Whipple's disease usually responds to tetracyclines, penicillin, or more commonly nowadays, co-trimoxazole. Prompt treatment is vital in patients with neurological disease, which may (if untreated) run a profoundly aggressive and, not unusually, rapidly fatal course. Successful reversal of neurological deficits, including cognitive impairment, may follow antibiotic treatment.

Coeliac disease

Coeliac disease (non-tropical sprue) is an immunologically mediated disorder resulting from intolerance to dietary gluten; it causes weight loss with steatorrhoea and/or diarrhoea, and malabsorption. In common with other enteropathies, neurological sequelae of a predictable nature may complicate coeliac disease as a direct consequence of malabsorption. Central nervous system complications apparently unrelated to deficiency states may also occur in perhaps 10 per cent of patients. Rarely, vasculitis is responsible, but the cause of the most commonly described and distinctive central nervous system association, a progressive cerebellar or spinocerebellar degeneration, with eye movement disorders, myoclonus, and occasionally epilepsy, remains unresolved.

Major psychiatric complications and dementia are well described as a significant cause of morbidity, and have been studied in detail.

Thyroid disease

Hyperthyroidism and myxoedema both carry neurological complications generally considered direct consequences of abnormal thyroxine levels—anxiety, tremor, and occasionally chorea in thyrotoxicosis; and lethargy, myopathy, and dementia in hypothyroidism (see Chapter 12.4). By contrast, Grave's ophthalmoplegia and Hashimoto's encephalopathy are both thought to be immunologically driven.

In dysthyroid eye disease, the orbit and extraocular muscles are oedematous and infiltrated with inflammatory cells and glycosaminoglycans, resulting in proptosis and a restrictive ophthalmopathy. Up-gaze limitation is the commonest presenting sign. Vision is occasionally threatened by a complicating infiltrative or compressive optic neuropathy. Circulating thyroid-stimulating hormone (TSH) receptor-stimulating antibodies cross-reactive with orbital fibroblasts are found. Steroid treatment and radiotherapy are equally effective.

Hashimoto's encephalopathy exhibits a female:male ratio of up to 9:1. Most cases are clinically and biochemically euthyroid at presentation, and two modes of presentation occur. The relapsing–remitting variety causes stroke-like episodes, with or without mild cognitive impairment, focal or generalized seizures, and episodes of encephalopathy. The second group present with a more diffuse progressive disease, with dementia, psychotic features, seizures, and occasionally myoclonus, tremor, and/or ataxia; focal neurological deficits are uncommon.

Imaging by CT or even MR is often normal, as is angiography, though isotope brain scanning may show patchy uptake. Spinal fluid examination may reveal a raised protein level but typically a normal cell count. Very high titres of antithyroid antibodies are found, usually antimicrosomal. Most patients respond well to steroid treatment; some have received further immunosuppressive therapy, such as cyclophosphamide or azathioprine.

Stiff man syndrome

Stiffness on examination of muscles occurs in an enormous number of disorders (Table 3). In the great majority, a clinical diagnosis can be made from the nature of the stiffness, the context, and the associated neurological and general clinical findings. Muscle stiffness as a primary disorder is much less common. It occurs in three major conditions – tetanus and neuromyotonia and the stiff man syndrome. Neuromyotonia has a peripheral origin in the distal axon and neuromuscular junction, while the stiff man syndrome is a CNS disease.

Stiff man (or person) syndrome is an uncommon disorder, relatively recently recognized and generally now agreed to be of autoimmune origin. It appears to be a disorder unique among CNS diseases – a primary, non-malignant immune-mediated process caused by antibodies directed against a specific subpopulation of (spinal) neurones. It may be associated with diabetes mellitus, or with systemic autoimmune diseases, particularly lupus, and rarely is seen as an apparent paraneoplastic disorder, but in the majority of cases it occurs in isolation.

Clinical features

It presents with adult onset slowness, aching discomfort and stiffness of muscles, mainly but not exclusively, axial, and with painful muscle cramps, progressing slowly over months and years. Spasms, often noise-, startle-, or action-induced, may be very severe – tendon and muscle rupture may occur. Walking may become clumsy and unsteady. There is no disturbance of sphincter function. Examination reveals normal power and tendon reflexes, downgoing plantar responses, and no abnormalities either of sensation or (barring spasms) coordination. However, axial and abdominal wall rigidity is apparent, and there may be proximal limb muscle stiffness, agonists and antagonists acting simultaneously. An hysterical origin for the symptoms is often wrongly assumed. Asymmetrical contraction of the paraspinal muscles causes a characteristic lordotic and often scoliotic posture.

Investigations

Brain and spinal cord imaging is normal. The spinal fluid is usually normal, but for the common finding of oligoclonal immunoglobulin bands. Electrophysiological muscle examination reveals continuous muscle activity despite invitation to relax, with normal motor unit morphology. ('The patient was unable to relax during the examination' should raise suspicion.) Importantly, voluntary contraction of antagonists fails to inhibit the activity in the muscle under examination. Abnormal activity – and likewise spasms – does not persist during sleep; its central origin is confirmed by its disappearance following pharmacological peripheral nerve block or spinal or general anaesthesia, in contrast to the abnormal activity demonstrable in neuromyotonic syndromes.

Pathogenesis and detection of specific antibodies

The syndrome is thought to result from an imbalance between excitatory (catecholaminergic) and descending inhibitory (g-amino butyric acid or GABA-ergic) influences on spinal motor neurones. Antibodies directed against glutamic acid decarboxylase (GAD), the enzyme responsible for producing GABA from glutamic acid, which therefore react with GABA-ergic neurones (and with pancreatic islet b-cells) are present in 60 per cent of patients. A clonal B cell response against GAD is apparent within the CSF, partly accounting for the oligoclonal immunoglobulin bands.

In patients with cancer and stiff man syndrome, antineuronal antibodies of a different specificity to a synaptic vesicle-associated protein amphiphysin, may be found. Additionally, in the more serious stiff or progressive encephalomyelitis with rigidity (**PEWR**), with stiffness accompanied by cranial neuropathies, myoclonus, ataxia, diminished tendon jerks, and (especially) extensor plantar responses, MRI brain stem and spinal cord changes occur, and the CSF shows a pleomorphic leucocytosis. The course is substantially more aggressive, with death in 3 to 10 years. GAD antibodies may be found, but in PEWR seen in the context of cancer, antibodies against amphiphysin can also be present.

Treatment

Benzodiazepines (particularly), tizanidine, and also baclofen and occasionally sodium valproate are used therapeutically. More experimental treatments have included intrathecal baclofen and paraspinal botulinum toxin. There is now Class 1b evidence for the value of intravenous immunoglobulin.

24.21 Developmental abnormalities of the central nervous system

*C. M. Verity, H. Firth, and C. ffrench-Constan**

Normal development of the human central nervous system (CNS)

The human CNS, like that of all vertebrates, develops from a two-dimensional sheet of cells into a complex three-dimensional structure. Within the CNS individual neurones establish precise connections over long distances. The resulting neural networks control and support behaviours ranging from simple reflex activities to the most complex functions of the brain. Given this complexity, it is not surprising that a range of abnormalities results from failures in distinct stages of development. This chapter describes normal development of the human CNS and uses it as a framework to discuss disorders of each phase as well as those that result from multiple disturbances of these complex processes. We have included only structural abnormalities of the CNS that are present at birth and have not reviewed the numerous metabolic and degenerative disorders that can affect the infant brain.

Induction

This is a process by which one group of cells acts upon another group so that the second group differentiates or in some way alters its behaviour. Following the development of the three cell layers of the early embryo (ectoderm, mesoderm, and endoderm), signals from the underlying mesoderm (the 'inducer') instruct a region of the ectoderm (the 'induced tissue') to adopt a neural fate.

Neural tube formation

The neural ectoderm folds to form a tube which separates from the ectoderm and runs most of the length of the embryo. Closure starts at a level corresponding to the future hindbrain/spinal cord junction and then proceeds both towards the head (rostrally) and the tail (caudally). The most caudal part of the neural tube is formed by the thickening of the neural plate and the subsequent formation of a cavity (rather than a tube as is seen rostrally).

Regionalization and specification

Once the neural tube has developed, specification of different regions and individual cells within these regions occurs. This patterning occurs in both the rostrocaudal and dorsoventral axis. The three basic regions of the CNS (forebrain, midbrain, and hindbrain) develop at the rostral end of the tube, with the spinal cord more caudally. Within the developing cord the specification of the different populations of neural precursors (neural crest, sensory neurones, interneurones, glial cells, and motor neurones) is observed in progressively more ventral locations. This process reflects the interaction between genes whose expression defines individual territories or cell types, and diffusible signalling molecules secreted by adjacent areas of the embryo.

Some of the genes and signalling molecules involved in these processes were originally identified by genetic studies in the fruit fly *Drosophila melanogaster*, and appear to be very highly conserved throughout evolution. Of particular importance are a family of genes, called homeotic genes, most of which contain a conserved sequence called a homeobox encoding a protein motif called a homeodomain. This motif binds DNA sequences involved in the regulation of expression of other genes important in development, and so can regulate cell differentiation. For example, homeotic genes have been shown in *Drosophila* to define the identity of individual segments of the fly's body, so that homeotic mutations alter segment identity. The same basic mechanism patterns the vertebrate CNS. In addition, two of the key extracellular signalling molecules, encoded by the genes *wingless* and *sonic hedgehog* (*shh*), were first identified in *Drosophila*.

An example of how these genes and signalling molecules interact is provided by the process of ventral induction. This is illustrated by the specification of motor neurones and glial cells in the spinal cord. Initially the cells of the tube have no axis. The notocord, a transient structure ventral to the neural tube, then produces *shh* protein. This induces the ventralization of the adjacent tube and the expression of two homeobox-containing genes (*PAX6* and *NKX2.2*) in this region. These genes in turn allow motor neurones to develop in the ventral tube, but this requires further exposure to *shh*. Because it is produced in ventral sites, the *shh* molecule is present in a gradient from ventral to dorsal, and this provides further patterning information. Motor neurone specification occurs at a higher concentration of *shh* than that required for the specification of the glial precursor cells. As a consequence, motor neurones develop correctly in a location ventral to the glial cells.

Proliferation and migration

Following the establishment of the basic plan of the CNS, the most dorsal cells of the tube (the neural crest) migrate away to form much of the peripheral nervous system. At the same time, cell proliferation and migration within the tube leads to thickening of the wall and the movement of the many different cell types to their correct locations. The developing forebrain cortex provides a good example. An area called the germinal matrix adjacent to the lumen of the neural tube (which will become the ventricular system) contains populations of neural stem cells that divide to generate committed precursor cells of the different cell lineages of the CNS—neurones and the two glial cell types, oligodendrocytes and astrocytes. These precursor cells then migrate to their final locations. Many of the neurones migrate along specialized cells called radial glial cells, whose processes span the entire thickness of the developing cortex, before leaving the glial fibre to join a specific cortical layer. The time at which the precursor cells are generated defines which type of neurone they will become, and the cortex is built in an 'inside-out' pattern with each neuronal type then migrating beyond its predecessors before leaving the radial fibre. In this way, the six layers of the cortex each containing different neuronal populations are established. Abnormalities of migration in mice and humans have been linked to specific genetic mutations. For example mice with abnormalities in an extracellular matrix molecule called reelin or in its receptors show aberrant patterns of cortical lamination and cerebellar development.

Connection and selection

Once each cell type is specified and in an appropriate location, axon outgrowth and the formation of synapses occurs. These connections are made both locally and over considerable distances, as for example in the contralateral connections made by axons running in the corpus callosum (a fibre tract crossing from one side of the brain to the other). The mechanisms by which the vast number of connections are made are complex and incompletely understood. There are both attractive and repulsive cues that guide growth cones within the CNS. Examples are the netrins, that are attractive to most outgrowing axons and are produced by the ventral floor

plate of the spinal cord before axons grow into it, and the semaphorins that can repel growth cones. In addition there is evidence that recognition molecules such as cadherins and ephrins can regulate cell–cell adhesion and intracellular signalling and allow axons to select precise targets once they have arrived in the appropriate location. In many cases such signalling and recognition molecules exist as large families of related molecules, a diversity that may underlie the development of such complex connections. Finally, cells that fail to establish the correct connections undergo programmed cell death (apoptosis) as a result of a failure to obtain factors produced by the target cells that are required for survival. In this way, errors in pathfinding or cell production can be corrected at a later stage. At the same time, neurones establish close interactions with glial cells that either form the myelin sheaths essential for rapid impulse conduction (oligodendrocytes) or regulate the extracellular environment of the neurone and so play a homeostatic role essential for correct function (astrocytes).

Although developmental abnormalities can occur at any stage of gestation, some developmental events such as neural tube formation and specification occur in the first month after conception. This is important from a clinical standpoint, as developmental abnormalities resulting from environmental factors can occur before pregnancy is confirmed. Dietary folic acid supplements can reduce the risk of neural tube defects but need to be taken from the very earliest stages of pregnancy and should be started before conception.

Structural abnormalities resulting from disturbances of normal CNS development

Disorders of neural tube formation

Introduction

The neural tube usually fuses completely between 18 and 26 days after ovulation. Failure of closure leads to malformations that include anencephaly, encephalocele, spina bifida, and spina bifida occulta. These neural tube defects are aetiologically related and if one member of a family is affected there is an increased risk in the relatives for all types of neural tube defect. They are malformations of the neuroectoderm which are associated to a variable extent with abnormalities of the surrounding mesodermal structures. The term dysraphism is used when there is continuity between the posterior neuroectoderm and cutaneous ectoderm.

Epidemiology

The prevalence of neural tube defects varies according to geography and race, although they are among the most common congenital abnormalities in most countries. High rates (more than 8 per 1000 births) have been reported in Northern Ireland, Egypt, India, and China. There are worldwide reports of decreasing prevalence rates. In England there was a peak in 1954 to 1955 followed by a substantial decline which started in the early 1970s. The epidemiological evidence suggests that this decrease was not entirely due to prenatal screening, and it also preceded the widespread use of periconceptual vitamin supplemention, so some of the decrease remains unexplained. By 1994 the prevalence of neural tube defects in England and Wales was just under 0.8 per 1000 total births. In the United Kingdom anencephaly and spina bifida are of approximately equal prevalence and together make up 95 per cent of all neural tube defects.

Aetiology

Genetic factors

Most neural tube defects are a complex interaction between several genes and environmental factors. Major genes have been identified in the mouse that may mutate and cause neural tube defects, but their relevance to human defects is still not clear. More is being discovered about the identity of modifier genes. For instance mutations in the methylene tetrahydrofolate reductase gene are associated with elevated blood homocysteine levels in pregnant women and and increased risk of neural tube defects. However, the relative risks are low (about twofold) and mutation analysis is not used in routine clinical practice. Neural tube defects occur in many different syndromes and many chromosome disorders, but if a neural tube defect is the only anomaly, karyotyping is not indicated.

Environmental factors

Periconceptual multiple vitamin supplements containing folic acid have been shown to reduce the incidence of neural tube defects. In England it is currently recommended that, to prevent a first occurrence of neural tube defect, women who are planning pregnancy should take 400 µg of folic acid daily before conception and during the first 12 weeks of pregnancy. To prevent recurrence of neural tube defect the dose should be 4 to 5 mg per day.

Some drugs taken during pregnancy may increase the risk of neural tube defects in the fetus. These include sodium valproate and folic acid antagonists such as trimethoprim, triamterene, carbamazepine, phenytoin, phenobarbitone, and primidone.

Prenatal diagnosis

a-Fetoprotein levels in maternal serum

The fetal liver is the main source of a-fetoprotein (AFP), which leaks through open neural tube defects into the amniotic fluid and then into the maternal blood. This abnormal increase in maternal serum a-fetoprotein is best detected at 16 to 18 weeks of pregnancy. Maternal serum screening does not detect closed defects (those covered by skin) and is less sensitive in women taking the antiepileptic drug sodium valproate.

Ultrasonography

This is recommended for all at-risk women—those with positive serum a-fetoprotein screening, those who have had one or more affected child, and those taking drugs associated with neural tube defects in the fetus. Anencephaly can be detected by ultrasound from the 12th week of gestation and spina bifida from 16 to 20 weeks (Fig. 1(a) and Fig. 1(b)). However, even the best ultrasonographers may occasionally miss spina bifida, particularly in the L5–S2 region.

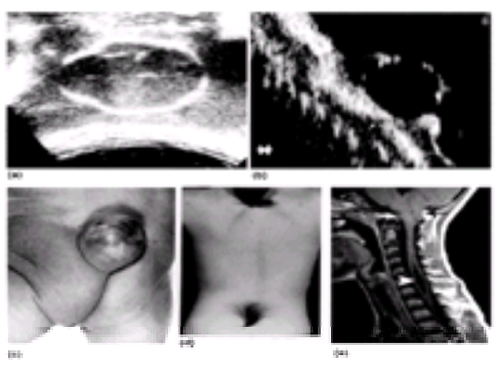

Fig. 1 (a) Prenatal ultrasound of a child with a neural tube defect, showing the 'lemon sign' resulting from the change in shape of the back of the skull (on the left-hand side in the image) which is associated with the Chiari II malformation described in the text. (b) Prenatal ultrasound of a child with a neural tube defect, showing a cystic lumbar meningomyelocele in the caudal neural tube. (c) Lumbar meningomyelocele. Photograph of a newborn infant. (d) Chiari I malformation and syringomyelia in an asymptomatic girl aged 11 years. Photograph of tuft of hair seen over the lumbar region at birth. The associated CNS malformations are shown in scan (e). (e) Chiari I malformation and syringomyelia. T_1-weighted sagittal MRI shows there is herniation of the cerebellar tonsils through the foramen magnum (arrow) and a syrinx of the lower cervical spinal cord (C5–C7) (arrow head). The associated tuft of lumbar hair is shown in photograph (d).

Amniocentesis

This has been largely superseded by detailed ultrasound imaging. When adequate ultrasound images cannot be obtained, amniocentesis with measurement of of a-fetoprotein and assay of neuronal acetylcholinesterase provides an alternative method of prenatal diagnosis.

Cranial dysraphism

Anencephaly

This is a lethal defect that results from failure of fusion of the rostral folds of the neural tube between days 18 to 25 of embryonic development. The cranial vault is absent and an angiomatous membranous mass lies on the floor of the cranium. The eyes are protruberant because of shallow orbits and there is variable involvement of the spinal cord. Before the advent of prenatal diagnosis by ultrasound most anencephalic babies were born in the last 3 months of gestation; now an increasing number of such pregnancies are terminated. In liveborn anencephalic babies the initial neurological examination may be surprisingly normal if brainstem structures are reasonably intact and seizures may be seen despite the absence of cerebral hemispheres. However, the infants usually die in hours or days.

Cephaloceles

A cephalocele is a herniation of cranial contents through a skull defect. There are several subtypes: a cranial meningocele contains only meninges, an encephalocele contains brain tissue, and a ventriculocele contains part of the ventricle within the herniated portion of brain. Cephaloceles are less common than anencephaly or spina bifida, occurring in 1 to 3 per 10 000 live births. They are associated with other brain abnormalities such as agenesis of the corpus callosum or abnormal gyration. They may be part of a recognized syndrome, so it is important to look for abnormalities in other parts of the body. Sometimes neurosurgery is indicated.

Posterior cephaloceles

This is the commonest group in Western countries and the majority are occipital encephaloceles. They are of variable size and may be above or below the tentorium. The latter are often associated with severe cerebellar defects, such as the Chiari III malformation (see under posterior fossa abnormalities). The prognosis depends on the size of the encephalocele, the site, and the associated abnormalities, such as hydrocephalus. Visual impairment may result from involvement of the occipital lobes. There may be motor and intellectual impairment and seizures.

Anterior cephaloceles

These are more common in some parts of Asia. Frontoethmoidal cephaloceles may protrude into the nose, the ethmoid, or the orbit. They often include olfactory tissue and frontal lobe tissue and can present with nasal blockage or cerebrospinal fluid leakage. Sphenoidal cephaloceles can cause pharyngeal obstruction and recurrent meningitis and may be associated with abnormalities in the secretion of somatotrophin, gonadatrophin, or antidiuretic hormone.

Spinal dysraphism

Spina bifida

This can be divided into spina bifida occulta, which consists of failure of closure of the vertebral arches without an external lesion, and spina bifida cystica in which there is a cystic lesion on the back. The lesion may be either a meningocele without neural tissue or a myelomeningocele in which the spinal cord is a component of the cyst wall.

The term rachischisis is used for the most severe defect, which is a widely patent dorsal opening of the spine, often associated with anencephaly.

Myelomeningocele

The spinal defect

This is the abnormality found in 80 to 90 per cent of children with spina bifida cystica. It is lumbosacral in about 80 per cent of cases and consists of a sac covered with a thin membrane which may leak cerebrospinal fluid (Fig. 1(c)). Neurological abnormalities depend on the level of the lesion, which is best judged clinically by determining the upper limit of sensory loss. There is usually a mixture of upper and lower motor neurone signs depending on the level. Whatever the level of the lesion, there is disturbance of bladder and bowel sphincters and also bladder detrusor dysfunction. The sensory level correlates with the severity of abnormalities in the urinary tract and is also related to long-term disability. Higher lesions of the cord are associated with bladder outlet obstruction, dilatation of the upper urinary tract, and chronic pyelonephritis.

Hydrocephalus

This complicates most cases of lumbosacral meningomyelocele. Ultrasound studies show hydrocephalus in about 90 per cent of cases at birth, even though the head circumference is normal. Usually it is associated with the Chiari II malformation (see below), although it may be due to aqueduct stenosis or have no clear structural cause. If there is evidence of progressive ventricular dilatation (often detected with ultrasound) or signs of increasing intracranial pressure, insertion of a ventriculoperitoneal shunt is usually necessary.

Chiari II malformation

This is present in about 70 per cent of cases of meningomyelocele. It is the most common of the four types of Arnold–Chiari malformation. It consists of downward protrusion of the medulla below the foramen magnum to overlap the spinal cord. The medulla is kinked and the cerebellar vermis indented by the posterior lip of the foramen magnum. The fourth ventricle is elongated and the midbrain distorted, which can cause early or late problems. These include palsies resulting from involvement of the lower cranial nerves and central apnoea (which may be misdiagnosed as epilepsy in older children).

Almost all cases of Chiari II malformation are associated with meningomyelocele. In contrast the other types of Arnold–Chiari malformations (I, III, and IV) are not associated with spina bifida and are dealt with in the section on posterior fossa abnormalities.

Management

Treatment of infants with meningomyeloceles became possible with the development of ventriculoatrial and ventriculoperitoneal shunts. In the early 1960s it was argued that closure of the defect within 24 h of birth reduced mortality and morbidity by avoiding infection and reducing trauma to the exposed neural tissue. The early active management of all cases was questioned by Lorber who proposed that surgery should be selective. He reported four adverse criteria that he thought were contraindications to treatment: a high level of paraplegia, clinically evident hydrocephalus at birth, lumbar kyphosis, and the presence of other major malformations. However, using these criteria the outcome was uncertain; many infants survived even though they did not have closure of the defect within 24 h, and some children with a supposedly good prognosis were left with major disabilities after surgery. Selective surgical management is therefore not universally practised and this remains a controversial area.

Now the emphasis has moved towards prevention. It is recommended that women planning to conceive supplement their diet with folic acid, which reduces the risk of neural tube defects. Screening of maternal serum for a-fetoprotein is possible and prenatal diagnosis by ultrasound and amniocentesis is available. This is discussed above in the section on neural tube defects.

Meningocele

Here there is protrusion of the meninges outside the spinal canal: the sac does not contain any neural tissue. Meningoceles account for about 5 per cent of cases of spina bifida cystica. There is no associated hydrocephalus and the neurological examination is usually normal. They must be distinguished from meningomyeloceles

because the prognosis is so different.

Occult spinal dysraphism

The term spina bifida occulta is often applied to a defect of the posterior arch of one or more lumbar or sacral vertebrae (usually L5 and S1). It is found incidentally by radiography in 25 per cent of children admitted to hospital and may be regarded as a normal variant. However, it must not be assumed that spina bifida occulta is always benign. If examination of the skin over the spine reveals a naevus, hairy patch (Fig. 1(d)), dimple, sinus, or subcutaneous mass, further evaluation is necessary. Even if there are no associated abnormalities of sphincter or limb control on MRI of the spinal cord is indicated. A spinal cord malformation may cause an asymmetrical lower motor neurone weakness with wasting, deformity, and diminished reflexes in the lower limb. Alternatively there may be a progressive gait disturbance with spasticity. Either presentation may be associated with disturbed bladder control. Several different abnormalities may be found.

Dorsal dermal sinuses may connect the skin surface to the dura or to an intradural dermoid cyst. They are most commonly found in the occipital and lumbosacral regions. An open sinus tract can cause recurrent meningitis so ideally they should be explored and excised before infections occur. Lipomyelomeningoceles present as a bulge in the lumbosacral region, usually lateral to the midline. They consist of a lipoma or lipofibroma attached to a low lying abnormal spinal cord and are often associated with a meningocele. Diastematomyelia is the presence of a sagittal cleft which divides the spinal cord into two halves, each surrounded by its own pia mater. A bony or cartilaginous spur may transfix the cord, fixing it in a low position as the child grows. The cleft is usually in the low thoracic or lumbar region, but cervical clefts have been reported. In 75 per cent of cases of diastematomyelia an overlying midline skin abnormality is present and plain radiographs show abnormalities in most cases—these include abnormal segmentation of vertebrae, spina bifida, and scoliosis.

Treatment of occult spinal dysraphism

If an abnormality involving the cord or nerve roots is found, there is often a good case for neurosurgical intervention. The aim is to free the spinal cord from its abnormal attachments to allow for growth and prevent further damage. Early intervention may prevent worsening motor deficits and urological complications, but the indications for intervention are controversial.

Other developmental abnormalities of the spinal cord

Syringomyelia

This is a tubular cavitation of the spinal cord as opposed to hydromyelia which is dilatation of the central canal of the cord—a distinction that may be difficult to make clinically. Syringomyelia is often associated with the Chiari I malformation and hydrocephalus (Fig. 1(e)). It tends to be in the cervical region but may involve the whole cord. It rarely becomes symptomatic in children. Treatment is controversial. Shunting of the abnormal cavity is sometimes performed and posterior fossa exploration may be undertaken if there is a Chiari I malformation.

Sacral agenesis

This is strongly associated with maternal diabetes mellitus. Absence of the acrum and coccyx is usually associated with abnormalities of the lumbosacral cord. There may be arthrogryposis at birth (defined as a fixed deformity of one or more joints). A flaccid neurogenic bladder causes incontinence and there are sensory and motor deficits in the legs.

Disorders of regionalization

Failure of normal development of the most anterior portion of the neural tube (the mediobasal prosencephalon) and associated structures due to disturbances in the process of ventral induction described above may result in various abnormalities of the brain and face. The most severe CNS abnormality is holoprosencephaly in which there is failure of the prosencephalon to separate into two cerebral hemispheres. The mildest is olfactory aplasia without other cerebral malformations. The severity of the associated facial abnormalities tends to parallel those in the brain. In the most severe facial abnormality there is anophthalmia and absence of the nose. However there may be just mild hypotelorism (closely set eyes), a single central incisor tooth, or the face may be normal.

Holoprosencephaly (prosencephaly)

This occurs with a frequency of approximately 1 in 14 000 births. There is failure of formation of the two cerebral hemispheres resulting in abnormalities of varying severity. The causes may be chromosomal, multifactorial, or monogenic and there may be associated facial and midline malformations.

Aetiology

This is time specific and stimulus non-specific. There is a very short vulnerable period, because ventral induction probably occurs prior to 23 days, just before the elaboration of the optic vesicles (24 days), which explains its relative rarity (6 per 10 000 live births in one study). Environmental factors may be important: it is at least 20 times more common in the infants of mothers with diabetes than in the general population.

Genetic factors are also important. At least 12 genetic loci and several holoprosencephaly (*HPE*) genes have been identified in humans. Some of these genes can be linked to signalling pathways described above in the section on CNS development. One (*HPE3* on chromosome 7q36) is the *sonic hedgehog* gene encoding a secreted protein required for ventral induction throughout the neuraxis. Mutations in PATCHED-1, the receptor for *sonic hedgehog*, have been found in individuals with holoprosencephaly. In addition *ZIC2*, present on chromosome 13q32 and encoding a human homologue of the *drosophila odd-paired* gene is implicated in *wingless* signalling. Two other genes, *SIX3* and *TGIF*, both encode homeodomain proteins of undefined function. A number of chromosomal abnormalities have also been recognized in association with holoprosencephaly. These include trisomy and other abnormalities of chromosome 13, partial deletion of the short arm of chromosome 18, ring chromosome 18, and partial trisomy of chromosome 7.

Clinical features

In alobar holoprosencephaly the completely undivided forebrain is in the shape of a horseshoe surrounding a single cavity. The thalami are fused but the brainstem and cerebellum are well developed. The associated facial abnormalities are severe—there may be anophthalmia or cyclopia in which there is a single orbit. In holoprosencephaly with median cleft lip there is marked hypotelorism. In semilobar holoprosencephaly the brain is divided into two hemispheres posteriorly but anteriorly the two hemispheres are fused (Fig. 2). In lobar holoprosencephaly there is almost complete separation of the hemispheres and the face may be normal. The head is usually microcephalic unless there is associated hydrocephalus.

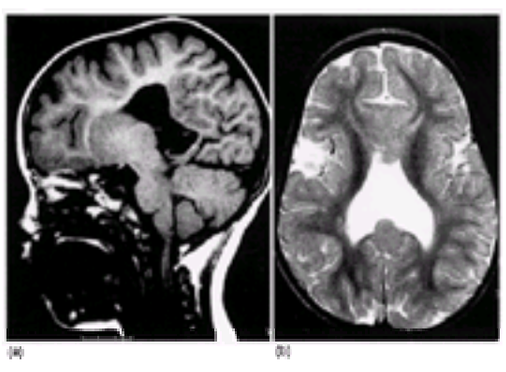

Fig. 2 (a) Semilobar holoprosencephaly in a girl aged 2 years imaged with T_1-weighted sagittal MRI. This midline view shows absence of the corpus callosum and fusion of the frontal lobes. (b) Semilobar holoprosencephaly in the same patient using T_2-weighted axial MRI. There is fusion of the frontal lobes of both cerebral

hemispheres and a common central ventricle.

The most severely affected infants die in the neonatal period. Less severely affected patients may live for months or years. The survivors often develop infantile spasms or other seizures. Some patients with significant structural abnormalities may survive to adulthood but usually there are severe learning difficulties. Associated anomalies include congenital heart disease, scalp defects, and polydactly. Holoprosencephaly may be part of syndromes such as the Meckel–Gruber syndrome and the Aicardi syndrome.

Genetic counselling

Families have been described in which there is dominant inheritance of minor features and one or more children with holoprosencephaly. It is therefore important to look for minor signs in both parents of an affected child. These include orbital hypotelorism, median cleft lip, flat nose with or without a single nostril, anosmia, and a single central incisor.

Prenatal diagnosis can be made by ultrasound from the 16th week of pregnancy and holoprosencephaly accounts for a proportion of the cases of hydrocephalus diagnosed antenatally. Orbital hypotelorism is a reliable diagnostic feature for antenatal diagnosis by ultrasound.

Disorders of cortical development

Modern brain imaging, in particular MRI, has resulted in the identification of many previously unrecognized developmental abnormalities of the cerebral cortex. Following the classification used by Aicardi this section is divided into disorders of proliferation, migration, and cortical organization.

Disorders of proliferation and differentiation

Microcephaly

This is an abnormally small head, which is disproportionately small in relation to the rest of the body. A child is microcephalic when the head circumference is below the normal range (less than the 0.4th centile), defined by head growth charts appropriate for sex and race. Some children with microcephaly are neurologically normal.

Genetic causes of microcephaly

There is a genetically determined type of microcephaly in which the inheritance is usually autosomal recessive with at least three loci currently identified, but may be autosomal dominant or X linked. Characteristically there is marked microcephaly but the neurological problems are relatively mild. They consist of fine motor incoordination and hyperkinetic behaviour with moderate learning difficulties and seizures. However, it is more usual to find that patients with microcephaly have more significant abnormalities of the nervous system such as pyramidal tract signs and profound learning difficulties. Microcephaly is a feature of more than 450 syndromes listed in the Oxford Dysmorphology Database, so it is a challenge to differentiate genetic from other causes.

Non-genetic causes of microcephaly

Ionizing radiation in the first two trimesters of the pregnancy, intrauterine infections, drugs and other chemicals, circulatory disturbance, and perinatal hypoxic–ischaemic events can all cause microcephaly. Poor dietary control in mothers with phenylketonuria is also an important cause of microcephaly, as the fetal brain is very sensitive to the toxic effects of phenylalanine. Sometimes serial head circumference measurements are necessary to make the diagnosis. When there is a significant perinatal insult to the brain the head circumference may be normal at birth with subsequent failure of growth in the first few months of life. However, the first head circumference measurement at birth may be misleading because of skull moulding during delivery.

It is important to perform a skull radiograph to look for evidence of early closure of all the cranial sutures (total craniosynostosis). In some types of genetic microcephaly the head size falls off as late as 32 to 34 weeks of gestation or even after birth. Prenatal diagnosis by ultrasound may be difficult.

Megalencephaly

The term macrocephaly is used when the head circumference is above the normal range for the age, sex, and race of the child. This may result from abnormalities outside the brain parenchyme such as hydrocephalus, arachnoid cysts, congenital abnormalities of the cerebral veins, fluid collections over the surface of the brain, or abnormalities of the skull. Cranial imaging is necessary to make the diagnosis. This discussion deals only with megalencephaly, which is increased size of the brain itself.

Many normal individuals have large heads. When assessing a child with a large head it is important to exclude a developmental or neurological abnormality. A large head may be part of a specific disorder, for example one of the neurocutaneous syndromes, or an overgrowth disorder such as Sotos syndrome. Large heads can run in normal families ('familial megalencephaly') and it is important to check the head circumference of the parents. However, there are kindreds in which some of the family members with large heads have learning problems.

Sometimes megalencephaly is associated with significant learning difficulties, autism, neurological abnormalities, and seizures, and this combination of features can have a genetic basis. The brains may have bulky gyri and usually all parts of the cerebrum are diffusely enlarged, with normal-sized or mildly enlarged ventricles. Occasionally particular parts of the brain such as the cerebellum are disproportionately large. No consistent microscopical alterations are reported in the cortex, but minor anomalies such as small heterotopias may be found. The pathogenesis of this type of megalencephaly is not clear: it may be caused by overproduction of CNS cells, possibly combined with failure of apoptosis.

Hemimegalencephaly or unilateral megalencephaly may involve all parts of the brain on the same side or there may be enlargement of one hemisphere only. In the affected hemisphere there are broadened and coarse gyri and sometimes areas of polymicrogyria. The microscopic abnormalities vary. There may be disorganized masses of grey matter without laminar organization or nodular heterotopias of grey matter: giant neurones may be found.

The neurological problems associated with hemimegalencephaly can be severe. Sometimes there are intractable seizures, which may start in infancy, associated with marked developmental delay and sometimes with hemiparesis. There may be overgrowth of one side of the face or of one side of the whole body. Some infants may present with prenatal or perinatal onset of seizures and die early. Others may develop seizures later which may be refractory to drug treatment, and they may be candidates for hemispherectomy.

Disorders of migration

Migration defects occur when neurones of the subependymal matrix zone lining the ventricular cavity (the ventricular zone) fail to reach their intended destination in the cerebral cortex. This results in either major or minor disturbances of development which may be focal or diffuse. If neurones fail to leave the ventricular zone entirely, periventricular heterotopias result. If neurones leave the ventricular zone but then fail to complete their migration in the cortex, this causes lissencephaly. If, however, only a subpopulation of neurones are affected and the others complete their migration normally, then this results in nodular or band heterotopias. Migration disorders are found as part of recognized syndromes and there are also acquired types resulting from intrauterine infections, circulatory disturbances, and toxins (alcohol or phenytoin for example).

Agyria–pachygyria (lissencephaly)

This is a group of disorders of varying severity. There may be complete absence of gyri, in which case the terms agyria or lissencephaly (greek: 'smooth brain') are

used. Pachygyria describes a reduced number of broadened and flat gyri with less folding of the cortex than normal. There may be varying degrees of agyria–pachygyria in the same brain.

Type I lissencephaly

Here the brain is small with only the primary and sometimes a few secondary gyri. The cortex is thick with the white matter forming a thin rim along the ventricles (Fig. 3(a)). In the brainstem the olivary nuclei are ectopic and the pyramids are hypoplastic or absent. In the cerebellum the dentate nuclei are abnormally convoluted. There may be associated agenesis of the corpus callosum. Infants with type I lissencephaly may be divided into the majority who have no dysmorphic features ('isolated lissencephaly sequence') and those with the dysmorphic features of the Miller–Dieker syndrome.

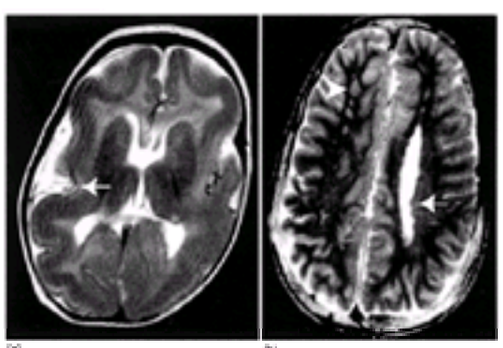

Fig. 3 (a) Lissencephaly type I in a girl aged 5 months who is visually and socially unresponsive, displays poor feeding, and increased tone. The T_2-weighted axial MRI shows a smooth cerebral cortex with absence of normal gyri and sulci. On the right a vertically orientated shallow sylvian fissure is seen (arrow). (b) Nodular heterotopias in a boy aged 13 years. The T_2-weighted axial image shows the nodular heterotopias are subependymal (arrow) and subcortical (arrow head).

The Miller–Dieker syndrome

Characteristically in this syndrome there is postnatal growth deficiency and occasional microcephaly. The dysmorphic features include a tall narrow forehead, a depressed nasal bridge, anteverted nares, midfacial hypoplasia, a prominent upper lip with a thin vermilion border, retrognathism, and hypervascularization of the retina. Hypotonia and seizures are associated. MRI and CT scans show lissencephaly together with a midline focus of calcification in the callosal remnant in about 40 per cent of cases (this is rarely seen in the isolated lissencephaly sequence). About 50 to 70 per cent of cases have a deletion of 17p13.3 by light microscopy and almost all the remainder have a submicroscopic deletion demonstrable by fluorescent *in situ* hybridization of chromosomes using gene probes. This region includes the *LIS1* gene, mutations in which are associated with isolated lissencephaly and which is also required for correct neuronal migration in mice. It has been suggested, therefore, that deletions of the *LIS1* gene cause the lissencephaly seen in the Miller–Dieker syndrome and that the facial dysmorphism is caused by loss of adjacent genes.

Isolated lissencephaly sequence

This is a heterogeneous group. Many have a deletion of, or mutations within, the *LIS1* gene. Mutations in a second gene, *doublecortin* (*DCX*) have also been shown to cause lissencephaly. *DCX* is on the X chromosome, explaining why inheritance of isolated lissencephaly sequence in some cases is X linked. While affected males in these families show the full isolated lissencephaly sequence phenotype, carrier females can show band heterotopia in which a subset of neurones fail to complete migration and form bilateral symmetrical ribbons of grey matter in the centrum semiovale. This is thought to reflect X inactivation of the normal *DCX* gene in these neurones, while those that inactivate the mutation-containing X chromosome migrate normally. In addition to *LIS1* and *DCX*, mutations in the human gene encoding *reelin* (RELN) have recently been described in lissencephaly associated with cerebellar hypoplasia. As described above, *reelin* gene mutations are found in some naturally-occurring mouse mutants with abnormal neuronal migration, and so this provides a direct link between the animal and human studies. Possible non-genetic causes include intrauterine cytomegalovirus infection and early placental insufficiency. Clinically there is severe mental retardation and diplegia together with partial seizures and infantile spasms.

Diagnosis of type I lissencephaly

The diagnosis of type I lissencephaly is made by CT or MRI, which show a thick cortical plate with no or few sulci separated from the white matter by an undulating border. The differential diagnosis includes peroxisomal disorders such as Zellweger syndrome, but these have their own specific features. Some cases are due to cytomegalovirus infection and there may be associated periventricular calcification. Prenatal diagnosis is not possible by ultrasound before 24 weeks as tertiary sulci do not appear before then.

Genetic counselling

In the Miller–Dieker syndrome, if a deletion is found in the *LIS1* gene and the parental chromosomes are normal, the recurrence risk is less than 1 per cent. In the isolated lissencephaly sequence, if chromosome and DNA studies are negative and the other differential diagnoses are excluded, the empirical recurrence risk is 5 to 7 per cent.

Type II lissencephaly or Walker–Warburg syndrome

This is also called 'cobblestone lissencephaly' and is a completely different malformation from type I lissencephaly. The smooth cortex has a granular surface and is covered with meninges that are thickened due to mesenchymal proliferation. The cerebellum is small with an absent vermis and the pyramidal tracts are usually absent. Hydrocephalus is present in 75 per cent of cases. Microscopically there is complete disorganization of the cortex which consists of neurones separated by bundles of gliomesenchymal tissue continuous with the meninges. More deeply there is a thin layer of white matter lying above islands of heterotopic grey matter. These abnormalities probably result from overmigration of neuroglial precursors through a disrupted pial–glial limiting membrane.

Clinical features

The clinical features include both nervous system and muscle abnormalities. The infants are very abnormal at birth. The eyes show retinal dysplasia, microphthalmia, and anomalies of the anterior segment. There may be hydrocephalus or sometimes microcephaly. Usually there is an elevated creatine kinase and necrosis of fibres in all muscles, similar to that seen in severe muscular dystrophy.

Diagnosis

The diagnosis of type II lissencephaly is confirmed by MRI or CT scan, which show that the cortex is thinner than in type I lissencephaly and there are characteristic trabeculae penetrating the cortex from the white matter with the appearance of a double cortical layer due to the subcortical heterotopic islands. There is agenesis of the cerebellar vermis and often a posterior encephalocele or large posterior fontanelle.

Differential diagnosis

There are a group of conditions involving muscle, eye, and brain that all follow recessive inheritance. It seems likely that the cerebro–ocular–muscle syndrome (COMS) is identical to the Walker–Warburg syndrome for which the gene locus is not yet identified. Fukuyama-type muscular dystrophy is associated with severe mental retardation. It is relatively common in Japan and is due to mutations in the Fukutin gene at 9q31–33. Muscle–eye–brain disease is found in Finland. The eye

and brain abnormalities are less severe and the gene locus is on 1p32–34.

Non-lissencephalic cortical dysgenesis

Polymicrogyria (microgyria) is the most important type of abnormality in this section, although the aetiology remains poorly understood. Sometimes the surface of the cortex is relatively smooth resembling pachygyria because the small gyri pile upon each other to form a thickened cortex. The histology of polymicrogyria varies. In unlayered microgyria there is a single cell layer between the white matter and the molecular layer. In classic four-layered microgyria the cortex consists of a molecular layer, an upper dense layer, a layer of low cellular density containing myelinated fibres, and a deep cellular layer. It is suggested that the developmental disturbance occurs near the fifth month of pregnancy. Case reports of polymicrogyria in the infant brain after maternal trauma or asphyxiation during the pregnancy suggest that the abnormality may sometimes be due to failure of cerebral perfusion with resulting hypoxia.

The clinical manifestations of polymicrogyria depend on the location and extent of the abnormalities. Small patches may be found incidentally in the absence of symptoms, but there may be involvement of the whole cortex, or areas of polymicrogyria may border porencephalic cysts in patients with neurological disabilities. There is a bilateral perisylvian syndrome (or anterior operculum syndrome) in which bilateral opercular abnormalities are seen on MRI, some of which have the appearance of polymicrogyria. These patients have a pseudobulbar palsy with dysarthria, and loss of voluntary control of the face and tongue leading to drooling and difficulty feeding. Familial occurrence has been reported on several occasions.

Heterotopias

Periventricular heterotopias are abnormal collections of neurones in the subependymal region. They may be part of a complex malformation syndrome such as the Aicardi syndrome. They may be isolated and clinically silent or associated with seizures. A gene responsible for periventricular heterotopia, the *filamin 1* (FLN1) gene, has been identified on the X chromosome. Filamin protein reorganizes the cytoskeleton, consistent with a role in cell migration. Families with periventricular heterotopia have been described in which females are affected while affected males appear to die before or soon after birth. It is likely that the heterotopias present in affected females result from X inactivation of the normal *FLN1* gene in those cells, while those cells inactivating the abnormal *FLN1* gene migrate normally. Males have only one X chromosome and so all cells will fail to migrate—a lethal phenotype in these families. However, in other families some surviving males with periventricular heterotopias have now been shown to have *FLN1* mutations.

Subcortical heterotopias can be divided into two groups. Nodular heterotopias of grey matter are found in association with other migration disorders and may be the cause of partial seizures (Fig. 3(b)). Subcortical laminar heterotopias are also known as band heterotopias or 'double cortex' and may be inherited as an X-linked trait, as discussed above. Patients with subcortical heterotopias often have seizures, which may be focal or generalized, and they may also have intellectual problems although some do develop normally.

Disorders of cortical organization

There is increasing interest in developmental abnormalities within the cerebral cortex that are relatively subtle compared with those described above, as they may represent important causes of epilepsy and developmental delay. It is likely that this group of disorders will become increasingly well recognized as imaging and other investigative techniques improve.

Cortical microdysgenesis

In 1971 Taylor and colleagues described localized cortical abnormalities in the brains of 10 patients with intractible epilepsy. The lesions could only be seen microscopically and consisted of an excess of large abnormal cells scattered throughout the cortical layers. The abnormal neurones were restricted to sharply delineated areas of cortex and also formed foci in the depths of sulci.

Experiments have been performed in rats using microelectrodes to freeze small areas of cortex, leading to microgyri at these sites. They show that focal cortical abnormalities are associated not only with alterations in the membrane properties and synaptic connections of the neurones directly involved, but also with much more widespread abnormalities of neuronal circuits. Thus there may be more global effects on cerebral function than expected from the size of the lesion.

Microscopic abnormalities of cortical arrangement have been described in the brains of patients with epilepsy or learning difficulties. They include persistence of the subpial layer, aggregates of large neurones in the plexiform zone, a fragmented appearance of the superficial neuronal layers, excess ectopic cells in the cortex, and excess numbers of cells in the molecular layer. Such abnormalities can be found in normal individuals. These abnormalities may cause cortical excitability in generalized epilepsy and localized temporal lobe cortical dysgenesis might lead to dyslexia. Cortical dysgenesis has been reported in autism, schizophrenia, and fetal alcohol syndrome. The extent to which these findings explain abnormal brain function is an area of active research.

Focal cortical dysplasia

It is now known that cortical dysplasias are an important cause of early-onset seizures that may be focal or generalized (Fig. 4(a), Fig. 4(b) and Fig. 4(c)). Patients with refractory epilepsy should therefore have the best possible imaging, even if they have generalized seizures. Resection of cortical dysplasias may improve seizure control, but this is a challenging field because the preoperative assessment must take into account the widespread anatomical and functional abnormalities associated with cortical dysplasias.

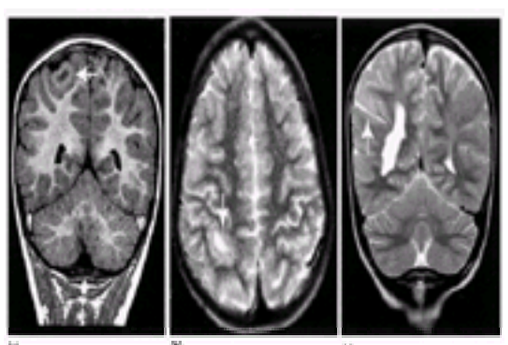

Fig. 4 (a) Cortical dysplasia in a boy aged 4 years. Focal seizures started at 1 year of age and consisted of a giggle, flexion of the left arm, and a vacant stare. T_1-weighted coronal MRI shows cortical dysplasia in the right parietal region (arrow). (b) The same patient. On T_2-weighted axial MRI, the cortical dysplasia is marked with an arrow. (c) Cortical dysplasia in a boy aged 3 years. Seizures commenced at 9 months of age and consisted of daytime absences and nocturnal generalized tonic–clonic seizures. A T_2-weighted coronal MRI shows an abnormal fissure in the cortex on the right (arrow). The right lateral ventricle is abnormal in size and shape.

Combined and overlapping cerebral malformations

There is overlap between the different malformations even though they are often described as distinct entities. This is not surprising—the teratogenic periods are so closely spaced that overlaps are likely if there is an environmental cause. Also, in genetically determined syndromes, more than one developmental process may be affected giving predictable combinations of cerebral malformations.

Agenesis of the corpus callosum

The true prevalence of this abnormality is not accurately known because it can be present without any symptoms. Estimated prevalence has varied from 0.05 to 70 per 10 000 in the general population, increasing to 230 per 10 000 in children with developmental disabilities.

Embryology

The corpus callosum forms within the commissural plate, a thickening of the lamina terminalis which is the frontal boundary of the neural tube. At 11 to 12 weeks the first fibres cross the midline to form the corpus callosum, which displaces the fornix and extends back in the occipital direction to assume the adult form by 18 to 20 weeks. There are two types of 'true' callosal agenesis. These are: (i) defects in which axons are unable to cross the midline and become large aberrant longitudinal fibre bundles, called Probst bundles, along the medial walls of the cerebral hemispheres; and (ii) defects in which the commissural axons or their parent cell bodies fail to form in the cerebral cortex. The former is probably the most common type, the latter is seen in the Walker–Warburg syndrome and other types of lissencephaly. There are also two secondary types: (i) absence associated with major malformations of the embryonic forebrain, such as holoprosencephaly; and (ii) degeneration or atrophy, as is seen in some syndromes in which the corpus callosum is thinned but not shortened.

Pathology

Agenesis of the corpus callosum may be complete or partial. Either the anterior or the posterior part may be missing. When there is complete absence there is no cingulate gyrus. There is associated enlargement of the occipital horns of the lateral ventricles, known as colpocephaly. Other associated abnormalities include cysts dorsal to the third ventricle, heterotopias, gyral abnormalities, cephaloceles, lipomas of the corpus callosum, eye abnormalities, nd hydrocephalus.

Aetiology

Isolated callosal agenesis may be inherited as an autosomal recessive, autosomal dominant, or X-linked recessive trait, but none of these loci have been mapped and non-syndromic genetic transmission is rare. It has been associated with several chromosomal rearrangements. These include trisomy 18, trisomy 13, and many deletions and duplications. Also it has been reported in more than 20 autosomal and many X-linked malformation syndromes. Callosal agenesis is part of the fetal alcohol syndrome and is seen in metabolic disorders including glutaric aciduria type 2, peroxisomal disorders, pyruvate dehydrogenase deficiency, and non-ketotic hyperglycinaemia.

Clinical findings

Non-syndromic forms are the most common. When agenesis of the corpus callosum is the only lesion there may be no symptoms, although tests of perception and language may demonstrate disturbances of integration of hemispheric function. However, even if there is no clearly defined syndrome, some patients have mental retardation, seizures, or cerebral palsy. Sometimes there is macrocephaly, which may be due to cysts lying dorsal to the third ventricle or to hydrocephalus.

Diagnosis

This depends on brain imaging (Fig. 5(a), Fig. 5(b) and Fig. 5(c)). The abnormalities that can be found are widely spaced parallel lateral ventricles, colpocephaly (enlarged posterior horns of the lateral ventricles), upward displacement of the third ventricle, absent callosal tissue, or midline dorsal cyst. Prenatal ultrasound allows diagnosis from the 20th week of gestation. After birth, MRI is best because it gives sagittal views of the corpus callosum. The scan should be carefully reviewed for other midline anomalies (such as agenesis of the septum pellucidum) or generalized defects (such as lissencephaly).

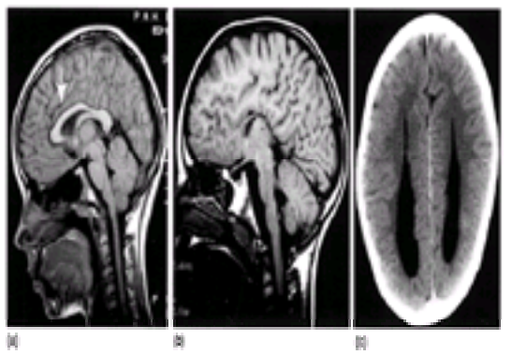

Fig. 5 (a) Normal brain in a girl aged 2 years. A T_1-weighted sagittal MRI shows normal corpus callosum and cingulate gyrus (arrow). (b) Agenesis of the corpus callosum in a girl aged 6 years who has microcephaly and moderate learning difficulties. A T_1-weighted sagittal MRI shows absence of the corpus callosum and of the cingulate gyrus, which normally runs parallel to the corpus callosum. (c) Agenesis of the corpus callosum in the same girl as (b). Axial CT shows typical appearance of parallel lateral cerebral ventricles, with divergence of the anterior horns of the ventricles and colpocephaly (dilated posterior part of the lateral ventricles).

The eyes should be examined to look for optic nerve hypoplasia (as seen in septo-optic dysplasia) or choroidal lacunae (as seen in the Aicardi syndrome). In neonates with seizures or other significant neurological problems the cerebrospinal fluid should be taken to measure glycine (raised in non-ketotic hyperglycinaemia) and lactate (raised in mitochondrial encephalomyelopathy). A karyotype should be performed and urine sent to measure amino and organic acids. If there is evidence of septo-optic dysplasia (see below), pituitary function should be checked.

Genetic counselling

This depends on the specific diagnosis. When callosal agenesis is discovered on antenatal scan the prognosis is difficult to assess because the isolated lesion can be associated with normal development. A decision to terminate the pregnancy may depend on the demonstration of associated abnormalities.

Porencephaly

The term porencephaly is often used indiscriminately for all large cavities in the brains of infants. Friede recommends using the term only for circumscribed hemispheric necrosis that occurs *in utero* before the adult features of the hemisphere are fully developed (Fig. 6(b)). The developmental origin of such lesions is shown by their smooth walls and from disturbances in the development of the adjoining cortex. These disturbances may take the form of polymicrogyria or of local distortion of the gyral pattern. In contrast, areas of damage resulting from insults in the terminal phase of the pregnancy or in postnatal life have irregular shaggy walls and do not alter the gyral environment except by atrophy or scarring.

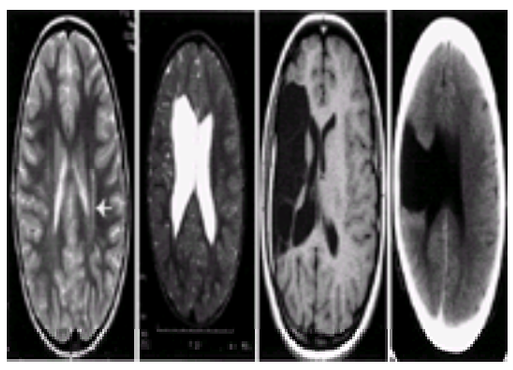

Fig. 6 (a) Cerebral palsy: spastic diplegia. Probable periventricular leucomalacia in a girl aged 6 years. There was threatened premature labour at 29 and 32 weeks, but she was born at term with no perinatal problems. She walked late with a diplegic gait. T_2-weighted axial MRI shows abnormal signal change lateral to the body of the left lateral ventricle and posterolateral to the posterior horn of the left lateral ventricle (arrow). This a characteristic distribution of periventricular leucomalacia, but such scan appearances should be interpreted with caution because there are other causes of white matter abnormalities in children (e.g. the leucodystrophies). (b) Cerebral palsy: left hemiplegia. Porencephalic cyst in a boy aged 18 months. He was delivered by forceps at 38 weeks with no resuscitation, but nasogastric feeding for several days after birth. At 10 months of age he was not moving the left arm normally. T_2-weighted axial MRI shows there is dilatation of the anterior horn of the right lateral ventricle with loss of overlying cerebral cortex and a small periventricular cyst adjacent to the anterior horn of the right lateral ventricle. These abnormalities may result from periventricular leucomalacia. Such loss of tissue due to *in utero* damage of the developing brain is called a porencephalic cyst. (c) Cerebral palsy: left hemiplegia. Tissue loss in middle cerebral artery territory in a young woman aged 17 years. There were no perinatal problems; reduced movement of left arm from 6 months of age; nocturnal generalized tonic–clonic seizures from 4 years of age; normal intelligence; abnormal posture of left hand; and shortening of the left leg. T_1-weighted axial MRI shows there is a loculated cystic lesion in the distribution of the supply of the middle cerebral artery. Also *ex vacuo* enlargement of the right lateral ventricle and small ipsilateral left hemicranium. (d) Open-lipped schizencephaly in a 49-year-old female. An axial CT scan shows there is a wide cleft joining the right lateral ventricle to the subarachnoid space.

Schizencephaly

This term is used to describe clefts which traverse the full thickness of the hemisphere, connecting the ventricle to the subarachnoid space. They are described as type I or 'fused-lip' when the walls of the cleft are opposed, and type II or 'open-lip' when cerebrospinal fluid separates the walls (Fig. 6(d)). Some authors think that the clefts are usually the result of destruction of brain tissue and the term porencephaly should be used for them all. However, there is now evidence that some of them are genetic—familial and sporadic cases have been recognized in association with mutations in the homeobox gene *EMX2*. This is one of the vertebrate homeobox genes expressed in the extended regions of the developing rostral brain of mouse embryos that are thought to play a role in patterning the forebrain. The clefts are frequently bilateral and symmetrical, the most severe form being large bilateral defects. Even when unilateral, they are often combined with cortical dysplasia of the opposite hemisphere.

Clinical features

These are variable, depending on the site and size of the lesion. Epilepsy is common and sometimes the only problem is isolated partial seizures.

There may be hemiplegia, quadriplegia, and learning difficulties of variable degree. If there is bilateral involvement of both opercular regions, there may be facial apraxia and speech difficulties. The diagnosis is best made by MRI.

Hydranencephaly

In this condition the cerebral hemispheres are mostly replaced by fluid-filled sacs. The defect typically corresponds to the territory of the anterior and middle cerebral arteries, although the major cranial arteries do not usually show evidence of obstruction. Preservation of the temporal lobes and the tentorial parts of the occipital lobes is common. The extent of preservation of the basal ganglia varies. The cause of hydranencephaly is not clear in many cases. It has been described after intoxication of pregnant women with gas at about the 25th week of gestation. It can result from intrauterine infections and has been described in association with a proliferative vasculopathy.

Affected infants may be born after a normal pregnancy and be surprisingly normal on neurological examination for the first few weeks of life. Gradually the infants become hypertonic and irritable. They may develop infantile spasms, which is surprising because of the almost complete lack of cerebral hemispheres. The head may enlarge because of associated hydrocephalus. The diagnosis can be made by transillumination of the skull, which lights up like a lantern in a darkened room. Similar appearances can be caused by hydrocephalus with a very thin cortical mantle, so MRI is indicated to confirm the diagnosis. Infants with hydranencephaly often die in a few months, but they may survive for several years and may need a ventriculoperitoneal cerebrospinal fluid shunt if there is progressive hydrocephalus.

Septo-optic dysplasia

This is the association of optic nerve hypoplasia with absence of the septum pellucidum. Disturbances of the hypothalamopituitary axis may occur. The most severely affected patients are blind and have severe learning difficulties. The optic discs have a characteristic double contour: the true disc at the centre is small and there is a peripheral ring about the size of a normal optic nerve head. It important to search for evidence of endocrine disturbances when these abnormal discs are identified—deficiences of growth hormone, corticotrophin, luteinizing hormone, and follicle-stimulating hormone have been described, together with hypoglycaemia and diabetes insipidus. Most cases are sporadic, but a homozygous mutation in the homeobox gene *HESX1* has been identified in familial septo-optic dysplasia. Also some sporadic cases of the more common mild forms of pituitary hypoplasia are associated with heterozygous mutations of the *HESX1* gene.

Malformations of posterior fossa structures

These malformations are now identified more accurately using prenatal ultrasound and MRI, which is superior to CT scanning for showing posterior fossa structures.

Cerebellar and brainstem development

Embrology

At the end of the fourth week of gestation the neural tube divides into the three primary brain vesicles—the prosencephalon, the mesencephalon, and the rhombencephalon. The last further subdivides into the metencephalon and the myelencephalon. The cerebellar hemispheres (neocerebellum) are derived primarily from the metencephalon, while the vermis (palaeocerebellum) is derived from the mesencephalon.

Experiments in animals demonstrate that a critical area for vertebrate cerebellar development occurs at the junction of the mesencephalon and the metencephalon in the region of the isthmus. An early abnormality in the isthmus that affects the mesencephalic contribution to midline cerebellar structures could contribute to the pathogenesis of syndromes that involve agenesis or hypoplasia of the cerebellar vermis, such as Joubert syndrome.

Aplasia and hypoplasia of the cerebellum

This is a heterogeneous group of conditions that affect cerebellar development in various ways—total cerebellar aplasia is exceptional and unilateral hypoplasia occurs. Neocerebellar aplasia (Fig. 7(a)) is characterized by a small vermis and extreme smallness or absence of the cerebellar hemispheres except for persistent flocculi. There may be associated anomalies in the brainstem such as dysplasia of the inferior olivary nucleus and other brainstem nuclei.

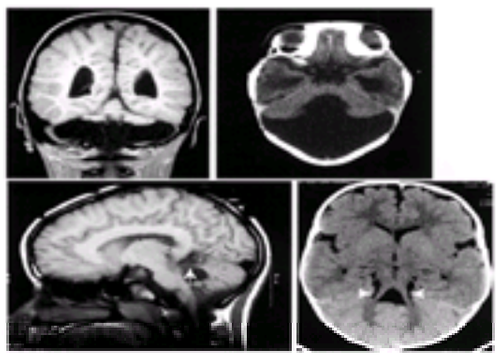

Fig. 7 (a) Cerebellar hypoplasia in a boy aged 5 years, who was born preterm at 26 weeks of gestation, with no neurological problems apart from absence seizures of unknown cause. T_1-weighted coronal MRI shows almost complete absence of the cerebellar hemispheres and hypoplasia of the cerebellar vermis. (b) Dandy–Walker malformation in a 1-year-old girl. Axial CT scan shows absence of the roof of the fourth ventricle. A large cyst is continuous with the fourth ventricle and fills the posterior fossa. (c) Joubert syndrome in a girl aged 10 years. T_1-weighted sagittal MRI shows the superior cerebellar peduncles run horizontally (arrow) and the cerebellar vermis is absent. (d) Joubert syndrome in a girl aged 9 months who is hypotonic and visually unresponsive, with 'wandering' nystagmus. Axial CT shows the superior cerebellar peduncles (arrows) run horizontally and stand out because of the absence of the vermis ('molar tooth sign'). The prominent fourth ventricle has a typical shape (sometimes looking like a 'bat wing').

Some cases are associated with genetic syndromes, many of which are poorly defined. Recent attention has been drawn to a group of disorders classified under the broad headings of pontocerebellar hypoplasia or olivopontocerebellar atrophy. Pontocerebellar hypoplasia is found in carbohydrate-deficient glycoprotein syndrome type 1 and cerebromuscular dystrophies (Walker-Warburg syndrome, Fukuyama syndrome, and muscle-eye-brain diseases—see above). There are at least two types of autosomal recessive pontocerebellar hypoplasias (type I and type II). MRI demonstrates cerebellar hypoplasia together with a hypoplastic ventral pons. It has been speculated that some of these cases are due to mutations of *engrailed* genes which are essential for the development of the segmental precursors of the pons and cerebellum in the mouse brain.

The Chiari malformations

There are four types. The Chiari II malformation is usually associated with a meningomyelocele and is dealt with in the section on neural tube defects. In the Chiari I malformation there is downward displacement of the lower cerebellum, including the tonsils. It rarely cause symptoms in childhood but may be associated with hydrocephalus and syringomyelia. The Chiari III malformation consists of downward displacement of the cerebellum into a posterior encephalocele and the Chiari IV malformation is a form of cerebellar hypoplasia.

Abnormalities of the vermis

Dandy–Walker malformation and Dandy–Walker variant

Two main complexes have been described. The Dandy–Walker malformation (Fig. 7(b)) consists of the following triad: (i) complete or partial agenesis of the vermis, (ii) cystic dilatation of the fourth ventricle, and (iii) enlarged posterior fossa with upward displacement of lateral sinuses, tentorium, and torcula. A Dandy–Walker variant has been recognized more recently and consists of variable dysplasia of the vermis without enlargement of the posterior fossa. There is an association between Dandy–Walker malformations and chromosomal abnormalities including trisomies 13 and 18. Dandy–Walker malformation is listed as a feature of 80 syndromes in the London Dysmorphology Database.

Prenatal ultrasound studies show that the majority of fetuses with both complexes have other anomalies. The commonest CNS anomaly was ventriculomegaly and the commonest non-CNS anomalies were structural heart defects. Other associated CNS abnormalities include holoprosencephaly, agenesis of the corpus callosum, occipital encephaloceles, and abnormal migration of the inferior olive.

Clinical features

The outcome of fetuses with both Dandy–Walker malformation and Dandy–Walker variant ranges from severe mental and physical handicap to normal development. In general the outcome is worst if there are associated abnormalities and best for isolated Dandy–Walker variant. Intrauterine deaths occur and some infants do not survive the neonatal period, the poor early outcome being related to the extra-CNS abnormalities. However, the abnormality is often recognized only when the infant is investigated for the signs of hydrocephalus, which may not become apparent until late in the first year of life. Sometimes there is a bulging occiput which alerts suspicion. Another presentation may be later in life with learning difficulties. Cerebellar signs tend not to be prominent, but cranial nerve palsies, nystagmus, and truncal ataxia have been described.

Diagnosis

The cerebellar vermis starts to form in the ninth week of gestation, beginning superiorly so that fusion of the two cerebellar hemispheres is completed when the inferior part of the vermis is formed at 15 weeks. However, in a small proportion of infants this happens later, so that conclusive prenatal ultrasound diagnosis cannot be made until 18 weeks. When the diagnosis is made there should be an exhaustive screen for associated structural and chromosomal anomalies because these determine the prognosis. Radiological diagnosis is relatively straightforward for the Dandy–Walker malformation. Dandy–Walker variant may be difficult to distinguish from a prominent cisterna magna or a retrocerebellar arachnoid cyst. Sagittal MRI can then help to differentiate whether the vermis is partly absent or alternatively is fully present but displaced.

Genetic counselling

If a chromosomal anomaly is identified or a syndrome diagnosis is made, appropriate counselling is given. If there are no associated abnormalities and the chromosomes are normal, the recurrence risk is 1 to 5 per cent.

Joubert syndrome

This rare autosomal recessive disorder is characterized by brainstem and cerebellar malformations. The disease is genetically heterogeneous, and one locus has been mapped to chromosome 9q.

Neuropathology

The neuropathological features include absence or hypoplasia of the posteroinferior part of the cerebellar vermis. In some cases enlargement of the fourth ventricle and the cisterna magna has been reported. Microscopically, heterotopias have been seen in the cerebellar hemispheres with fragmentation of the dentate nuclei. Brainstem abnormalities include absence of the pyramidal decussation, abnormal inferior olivary nuclei, and subtle dysplasias in the nuclei of the solitary and descending trigeminal tracts and of the dorsal columns.

Clinical features

The common abnormalities are marked hypotonia (particularly in the neonatal period and infancy), poor balance (walking occurs in 50 per cent of cases and is late—at approximately 4 years), and variable cognitive problems (some affected children are unable to talk but others develop language, read, and write). Typically CT or MRI shows the 'molar tooth' sign in the axial plane, which consists of: (i) a deeper than normal posterior interpeduncular fossa, (ii) prominent or thickened

superior cerebellar peduncles, and (iii) vermian hypoplasia or dysplasia. MRI in the coronal and axial plane shows clefting of the vermis; in the sagittal plane it shows an abnormally shaped and rostrally placed fourth ventricle (Fig. 7(c) and Fig. 7(d).

The associated abnormalities are dysmorphic facial features (high rounded eyebrows, broad nasal bridge, epicanthus, anteverted nostrils, triangular-shaped open mouth with irregular tongue protrusion, low-set coarse ears), episodic hyperpnoea and/or apnoea in up to 75 per cent of patients (most marked in the neonatal period), eye abnormalities (retinal dysplasia, colobomata, nystagmus, strabismus, ptosis, and oculomotor apraxia), and microcystic renal disease.

Neurological syndromes resulting from disturbances of brain development

The cerebral palsies

Introduction

The cerebral palsies are defined as a heterogeneous collection of non-progressive disorders of movement and posture due to defects or lesions of the immature brain.

It can be seen that this is a broad definition, but it does need to be used carefully. It is not satisfactory to label a child with neurological problems as suffering from 'cerebral palsy' and go no further. It is important to determine the type and distribution of the abnormality of motor control. In addition to motor deficits, patients with cerebral palsy may suffer with other neurological problems, such as learning difficulties, epilepsy, and hearing or visual loss. It is important to evaluate these, although they are not present in all cases.

Although the underlying causes of the cerebral palsy syndromes are by definition not progressive, the symptoms and signs of cerebral palsy do change with age. For instance some children who are destined to have major problems with spasticity are initially very hypotonic. In some cases it can be difficult to be sure whether or not a child with suspected cerebral palsy has a progressive underlying disorder. It may be necessary to allow the passage of time and children may be 3 or 4 years old before the diagnosis of cerebral palsy can be made with confidence.

Classification

Patients may be classified according to the type of motor abnormality as follows: spastic, dyskinetic (dystonic or athetoid), ataxic, or hypotonic. The clinical picture is rarely clear-cut and individuals may exhibit complex mixtures of motor disability.

Patients are subclassified according to the distribution of motor abnormality—in diplegia the legs are involved more than the arms, in quadriplegia all four limbs are involved, and in hemiplegia just one side of the body is involved.

In practice there is considerable interobserver disagreement when classifying patients with cerebral palsy. However, it is important to use a classification system for research and management because different types of cerebral palsy tend to have distinct causes, different associated deficits, and different prognoses.

Epidemiology

There is a relative shortage of data from developing countries, so the statistics quoted here are for developed countries. Although the risk of cerebral palsy is higher for preterm infants, most children with cerebral palsy are born at term. Overall cerebral palsy rates are therefore determined mainly by the numbers of term infants born with cerebral palsy.

Overall cerebral palsy rates since the mid-1950s have remained remarkably constant at about 2 to 2.5 per 1000 live births, although there have been some fluctuations with time. In 1970 the rate fell to 1.5 in Sweden, Western Australia, and Mersey (United Kingdom), rising again in the 1980s.

Cerebral palsy rates stratified by birth weight show marked changes with time. Most population-based registers have shown increases in rates in infants of very low birth weight (less than 1500 g) since the 1970s. For instance, in Mersey in the early 1970s the rate in infants of very low birth weight fluctuated around 10 per 1000 live births. In the late 1970s the rate increased sharply to about 50 per 1000 live births, presumably because more children of very low birth weight were surviving with neurological deficits. This increase was seen for all cerebral palsy types. However, to put the increasing cerebral palsy rates in survivors of very low birth weight in perspective, during this time an increasing proportion of patients were also surviving unimpaired. Another important point is that very low birth weight survivors with cerebral palsy are only a small proportion of the total number of children with cerebral palsy and therefore have very little effect on overall cerebral palsy rates.

Relative rates of the different types of cerebral palsy vary according to the series. In the Western Australian Cerebral Palsy Register 1980–1992 cohort the proportions of cases of congenital (as opposed to postneonatal) cerebral palsy were as follows: spastic hemiplegia 33.6 per cent, spastic diplegia 29.7 per cent, spastic quadriplegia 18.1 per cent, ataxic 7.6 per cent, dyskinetic 10.0 per cent, and hypotonic 0.9 per cent.

Aetiology

Although it has been thought that cerebral palsy results primarily from 'birth asphyxia', recent studies suggest that abnormal events around the time of birth play only a limited role. Genetic causes are clearly important as there can be a significant recurrence risk to future children, particularly in populations where consanguineous marriage is relatively common. Families have been reported in which spastic diplegia and quadriplegia (often with associated mental retardation) appear to be inherited in autosomal recessive, autosomal dominant, or X-linked recessive patterns. It is said that the highest risk of recurrence is in the category of children with ataxic cerebral palsy: both autosomal dominant and autosomal recessive inheritance have been reported. However, there are many conditions which cause ataxia in children. It is therefore important to search for an underlying cause before giving genetic advice, rather than to 'lump' this group and give an overall recurrence risk.

Other possible causes before conception or in early pregnancy

Maternal iodine deficiency in early pregnancy may cause endemic cretinism (which causes spastic diplegia and deafness): this is the most important cause of cerebral palsy worldwide. Abnormal thyroid function in pregnancy may play a role in developed countries. Exposure to toxins during pregnancy may cause cerebral palsy—recognized examples are methylmercury, alcohol, and carbon monoxide poisoning. Viral infections which are vertically transmitted before the third trimester often result in cerebral malformations—those best known are toxoplasmosis, rubella, and cytomegalovirus. Finally, there are some fetal malformation syndromes that include brain abnormalities and cause cerebral palsy.

The role of very preterm birth

The rate of cerebral palsy among neonatal survivors born before 33 weeks is up to 30 times higher than among those born at term. This may be because of increased survival of very preterm infants whose brains are already damaged or because preterm infants are vulnerable to cerebral damage after birth. It seems likely that there is a combination of these mechanisms. Cerebral ultrasound scans performed in newborn babies have shown that the strongest predictor of cerebral palsy in these infants is periventricular leucomalacia. This term is used for abnormal echolucency, often associated with cystic change, which is found particularly in the white matter dorsolateral to the lateral ventricles (Fig. 6(a)). It is difficult to time the onset of the pathological processes that lead to the appearance of these lesions. At present there is evidence that many different factors result in preterm birth and it is not known how they contribute to cerebral palsy.

The role of intrauterine growth restriction

Babies born small for their gestational age are at increased risk of cerebral palsy and the risk increases with the degree of birth weight deficit. The underlying mechanism is not clear and the majority of small-for-dates infants do not have cerebral palsy.

The role of multiple births

The prevalence of cerebral palsy is much higher in twins than in singletons, particularly in those who survive after the other twin has died *in utero* and in monochorionic twins. The risk rises with the number of fetuses carried. Causes include low birth weight, congenital anomalies, cord entanglement, and abnormal vascular connections.

The role of birth asphyxia

In the 1970s it was expected that more intensive monitoring of the fetus during labour, coupled with earlier obstetric intervention, would improve neonatal outcome. The major effects of electronic monitoring of the heart rate during labour have been an increase in caesarean section rates and a reduced rate of neonatal seizures, however it has had no impact on the rates of cerebral palsy. The proportion of cerebral palsy cases associated with intrapartum events has been estimated by several epidemiological studies to be only about 10 per cent. However, there may be some cases caused by intrapartum events that are preventable.

In 1999 a consensus statement for the International Cerebral Palsy Task Force outlined a template for defining a causal relationship between acute intrapartum events and cerebral palsy. The statement emphasized the difficulty of retrospectively identifying the antenatal causes of cerebral palsy in the individual case and the non-specific nature of the clinical signs that lead to the suspicion of fetal hypoxia in labour. It proposed that the terms 'fetal distress' and 'birth asphyxia' should be replaced by the term 'non-reassuring fetal status' and suggested eight criteria for defining an acute intrapartum hypoxic event. The hope is that more general use of these criteria will reduce the number of cases of cerebral palsy that are wrongly attributed to an acute event during labour.

Cerebral palsy acquired after the neonatal period

Cerebral palsy registers in Sweden, Mersey, and Western Australia report rates varying from about 1 to 6 per 10 000 live births. Causes include CNS infections, accidental and non-accidental head injuries, cerebrovascular accidents, and hypoxia (suffocation, near drowning).

Brain imaging in children with cerebral palsy

The pathological processes that cause cerebral palsy have been investigated using ultrasonography, MRI, and CT scanning. One study found that about a quarter of children with a hemiplegia had normal CT scans, whilst an MRI study of a heterogeneous group of children with cerebral palsy found abnormalities in 93 per cent of the patients.

The studies have in many cases been performed years after birth on heterogeneous groups of children with cerebral palsy attending specialized clinics. The commonest lesion in preterm infants is periventricular leucomalacia, which is necrosis of periventricular white matter in the watershed regions dorsal and lateral to the lateral ventricle (Fig. 6(a)). This is said to be characteristic of damage in the early third trimester. In term infants there are a number of different findings, which are said to occur only in infants born at or near term. These are infarcts in the arterial border zones in the parasagittal regions leading to cortical and subcortical injury, bilateral lesions of the basal ganglia and the thalamus, areas of subcortical leucomalacia, and multicystic leucomalacia (replacement of the brain tissue by fluid-filled cysts). Periventricular leucomalacia and localized gyral abnormalities are also seen in infants born at term.

Children with hemiplegias are sometimes found to have periventricular leucomalacia, porencephalic cysts (Fig. 6(b)), or cortical/subcortical lesions in the middle cerebral artery territory distribution (Fig. 6(c)). The lesions tend to be unilateral, but bilateral lesions are seen. Rarely they may have schizencephaly (Fig. 6(d)), focal pachygyria, or focal heterotopia.

Although brain scans in children with cerebral palsy are performed a long time after the insult, the nature of the lesions allows some assessment of the timing of cerebral damage. Like the epidemiological studies the brain imaging studies suggest that perinatal brain injury occurs in a relatively small proportion of cases.

Life expectancy

Different studies have followed patients with cerebral palsy for 10 years or more and have yielded similar findings. The survival rates have been about 90 per cent when all the types of cerebral palsy are considered together. The prognosis is best for those with hemiplegia and worst for those with quadriplegia. A population-based study in Canada found that 30-year survival rates were: hemiplegia 96 per cent, diplegia 95 per cent, and quadriplegia 83 per cent. The factors associated with reduced survival rates are severe mental retardation, lack of basic functional skills (mobility, independent feeding), and epilepsy.

Hydrocephalus

This results from expansion of the ventricles secondary to a block in the normal flow pathway of cerebrospinal fluid. Cerebrospinal fluid is produced by the choroid plexus in the lateral ventricles, from where it flows through the foramen of Munro into the third ventricle and then the fourth ventricle via the aqueduct of Sylvius. It leaves the ventricular system via small openings in the roof of the fourth ventricle, the foramina of Magendie and Luschka. From here the fluid flows in the subarachnoid space before being reabsorbed into the blood supply via arachnoid villae.

Two major forms of hydrocephalus are recognized. In communicating hydrocephalus the ventricular pathways are clear and a failure of reabsorption (following, for example, bleeding into the subarachnoid space) results in increased cerebrospinal fluid volume. In obstructive or non-communicating hydrocephalus the blockage occurs at one of the ventricular levels, with expansion of the ventricular system above the block (Fig. 8). The major clinical sign that results is increasing head circumference following the ventricular enlargement, and this allows the distinction from cases in which increased ventricular size reflects cerebral atrophy. Mental retardation can result from both the damage associated with ventricular expansion and other abnormalities associated with the underlying cause of the problem.

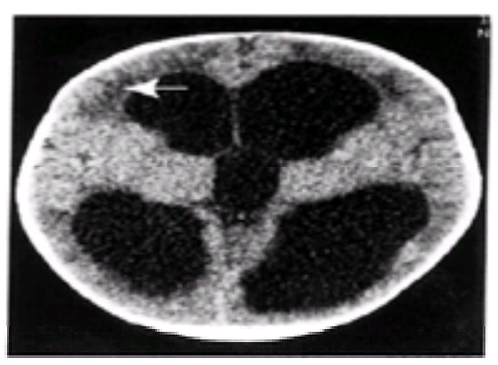

Fig. 8 Aqueduct stenosis in a boy aged 1 month with a bulging anterior fontanelle and increasing head circumference. Axial CT shows a gross dilatation of the third and lateral ventricles (the fourth ventricle is not shown, but was normal in size). Note the periventricular low density due to transependymal exudation of cerebrospinal fluid under pressure (arrow).

Sometimes hydrocephalus is genetically determined; stenosis of the aqueduct between the third and fourth ventricle can result from mutations in the cell adhesion molecule L1-CAM. Hydrocephalus then occurs in association with hypoplasia of the corpus callosum, mental retardation, spastic paraplegia, and adducted thumbs. This X-linked syndrome has been given the extremely unfortunate acronym CRASH syndrome and mutations in *L1-CAM* are found in as many as 75 per cent of cases with a family history and 15 per cent of apparently isolated cases. The developmental abnormalities of the cerebellum in both the Dandy–Walker syndrome and the Arnold–Chiari malformation (see above) may also be associated with obstructive hydrocephalus. While treatment via a ventriculoperitoneal shunt can relieve the obstruction, the other abnormalities associated with these developmental problems remain.

Effects of alcohol on the developing nervous system

Worldwide, alcohol is one of the commonest causes of learning difficulty and neurobehavioural disturbance in young children. The incidence of fetal alcohol sydrome depends on geographical location. An international survey in 1997 found that in the United States the incidence per 1000 live births in Seattle was 2.8 and in Cleveland was 4.6. The combined rate of fetal alcohol sydrome and alcohol-related neurodevelopmental disorder in Seattle was estimated at nearly 1 per cent of all live births. The reduced brain mass and neurobehavioural disturbances associated with fetal alcohol syndrome may be related to the recent observation in rats that ethanol can trigger widespread apoptotic neurodegeneration.

Regular and binge drinking can both cause fetal alcohol syndrome and alcohol-related neurodevelopmental disorder. Unlike many other teratogens, alcohol has harmful effects throughout pregnancy. There is a significant risk of fetal alcohol syndrome associated with high-dose exposure (estimated blood alcohol concentrations of 150 mg per decilitre or more, at least weekly for several weeks in the first trimester).

In addition to microcephaly, structural anomalies of the brain such as partial or complete agenesis of the corpus callosum or cerebellar hypoplasia may occur. Children with fetal alcohol syndrome may have impaired fine motor skills, sensorineural deafness, poor hand–eye co-ordination and a poor tandem gait. A complex pattern of behavioural and cognitive abnormalities is observed following exposure to teratogenic levels of alcohol in pregnancy. These include learning difficulties, poor impulse control, problems with social perception, deficits in higher level receptive and expressive language, poor capacity for abstraction, and difficulties with memory, attention, and judgement.

Congenital infections

Cytomegalovirus, herpes simplex, parvovirus, rubella, syphilis, toxoplasmosis, and varicella are all recognized as teratogens. Primary infection rather than reinfection of the mother during pregnancy is more likely to result in congenital infection. The risk of congenital infection and the outcome of such infection is crucially dependent on the stage of pregnancy. This brief account focuses on the effects of congenital infection on the developing nervous system.

Congenital infection should be considered in the differential diagnosis of microcephaly. Intracranial calcification identified on a cranial ultrasound or CT scan during the investigation of developmental delay or seizures should arouse suspicion of congenital infection, especially cytomegalovirus or toxoplasmosis (calcification is not picked up well by MRI). Detailed ophthalmological assessment may reveal clues such as chorioretinitis or cataract that may help in the retrospective diagnosis of congenital infection. Chorioretinitis (pigmentary retinopathy) is characteristic of intrauterine infection by cytomegalovirus or toxoplasmosis. Audiometry is important since sensorineural deafness is a common sequel to congenital infection with cytomegalovirus, rubella, and toxoplasmosis.

The risk of maternal–fetal transmission with primary cytomegalovirus infection is as high as 40 per cent, however fewer than 10 per cent of infants with intrauterine infection are symptomatic at birth. Of those who are symptomatic as neonates, approximately 90 per cent have some of the characteristic features including microcephaly, periventricular calcification, chorioretinitis, optic atrophy, and sensorineural deafness. Of the 90 per cent of infants who are asymptomatic at birth, approximately 15 per cent have sequelae including sensorineural deafness and/or developmental delay.

Intrauterine infection with herpes simplex virus is rare. Congenitally affected infants may have microcephaly, chorioretinits, and microphthalmos. Neonatal infection acquired at the time of delivery, which may occur with primary infection of the mother with herpes simplex virus in the third rimester, is a commoner cause of neurodisability than congenital infection. Neonatal infection may cause meningitis and encephalitis with resulting neurological damage. The risks of perinatally acquired infection may be reduced by appropriate obstetric intervention (such as delivery by caesarian section for women with active genital lesions resulting from herpes simplex virus) and by treatment of affected neonates with acyclovir.

The classic triad of defects associated with congenital rubella syndrome is sensorineural deafness, congenital heart disease, and eye abnormalities (retinopathy, cataracts, microphthalmos, and congenital glaucoma). Microcephaly and developmental delay may also occur. The spectrum of defects in an individual child is determined by the stage of pregnancy at which intrauterine infection occurs. The risk of congenital infection is more than 90 per cent below 10 weeks and falls to zero beyond 18 weeks.

The risk of intrauterine infection with toxoplasmosis increases with the stage of pregnancy at which the mother acquires her primary infection; however the sequelae of intrauterine infection diminish with advancing gestation. Congenital toxoplasmosis syndrome includes hydrocephalus, intracranial calcification, microcephaly, seizures, and developmental delay. There may also be sensorineural deafness and chorioretinitis with visual impairment.

Congenital varicella syndrome follows primary maternal varicella occurring at 1 to 20 weeks of gestation, but the risk of sequelae is small at around 2 per cent. Cataracts and chorioretinitis may occur together with hypoplasia of the optic disc. Microcephaly and porencephaly have been described.

Clinical approach to diagnosis and genetic counselling

Assessing the nervous system in children

History

General

The importance of the history cannot be overemphasized. Children may give a history themselves, but usually the parents or carers are an essential source of information and this may be amplified by teachers, therapists, and other health professionals.

Past history

The pregnancy details are important. Significant events in the first trimester may be a threatened miscarriage, hyperemesis, or a viral infection—the mother may have been taking medication. Later there may have been unsatisfactory fetal growth (perhaps poor head growth assessed by ultrasound) or reduced fetal movements. The perinatal history is relevant, including weeks of gestation at the time of delivery, details of labour and delivery, birth weight, and head circumference. In the neonatal period the infant may have required treatment for early hypoglycaemia, seizures, or breathing or feeding difficulties. A developmental history is essential—particular areas of concern in infants are lack of social response, absence of a social smile, poor fixing and following of the eyes, and lack of symmetrical organized limb movements. Later a characteristic pattern of delayed development may emerge—for instance global delay is found in the most severe brain abnormalities or there may be mainly motor delay in the milder forms of cerebral palsy.

Family and social history

Information should be obtained about first-degree and more distant relatives. Considerable effort may be needed to obtain relevant facts—some families conceal or do not know about relatives with severe disability, perhaps because they are in instituitions. It is important to know about consanguinity, also about epilepsy, motor disorders, and severe or mild learning disabilities. Social factors are important in determining the environment in which the child grows up and they also determine the quality of care available for a child with significant disability.

Examination

Observation of spontaneous activity is essential. The form of this depends on the degree of disability, but if the child is able to play this should be encouraged. It may be helpful to use toys, bricks, beads for threading, paper, and crayons. The quality and symmetry of spontaneous movements should be noted and also any abnormal movements. It is best to assess muscle power by watching the child run, jump, and climb stairs. Fine motor function can be assessed whilst the child is drawing or threading beads.

Developmental assessment may be formally undertaken in infants using one of the standardized schedules, such as the Bailey Scales of Infant Development or the

Denver Developmental Screening Test. Later the Wechsler Preschool and Primary Scale of Intelligence (WPPSI) and the Wechsler Intelligence Scale for Children (Revised) (WISC-R) may be used. The latter assessments are usually undertaken by a clinical or educational psychologist.

The conventional examination of the nervous system may be difficult in infants or young children. The examiner may need to adapt the order of events or even come back later—a useful assessment cannot be made if an infant is deeply asleep or upset and crying. Examination of the cranial nerves should be made as much like play as possible by using a toy to observe eye movements and by encouraging the child to smile, whistle, close the jaw tight, stick out the tongue, and so on.

Dysmorphic features are particularly relevant in the context of a suspected abnormality of the nervous system. There may be birth marks (capillary haemangiomata of the face in Sturge–Weber syndrome or midline skin abnormalities such as hairy patches or dimples over the spine in cord abnormalities). Other important skin abnormalities may not be very obvious at birth but become so in infancy or early childhood. Examples are the pale ash-leaf patches, shagreen patches, and angiofibromas of the face ('adenoma sebaceum') that are found in tuberous sclerosis or the café-au-lait patches found in neurofibromatosis type I.

A full eye examination is essential. In babies it may be necessary to dilate the eyes and come back to perform fundoscopy whilst the child is feeding (and therefore quiet!). Indirect ophthalmoscopy by an experienced ophthalmologist is probably best for older children. There may be hypo- or hypertelorism which may be associated with midline defects of the brain (for example hypotelorism in holoprosencephaly and hypertelorism in agenesis of the corpus callosum), so the interpupillary distance and the distance between the inner canthi should be measured and checked on standard charts. There may be abnormalities of the iris (such as colobomata in trisomy 13, the CHARGE association, and other syndromes that involve the nervous system; Lisch nodules in neurofibromatosis type I; or Kayser–Fleischer rings in Wilson's disease). Pale hypoplastic optic nerve heads are seen in septo-optic dysplasia and other congenital and acquired conditions. Significant retinal abnormalities include the chorioretinitis seen in congenital toxoplasmosis or cytomegalovirus infections and the retinal 'lacunae' seen in Aicardi syndrome.

Growth should be assessed by measuring weight, length (height), and head circumference and plotting them on standard charts. In particular the head circumference should be related to the age of the child and to the other measurements (see sections on microcephaly and megalencephaly above). Changes with time may be significant—for instance, after a severe perinatal insult, the head circumference may initially be in the normal range and then fall progressively further below the expected centile line in the first few months of life, which can be important in dating the insult to the brain. Babies may be upset by having their heads measured, so this is best left to the end of the examination.

Investigations

The cornerstone of investigations in children or adults with suspected disorders of CNS development is MRI to investigate brain structure. It is important to discuss the investigation with a neuroradiologist as special imaging sequences not normally performed may be required to visualize relevant abnormalities, for example subependymal nodules in tuberose sclerosis. Infants and young children may require sedation or anaesthesia for the procedure. CT scanning does not provide the resolution of CNS structure obtained with MRI, but may be valuable if intracerebral calcification is suspected (as in tuberous sclerosis or cytomegalovirus infection).

Further investigations will depend on the specific diagnosis in question. Metabolic disorders can cause structural abnormalities in the developing CNS, and routine investigations that may be appropriate include plasma and urine amino acids, together with urine organic acids. In addition, further specific investigations may be indicated, for example in suspected Zellweger's syndrome which is associated with pachygyria and which is caused by abnormalities of very long chain fatty acid metabolism. Mutation analysis of specific genes may confirm a clinical diagnosis. Fluorescent *in situ* hybridization studies of chromosome regions using labelled probes that will bind (hybridize) to specific gene sequences may detect microdeletion syndromes such as Miller–Dieker by revealing an absence of fluorescent labelling on one of the pair of chromosomes.

These investigations may then allow diagnosis and accurate assessment of risks for other family members following extended family testing. Molecular genetic techniques are improving very rapidly and new tests will become available. It is therefore valuable to take blood in order to extract and store DNA or establish a lymphoblastoid cell line if no precise diagnosis can be reached, especially if life expectancy is short. Immediately after death it may be appropriate to obtain a muscle or liver biopsy to help establish a diagnosis. Also skin may be obtained to establish a fibroblast culture. Later other tissues can be frozen if a full postmortem examination is performed. The ability to perform new tests many years after the death of the index case may be extremely valuable to other family members concerned about risks to their own offspring.

Risk assessment, prenatal diagnosis, and genetic counselling

When families request genetic advice regarding a developmental disorder of the nervous system they usually have four questions in mind: what is it?, why did it happen?, will it happen again?, and what can be done to reduce the chance of it happening again, or to detect it if it does? If it is possible to make a specific diagnosis, these questions can often be answered with some accuracy.

Risk assessment

An important component of risk assessment is the construction of a three-generation family tree, with detailed enquiry and if necessary examination and investigation of close relatives for subtle expression of a disorder, or evidence of carrier status. Sometimes the diagnosis will immediately identify the recurrence risk. For example Zellweger syndrome always follows an autosomal recessive pattern of inheritance (hence there is a 1 in 4 risk of recurrence in future pregnancies). For many of the developmental anomalies discussed in this chapter, the causes are heterogeneous with a variety of different mechanisms resulting in similar clinical endpoints.

The assessment of holoprosencephaly provides an example of the steps involved in risk assessment. It may occur in an individual with a chromosomal anomaly such as trisomy 13, or a variety of subtle chromosome deletions such as del (18p), del (7q). It may also follow an autosomal dominant pattern of inheritance with incomplete penetrance and variable expression (mutations in the *sonic hedgehog* gene in some families), or be a feature of a recognizable syndrome such as Smith–Lemli–Opitz, which follows an autosomal recessive pattern of inheritance. Assessing the risk for a particular family depends upon careful integration of the clinical picture in the affected individual with information from the family tree and the results of investigations.

If it is not possible to identify the precise aetiology, and common causes have been excluded as far as possible by appropriate investigation, it is usually possible to offer an empirical recurrence risk after examination of the parents. For example, in a family where the child has holoprosencephaly with no additional features suggestive of a syndromic cause and who has normal chromosomes, the next step is a careful examination of both parents to look for the subtle features of autosomal dominant holoprosencephaly (such as single central incisor, hypotelorism). They should also both have a cranial MRI. If these assessments are normal, then the empirical recurrence risk is 5 to 6 per cent.

Prenatal diagnosis

Prenatal diagnosis and termination of affected pregnancies is only one of a range of reproductive options open to parents at increased risk of having children with neurodevelopmental abnormalities, but for many couples it is the option of choice. Other options include embarking on a further pregnancy and accepting the risk of recurrence, or electing against any further pregnancies and perhaps considering adoption. For the majority of developmental disorders of the nervous system, preimplantation genetic diagnosis is not yet feasible. For a condition following mendelian inheritance the option of donor gametes could be discussed. For a condition with a strong environmental component it is imperative that measures are taken to minimize the risk of exposure in a future pregnancy. For neural tube defects, periconceptual supplementation with high-dose folate has been shown to reduce the risk of recurrence in future pregnancies (see above).

When a specific diagnosis has been made and a chromosomal anomaly, genetic mutation, or biochemical defect has been identified, it is usually possible to offer prenatal diagnosis by chorionic villus sampling at 11 weeks of gestation in a future pregnancy. If this is not the case, detailed ultrasound scanning may be helpful in some instances; for example, neural tube defects where anencephaly can be clearly visualized by 13 to 14 weeks of gestation, and spina bifida by 18 to 20 weeks. For other conditions such as isolated lissencephaly, no features are likely to be visible on an ultrasound scan before 24 weeks of gestation, and for isolated microcephaly often not until 32 to 34 weeks of gestation or later. The limitations of detailed ultrasound scanning in these circumstances will need to be discussed frankly with the parents.

Genetic counselling

Providing accurate genetic advice about developmental anomalies of the nervous system is a challenging task. Referral for specialist advice is strongly

recommended.

---

*We are very grateful to Dr Nagui Antoun (Addenbrooke's Hospital, Cambridge), Dr Fred Pickworth (Norfolk and Norwich Hospital), and Mr Paul Chamberlain (John Radcliffe Hospital, Oxford) for the images shown in this chapter and for advice on their interpretation.

24.22.1 Introduction: structure and function

M. Hanna

Basic anatomy of skeletal muscle

We possess more than 150 voluntary (skeletal) muscles most of which are attached to the skeleton at both ends through tendons. Complex voluntary movements of the body are achieved by integrated activity of different skeletal muscle groups. To the naked eye a transverse section of any skeletal muscle reveals small units known as muscle fascicles. Each skeletal muscle fascicle is composed of many basic structural units known as muscle fibres (Fig. 1). Muscle fibres are cylindrical structures that may be several centimetres long and 50 to 100 µm in diameter. A muscle fibre is a highly specialized cell. Like any other cell it has a membrane (the sarcolemma), it contains cytoplasm (the sarcoplasm), and it has an endoplasmic reticulum (the sarcoplasmic reticulum) as well as other subcellular organelles such as mitochondria. However, unlike cells from many other tissues, muscle cells are multinucleate. Typically the nuclei are positioned at the edges of the muscle fibre. The sarcolemma of muscle fibres possesses specialized regions known as motor endplates. These endplate regions are the points at which the axon innervating a muscle fibre forms synapses. Release of acetylcholine from the presynaptic region transmits the axonal action potential to the muscle fibre membrane by binding to postsynaptic acetylcholine receptors located in the sarcolemma at the endplate. The sarcolemma is differentially permeable to ions. This allows different concentrations of ions to be maintained inside and outside the membrane and this is critical in maintaining the resting membrane potential. A chain of important structural proteins maintain the integrity of the sarcolemma by linking intracellular muscle fibre cytoskeletal proteins to the extracellular matrix. These structural proteins include dystrophin (located in a subsarcolemmal distribution), the dystrophin-associated glycoprotein complex (a trans-sarcolemmal protein complex), and laminin (located extracellularly). These important proteins may be dysfunctional in certain forms of genetic muscle diseases (see Chapter 24.22.2).

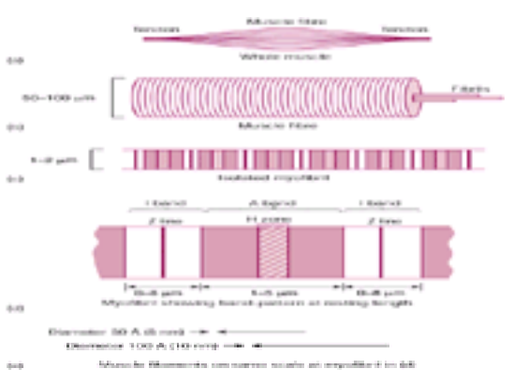

Fig. 1 The dimensions and arrangement of the contractile components in a muscle. The whole muscle (a) is made up of fibres (b) which contain cross-striated myofibrils (c, d). These are constructed of two types of protein filaments (e), put together as shown in Fig. 2. (Reproduced from Huxley and Hanson, 1960, with permission.)

After staining, or if suitably illuminated, muscle fibres are seen to have regular cross-striations that extend right across the inside of the fibre, dividing it up into sarcomeres (Fig. 1). The parts of the cross-striations are identified by letters. The light I band is divided by the dark Z line and the dark A band has the lighter H zone in its centre. The region between two adjacent Z lines is called a sarcomere. The cross-striations are due to the presence of the principal contracile filamentous proteins, actin and myosin, in the sacroplasm. These filamentous proteins are arranged in rod-like structures known as myofibrils. A single myofibril contains many protein filaments. In life, myofibrils are transparent on routine light microscopy, but if viewed with a polarizing microscope, a typical pattern of cross-striations can be seen within individual myofibrils. The correct understanding of the basic microscopic anatomy of this pattern of cross-striations was critical to the discovery of the sliding filament theory of skeletal muscle contraction.

The sliding filament theory of skeletal muscle contraction

The protein filaments contained within myofibrils are of two types; the thin filaments are composed of actin, tropomyosin, and troponin and the thick filaments are composed of myosin (Fig. 2). The thick filaments are approximately twice the diameter of the thin filaments.

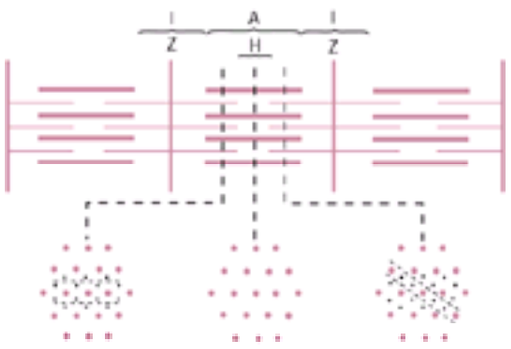

Fig. 2 Diagram illustrating the arrangement of the different kinds of protein filament (thick filaments: myosin; thin filaments: actin) in a myofibril. At the top are three sarcomeres drawn as they would appear in longitudinal section. Below are transverse sections through the H zone and other parts of the A band where the thick and thin filaments interdigitate. The plane of section determines whether, in electron micrographs, there seem to be one or two thin (actin) filaments between two thick (myosin) ones. (Reproduced from Huxley and Hanson, 1960, with permission.)

The thick filaments are lined up to form the A bands, whereas the array of thin filaments forms the less dense I bands. The lighter H bands in the centre of the A bands are the regions where, when the muscle is relaxed, the thin filaments do not overlap the thick filaments. The Z lines transect the myofibrils and connect to the thin filaments. If a transverse section through the A band is examined under the electron microscope, each thick filament is found to be surrounded by six thin filaments in a regular hexagonal array (Fig. 2). The myosin molecules have large globular heads at their C-terminal portions (Fig. 3). The heads contain an actin-binding site that hydrolyses ATP. During muscle contraction, cross-linkages occur between the heads of the myosin molecules and the actin molecules (Fig. 3).

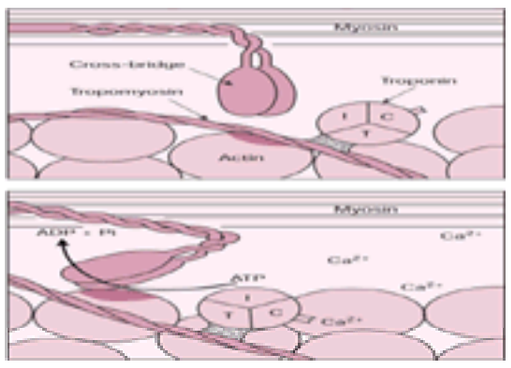

Fig. 3 Initiation of muscle contraction by Ca^{2+} ions. The cross-bridges (heads of myosin molecules) attach to binding sites on actin (striped areas) and swivel when tropomyosin is displaced laterally by binding of Ca^{2+} ions to troponin C. (Modified from Katz AM, 1975, Congestive heart failure. *New England Journal of Medicine* **293**, 1184.)

The thin filaments are composed of two chains of actin that form a long double helix. Tropomyosin molecules are long filaments located in the groove between the two chains of actin. Troponin molecules are small globular units located at intervals along the tropomyosin molecules. Troponin has three components: troponin T, responsible for binding to tropomyosin; troponin I, which inhibits the interaction of actin and myosin; and troponin C, which contains the binding sites for the Ca^{2+} ions that initiate contraction (Fig. 3).

The process by which shortening of the contractile elements of muscle is brought about is sliding of the thin filaments over the thick filaments. The width of the A band is constant, whereas the Z lines move closer together when the muscle contracts and further apart when it is stretched. The sliding during muscle contraction is produced by breaking and reforming of the cross-linkages between actin and myosin. The immediate source of energy for contraction is hydrolysis of ATP localized to the myosin head.

Neural activation of muscle fibres—the motor unit

The motor unit is the final common pathway for all voluntary muscle activity. The motor unit is composed of an anterior horn cell (located within the spinal cord), its peripheral axon, the axon terminal branches, the associated neuromuscular junctions, and the muscle fibres innervated. The muscle fibres of a single motor unit are spatially dispersed throughout a muscle and only a few fibres innervated by the same anterior horn cell are contiguous. The number of motor units varies greatly between muscles, from approximately 1000 in leg muscles to 100 in intrinsic hand muscles. The number of muscle fibres per motor unit also varies greatly. Motor units also differ in physiological and biochemical characteristics. Two main types of motor units are recognized, each composed of a single muscle fibre type. Type 1 muscle fibres contain many mitochondria and are slightly smaller than type 2 muscle fibres as they contain myofibrils, which are more slender. Type 1 fibres contain a high concentration of oxidative enzymes and more fat. Type 2 fibres are larger, contain fewer mitochondria, but have a higher concentration of glycogen and enzymes involved in anaerobic metabolism such as myophosphorylase. All skeletal muscles contain a mixture of both fibre types, typically in a chequerboard pattern when stained appropriately (with the myofibrillar ATPase reaction) and visualized under light microscopy (Fig. 4). Type 1 fibres are also known as slow fibres since they contract and relax slowly and are abundant in muscles concerned mainly with maintaining posture. In contrast, type 2 fibres contract and relax quickly and are also known as twitch fibres. Type 2 fibres can be further subdivided into type 2a and 2b based on their intensity of staining with myofibrillar ATPase reaction at different pHs (Table 1).

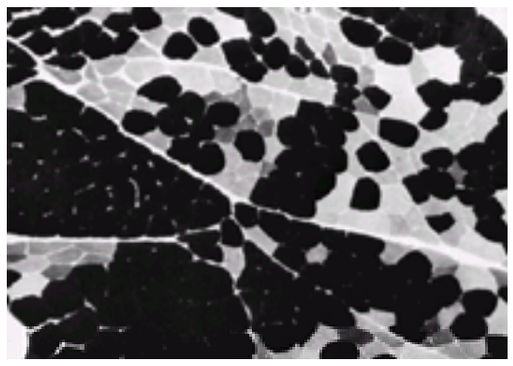

Fig. 4 A transverse section of human skeletal muscle obtained by biopsy from a patient with spinal muscular atrophy stained for the myofibrillar ATPase reaction after preincubation at pH 4.6. There is extensive evidence of fibre type grouping, particularly of the type 1 fibres, resulting from reinnervation. Magnification ×150. (Kindly supplied by Dr Margaret Johnson.)

Normally muscle fibres do not contract in isolation, rather the muscle fibres which comprise the motor unit contract together in response to depolarization of an anterior horn cell. Such depolarization is transmitted along the axon until it invades the nerve terminal. This results in opening of voltage-gated calcium channels located in the presynaptic membrane. Calcium enters the nerve terminal down an electrochemical gradient. The resulting increase in presynaptic calcium concentration promotes fusion of acetylcholine-containing vesicles normally present in the nerve terminal with the presynaptic membrane. Quanta of acetylcholine are released into the synaptic cleft and diffuse to the postsynaptic membrane to bind to and activate acetylcholine receptors. Acetycholine binding causes opening of its receptor channel allowing cations to enter the muscle fibre in the endplate region. This cation flux depolarizes the postsynaptic membrane resulting in a mini-endplate potential. The summation of endplate potentials results in the excitation of the postsynaptic membrane, which is then conducted along the muscle fibre membrane. The excitation is transmitted into the muscle fibre by invaginations of the sarcolemma known as the T-tubule system. Activation of calcium channels in the T-tubule system membrane results in opening of calcium channels in the sarcoplasmic reticulum. Calcium is then released into the muscle fibre cytoplasm, initiating muscle contraction.

Energy production in skeletal muscle

Resting skeletal muscle requires remarkably little energy. However, the requirement for energy production may increase dramatically in response to exercise, since energy is required for muscle contraction. Adenosine triphosphate (ATP) is the main source of energy in muscle. ATP is required for shortening of the contractile filaments and also for the active reuptake of calcium into the sarcoplasmic reticulum after each muscle contraction. Maintenance of electrochemical gradients across the sarcolemma also requires ATP. Resynthesis of ATP from ADP is essential for normal muscle function. The two main energy-producing pathways in muscle are glycolysis in the sarcoplasm and oxidative phosphorylation in the mitochondria. Resynthesis of ATP from ADP is also aided by phosphocreatine and the creatine kinase reaction. Creatine kinase catalyses the transfer of high-energy phosphate from phosphocreatine to ADP in circumstances in which ATP demand may outstrip ATP production, for example at the very beginning of exercise before oxidative phosphorylation or glycolysis is activated. Glycolysis is the main pathway of ATP synthesis in anaerobic conditions and results in the generation of lactate. Oxidative phosphorylation is the major ATP-generating pathway in aerobic conditions. The main fuel sources in skeletal muscle are glucose, glycogen, and fatty acids. In anaerobic conditions, glycogen is the main energy source. In aerobic exercise, glycogen and glucose are utilized initially, but after approximately 30 min, fatty acids are the main energy source. In resting aerobic muscle, fatty acids provide the principal source of fuel. Several muscle diseases are recognized in which energy metabolism is impaired and are known as the metabolic myopathies.

Diseases of human skeletal muscle—overview

Human muscle diseases may be conveniently divided into those which are genetically determined and those which are acquired (Table 2).

The clinical history in muscle diseases

Although a muscle biopsy is usually needed to determine the exact type of muscle disease, the clinical history and examination are usually sufficient to determine whether a muscle disease is present or absent. Since many muscle diseases are genetically determined, it is particularly important to consider the family history. A careful drug history is also essential.

Although many diseases may affect skeletal muscle (Table 2), there are three main symptoms with which patients may present: muscular pain, muscular weakness, and fatiguability. A further important but less common symptom is darkening of the urine (pigmenturia) due to release of myoglobin from damaged muscle. This occurs particularly in the metabolic myopathies. Unless pigmenturia has been dramatic, patients may not volunteer this symptom. Muscle pain is a common symptom, but in only about one-third of patients presenting with this symptom will an underlying muscle disease be identified. In those without a definable muscle disease, many are considered to have a psychogenic cause for their muscle pain, although some may have as yet undefined disorders of muscle metabolism. Sometimes it can be difficult for the patient and the physician to distinguish between pain originating in muscle and pain originating in joints or bones. Certain rheumatological diseases may result in joint pain as well as muscle pain. For example, systemic lupus erythematosus may cause arthritis and polymyositis. Muscle pains may take the form of cramps, which are involuntary contractions of muscle groups. Simple muscle cramps are not uncommon in the elderly and frequently occur at night. There is usually no underlying muscle disease but drugs such as diuretics (which induce hypokalaemia) may be implicated. In younger patients, muscle cramps may be the presenting feature of a metabolic muscle disease such as McArdle's disease. Muscle pain brought on by exertion is a particular feature of the metabolic muscle diseases. Muscle contractures may also be a source of muscle pain in patients with metabolic myopathies. Patients experience a pain similar to a cramp, but unlike a cramp, electromyography reveals that a contracture is electrically silent.

Muscle weakness is a common feature of muscle diseases and the distribution of weakness in most is in the proximal limb muscles. Patients may complain of difficulty performing tasks which involve lifting their arms up to or above their head, such as brushing hair. Proximal lower limb muscle weakness causes difficulties getting out of low chairs and in climbing stairs. Muscle diseases often affect the limb musculature symmetrically—although there are important exceptions to this. For example, one of the common autosomal dominant muscular dystrophies, fascioscapulohumeral muscular dystrophy, often affects the limb muscles in an asymmetrical fashion. Some muscle diseases may affect the facial musculature as well as that of the limb. Symptoms may include difficulty in whistling, in closing the eyes, or in articulating. Respiratory muscle disease may cause breathlessness. It is important to determine the natural history of muscle weakness. In most genetically determined muscle diseases, weakness progresses slowly over years; occasionally the patient may experience attacks of weakness separated by periods when they seem to have normal strength, as in the periodic paralyses. The muscle weakness in the inflammatory muscle diseases usually develops more rapidly.

Fatiguability is defined as an increase in weakness with exercise. Patients may describe that they can start a particular physical activity but the longer they continue the weaker they become. They may also complain that they become weaker as the day goes on. Myaesthenia gravis, a disorder of neuromuscular transmission, is the principal cause of fatiguability. In patients with myaesthenia gravis, fatiguability can usually be demonstrated at the bedside. Patients with metabolic muscle diseases may also experience fatiguability.

The physical examination in muscle disease

The examination may be broadly divided into two aspects. First, an examination is made to establish whether there are any clues to the cause of the muscle disease. In this context, the general physical examination is very important. Particular attention is paid to eliciting signs which might indicate an underlying endocrine or rheumatological disorder. For example, signs of hyper-/hypothyroidism, Cushing's syndrome, or of rheumatological disorders such as systemic lupus erythematosus. Inspection of the skin may reveal the appearances of dermatomyositis. The second part of the examination involves examining the muscular system to determine the extent and severity of the condition; this may in addition give further clues to the aetiology. The muscles are inspected for any atrophy or hypertrophy (as occurs in some muscular dystrophies) or for any spontaneous activity of the muscle fibres (such as fasciculation, which might indicate an anterior horn cell disorder). The muscles should be palpated for any tenderness or swelling, which may occur in inflammatory muscle diseases. Myotonia is a delayed relaxation of muscle after contraction. This may be observed by asking the patient to clench their fist and then to open it rapidly. A patient with myotonia is unable to open the clenched fist rapidly due to an inability to relax the contracted muscles quickly. Myotonia may also be evident on percussion of muscle. The examination of muscle power is carried out systematically starting with the cranial musculature before proceeding to the arms and legs. The degree of weakness is assessed with reference to the Medical Research Council grading scale (0 to 5). The distribution of weakness is also noted, since different muscle diseases have characteristic patterns of weakness. Bedside assessment of respiratory muscles including the diaphragm is also important, although detailed assessment of these muscles requires formal spirometry. Finally, the tendon reflexes are elicited. These are generally preserved in acquired muscle diseases, except when there is advanced weakness; however, they may be lost relatively early in the course of dystrophies.

Investigating the patient with muscle disease

Investigations are generally only instituted when the history and examination have provided clear evidence that the patient has symptoms and/or signs of muscle disease. The investigations are aimed primarily at determining the exact type of muscle disease as it is essential to establish whether the patient has a treatable muscle disease, such as an inflammatory myopathy. Many investigations of increasing complexity and invasiveness are available.

Simple blood tests allow an assessment of the endocrine and nutritional status of the patient (such as thyroid function, the consumption of excess alcohol, or the presence of vitamin D deficiency). Measurement of the blood creatine kinase is important as this can be an indicator of the degree of muscle fibre damage or necrosis. The creatine kinase is generally elevated in the inflammatory muscle diseases and in many of the muscular dystrophies.

Increasingly, DNA-based testing is available from simple blood samples. This can be particularly helpful and in some situations may obviate the need for further more-invasive tests, such as a muscle biopsy. For example, if analysis of the dystrophin gene on the X chromosome identifies a pathogenic mutation known to associate with Duchenne muscular dystrophy, the diagnosis is confirmed. It is likely that there will be greater availability of DNA-based tests for genetic muscle disease in the future and this will become an increasingly important aid to diagnosis.

The diagnosis of metabolic muscle diseases may be achieved by specific dynamic tests. For example, McArdle's disease can be diagnosed using the ischaemic lactate test, and mitochondrial disease may be suspected on the basis of subanaerobic exercise tests (both these tests are described in the relevant section).

Detailed nerve conduction studies and electromyography are useful in determining whether a patient has a neuropathy, a defect in neuromuscular junction transmission, or a myopathy. Electromyography is useful in characterizing any spontaneous activity of muscle, such as fasciculations or myotonia. Although electromyography is generally useful in confirming the presence of a myopathy, it is less useful in determining the cause.

Muscle biopsy allows a detailed analysis of the internal architecture of muscle and is an extremely valuable and safe investigation in carefully selected patients. Using a range of histochemical stains, histochemical enzyme reactions, and immunological techniques on frozen muscle biopsy sections, much information of diagnostic use can be obtained. Different muscle diseases often reveal characteristic patterns of abnormalities, which are usually identified by light microscopic techniques. Using basic histochemical stains the features of different muscular dystrophies are generally similar; the most common features being marked variations in fibre diameter, internal nuclei, fibre splitting, fibre necrosis and regeneration, and increase in connective tissue. However, a more precise diagnosis of the type of muscular dystrophy can now be obtained by immunostaining techniques. Antibodies which are raised against specific membrane proteins allow quantitative analysis. For example, staining using antibodies directed against dystophin reveals no or very little dystrophin in cases of Duchenne muscular dystrophy (Fig. 5). Prominent inflammatory infiltrates are typically seen in muscle sections from patients with inflammatory myopathies. Figure 5, Figure 6, and Figure 7 show the muscle biopsy features of some of the metabolic myopathies. In some cases the changes seen on the biopsy clearly indicate a myopathic process, but it is not possible to be more specific in the absence of typical immunological, inflammatory, or metabolic changes.

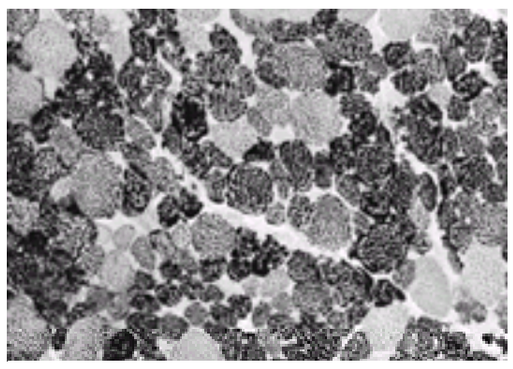

Fig. 5 A transverse section of human skeletal muscle obtained from a patient with carnitine deficiency and stained with Sudan black B. The massive accumulation of neutral fat, especially with the type 1 fibres, is evident. Magnification ×196.

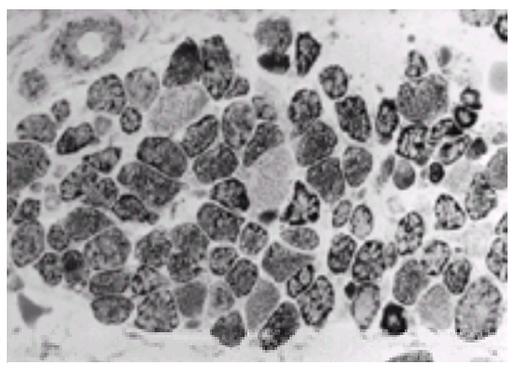

Fig. 6 A transverse section of skeletal muscle obtained from a patient with mitrochondrial myopathy, stained for the MADH-TR reaction. The type 1 fibres are darkly stained and show the typical reticulated appearance of so-called 'ragged-red fibres' with massive mitochondria, particularly in many fibres just deep to the sarcolemma. Magnification ×384. (Kindly supplied by Dr Margaret Johnson.)

24.22.2 Muscular dystrophy

K. Bushby

Introduction

Muscular dystrophy is not a single disease. Many different types of muscular dystrophy can be recognized: all are primary, genetically determined disorders of muscle and all cause muscle weakness, which is usually progressive. The various types of muscular dystrophy share several characteristic findings on muscle biopsy, most notably a variation of fibre size, evidence of muscle fibre necrosis, and usually replacement of muscle tissue by fat and fibrous tissue. These pathological findings are often but not always accompanied by elevation of the serum creatine kinase. While the key clinical sign in muscular dystrophy is muscle weakness, the distribution of that weakness and the association with other features such as wasting, hypertrophy, and joint contractures are the defining features which are most helpful in making a clinical diagnosis, together with age at presentation and rate of progression. Unusual manifestations of muscular dystrophy are muscle pain, rhabdomyolysis, and myoglobinuria. Compli-cations may include cardiac and respiratory failure or anaesthetic problems. These complications may be specific to particular types of muscular dystrophy. Taken in conjunction with the clinical findings in any patient, precise diagnostic tests (either through DNA analysis or protein analysis of a muscle biopsy sample) are available for a growing number of these disorders, as knowledge of the underlying mechanism of disease for each of these entities has increased. Confirmation of the type of muscular dystrophy in any individual patient is critical to the provision of appropriate management, prognostic advice, and genetic counselling. No form of muscular dystrophy is currently curable, although various experimental therapeutic procedures are under investigation.

Classification of the muscular dystrophies

Various classifications of the muscular dystrophies have been proposed, reflecting historical advances in the understanding of this group of diseases (Box 1). The current basis for classification combines an appreciation of the clinical features with the ability to determine the molecular basis for the disease. Therefore the eponymous names (for example Duchenne muscular dystrophy) still in common usage reflect the detailed clinical descriptions provided by early clinicians: other disease names reflect the recognized pattern of muscle involvement in a particular condition (for example facioscapulohumeral muscular dystrophy). Disease designations based on the genetic or protein defect in a particular disorder (for example dystrophinopathy) are becoming more widely used, reflecting the fact that some disorders previously believed to be clinically distinct actually represent different manifestations of lesions at the same locus. Genetic analysis has also revealed an unsuspected level of heterogeneity with different genetic causes for disorders which show superficial clinical similarities. This can be seen most strikingly within the 'limb girdle' group of muscular dystrophies.

Box 1 Basis of the classification of muscular dystrophies

- Clinical description.
- Genetics (autosomal dominant/recessive/X-linked).
- Underlying gene/protein defect.
- Localization or function of the protein involved.

The pathophysiology of the muscular dystrophies

Biochemical and physiological experiments failed to shed any light on the mechanisms by which muscular dystrophy could arise, and it has only been since the cloning of the *dystrophin* gene in 1987 that progress has been made. It is now quite clear that proteins involved in several different functions within the muscle cell can, when altered or absent, cause muscle damage and account for the pathological and clinical features of a muscular dystrophy. Some of these proteins are components of the membrane of the muscle fibre which may have a structural or signalling role, others are components of the nuclear envelope or are muscle-specific enzymes (see Fig. 1).

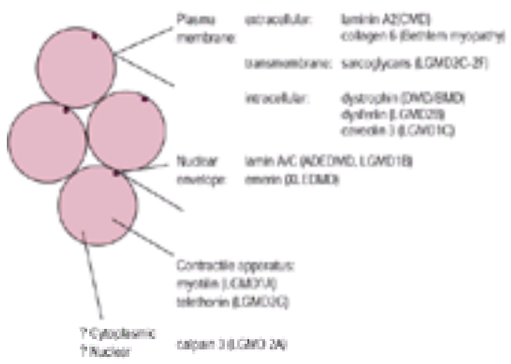

Fig. 1 Schematic diagram to show localization within the muscle fibre (where known) of the proteins known to be involved in producing a dystrophic phenotype. In particular, groups of proteins localizing to the plasma membrane or nuclear envelope have been implicated in a number of different types of muscular dystrophy.

General points on the diagnosis of muscular dystrophy

Box 2 summarizes some of the major considerations in arriving at the correct diagnosis of a muscular dystrophy. History taking at the time of presentation (Box 3) may be particularly informative. The clinical history may be pathognomonic. Detailed diagnostic information is given in the following text relating to specific diseases. The main tools for specific diagnosis in muscular dystrophy are the use of antibodies for the immunolabelling of muscle biopsy sections and/or the application of specific DNA-based genetic analysis.

Box 2 Diagnosis of muscular dystrophy

- History (especially motor milestones, age at onset, physical prowess as a child).
- Age of patient (congenital/childhood/teenage/adult presentation).
- Pattern of muscle involvement on examination (predominantly proximal/distal, upper limb/lower limb, symmetrical/asymmetrical).
- Pattern of associated features on examination (contractures, muscle wasting, hypertrophy).
- Level of serum creatine kinase in active disease (massive elevation in dystrophinopathy, sarcoglycanopathy, dysferlinopathy, calpainopathy, congenital muscular dystrophy (some); moderate elevation in facioscapulohumeral muscular dystrophy, Emery Dreifuss muscular dystrophy, congenital muscular dystrophy (some); normal to mild elevation in autosomal dominant limb girdle muscular dystrophy, facioscapulohumeral muscular dystrophy (some)).
- Electromyography (to exclude neurogenic causes of weakness, especially if serum creatine kinase is not markedly elevated).
- Muscle imaging (ultrasound scans can confirm muscle involvement, but to confirm pattern of muscle involvement need MRI/CT).
- Muscle biopsy, histology, and storage of frozen biopsy material for further analysis.
- Specialized analysis of muscle biopsy (immunocytochemistry, immunoblotting, electron microscopy).
- DNA analysis.

Box 3 History taking in muscle disease

- Question in detail about early motor development.
- Eliciting what actually were the first symptoms experienced by a patient may be difficult but is important in highlighting the initial pattern of muscle involvement—lower limb versus upper limb/proximal versus distal musculature.
- Asking 'when were you at your fastest' may be informative in determining age of peak motor performance.
- Ask about performance at school sports.
- Particularly useful indicators in that respect are the ability to climb ropes (upper girdle weakness), muscle pain on running, a tendency to spend all the time in goal at football(!).
- Do not assume that difficulty climbing stairs always indicates proximal muscle weakness—it may reflect an inability to push up on the toes.
- Ask specifically about the ability to stand on tiptoe/stand on heels. The need to wear heels on shoes at all times may indicate Achilles tendon contractures.
- Patients who had early Achilles tendon contractures may have had them operated on before being referred for diagnosis. Ask about this.

General points on the management of the muscular dystrophies

Despite the fact that no cures for muscular dystrophy are established, there are many issues for management which may be important or specific to the various types. However, there is as yet little systematic or comprehensive clinical research into management and randomized trials of management regimes are few and far between. It is nonetheless appropriate that where possible, patients with a diagnosis or a suspected diagnosis of muscular dystrophy should be referred to a specialist clinic. The multidisciplinary approach of these clinics ensures that patients have access to the full range of diagnostic facilities, are able to obtain specialized physiotherapy advice, and can obtain accurate genetic counselling where this is required. Access to patient support organizations and their staff is also of paramount importance. The diagnosis of any kind of muscular dystrophy, in that it inevitably implies a progressive and incurable disease, possibly with implications for children or other relatives, is a considerable burden and one which needs to be recognized and supported.

The congenital muscular dystrophies

The congenital muscular dystrophies (**CMD**) are defined by their very early childhood onset. They comprise a number of disorders with different molecular pathological bases for the diseases.

Presentation

1. Neonatal presentation:
   - hypotonia, which may be prenatal
   - feeding problems (usually mild)
   - joint contractures, especially knees, hips, and ankles (see Fig. 2).

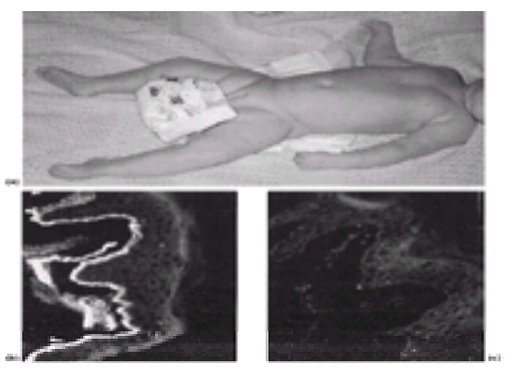

Fig. 2 (a) Typical clinical picture of a baby presenting with merosin negative muscular dystrophy. Note the hypotonic posture, and mild contractures of the hips, knees, and ankles. (b), (c) Immunofluorescence picture of skin biopsy labelled with an antibody to laminin A2 (merosin) showing normal and absent

labelling patterns. This investigation can be carried out on a variety of tissues including skin, muscle, or placenta.

2. Early childhood presentation:
   - delayed motor milestones
   - failure to thrive
   - repeated respiratory infections.
3. Later childhood presentation (rare):
   - mainly proximal muscle symptoms
   - history of delayed motor milestones
   - rigid spine, contractures of ankles, hips, and knees.

Differential diagnosis

In the neonatal and early childhood presentation the main clinical diagnostic confusion (after excluding central causes of hypotonia) – may be with spinal muscular atrophy (check *SMN*/*NAIP* genes), congenital myotonic dystrophy (facial weakness is usually more pronounced and diagnosis can be excluded on genetic testing), and congenital myopathy (may be distinguished on muscle biopsy). In all of these conditions, serum creatine kinase is either normal or much lower than seen in many congenital muscular dystrophies.

With later childhood presentation the differential diagnosis is as above, plus Duchenne muscular dystrophy (though calf hypertrophy is usually more pronounced and serum creatine kinase is typically higher—biopsy will exclude the diagnosis) or childhood presentation of a limb girdle type of muscular dystrophy.

Classification

There are several recognized forms of congenital muscular dystrophy, and as there is considerable heterogeneity in the group which remains, many more different entities are ultimately likely to be distinguished at the genetic level. The first level of subdivision is on the basis of whether clinically there is a 'pure' muscle phenotype, or whether there is also prominent involvement of the central nervous system and eyes. In the types of congenital muscular dystrophy with a 'pure' muscle phenotype clinically, the next major subdivision is based on the presence or absence of a muscle protein merosin or laminin A2. Examination of collagen VI labelling in the muscle fibre may also be informative (see Table 1).

Establishing the diagnosis

Serum creatine kinase may in some kinds of congenital muscular dystrophy be normal, but is typically elevated at least twofold, and up to 20-fold or more in the laminin A2 deficient group. Muscle biopsy shows dystrophic changes and examination of LAMA2 or collagen VI in muscle or skin is used to distingush cases with normal and abnormal or absent protein. Secondary changes in laminin A2 probably reflect the involvement of a number of different primary mutations. Mutations in the gene *FKRP* are responsible for some of these cases. Magnetic resonance imaging of the brain is a useful adjunct to diagnosis as it will confirm the presence of white matter changes always present after 6 months of age in primary LAMA2 deficiency, and the characteristic brain malformations in the other types of congenital muscular dystrophy (see Table 1).

Prognosis and management

The muscle weakness in congenital muscular dystrophy may be relatively static, but the complications of that weakness can be severe, and vary according to the precise diagnosis. The degree of muscle weakness is quite variable. In primary laminin A2 deficient congenital muscular dystrophy, the severity of the disease correlates roughly with the abundance of laminin A2 in the muscle, with children completely lacking laminin A2 rarely achieving independent ambulation. Others may learn to walk independently but this is usually much later than usual, and these children may later lose this ability. Joint contractures and scoliosis are major complications of the disease and cause much additional disability, requiring careful management by physiotherapy, standing regimes, splinting, bracing, and surgery where appropriate. Feeding problems may be intractable and lead to chronic malnutrition unless treated by nasogastric or gastrostomy feeding. Malnutrition may contribute to susceptibility to chest infections, which is also heightened by weakness of the respiratory muscles. These children are at risk of respiratory failure and their follow-up should include monitoring for this complication which can be effectively managed by the provision of non-invasive home nocturnal ventilation. Cardiac failure is reported in some children, mainly in the group lacking laminin A2.

The overall prognosis depends on the type of congenital muscular dystrophy. Children with the most severe forms are at risk of dying in early childhood. If they survive this period, with appropriate management of feeding problems, respiratory, and cardiac complications, survival into adult life is the norm. In the 'pure' forms of congenital muscular dystrophy the intellect is normal, and these children should be encouraged to pursue the best possible education, with appropriate support for their physical difficulties. Fukuyama congenital muscular dystrophy (FCMD), muscle–eye–brain disease (MEBD), and Walker–Warburg syndrome (WWS) may be dominated by intellectual and visual handicap. General management issues remain the same; however, on the whole all of these groups carry a much poorer prognosis (see Table 1).

Genetic counselling

All these disorders are autosomal recessive in inheritance. As the molecular basis for these disorders becomes better established, specific prenatal and carrier testing will become more widely referable in this group of conditions.

Dystrophin deficiency

This group, including two of the most common forms of muscular dystrophy, Duchenne and Becker muscular dystrophy, involve the same gene and protein. These are X-linked diseases, caused by mutations, most of which are deletions, in the *dystrophin* gene.

Presentation

Duchenne muscular dystrophy

- All patients are symptomatic within the first 3 years of life though the mean age at diagnosis is 4 years 10 months.
- Motor milestones are often delayed (half of cases are not walking by 18 months).
- Speech is also frequently delayed.
- Patient is unable to run—there is a pronounced waddling gait on attempting to rush.
- Patient is unable to jump with both feet together or to hop—there is no spring in the step.
- 'Climbs up legs' on rising from the floor—Gower's manoeuvre.
- Rarely presents with anaesthetic complications.

Becker muscular dystrophy

- The mean age at onset of Becker muscular dystrophy is 11 years, though the range of age at presentation is extremely wide and the diagnosis may be made at any age.
- A proportion will have had delayed motor milestones (this may correlate as much with reduction in IQ as with major motor problems at that age).
- Many describe being unable to keep up with peers at school.
- Difficulty with high steps, climbing hills.
- Muscle pains after exercise are a common complaint especially in teenagers (rarely myoglobinuria).

Manifesting carriers of Duchenne muscular dystrophy/Becker muscular dystrophy

A highly variable group, who may occasionally be as severely affected as those with Duchenne muscular dystrophy or as mildly or more mildly than those with Becker muscular dystrophy.

Dystrophin-associated cardiomyopathy

Symptoms and signs of hypertrophy progressing to dilated cardiomyopathy in the absence of major muscle symptoms. Some patients have elevated serum creatine kinase.

Establishing the diagnosis

The clinical presentation of Duchenne muscular dystrophy is very characteristic. Hypertrophy of the calf muscles is almost universal (see Fig. 3), sometimes accompanied by muscle hypertrophy elsewhere, most frequently involving deltoid, parts of the quadriceps, the tongue, and masseters. Wasting of the pectoral and scapular muscles leads to hypotonia around the shoulders detected as the child 'slipping through the hands' on being lifted. In the lower limbs, quadriceps power is weaker than that of the hamstrings. Formal examination of a small child may be difficult, and the main clinical tool is observation of walking, attempting to run, jump, and climb stairs, and to rise from the floor. It is imperative to give the child space to attempt to run, as this will bring out the lack of spring in the step and the lack of fluidity of the attempted running.

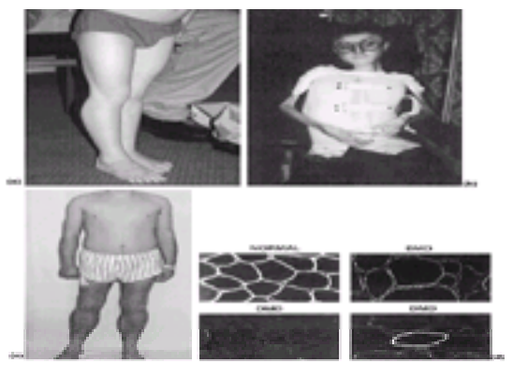

Fig. 3 (a) Child with Duchenne muscular dystrophy at presentation, showing the marked calf and quadriceps hypertrophy and tendency to rise onto the toes. (b) Teenage boy in the later stages of the disease, showing the complications of marked immobility, scoliosis, and muscle wasting. This young man has now been maintained on home nocturnal ventilation successfully for more than 7 years. (c) Clinical pattern at presentation in a young man with Becker muscular dystrophy. Note hypertrophic muscles in calves and quadriceps and mild wasting around the shoulder girdle. (d) Immunocytochemical analysis of dystrophin in normal muscle, Becker muscular dystrophy muscle, and Duchenne muscular dystrophy muscle. In normal muscle, dystrophin labels evenly around the periphery of the muscle fibres. This labelling is typically patchy and reduced in Becker muscular dystrophy, and is either completely or nearly completely absent in Duchenne muscular dystrophy.

Becker muscular dystrophy has been described as a 'slow motion version of Duchenne muscular dystrophy' in that the pattern of muscle involvement in these two allelic disorders is essentially identical (see Fig. 3), but progresses at a much slower rate in Becker muscular dystrophy. Patients with Becker muscular dystrophy may be quite strong on formal muscle examination, but tend to show subtle signs of proximal muscle weakness on climbing stairs or running. They frequently have hypertrophy involving the same muscle groups as seen in Duchenne muscular dystrophy. Some patients have pes cavus.

Serum creatine kinase is always massively elevated, even to more than 200 × normal, but levels of serum creatine kinase do not distinguish the severity of the disease. Muscle biopsy and electromyography are non-specifically dystrophic. Molecular confirmation of the diagnosis is essential to assist in defining prognosis and to provide appropriate genetic counselling. Genetic analysis readily confirms the diagnosis in the 60 to 80 per cent of patients in whom a deletion of the *dystrophin* gene is present: in all patients the diagnosis can be established by the finding of absent or reduced dystrophin in the muscle biopsy (see Fig. 3). This analysis also allows the distinction of dystrophinopathy from the rarer (in most populations) limb girdle types of muscular dystrophy.

Prognosis

Within the 'dystrophinopathy' group the prognosis is highly variable. By definition, those patients with Duchenne muscular dystrophy lose the ability to walk by the age of 12. The development of scoliosis, respiratory failure, and cardiomyopathy (see Box 4) during the teenage years can all be managed so that survival into or beyond the late 20s is becoming more common. Patients with Becker muscular dystrophy are ambulant beyond 16 years of age, and may remain able to walk independently into their fifth decade or longer. These patients are susceptible to cardiac failure at any age from the teens onward and should be monitored for this complication on a regular basis (see Box 4). Respiratory failure is a late complication in Becker muscular dystrophy and correlates with very late stage disease. Lifespan in Becker muscular dystrophy may be normal, or reduced in more severe disease. An 'intermediate' group is also recognized who lose ambulation between 12 and 16: their overall prognosis is also intermediate between Duchenne muscular dystrophy and Becker muscular dystrophy. Around 8 per cent of carriers of Duchenne muscular dystrophy or Becker muscular dystrophy may develop some signs of the disease: rarely this is in a full blown form comparable to the disease in the boys. In practise, there is a continuum of severity with the highest incidence in the Duchenne muscular dystrophy group (birth incidence 1 in 3500 male live births). As lifespan is so much longer in the Becker muscular dystrophy group, however, the prevalence of the two conditions is roughly similar (about 24 per million population in northeast England).

Box 4 Practice point: cardiac involvement in dystrophinopathy

- All patients with dystrophinopathy are at risk of developing cardiomyopathy which progresses with age. It is frequently asymptomatic, and needs to be sought through full cardiac assessment including echocardiography, as treatment with antifailure medication may improve function and prognosis.
- Cardiac transplantation has been used successfully in patients with Becker muscular dystrophy and manifesting carriers of dystrophinopathy.
- Cardiac compromise is the major determinant of operative risk in boys with Duchenne muscular dystrophy, and all should have a full cardiac assessment in advance of any surgery at any age.

Over the whole group, there is a correlation between dystrophin abundance (as measured in a muscle biopsy sample) and severity: children with completely absent dystrophin tend to be confined to a wheelchair slightly earlier than children whose biopsies contain low levels of dystrophin. Patients with Becker muscular dystrophy have much higher levels of dystrophin (Fig. 3). These dystrophin levels also correlate in most cases with the type of mutation found in the *dystrophin* gene—in Duchenne muscular dystrophy most deletions are out of frame, not supporting the production of dystrophin, while Becker muscular dystrophy patients typically have in-frame deletions, allowing the production of a reduced amount of dystrophin of a slightly smaller size.

While these correlations are useful in a general sense, they are not absolutely predictive of outcome in an individual case, and must always be taken in the context of the clinical features of the patient. They can be useful though in giving the best possible guide to prognosis, especially in those patients with Becker muscular dystrophy who present early or who are identified by neonatal screening or the incidental finding of a high serum creatine kinase level.

Management

Duchenne muscular dystrophy—the early stages

Proper management of a child with Duchenne muscular dystrophy starts with awareness of the possibility of the diagnosis in any boy who is not walking by the age of 18 months or whose mobility is poor compared with his peers. The current mean age at diagnosis of nearly 5 years reflects a typical but unacceptable delay of at least 2 years since the onset of disease is noticed by the parents. The principal impetus to early diagnosis at present is the ability to offer parents the option of prenatal diagnosis in subsequent pregnancies. When specific treatments become available, there will also be a need to implement such treatments before the disease is too advanced.

Once the diagnosis has been considered, measurement of the serum creatine kinase will confirm the suspicion and ideally a referral into a specialist unit should be made at this stage. The specialist unit should have rapid-track access to DNA diagnostic and muscle biopsy facilities to confirm the diagnosis as quickly as possible. Duchenne muscular dystrophy is a devastating diagnosis, and should be given to the family following guidelines for the best practice for disclosure of bad news—the parents should be seen together wherever possible in complete privacy, they should have time to sit and ask questions, and have access to experienced staff for support and further information. Access to support groups and the relevant national charity is also appropriate. Supporting information should also be passed immediately to the general practitioner, health visitor, and school who may never have looked after a child with this type of condition before.

Since Duchenne muscular dystrophy is an X-linked condition, early access to genetic counselling is also vital shortly after diagnosis (see Box 5).

Box 5 Genetic counselling in dystrophinopathy is an essential part of the management of any family where a diagnosis of dystrophinopathy has been made because the potential implications go far beyond the index case

- These are X-linked diseases.
- The new mutation rate in the dystrophin gene is high.
- Most cases of Duchenne muscular dystrophy are born now in families with no prior history of the disease.
- None the less, even in these families, other female relatives (through the maternal line) are at risk of being carriers.
- The essential piece of information is the delineation of the dystrophin mutation in the affected child (easy to find in the 60 per cent in whom the mutation is a deletion, harder and much more specialized if it is not).
- In the presence of a known mutation, female relatives can be offered testing directly to see if they are carriers or not.
- They may choose to have prenatal diagnosis on the basis of that testing.
- Even if mothers of boys with Duchenne muscular dystrophy can be shown not to be somatic carriers of the mutation in their son, they still may have a proportion of egg cells containing the mutation (a situation known as 'germline mosaicism'). They therefore remain at a 10 to 20 per cent risk of having another affected child in a future pregnancy.
- Boys with Duchenne muscular dystrophy do not often have children, but men with Becker muscular dystrophy often do (overall fitness reduced to around 2/3). All of their daughters are obligate carriers of Becker muscular dystrophy, but none of their sons are at risk.

In the early stages of the disease it is advisable for the child to be introduced to a community physiotherapist for advice on stretching, which at this stage can usually concentrate on the ankles and hips, with the emphasis on the maintenance of symmetry. Boys frequently develop a toe-walking gait which is partially compensatory for their proximal muscle weakness—walking splints or ankle–foot orthoses are therefore not appropriate at this stage and any early Achilles tendon contractures are better managed through passive stretching and night-time below-knee splints. At the point at which walking becomes impossible independently, the child can often be rehabilitated in long leg callipers or knee–ankle–foot orthoses. Lengthening of the Achilles tendon is often necessary to allow the child to do well with knee–ankle–foot orthoses. The length of time children walk in knee–ankle–foot orthoses varies from child to child—residual muscle strength is probably the best predictor of how long a child will use them for mobility, but motivation on the part of the child's family and school is also a key factor.

Despite a consensus that use of corticosteroids does prolong ambulation for up to a couple of years, various questions about side-effects and long-term complications remain and thus corticosteroids are not universally used. Where steroids are considered, intermittent treatment probably offers the best balance between efficacy and side-effects.

Duchenne muscular dystrophy—after mobility is lost

Inevitably there comes a point in Duchenne muscular dystrophy where even the ability to stand supported in knee–ankle–foot orthoses is lost and the child is confined permanently to a wheelchair. The provision of an electric chair with indoor and outdoor access is critical to the best possible maintenance of independence. Seating in the chair should also be carefully addressed to promote an upright and symmetrical posture. Scoliosis is an almost universal complication of Duchenne muscular dystrophy and close liaison with the orthopaedic department is necessary to co-ordinate management which in the long term is likely to include spinal surgery. Physiotherapy priorities shift towards postural support, the prevention and containment of contractures, and respiratory maintenance. Measurements of forced vital capacity carried out regularly provide an indication of the trend of respiratory function—forced vital capacity usually plateaus soon after confinement to a wheelchair and thereafter falls. The timing of surgery for scoliosis therefore needs to take this variable into account, though cardiomyopathy is probably an even greater risk factor in the timing of surgery (see Box 4).

As forced vital capacity falls further, boys are at serious risk of chest infections and ultimately nocturnal respiratory failure. Symptoms of this respiratory failure may be extremely insidious and totally missed unless explicitly sought (see Box 6). Routine overnight pulse oximetry (which can readily be carried out at home provided the equipment is available) can show a trend of deteriorating overnight oxygenation and, together with the monitoring of symptoms, highlight the time at which elective nocturnal respiratory support, ideally initially at least through non-invasive means, should be provided. Such respiratory support abolishes symptoms, reduces the tendency to chest infections, and undoubtedly improves lifespan.

Box 6 Respiratory failure in neuromuscular disease is a complication which needs to be specifically sought

- It may be the result of intercostal muscle or diaphragmatic weakness or a combination of the two. The presence of a scoliosis or other spinal deformity may be an additional factor.
- Nocturnal problems tend to dominate.
- Frank symptoms of morning CO_2 retention may be seen (poor colour, morning sickness, headaches, confusion) but these are late symptoms and the problem should be detected by investigation or careful history taking before this stage.
- Increasing frequency of chest infections may indicate incipient respiratory failure.
- Subtle signs include loss of appetite and weight loss, loss of energy and enthusiasm.
- Poor sleep, increasing wakefulness at night, inability to lie flat may also be seen together with a tendency to fall asleep during the day.
- Difficulties swallowing and difficulty completing sentences may also be seen.
- In many muscle diseases, the main risk of respiratory failure is when the patient is no longer able to walk independently and weakness is pronounced (for example Duchenne muscular dystrophy, Becker muscular dystrophy, congenital muscular dystrophy, facioscapulohumeral muscular dystrophy, limb girdle muscular dystrophy, etc.).
- In other muscle diseases, respiratory failure may be an earlier feature and present while the patient is still ambulant (for example multicore and other congenital myopathies, some forms of congenital muscular dystrophy).

In the late stages of Duchenne muscular dystrophy, nutrition may be of concern. Loss of weight occurs in most boys as the disease progresses, and issues of diet and the possibility of supplemental nutrition need to be addressed.

The actual cause and timing of death in Duchenne muscular dystrophy is hard to predict. Some patients will die of a particularly severe chest infection. In others cardiomyopathy may be difficult to control or a cardiac arrhythmia may arise. Early onset of cardiomyopathy is a poor prognostic sign. Talking about death to these patients and their parents, helping them to prepare and also addressing their fears and uncertainties is another important but easily neglected aspect of management.

Education

On average, children with Duchenne muscular dystrophy have an IQ around one standard deviation below the normal mean; often a striking verbal-performance deficit is also observed. Schooling should offer the best possible environment for learning, including full attention to information technology equipment, while

supporting the very real physical needs of the child. Families and areas vary as to whether this will be best provided through mainstream or special schooling. With a good education and medical support, boys with Duchenne muscular dystrophy and the appropriate intellectual potential can go on to higher education, and where possible, should be encouraged to do so.

Becker muscular dystrophy

Management issues in Becker muscular dystrophy tend to cover the same broad areas as Duchenne muscular dystrophy, but with the deterioration in muscle function over a much longer timescale. Certain complications, such as scoliosis, are very unusual. Other complications, such as cramping muscle pains after exercise, which can be a particular problem in the teenage years, are more common. Despite the fact that Becker muscular dystrophy is much milder than Duchenne muscular dystrophy it can represent a considerable and insurmountable disability for the person who has it, and problems with adjustment, poor self-esteem, and poor body image are all fairly common in this group. No hard data exist to define completely any intellectual problems in Becker muscular dystrophy, but on average it is likely that this group has a general reduction in IQ, though probably not to the extent seen in Duchenne muscular dystrophy. Cardiac complications may occur at any age in Becker muscular dystrophy (see Box 4): respiratory complications tend to be a feature of the late stages of the disease.

Facioscapulohumeral muscular dystrophy

Facioscapulohumeral muscular dystrophy is an example of a muscular dystrophy named for the most characteristic pattern of muscle involvement observed (that of involvement of the facial, scapular, and humeral muscles predominantly). However, other muscle groups usually become involved with time and may even be involved at onset.

Presentation

- Age at presentation is variable. Most affected individuals manifest some symptoms by their teens or twenties. Occasionally symptoms may be very minor, even late in adult life.
- Symptoms may, unusually for a muscular dystrophy, be very markedly asymmetrical.
- Early symptoms typically include facial weakness (inability to bury eyelashes or puff cheeks; this often goes unnoticed), shoulder girdle weakness manifesting as problems in reaching high shelves, changing lightbulbs, or climbing ropes, and foot drop.

An infantile form of facioscapulohumeral muscular dystrophy is recognized with early childhood onset, extremely marked facial weakness and progressive weakness of both the shoulder and pelvic girdle musculature. Lumbar lordosis may be profound. Hearing loss and retinal telangiectasia may be seen in any patient with facioscapulohumeral muscular dystrophy but are particularly associated with this most severe form of the disease.

Differential diagnosis

The clinical pattern of facioscapulohumeral muscular dystrophy can be very distinctive, and the asymmetry of muscle involvement is a major clue. However, facial weakness may be very variable, and if it is absent or subtle, confusion can arise with forms of limb girdle muscular dystrophy.

Diagnostic investigations

Serum creatine kinase may be normal or mildly elevated. Muscle biopsy and electromyography (EMG) provide supportive evidence for a muscular dystrophy; some inflammatory features are sometimes also seen in the biopsy. Most cases (if not all) of facioscapulohumeral muscular dystrophy are linked to chromosome 4q35. Although the nature of the gene responsible for facioscapulohumeral muscular dystrophy is not yet known, a DNA-based test is available which can confirm the diagnosis in 95 per cent of cases. This test involves the demonstration of a DNA deletion which is consistently associated with the disease. It is likely that this deletion alters the expression of an unknown gene close to the telomere of chromosome 4q (position effect variegation).

Prognosis and management

Infantile facioscapulohumeral muscular dystrophy is a progressive disease which leads to early confinement to a wheelchair and the development of such complications as scoliosis and respiratory failure. This condition is most frequently seen as a result of a new dominant mutation in cases with no family history, and these children often have particularly large DNA deletions on chromosome 4. The development of a lumbar lordosis, seen also in later onset facioscapulohumeral muscular dystrophy, together with secondary hip flexion contractures, can be very disabling. Bracing may be partially successful at controlling the lordosis, but at the expense of some loss of mobility.

More typically, facioscapulohumeral muscular dystrophy is a slowly progressive disease. As the disease progresses it can involve the proximal as well as the distal lower limb muscles. Around 20 per cent of patients with facioscapulohumeral muscular dystrophy will become unable to walk independently, most over the age of 40. Involvement of the proximal lower limbs before the age of 20 years is a poor prognostic sign, indicating an increased likelihood of needing to use a wheelchair. Some patients describe progression as being stepwise in nature, with periods of faster deterioration alternating with phases of plateauing of their symptoms. Footdrop is a common complaint, which can be helped by the provision of daytime ankle–foot orthoses. A significant proportion of patients with facioscapulohumeral muscular dystrophy complain of painful muscles, for which no cause can be found, and for which pain relief may be difficult. Some patients find swimming or a small dose of antidepressants useful for this symptom. More severely affected patients with facioscapulohumeral muscular dystrophy may develop respiratory failure or swallowing problems and these complications should be sought. Cardiomyopathy is rarely reported.

Genetic counselling

Facioscapulohumeral muscular dystrophy is an autosomal dominant disease and as such an affected person has a 50 per cent chance of transmission to his or her offspring, regardless of sex. Use of the new DNA diagnostic techniques have shown that up to 30 per cent of cases of facioscapulohumeral muscular dystrophy may represent new dominant mutations. Germline mosaicism is also common. Genetic analysis has also shown a higher proportion of asymptomatic gene carriers than expected, with females overrepresented in this group. The availability of a relatively straightforward genetic test in this disorder has opened up the possibility of presymptomatic and prenatal testing, which were previously impossible. However, despite an overall correlation between the size of the deletion found and the severity of the symptoms, the DNA test is not useful in predicting the severity of the disease—people in individual families with apparently the same sized deletion may have a very variable experience of the disease (see Fig. 4).

Fig. 4 Mother and daughter with facioscapulohumeral muscular dystrophy. The mother is extremely mildly affected and has minimal symptoms. By contrast the daughter was affected from early childhood and has been wheelchair dependent outside from her early teens. Note the daughter's expressionless face and her posture—she is leaning forwards due to a combination of her marked lumbar lordosis, a major feature of the condition, and hip flexion contractures.

Emery Dreifuss muscular dystrophy

Emery Dreifuss muscular dystrophy has a highly characteristic phenotype. X-linked recessive, autosomal dominant, and autosomal recessive forms are recognized, and the genes involved in these conditions both encode proteins which are components of the nuclear envelope (see Fig. 5). The gene involved in X-linked Emery Dreifuss muscular dystrophy is *emerin*, and the gene involved in autosomal dominant and autosomal recessive Emery Dreifuss muscular dystrophy is *lamin A/C*.

Fig. 5 Muscular dystrophy phenotypes characterized by prominent contractures. (a) This patient has autosomal dominant Emery Dreifuss muscular dystrophy, with a proven mutation in his *lamin A/C* gene. The elbow and Achilles tendon contractures seen here, combined with his markedly rigid spine, are very similar to the pattern of contractures and weakness seen in the X-linked form of the disease. (b) Bethlem myopathy in a woman with marked contractures of the elbows, ankles, and spine. In addition she has finger flexion contractures, demonstrated here by attempting to straighten the fingers with the wrist extended.

Presentation

- Patients may present at any age, most typically in the early teens, though symptoms may be present much earlier than that.
- Contractures of the ankles and elbows and rigidity of the spine often predate any clear weakness.
- Consequently, these patients have frequently had Achilles tendon release before the diagnosis is suspected.
- Weakness and wasting are typically humeroperoneal in distribution.
- A key part of these conditions, which may rarely be present at presentation, is cardiac involvement, most typically arrhythmias (see below). An alternative phenotype (limb girdle muscular dystrophy 1B, see Box 7 and Fig. 5) exists in combination with mutations in the same gene as autosomal dominant Emery Dreifuss muscular dystrophy (*lamin A/C*). These patients may present with purely cardiac disease, or with a more proximal 'limb girdle muscular dystrophy' presentation, without prominent contractures. *Lamin A/C* mutations are also described in patients with partial lipodystrophy without prominent muscle weakness.

Box 7 Autosomal dominant Emery Dreifuss muscular dystrophy and limb girdle muscular dystrophy 1B—the 'laminopathies'

- These disorders are caused by mutations in the lamin A/C gene. Lamin A/C, like emerin, is a component of the nuclear envelope.
  - The phenotype is variable, depending on the presence or not of contractures as a major component of the phenotype.
  - Where contractures are present, these typically involve the elbows, Achilles tendons, and spine. In these patients, there is often a humeroperoneal pattern of muscle weakness as in X-linked Emery Dreifuss muscular dystrophy.
  - Where contractures are less of a feature, patients typically present with proximal muscle weakness.
  - In both groups, cardiac involvement is the most important complication. Arrythmias may lead to sudden death and should be sought and treated appropriately.
  - A phenotype with exclusively cardiac involvement has also been described.
  - New mutations and germline mosaicism is common in this group.

Confirming the diagnosis

Serum creatine kinase is typically mildly elevated in Emery Dreifuss muscular dystrophy. Muscle biopsy shows non-specific histological features: in X-linked Emery Dreifuss muscular dystrophy, emerin is absent in muscle and skin. Detection of mutation in the *emerin* gene is necessary to offer genetic counselling to female relatives at risk of being carriers.

The involvement of *lamin A/C* (the gene responsible for autosomal dominant Emery Dreifuss muscular dystrophy) cannot be determined by antibody analysis in muscle, but requires the demonstration of a *lamin A/C* mutation. A secondary deficiency of laminin b-1 may be seen in muscle from some patients with autosomal dominant Emery Dreifuss muscular dystrophy, but is not specific to this condition. Many *lamin A/C* mutations arise *de novo*, and germline mosaicism is common.

Differential diagnosis

Other muscular dystrophies may present with contractures as an important component (Fig. 5). Some forms of congenital muscular dystrophy may be associated with contractures and a rigid spine. Bethlem myopathy may present congenitally (often with torticollis) or in early childhood: here finger flexion contractures, elicited especially on wrist extension, are more prominent and cardiac involvement is not associated. Bethlem myopathy is itself genetically heterogeneous, involving mutations in any of the genes for collagen 6A1, 6A2, and 6A3. Like autosomal dominant Emery Dreifuss muscular dystrophy, some cases of Bethlem myopathy show a secondary reduction in laminin b-1 staining in muscle biopsy: the significance of this is uncertain.

In some cases, calpainopathy (limb girdle muscular dystrophy 2A) may be associated with contractures of the ankles, elbows, fingers, and paraspinal muscles. However, the associated weakness here is predominantly proximal and of a characteristic distribution (see below). These patients have typically a higher creatine kinase, absent calpain 3 on biopsy and *CAPN3* mutations.

Prognosis and management

The prognosis in Emery Dreifuss muscular dystrophy relates almost directly to the ability to manage the life-threatening arrhythmias to which every patient with either the X-linked or dominant form is susceptible. Severe arrhythmias are inevitable by the third decade. All patients with this diagnosis should therefore be under regular cardiological review, and cardiac pacing once a rhythm disturbance is detected may be life-saving. However, in autosomal dominant Emery Dreifuss muscular dystrophy the risk of cardiomyopathy remains and may be less amenable to routine treatment.

Management of the contractures in Emery Dreifuss muscular dystrophy is the other main issue, and will involve close liaison with a physiotherapist. Operative treatment of contractures, especially at the Achilles tendons, is commonly performed, but while such surgery does work in the short term, contractures often recur. With increasing age, however, contractures often stabilize. Muscle weakness may worsen but progression is usually very slow.

The limb girdle muscular dystrophies

The broad definition of limb girdle muscular dystrophy comes from the classification of Walton and Nattrass in 1954 when the term was suggested to describe those patients with weakness of the proximal musculature who did not fulfil the criteria for the X-linked muscular dystrophies or for facioscapuluhumeral muscular dystrophy. The term has always encompassed a heterogeneous group of disorders: now that many of them can be distinguished at the gene or protein level it is no longer sufficient to use it without qualification as to the specific type of disease (see Table 2 and Table 3). The type of limb girdle muscular dystrophy may be suggested by the precise pattern of muscle involvement, with confirmation from a combination of genetic and protein analysis. The ability to provide a precise diagnosis in limb

girdle muscular dystrophy has greatly improved the prognostic and genetic information which can be given to these patients.

The approach to diagnosis in limb girdle muscular dystrophy

Could it be dominant disease?

Autosomal dominant limb girdle muscular dystrophy represents only around 10 per cent of the total limb girdle muscular dystrophy population, and limb girdle muscular dystrophies 1A, 1C, 1D, and 1E have been very rarely reported (see Table 2). In families with a dominant history the most likely diagnoses are facioscapulohumeral muscular dystrophy (exclude facioscapulohumeral muscular dystrophy on DNA analysis especially if there is any suspicion of facial weakness), limb girdle muscular dystrophy 1B (allelic with autosomal dominant Emery Dreifuss muscular dystrophy—see Box 7), and Bethlem myopathy. New mutations are common, however, so that if the clinical features are suggestive of one of these disorders, then the diagnosis should be pursued even in the absence of a family history. Features which should raise the suspicion of dominant disease are less marked elevation of creatine kinase (typically normal to fives times normal in dominant disease and much higher than this in active recessive disease) or the presence of early and prominent contractures.

What is the age and nature of the presentation?

Variability in the age of presentation and of rate of progression is usual in the various autosomal recessive types of limb girdle muscular dystrophy. However, some broad conclusions can be helpful (Fig. 6). Childhood presentation is most common in sarcoglycanopathy, which may superficially resemble dystrophinopathy, with frequent calf (and other muscle) hypertrophy. Adult onset cases are less frequent and are essentially 'Becker like' in presentation. However, whatever the age at presentation, in sarcoglycanopathy, quadriceps is almost always stronger than the hamstrings. This is the reverse of the pattern seen in dystrophin deficiency. Calpainopathy may present with early childhood symptoms, especially contractures of the Achilles tendons, but onset is most commonly between 8 and 15 years of age. Dysferlinopathy typically presents in the late teens or early twenties, and early features may include proximal weakness or distal involvement (usually manifesting as difficulty standing on tiptoe).

Fig. 6 Typical clinical pictures of patients with different types of autosomal recessive limb girdle muscular dystrophy. (a) Calpainopathy or limb girdle muscular dystrophy 2A; note the predominantly atrophic pattern of muscle involvement and Achilles tendon contractures. The stance is often wide-based due to the imbalance of the hip abductors and adductors. (b) Dysferlin deficiency or limb girdle muscular dystrophy 2B. Note the wasting of the posterior calf muscles and flat-footed stance. (c) Child with g sarcoglycanopathy or limb girdle muscular dystrophy 2C. Note the lordotic posture and scapular winging, both of which may be more marked at presentation in sarcoglycanopathy than in dystrophin deficiency. (d) Adult with g sarcoglycanopathy, to illustrate the variability in severity of sarcoglycan deficiencies and the muscular hypertrophy which may be as marked or more marked than in dystrophin deficiency.

Which investigations should be performed?

Serum creatine kinase is greatly elevated in all forms of autosomal recessive limb girdle muscular dystrophy, but may be only marginally elevated or within the normal range in autosomal dominant limb girdle muscular dystrophy. EMG confirms a primary myopathic process and standard analysis of the muscle biopsy shows dystrophic changes (which especially in dysferlinopathy can be accompanied by evidence of inflammation). Specialized investigations are always necessary to attempt to determine the type of limb girdle muscular dystrophy, and require a muscle biopsy as the starting point for immunologically based diagnosis (see Fig. 7), taken in conjunction with the clinical features.

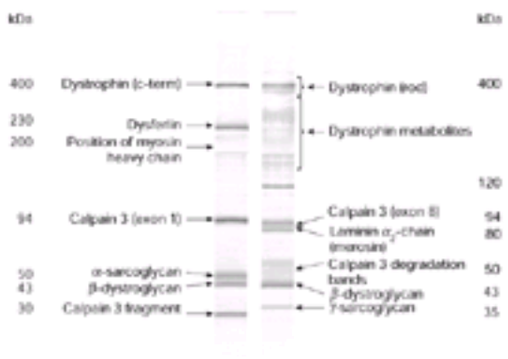

Fig. 7 Multiplex Western blotting as an approach to diagnosis in limb girdle muscular dystrophy. Two strips of a Western blot of control human skeletal muscle protein extracts immunostained with a mixture of antibodies to the proteins indicated. Absence or reduced intensity of a particular species compared with the other proteins labelled in the same lane can indicate which gene and protein is implicated in that patient's disease. (By courtesy of Dr L. V. B. Anderson, University of Newcastle upon Tyne.)

Scheme for specialized investigations

Do the clinical features or family history suggest a specific disorder (see Box 8, Box 9, and Box 10)? If so look for that first.

Box 8 Clinical features of sarcoglycanopathies

- Most frequently present in childhood, but may present at any age. Intrafamilial variability is common.
- These conditions are most closely related clinically to dystrophinopathy which will be the major differential diagnosis and have a similar spectrum of severity.
- Typically motor milestones are less delayed than in dystrophinopathy.
- Muscle hypertrophy is common.
- Intelligence is not affected.
- Cardiomyopathy is an important complication, though not universal, and should be sought through careful surveillance.
- Respiratory failure is an important late complication.
- Scoliosis is seen in the most severely affected individuals.
- Prognosis overall is typically better than dystrophinopathy presenting at a similar age.

Box 9 Clinical features of calpainopathy

- This is the most common form of limb girdle muscular dystrophy in most populations.
- May present at any age but typically 8 to 15 years.
- Highly selective muscle involvement: posterior thigh weakness, and wasting; scapular winging common at onset.
- Muscle hypertrophy rare—tends to be predominantly atrophic pattern.
- Preservation of hip abductor muscles even at late stages contributes to characteristic wide-based stance.
- Most have Achilles tendon contractures: a subgroup presents with much more prominent contractures in an Emery Dreifuss muscular dystrophy-like pattern.
- Progression is variable but never as fast as Duchenne muscular dystrophy.
- Cardiac involvement is not common but respiratory impairment may be seen in late stages.
- Prognosis in all but the most severe and early onset cases is good.

Box 10 Dysferlinopathy: clinical features

- Presentation most commonly in late teens or early twenties.
- Patients often report good muscle prowess before onset of disease. Serum creatine kinase may not be massively elevated in presymptomatic cases.
- Occasional patients present with unilateral calf swelling which may be tender and lead to the clinical diagnosis of myositis.
- Primary muscle involvement is always in the lower limbs, with absence of upper girdle involvement at onset.
- Lower limb involvement may be of proximal muscles or distal muscles. The distal muscles involved first are typically posterior (leading to difficulty standing on tiptoe as an early feature) but may be anterior.
- Progression is typically slow and life expectancy is not reduced. This is the usually mildest type of limg girdle muscular dystrophy.
- Cardiomyopathy is not reported and respiratory involvement is usually mild and at a very late stage only.
- This phenotype is genetically heterogeneous, with another locus for Miyoshi myopathy on chromosome 10.
- The main differential diagnosis, especially in patients presenting with distal weakness, may be an alternative form of distal myopathy. Typically here the creatine kinase is not so high.

The sarcoglycanopathies

Dystrophin staining may be mildly abnormal in these patients reflecting the close and interdependent relationship between the proteins of the dystrophin associated complex; but the predominant abnormality on immunolabelling or immunoblotting will be the absence or reduction of one or more of the sarcoglycans. The pattern of reduction of these proteins may give a clue as to the primary gene involvement. In g sarcoglycanopathy, there may be preservation of some or all of the other sarcoglycans, with specific loss of g sarcoglycan. a Sarcoglycanopathy may similarly present with a selective reduction, or with more widespread loss or reduction in labelling for all members of the complex. In † and b sarcoglycanopathy there is typically loss of the whole sarcoglycan complex. Determining the primary protein involved is important to direct genetic analysis. Detection of the mutation is necessary to offer prenatal diagnosis and specific genetic counselling, but as there are few recurrent mutations in the *sarcoglycan* genes the search for mutations can be very time-consuming: hence the need to obtain the best possible information from immunolabelling before embarking on detection of mutations.

Calpainopathy

Here the sarcoglycans are normal, as is dystrophin. Currently available antibodies to calpain 3 do not work on tissue sections but need to be used on immunoblotting. Detection of reduced or absent calpain on immunoblotting (Fig. 7) indicates the need to search for *calpain 3* mutations, which are highly variable, generally non-recurrent, and which may involve any part of the large (24 exons) gene. However, a secondary reduction in calpain 3 may also be seen in some cases of dysferlin deficiency. Hence the need to use all antibodies in combination to ensure that the primary problem can be identified correctly and the appropriate gene searched for mutations.

Dysferlinopathy

Here all other proteins with the possible exception of calpain 3 are within the normal range and deficiency of dysferlin can be demonstrated on tissue sections or immunoblotting. Decreased or absent dysferlin in muscle is an indication to proceed to mutation detection. The *dysferlin* gene is very large (55 exons), and as with the other forms of limb girdle muscular dystrophy, mutations are highly variable.

Laminopathy

Some (but by no means all) patients with *lamin A/C* mutations have a secondary reduction of the muscle protein laminin b-1 on immunolabelling of tissue sections. The confirmation of the diagnosis is by demonstration of a *lamin A/C* mutation.

Other forms of limb girdle muscular dystrophy

Limb girdle muscular dystrophy 2G and 2H appear relatively restricted in their geographical distribution. Limb girdle muscular dystrophy 2I is seen worldwide and is due to mutations in *FKRP*. This type of locus can be associated with cardiomyopathy.

Management

Once the diagnosis is secure, management should include monitoring and treatment for the specific complications of the various subtypes. If a clear diagnosis is not possible (for example where appropriate samples are not available or where the diagnosis cannot be reached even after exhaustive investigation) the management should as a minimum include physiotherapy and regular cardiac and respiratory surveillance.

Oculopharyngeal muscular dystrophy

Oculopharyngeal muscular dystrophy is unusual in that it has an exceptionally late presentation.

Presentation

- Presentation is typically in the sixth decade.
- It commonly presents with ptosis, dysphagia to solids, and dysphonia which may be as severe as in myotonic dystrophy.
- Other features include ophthalmoparesis, facial weakness, and proximal muscle weakness.

Diagnosis

The muscle biopsy in oculopharyngeal muscular dystrophy typically shows the presence of rimmed vacuoles and intranuclear inclusions. DNA analysis confirms the presence of an expanded guanine–cytosine–guanine repeat in the *poly(A) binding protein 2* gene.

Prognosis and management

Ptosis can be managed surgically, but frequently recurs. Dysphagia may respond, at least partially, to surgical intervention with myotomy of the cricopharyngeal muscle and other annular muscle fibres. Potentially life-threatening complications may include aspiration pneumonia and regurgitation. Progression of the limb muscle

weakness is highly variable.

Genetic counselling

Oculopharyngeal muscular dystrophy is an autosomal dominant disorder. Genetic analysis offers the potential for presymptomatic testing if this is specifically sought.

Prospects for specific treatment in muscular dystrophy

Drug treatments have a limited place in the treatment of muscular dystrophy at present. Despite many small-scale studies reporting the beneficial use of steroids in prolonging ambulation in Duchenne muscular dystrophy and possibly the sarcoglycanopathies as well, these treatments are not universally applied due to reservations about side-effects and the true cost–benefit equation for this intervention. Steroids do not appear to be beneficial in facioscapulohumeral muscular dystrophy: b agonists are currently under trial in this condition after some fairly positive findings in a pilot study.

Treatments to modify the underlying disease are not yet available for clinical application. Gene transfer experiments in animal models have proved the general feasibility of this approach to these genetic diseases, at least on a small scale. Modification of mutations, either by drugs or other means, is an area of research, as is the concept of upregulating the production of ancillary proteins.

Supportive treatment for patients and their families remains the mainstay of treatment at present, and this is likely to be the case for the current generation of patients at least. This treatment is ideally provided through a specialized multidisciplinary team, bringing together with the 'myologist' the skills of medical and associated colleagues from physiotherapy, occupational therapy, genetics, cardiology, respiratory medicine, and orthopaedics.

With the rate of change in the last few years in the information we have available about genetically determined diseases, the most up to date reviews of the subject may be found on the Internet rather than in traditional textbooks. Online Mendelian Inheritance in Man (http://www3.ncbi.nlm.nih.gov/) provides a good starting point for up to date information on a range of subjects. The Leiden muscular dystrophy database (http://www.dmd.nl/) offers specific information on the muscular dystrophies.

24.22.3 Myotonia

David Hilton-Jones

Introduction

The term myotonia, and related terms such as paramyotonia and neuromyotonia, cause much confusion. Various diseases accompanied by myotonia have different molecular origins and many associated symptoms and signs. Myotonia can be considered as a symptom, as a physical sign, or as a neurophysiological phenomenon, but understanding is perhaps best served by discussing these in reverse order.

The basic neurophysiological finding is of repetitive muscle-fibre action potentials following a stimulus, which may be voluntary contraction or muscle percussion. The repetitive electrical activity causes muscle contraction, and thus myotonia is characterized by delayed muscle-fibre relaxation following such a stimulus. Electromyography demonstrates the repetitive firing. Characteristically, the discharge gradually declines in amplitude and frequency, producing the so-called 'dive-bomber' sound in the monitoring loudspeaker.

As a physical sign, myotonia is demonstrated either as delayed muscle relaxation following voluntary contraction (for example grip myotonia, Fig. 1), or as persistent muscle dimpling following percussion (percussion myotonia, Fig. 2).

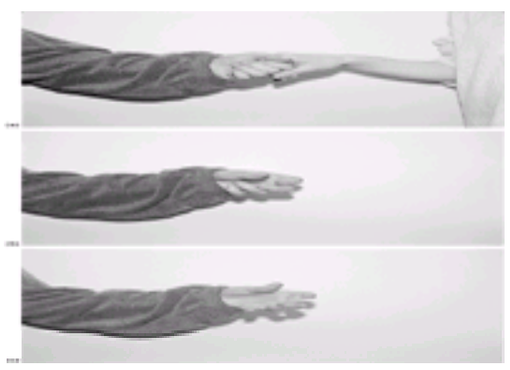

Fig. 1 Grip myotonia. The patient was asked to grip the examiner's fingers tightly for 3 s, and then to release the grip as rapidly as possible. The following two photographs were taken at 3-s intervals.

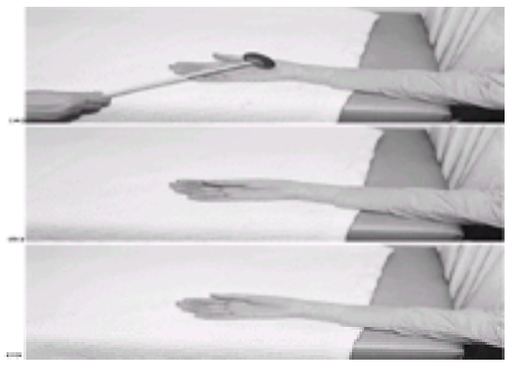

Fig. 2 Percussion myotonia. Following a sharp tap, the thenar eminence muscles contract and then relax slowly (subsequent photographs taken at 3-s intervals).

As a symptom, complaints relating to myotonia differ between patients with myotonic dystrophy, which is by far the most common cause of myotonia, and those with myotonia congenita. In myotonic dystrophy, even when grip myotonia is readily evident on examination, the patient may offer no symptoms. They are more likely to complain of hand weakness than of myotonia. When the myotonia is symptomatic, the patient complains of difficulty releasing objects after a tight grip. This is sometimes striking. One patient first noted grip myotonia in early adult life, when he was appointed as a teacher at a school—as his future headmaster shook his hand to congratulate him, he was embarrassingly unable to release his grip. In myotonic dystrophy, bulbar symptoms relating to myotonia are quite common—patients complain of their tongue or jaw 'locking' when speaking or swallowing and tongue myotonia on percussion may be demonstrated.

By contrast, in myotonia congenita weakness is absent and the myotonia, which is generalized, is problematic, particularly in the lower limbs. Patients complain of stiffness which is most evident on trying to initiate movement after rest. Thus, the patient who has been sitting in the waiting room rises and walks with profound leg stiffness, somewhat reminiscent of spasticity, into the consulting room. A classic presentation is the soldier on the parade ground—after a prolonged period 'standing to attention', the order to march results in his falling due to leg muscle stiffness. One such patient also demonstrated marked grip myotonia—on an unfortunate occasion he alighted from a bus but, unable to release his grip from the handrail before the bus departed, was dragged along the road.

In most disorders, myotonia lessens with repeated activity of the muscle. Thus, the sign becomes less striking with repeated percussion of the thenar eminence or attempts to demonstrate grip myotonia. As a symptom, for example, the leg stiffness in myotonia congenita lessens as the patient continues to walk. In paramyotonia the reverse is seen, with myotonia increasing with activity—so-called paradoxical myotonia. Some, but by no means all, patients complain that their myotonia is worse in the cold. This is again a particular characteristic of paramyotonia.

Classification of myotonic disorders

As with many other inherited neuromuscular disorders, nomenclature and classification are currently in a state of flux as molecular mechanisms are being unravelled. For clinical purposes a useful distinction is between those multisystem disorders in which weakness is a significant feature, and which are therefore referred to as dystrophies, and the non-dystrophic myotonias (Table 1).

The nomenclature for the gene loci of myotonic dystrophies has been revised recently. Classic myotonic dystrophy was previously called dystrophia myotonica, which gave rise to the abbreviation DM. It shows no genetic heterogeneity, all cases being associated with a trinucleotide repeat expansion in the 3' untranslated region of a

novel protein kinase gene on chromosome 19q. This locus is referred to as DM1. Many cases of proximal myotonic myopathy, a recently described disorder, are linked to chromosome 3q, and that locus is designated DM2. However, some cases of proximal myotonic myopathy do not link to DM2. As yet, other loci have not been identified, but as they are they will be designated DM3, DM4, and so on.

The most common non-dystrophic myotonias are the autosomal dominant and recessive forms of myotonia congenita, both of which are caused by mutations of the skeletal muscle chloride channel (*CLC-1*) gene. Different mutations of the skeletal muscle sodium channel gene (*SCN4A*) give rise to hyperkalaemic periodic paralysis and related disorders, including paramyotonia congenita. These chloride and sodium channelopathies, together with the calcium channel disorders causing hypokalaemic periodic paralysis, are discussed further in Chapter 24.22.5.

Schwartz–Jampel syndrome is a very rare recessive disorder of infantile onset, characterized by skeletal abnormalities, abnormal facial appearance, and abnormal muscle electrical activity. Electromyography may show typical myotonia as well as periods of continuous electrical activity which are probably neural in origin. It is genetically heterogeneous. Some cases are linked to chromosome 1p. One patient with a clinical diagnosis of Schwartz–Jampel syndrome was subsequently found to have a sodium channel mutation.

Myotonic dystrophy

Myotonic dystrophy is the most frequent cause of myotonia and indeed is also the most prevalent muscular dystrophy in adults. It is a multisystem disorder that has very important (but sometimes rather neglected) manifestations other than skeletal muscle dysfunction, involving cardiac conduction tissues, smooth muscle, eyes, and the central nervous system. Clinical severity ranges from death *in utero* to a condition so mild that it may be asymptomatic and without abnormal physical signs in old age. The molecular basis is now known (an expansion of an unstable trinucleotide repeat in a gene coding for a novel protein kinase), but it is not yet clear how this leads to the various manifestations of the disease. Myotonic dystrophy provides a dramatic example of the phenomenon of 'anticipation', by which succeeding generations may be much more severely affected than their predecessors, and this correlates with the size of the genetic expansion.

Epidemiology

The disease is seen worldwide, with a particularly high frequency in French Canadians in Quebec (originating from a single immigrant couple). Incidence and prevalence figures are unreliable, and probably mostly underestimates, because of the difficulty in ascertaining asymptomatic individuals. A generally accepted prevalence value is 5/100 000 population.

Pathogenesis

The molecular basis is the expansion of a trinucleotide (cytosine–thymine–guanine, **CTG**) repeat sequence in the 3' untranslated region of the myotonic dystrophy protein kinase (*DMPK*) gene on chromosome 19q. The function of this novel putative serine–threonine protein kinase is unknown. In the normal population the size of the repeat is in the range $CTG_{5–37}$, with a trimodal distribution of 5, 11 to 17, and 19 to 37 repeats. Expansions in the range $CTG_{37–49}$ are believed to represent premutations. Individuals with myotonic dystrophy have repeats in the range $CTG_{50–5000}$ and, as noted below, there is a correlation between the size of the repeat and clinical severity, and an inverse correlation between repeat size and age of onset.

A fundamental concept is that the expanded gene is unstable. It is mitotically unstable, and so the size of the gene increases with age. There is somatic mosaicism, so that the expansion is not the same size in different tissues. Diagnostic studies are based on measurement of the expansion size in blood lymphocyte DNA.

More important is intergenerational CTG-repeat instability, which explains why the disease tends to increase in severity in subsequent generations. The gender of the parent of origin is important. In most transmissions the allele size increases. However, there appears to be a threshold limit for sperm, and males never transmit the very large expansions associated with congenital myotonic dystrophy (see below), which only occurs when the mother is the gene carrier. There is some evidence of meiotic drive, which leads to preferred transmission of the abnormal expanded allele.

It remains uncertain as to how the basic molecular abnormality causes the various manifestations of the disease. One theory is that the expansion affects the expression of other genes in the DM locus apart from *DMPK*, such as the DM locus-associated homeodomain protein (*DMAHP*) gene. Another theory is that nuclear accumulation of RNA transcripts from the expanded *DMPK* gene affects processing of other mRNAs, thus having a knock-on effect on the translation of many proteins.

Clinical features

From the above it is apparent that there is a continuous distribution of expanded allele size, and that there is a relationship between allele size and disease severity, and between allele size and age of onset. While accepting that some patients will fall between these categories, for practical clinical purposes myotonic dystrophy can be considered to give rise to three main patterns of disease:

- congenital
- classic or early adult onset
- late onset, asymptomatic, or oligosymptomatic.

Because it is the best known, and illustrates the multifarious manifestations of myotonic dystrophy, the classic form will be discussed first.

Classic form

Onset is in adolescence or early adult life. The principal manifestations are summarized in Table 2. A number of rarer or clinically less important associations are also recognized. These include reduced fertility, testicular atrophy, insulin resistance (but rarely overt diabetes), retinopathy, eye movement disorder, peripheral neuropathy, disturbed tests of endocrine function, hypotension, pilomatrixomas, and reduced levels of immunoglobulins and complement.

Skeletal- and smooth muscle

The features of myotonia have already been discussed. The distribution of muscle weakness is highly characteristic. Wasting and weakness of the facial muscles, combined with premature male-pattern balding, gives rise to the typical facial appearance of the condition (Fig. 3). The temporalis muscle is atrophic, giving a sunken appearance over the temples. There is ptosis. Eye closure is weak and in severe cases the sclera may remain visible. The jaw tends to hang down. Neck flexion is weak and in some, but not all patients, there is evident atrophy of the sternomastoid muscles. In the limbs, and in marked contrast to most other myopathic disorders, the weakness is predominantly distal. In the upper limbs there is weakness and wasting of the small hand muscles and of the long wrist and finger flexor and extensor muscles in the forearm. There is often profound weakness of grip and the patient complains of difficulty with tasks such as wringing-out a cloth and removing the lid from a bottle. A simple hand-held dynamometer reveals the extent of the weakness—whereas a normal female would easily exceed 35 kg, patients of either sex may manage only 1 or 2 kg. In the lower limbs there is weakness of ankle dorsiflexion, presenting as tripping easily and foot drop. As the disease advances, weakness becomes evident more proximally, but the marked distal predilection remains throughout.

Fig. 3 Adult-onset myotonic dystrophy. Typical facial features (see text).

Bulbar muscle weakness presents with dysarthria and dysphagia. Smooth muscle involvement contributes towards the dysphagia. Symptoms akin to those of irritable bowel syndrome are frequent. Constipation is common, pseudo-obstruction rare. There may be evidence of incoordinate uterine contraction in labour.

Ocular

Cataracts develop at an early age. The initial manifestation is multicoloured opacities in the subcapsular regions, readily seen on slit-lamp examination. Identification of cataracts used to be important in screening asymptomatic family members for the disease, but that has now been replaced by DNA testing. In practice, the cataracts are managed as any other cataracts, being operated on when vision is significantly impaired. Early-onset cataracts should always raise the suspicion of myotonic dystrophy.

Central nervous system

Central nervous system disease is expressed in two main ways. As a group, patients with myotonic dystrophy have a lower IQ than average, but many mildly affected patients have intelligence within the normal range. They are often perceived as apathetic or lacking self-motivation. There is some neuropsychological evidence of specific defects of frontal lobe functioning. The second principal feature is excessive daytime sleepiness which affects over three-quarters of patients, some profoundly. This appears to be a central phenomenon and is only rarely attributable to obstructive sleep apnoea/nocturnal sleep disturbance.

Cardiovascular

Cardiovascular dysfunction is arguably the most important extramuscular manifestation of myotonic dystrophy and is probably responsible for most of the not infrequently reported cases of sudden unexpected death. The most commonly recognized pattern is of progressive conduction disturbance. Thus, in very early cases the ECG is normal. Subsequently, the P–R interval gradually lengthens until first-degree block is present. Later features include bundle branch and complete heart block. Tachyarhythmias also occur, most frequently atrial flutter or fibrillation. Symptoms include palpitation, dizzy spells, and fainting. Prolonged ECG monitoring and sometimes intracardiac electrophysiological studies are indicated if such symptoms are reported, or the standard ECG shows significant change. All patients should have an ECG annually, and be advised to report any cardiac symptoms immediately. Rhythm disturbances precipitated by anaesthesia or surgery are common, as are respiratory problems. For these reasons, patients should carry a medical alert bracelet/medallion and, for elective admissions for surgery, be reminded to inform the anaesthetist of their diagnosis. The latter is particularly important for asymptomatic individuals diagnosed on the basis of DNA studies following family screening, as they may not consider themselves to be at risk—they are. Although there is some correlation between cardiac involvement and overall severity of the myotonic dystrophy, it is not absolute and individuals with minimal muscle involvement may have significant ECG changes.

Heart muscle disease, as opposed to disordered cardiac conducting tissues, is not clinically significant and routine echocardiography is not required.

Respiratory

Recurrent chest infections are common and relate to respiratory muscle weakness and the tendency to aspirate. In advanced disease, death is often secondary to pneumonia. Respiratory insufficiency may become apparent following anaesthesia, with difficulty in weaning from the ventilator. Chronic hypoventilation and hypercapnia may cause excessive daytime sleepiness, but in practice is much less common than the presumed central mechanism already mentioned. However, it must be considered and excluded (for example by overnight oximetry and blood gas measurements) if felt to be a possibility. Particular warning features would include a history of disturbed night-time sleep, snoring, waking with headaches, and the development of secondary polycythaemia.

Congenital myotonic dystrophy

By simple definition, this form of myotonic dystrophy is evident at birth, but in reality the spectrum of early-onset myotonic dystrophy is much wider. The exclusive (with only very rare exceptions) maternal transmission of congenital myotonic dystrophy has already been discussed. Many fetuses carrying large expansions are aborted spontaneously in early pregnancy and there is a high rate of fetal wastage. Because of the unstable nature of the CTG-repeat and the associated phenomenon of anticipation, it is not uncommon for the mother to be unaware of her own diagnosis at the time of birth. In that situation, the diagnosis in the infant is not always immediately apparent, as there are no entirely specific clinical features. In other infants the disorder is not evident at birth and thus is not strictly congenital, but symptoms become apparent within the first few years of life.

There is often a history of polyhydramnios and poor fetal movement in the pregnancy. The child is born hypotonic ('floppy') and talipes is present in about one-half. Respiratory and feeding difficulties may necessitate assisted ventilation or an oxygen tent, and feeding by nasogastric tube. Some die in the neonatal period from respiratory complications, but somewhat surprisingly, there are few further deaths in the survivors until the late teens and early adult life. There is generalized weakness, including the face—the jaw hangs open and the mouth has a characteristic tented or carp-like (as in fish) appearance. Myotonia is not evident clinically and even electromyographically may not appear for several years.

In those who survive, hypotonia resolves and motor function improves over the following few years, but during adolescence the features of the classic adult form of the disease appear (Fig. 4).

Fig. 4 Myotonic dystrophy. The affected mother's two children have the congenital form of the disease.

Mental retardation is invariable and may be severe. Most require special-needs schooling. Bowel involvement is common with faecal soiling and irregular bowel habit. Curiously, cataracts are relatively uncommon.

The overall prognosis is poor. Some 25 per cent die in the first 18 months of life, most in the neonatal period. One-half survive into the mid-30s, death most commonly resulting from respiratory involvement, but with a proportion of sudden deaths almost certainly due to cardiac conduction defects. Few achieve an independent adult life.

Late-onset form

This form is associated with a small CTG-repeat expansion. It is typically asymptomatic or oligosymptomatic and is diagnosed during family studies or by an alert ophthalmologist when the patient presents with cataracts. Skeletal muscle disease may be absent, or confined to mild myotonia and weakness confined to the hands. Balding may be a feature. It is not uncommon to see the parents of a patient with the classic adult form of the disease and not be able to identify the transmitting parent on clinical examination.

Importantly, even patients with such minimal symptoms may occasionally develop significant cardiac conduction problems and they should have annual electrocardiograms.

Management

The essential management issues in myotonic dystrophy are:

- genetic counselling
- annual ECG
- anaesthetic risks
- physical therapies
- cataract surgery.

A particular concern relates to the genetic phenomenon of anticipation and the potential for an asymptomatic mother, ignorant of the diagnosis, to give birth to a congenitally affected child. When the diagnosis of myotonic dystrophy is established in a family member it is imperative that at-risk relatives are offered screening. Prenatal diagnosis, by chorionic villous sampling, can then be offered.

Annual ECG should be performed in all patients. They and their medical attendants must be aware of the cardiorespiratory complications associated with anaesthesia. They should be encouraged to wear an appropriate medical alert bracelet or medallion. A few patients require nocturnal positive-pressure ventilation by face mask, but most excessive daytime sleepiness is not related to respiratory insufficiency. Recurrent chest infections are common. Annual influenza vaccination should be advised. Pneumococcal vaccination is also given but is of uncertain value.

Physiotherapy and occupational and speech therapy all have a role, as does the use of orthotic devices (for example for foot drop). Bowel problems in the congenital form require specific advice and counselling.

Cataract surgery is required when vision is significantly impaired.

Proximal myotonic myopathy

In the last few years a number of families have been described with an autosomal dominant multisystem disorder similar to myotonic dystrophy, but who do not have the chromosome 19 CTG expansion. Many, but not all, show linkage to chromosome 3q. In some countries (such as Germany) these conditions seem to be almost as common as myotonic dystrophy, but in others (such as the United Kingdom) they appear to be rare. Some issues concerning classification were discussed earlier.

Various names and abbreviations have been given to these conditions, including proximal myotonic myopathy, proximal myotonic dystrophy and DM2.

Despite the superficial similarities to myotonic dystrophy, there are also differences. Onset is usually in adult life. Myotonia tends to be more symptomatic than in myotonic dystrophy and patients complain of stiffness and muscle pain. Unlike myotonic dystrophy, the weakness tends to be more marked proximally, and may show significant fluctuation from day to day. Cataracts may be indistinguishable from those seen in myotonic dystrophy. Cardiac conduction problems appear to be less common. Male hypogonadism and deafness occur. There is considerable clinical variability even between families linked to the same chromosome 3q locus, indicating allelic heterogeneity.

24.22.4 Metabolic and endocrine disorders

David Hilton-Jones and Richard Edwards

Introduction

This section deals with disorders of voluntary muscle that arise either as the result of a disturbance of muscle metabolism, or disordered ion flux. In many cases precise mechanisms have yet to be defined.

The term 'metabolic myopathy' is applied to those disorders in which there is a primary defect, usually an enzyme deficiency, in the biochemical pathways associated with energy generation (ATP synthesis). This group includes the mitochondrial disorders, which are some of the most common causes of primary metabolic myopathy seen in clinical practice.

Endocrine myopathies and nutritional and toxic myopathies, including those that are drug-induced, can be considered as secondary (acquired) metabolic myopathies.

Defects in genes coding for subunits of the skeletal-muscle sodium and calcium channels underlie primary hyperkalaemic and hypokalaemic periodic paralysis, respectively. Both autosomal dominant and autosomal recessive myotonia congenita are caused by mutation in the skeletal-muscle chloride channel. Mutations affecting two skeletal-muscle calcium channels, the dihydropyridine (**DHP**) and ryanodine (**RYR1**) receptors, are associated with malignant hyperthermia (**MH**). The congenital myopathy central core disease is allelic to MH and is associated with *RYR1* mutations.

The cardinal symptoms of myopathy are weakness, fatigue, and/or pain; altered excitability may also occur. It is important that the physician appreciates several points:

- There are non-specific effects, such as loss of muscle, that may be far more important as a cause of weakness than the energetic consequences of the biochemical defect. Visual inspection and circumference measurements tend to underestimate the extent of wasting, which may be better documented by quantitative scanning methods (magnetic resonance imaging (**MRI**) or computed tomography (**CT**)).
- Not all the biochemical abnormalities cause symptoms. Clinical expression of the underlying defect depends on the habitual demands on the muscle for movement and weight-lifting.
- A patient with a metabolic myopathy may have common, non-myopathic, musculoskeletal complaints which have no relation to the inherited or acquired defect.
- Muscle symptoms may have no physiological connection with the underlying defect and may be consequences of somatization or other psychological process.
- The practical assessment of metabolic myopathy should include consideration of the WHO ICIDH-2 (2000) classification of the functioning and disability criteria of impairment, activities, and participation (revised from the International Classification of Impairments, Disabilities, and Handicaps (**ICIDH**) of WHO 1980). In this generic consideration, the relationship between antigravity muscle strength and the body weight to be carried is crucial: performance may be improved as much or more by weight reduction as by therapeutic attempts to reverse the myopathy, providing that calorie restriction does not aggravate the metabolic defect—for example, in the case of carnitine palmitoyl transferase deficiency, where carbohydrate starvation may exacerbate the energy supply problem of the underlying enzyme defect.
- An objective assessment of a response to treatment requires the measurement of individual muscle strength and/or timing of the performance of tasks relevant to the patient's symptoms and the everyday life demands placed on the diseased muscles.
- Metabolic myopathies are unusual or rare conditions that are very variable in presentation. They are not easy to discuss in the light of current, evidence-based healthcare philosophies, which are largely based on the results of randomized controlled trials (**RCTs**) of therapeutic interventions. The treatments of the metabolic myopathies tend to fall under the general rubric of 'orphan drugs' and 'orphan diseases', since, as with other rare diseases, a commercial return on the investment in research and development to deliver effective treatments is unlikely. Furthermore, in view of their rarity, there is little or no chance of formal treatment evaluation by RCTs. These conditions are therefore still to be evaluated by thoughtful clinical research employing the most relevant modern biochemical and physiological approaches.
- The patient with a metabolic myopathy is a person, and therefore far more important and complex to understand and help than the underlying metabolic diagnosis, difficult though that may be. It is essential to the humane and effective management of such a patient to see the individual as coping in a personal and social sense despite the metabolic impairment. The aim is to determine what is likely to best improve the patient's overall quality of life. Here, as with other disabilities, the constructive analysis and recommendations of the World Health Organization are useful as a basis for working with the patient to determine an individual management plan. (Table 1).

Primary metabolic myopathies

The principal energy currency of living cells is adenosine triphosphate (**ATP**). Whereas in most organs the rate of ATP utilization is fairly constant, in voluntary muscle the change from rest to strenuous activity may increase the demand on ATP generation several thousand-fold. If that demand is not met, contractile failure (that is to say, fatigue or weakness) will develop and may be accompanied by the destruction of muscle fibres. In many of the primary metabolic myopathies it is often assumed that exercise-induced symptoms relate to a failure of ATP generation, and although this is probably not always correct, it is a useful generalization. Whilst exercise-induced symptoms are often a striking feature of this type of metabolic myopathy, they are not always present. Some patients develop a chronic progressive myopathy.

The main fuels providing energy for ATP generation in skeletal muscle are glycogen, fatty acids, and glucose (Fig. 1). Their relative contributions depend upon the state of nutrition and, more importantly, the level and duration of exercise. A gross oversimplification of these pathways aids understanding of the clinical features of the different forms of metabolic myopathy.

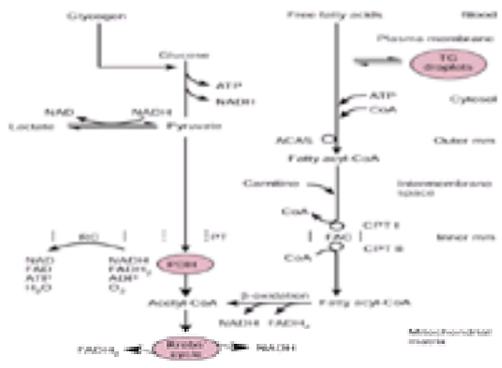

Fig. 1 Major pathways associated with energy production in skeletal muscle. ACAS, acyl-CoA synthetase; ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoA, coenzyme A; CPT, carnitine palmityl transferase; FAC, fatty acyl-carnitine; FAD, flavin adenine dinucleotide; $FADH_2$, reduced FAD; mm, mitochondrial membrane; NAD, nicotinamide adenine dinucleotide; NADH, reduced NAD; PDH, pyruvate dehydrogenase complex; PT, pyruvate translocase; RC, respiratory chain; TG, triglyceride.

At rest, the main fuel source is circulating free fatty acids, with a lesser contribution from circulating glucose. Small amounts of ATP may be generated directly from glycolysis, but the production of the energy-rich electron carriers (reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide ($FADH_2$)) from fatty acid b-oxidation, and the Krebs' cycle are more important. Transfer of electrons to molecular oxygen through the electron transport chain of the mitochondria releases energy for the generation of ATP (oxidative phosphorylation)

The increased demand on ATP generation during early strenuous exercise cannot be met by oxidative pathways. The resting blood flow provides an inadequate delivery of oxygen and substrate, and compression of blood vessels by the contracting muscle exacerbates the problem. ATP is therefore generated by the breakdown of muscle-fibre stores of glycogen (anaerobic glycolysis). The relative lack of oxygen leads to increasing levels of NADH and pyruvate. NADH accumulation would inhibit glycolysis, and thus ATP generation, and is avoided by the reduction of pyruvate to lactate, explaining the lactic acidosis seen in disorders of oxidative metabolism.

Adaptive processes occur as exercise continues; muscle blood flow increases, the respiratory rate rises, and free fatty acids are mobilized from adipose stores. Glycogen stores in muscle become depleted and circulating free fatty acids become the main energy source, with a very small contribution from circulating glucose.

Certain deductions can be made from the above that are largely borne out in clinical practice. Disorders of glycogen and glucose metabolism are typically asymptomatic at rest, but produce symptoms early in exercise when anaerobic glycolysis is important for energy supply. If low levels of exercise can be sustained, symptoms can improve as fatty acid oxidation increases ('second wind' phenomenon in McArdle's disease). Disorders of fatty acid metabolism, insufficient to cause symptoms at rest, are likely to be exposed by sustained exercise and fasting. The central role of oxidative phosphorylation explains why disorders of the respiratory chain may be symptomatic at rest. The clinical presentation will also depend upon whether the enzyme defect is restricted to skeletal muscle or is more generalized, thereby causing dysfunction of other tissues and organs. Systemic features may dominate in disorders of b-oxidation and in mitochondrial disorders but are absent in McArdle's disease because the defective enzyme is muscle-specific.

Disorders of glycogen and glucose metabolism (see also Section 11.3)

Several of the glycogenoses show significant skeletal-muscle involvement. The major pathways of metabolism, and the enzymes associated with these disorders, are shown in Fig. 2. They are autosomal recessive disorders, except for the X-linked recessive, phosphoglycerate kinase deficiency. In most of these disorders the serum creatine kinase is elevated at rest, and massively so after exercise-induced muscle damage.

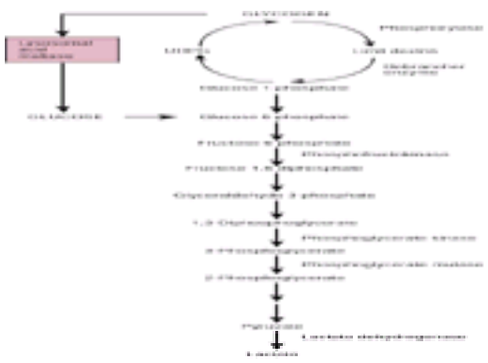

Fig. 2 Pathways of glycogenolysis and glycolysis. Enzymes known to be associated with particular clinical syndromes are shown.

Acid maltase deficiency (type II glycogenosis)

Acid maltase is a lysosomal enzyme not directly involved in energetic pathways, and exercise-induced symptoms are absent. In the infantile form (Pompe's disease) there is widespread organomegaly as well as skeletal-muscle involvement, and death occurs by the age of 2 years due to cardiac or respiratory failure. The adult form is of considerable importance and has probably been underdiagnosed. The most obvious feature is a slowly progressive, painless, proximal myopathy. Diaphragmatic involvement is an important characteristic, and many of these patients first present with respiratory failure. Nocturnal assisted ventilation alleviates sleep-disordered breathing and may prolong survival for many years. Muscle biopsy showing glycogen-containing vacuoles is usually suggestive; but the definitive diagnosis is established by enzyme assay in muscle, fibroblasts, or leucocytes, or by demonstrating glycogen granules by Periodic acid–Schiff (**PAS**) staining in lymphocytes on a peripheral blood film.

There is an intermediate juvenile form, with limited survival.

Myophosphorylase deficiency (type V glycogenosis—McArdle's disease)

The onset of symptoms is usually during childhood, and the cardinal features are pain, weakness, and stiffness of muscles early in exercise, relieved by rest. Strenuous exercise, such as helping to push a car or lift heavy furniture, may induce painful, electrically silent, muscle contractures. Muscle fibre breakdown is reflected in myalgia and myoglobinuria (dark red/black urine), which, if severe, may cause renal failure. Muscle breakdown is accompanied by a large release of creatine kinase (**CK**) into the blood, and a failure to see such a rise in serum CK levels should cast doubt on a diagnosis of myoglobinuria. Conversely, if renal failure is present then no myoglobinuria may be seen and the only evidence of rhabdomyolysis is the raised CK level. However, symptoms may ease ('second wind' phenomenon) if low levels of activity are maintained, as circulating free fatty acids and glucose become available as alternative fuels.

Progressive proximal weakness frequently develops and is sometimes the mode of presentation in late-onset cases.

Failure of lactate generation (accompanied by increased blood ammonia and hypoxanthine concentrations) during ischaemic forearm exercise is consistent with the diagnosis. However, this is not specific since it also occurs in other glycogenolysis disorders, and may be seen to some extent in acquired conditions such as alcoholic myopathy or hypothyroidism. Also, the test may give a misleading ('false-negative') result if the myophosphorylase deficiency is only partial. The definitive

diagnosis is established by histochemical demonstration of the absence of phosphorylase staining (or by enzyme assay) on muscle biopsy, or by genetic studies of the coding and expression of muscle phosphorylase.

Debrancher enzyme deficiency (type III glycogenosis—Cori–Forbes disease)

In infancy and childhood the main features of this disorder are hepatomegaly, hypoglycaemia, and failure to thrive. During adolescence muscle symptoms become more prominent. A small group of patients first present during adult life with muscle symptoms, but may give a history of a protuberant abdomen in childhood. Both exercise intolerance and a slowly progressive proximal myopathy are present.

It has recently been recognized that most patients develop a potentially fatal cardiomyopathy.

The ischaemic forearm test shows impaired lactate generation, muscle biopsy shows glycogen accumulation, and the administration of glucagon fails to produce a hyperglycaemic response. Enzyme assay can be performed on muscle, liver, erythrocytes, and leucocytes.

Phosphofructokinase deficiency (type VII glycogenosis—Tarui's disease)

The clinical picture is very similar to that of myophosphorylase deficiency, but a phosphofructokinase (**PFK**) deficiency in erythrocytes leads to the additional features of haemolytic anaemia and gout. Unlike patients with myophosphorylase deficiency, ingested glucose does not improve exercise tolerance in those with PFK deficiency because of the position of PFK in the sequence of enzymes in the glycolytic pathway (Fig. 2). Diagnosis is established by enzyme assay in muscle.

Defects of distal glycolysis

Deficiencies of phosphoglycerate kinase, phosphoglycerate mutase, and lactate dehydrogenase have been described recently. All three are associated with exercise intolerance and myoglobinuria. It is possible that other defects of glycolysis, causing similar symptoms, remain to be discovered.

Treatment

There is, as yet, no specific treatment for any of the disorders described above. Attempts at dietary manipulation have generally proved unsuccessful. Patients must be aware of the risk to renal function from myoglobinuria, and try to avoid intense exercise. There is evidence, in patients with muscle pain due to McArdle's disease and other metabolic myopathies, that maintaining a reasonable level of aerobic fitness is beneficial, by sustaining sufficient activity of muscle mitochondria to provide energy from oxidative phosphorylation to adapt for the deficiencies in energy availability from glycogenolysis.

Disorders of lipid metabolism

Unlike glycolysis, lipid metabolism is entirely dependent upon oxidative processes. Moreover, there is a close relationship between the disorders described below and defects of the mitochondrial respiratory chain; for example, lipid accumulation in muscle is a common histological feature in respiratory chain disorders.

Free fatty acids, mainly from the blood but also from triglyceride droplets stored within muscle fibres, are a major fuel at rest and during sustained exercise (see Fig. 1). They are converted to fatty acyl-coenzyme A (**CoA**) at the outer mitochondrial membrane which, within the mitochondrial matrix, can undergo b-oxidation. A transport system involving carnitine and the enzyme system carnitine palmityl transferase (**CPT**) is required to enable fatty acyl-CoA to cross the inner mitochondrial membrane. Defects involving carnitine, CPT, and b-oxidation are recognized.

Carnitine deficiency

Muscle carnitine deficiency, causing fluctuating weakness and lipid storage (intracellularly in myocytes), and systemic carnitine deficiency causing weakness and recurrent, often fatal, Reye-like episodes, have been described. It has become apparent that in most cases of so-called systemic carnitine deficiency, and perhaps even in some purely myopathic cases, the carnitine deficiency is secondary to another metabolic disorder: most commonly defects of b-oxidation or of the mitochondrial respiratory chain.

Defects of b-oxidation

Many enzyme deficiencies have been described, but clinical features are limited. They may present during the neonatal period with hypotonia, hypoglycaemia, cardiomyopathy, failure to thrive, and early death. Such defects may be a cause of some cases of sudden infant death syndrome. Later-onset cases develop Reye-like crises, muscle weakness, and cardiomyopathy. Secondary carnitine deficiency is common. A high carbohydrate and low fat diet may help.

Carnitine palmitoyl transferase deficiency

This rare disorder shows a male predominance. Symptoms are precipitated by sustained exercise (for example, a route march) or prolonged fasting, and consist of muscle pain followed by myoglobinuria, which may cause renal failure. The diagnosis may be suggested by showing impaired ketone body production during fasting, but is proven by enzyme assay in skeletal muscle. A high carbohydrate, low fat diet may reduce the number of attacks.

Myoadenylate deaminase deficiency

Deficiency of myoadenylate deaminase has been suggested as a cause of exercise-induced myalgia, weakness, and cramps but its exact status remains controversial. It is almost certainly an unusual cause of significant myalgia. It has been described as an incidental finding in muscle needle biopsies taken from normal volunteers to study muscle chemistry in sports science research. The enzyme catalyses the reaction adenosine monophosphate (**AMP**) ® inosine monophosphate (**IMP**) + ammonia (NH3). Theoretically, this reaction may aid ATP production by removing AMP and increasing flux through the adenylate kinase reaction 2ADP® ATP + AMP. The diagnosis is established from the absence of a rise in the plasma ammonia level during forearm exercise testing and from the histochemical demonstration of absent enzyme activity.

Endocrine myopathies

Although weakness is a common symptom in many endocrine disorders, the mechanisms are generally poorly understood. However, the myopathy responds to treatment of the underlying hormonal disorder, and extensive investigation of the myopathic component is rarely required. The commonest pattern is limb-girdle weakness.

Thyroid disorders (see also Chapter 12.4)

Thyrotoxicosis

Typically, weakness develops shortly after the onset of other thyrotoxic symptoms, and 80 per cent of patients have demonstrable weakness at presentation. The shoulder-girdle muscles tend to be involved before the pelvic musculature. Muscle atrophy is usually slight. Asymmetrical and distal weakness, myalgia, cramps, and fasciculations are rare findings.

The serum creatine kinase level is usually normal, but electromyography shows features consistent with muscle disease. The myopathy responds to treatment of the thyrotoxicosis.

Thyrotoxic periodic paralysis

Most cases have been reported in individuals from the Orient, with a strong male predominance. Clinical features closely mimic those of familial hypokalaemic periodic paralysis. The weakness is disproportionate to any muscle wasting. The onset of paralytic attacks usually follows the development of hyperthyroid symptoms but the attacks cease when the patient is rendered euthyroid.

Thyroid ophthalmopathy (Graves' ophthalmoplegia)

The classic features of this condition include eyelid lag, retraction, and swelling, as well as progressive swelling of the extraocular muscles and orbital soft tissues leading to proptosis and diplopia and, in severe cases, corneal ulceration, papilloedema, and optic atrophy. An extremely important but often missed variant is the patient who presents with minimal diplopia only.

In mild cases, MRI or CT imaging is useful for detecting extraocular muscle swelling. Simple tests of thyroid function may be normal. Estimation of antithyroglobulin and antimicrosomal antibodies, and the performance of a thyrotrophin-releasing hormone (**TRH**) stimulation test may be required. Thyroid-stimulating immunoglobulins are present in most patients.

If thyrotoxic, the patient should be rendered euthyroid. Lid retraction may respond to topical 10 per cent guanethidine. Persisting major eye problems may require high-dose prednisolone, plasma exchange, or orbital decompression. Tarsorrhaphy protects the cornea.

Thyroid disease and myasthenia

Patients with myasthenia gravis have an increased incidence of thyroid disease, including hyperthyroidism, hypothyroidism, Hashimoto's thyroiditis, and increased antibodies to thyroglobulin or microsomal fractions. Thyroid disease may pre-date or follow the onset of myasthenia and must be considered as a cause of deterioration in an otherwise stable patient with myasthenia. Some 5 per cent of patients with myasthenia will develop thyroid disease, but only about 0.1 per cent of thyrotoxic patients develop myasthenia.

Hypothyroidism

Although hypothyroid myopathy may be asymptomatic, mild weakness is probably present in most patients. Muscle biopsy characteristically shows evidence of type II (fast twitch, glycolytic, high intrinsic force) muscle fibre atrophy with type I fibre dominance. Even in the absence of weakness the serum creatine kinase level is often markedly raised. Slow relaxation of the tendon jerks may be present in isolation. Muscle pain and cramps are common. In children, the combination of hypothyroidism, weakness, and muscle hypertrophy is referred to as the Kocher–Debré–Semelaigne syndrome. In adults, Hoffman's syndrome describes the combination of hypothyroidism, weakness, muscle hypertrophy, cramps, and myoedema (the formation of a localized ridge of muscle following direct percussion). They probably represent variants of the same disorder.

All hypothyroid myopathic symptoms respond to thyroxine replacement.

Pituitary–adrenal axis disorders

Clinically, the most important of these is iatrogenic steroid myopathy, discussed below under 'Glucocorticoid excess'.

Acromegaly

Proximal weakness, pelvic more than shoulder girdle, is present in about one-half of patients. Common complaints include tiredness, weakness, and myalgia; muscle wasting is slight. Serum creatine kinase levels are normal or slightly raised. Normalizing growth-hormone levels improves the myopathy, but recovery may be incomplete.

Hypopituitarism

Growth-hormone deficiency in childhood impairs muscle and skeletal development proportionately; weakness is not usually a feature. In adults, panhypopituitarism causes generalized weakness and fatigue, which usually responds to thyroxine and cortisone-replacement therapy. Replacement of growth hormone in growth hormone-deficient adults has been associated with varying degrees of improvement in the strength of wasted muscles.

Glucocorticoid excess

ACTH excess, from a functioning pituitary adenoma or from ectopic production, is usually associated with high glucocorticoid levels, producing pituitary or ectopic Cushing's syndrome. Weakness is common and thought to relate to glucocorticoid excess. Weakness may occur in Nelson's syndrome, in which there is a high level of ACTH but no glucocorticoid excess.

The myopathy associated with Cushing's syndrome is probably related to glucocorticoid excess, and the clinical features are essentially the same as those of iatrogenic steroid myopathy. The 9a-fluorinated steroids, including dexamethasone, triamcinolone, and betamethasone, appear to have the greatest myopathic potential. Topical steroids can cause myopathy.

The most common picture is of a slowly progressive limb-girdle wasting and weakness, pelvic more than shoulder girdle, often accompanied by myalgia. The drug-induced form may have a more acute onset. Myopathy without other features of glucocorticoid excess is unusual. The serum creatine kinase level is usually normal and muscle biopsy shows non-specific type II fibre atrophy.

Steroid withdrawal is followed by recovery over several months. If steroid therapy for the primary disorder has to be continued then a non-fluorinated compound such as prednisolone should be used, preferably on an alternate-day basis. Successful treatment of Cushing's syndrome leads to recovery.

Conn's syndrome

Weakness is present in about 75 per cent of patients and is due to the associated hypokalaemia. Secondary hypokalaemic periodic paralysis may occur.

Addison's disease

Weakness, fatigue, and myalgia occur in up to one-half of patients. Rare myopathic presentations include progressive flexion contractures and secondary hyperkalaemic periodic paralysis.

The serum creatine kinase level is normal or slightly increased. Glucocorticoid replacement therapy is curative.

Disorders of calcium, vitamin D, and parathyroid hormone metabolism (see also Chapter 12.6)

There are complex interactions between vitamin D metabolism, calcium and phosphate homeostasis, and parathyroid hormone activity. Myopathy occurs in several clinical situations, but the precise pathophysiological mechanisms are unclear.

Osteomalacia

Weakness is the presenting symptom in one-third of patients, affecting predominantly the pelvic girdle musculature. Bone pain is prominent. The serum creatine

kinase level is usually normal. Muscle biopsy may show type II fibre atrophy, sometimes severe.

The pain responds fairly rapidly to vitamin D treatment, but the weakness recovers more slowly and may be incomplete.

Primary hyperparathyroidism

Myalgia, stiffness, and complaints of fatigue are common, but overt weakness is rare. Symptoms resolve when the underlying parathyroid adenoma is removed and serum calcium levels fall.

Renal osteodystrophy

Endstage renal failure is frequently accompanied by a predominantly pelvic girdle myopathy, sometimes with buttock and thigh pain. Symptoms respond to dialysis, transplantation, or vitamin D treatment.

Dialysis osteodystrophy

Some patients undergoing dialysis develop a severe myopathy with bone pain, fractures, and vitamin D resistance. It probably relates to aluminium toxicity. Fatigue and muscle weakness are common. Objective muscle testing is needed to distinguish true changes in muscle function from the non-specific causes of fatigue and ill health seen in patients on dialysis.

Ischaemic myopathy

Rarely, a painful ischaemic myopathy with arterial narrowing due to calcium deposition complicates renal failure. Skin ulceration and bowel infarction may also occur.

Nutritional and toxic myopathies

Whilst malnutrition causes muscle wasting, specific myopathic effects of nutritional deficiencies are uncommon, a notable exception being vitamin D deficiency, discussed above. Myopathies due to ingested toxins are relatively more common than the inherited metabolic myopathies and include those due to alcohol, and therapeutic-drug excess or idiosyncrasy.

Alcoholic myopathies

Chronic alcoholics may develop subacute or slowly progressive, proximal muscle weakness with mild-to-moderate wasting, and with muscle-biopsy evidence of type II fibre atrophy, mainly affecting the lower limbs. Occasionally the wasting is more generalized, since alcoholism may be associated with neurogenic muscle atrophy secondary to concomitant thiamin deficiency and more generalized malnutrition. It is thus still debated whether the so-called chronic alcoholic myopathy is purely myopathic, neuropathic, or both, and whether the cause is a direct toxic effect of alcohol or a secondary phenomenon, perhaps relating to malnutrition. Abstinence may lead to some degree of recovery.

Much more dramatic is acute alcoholic myopathy ('alcoholic rhabdomyolysis'), which usually occurs during or shortly following a binge. There may be widespread cramps, pain, and weakness. However, the most striking feature is the development of extremely painful muscle swelling, which may be localized or generalized. Myoglobinuria presents a threat to renal function, and hyperkalaemia may be present in severe cases. The serum creatine kinase is elevated and muscle biopsy shows acute necrosis. Recovery, which may be incomplete, occurs over several weeks.

Vitamin E deficiency

Vitamin E deficiency probably causes a myopathy, but interpretation is confused by the presence of additional neurological problems including neuropathy and ataxia.

Drug-induced myopathies

Drug-induced neuromuscular disorders are common, under-recognized and under-reported. Numerous drugs have been implicated, several mechanisms are responsible (Table 2), and some drugs can affect both muscle and peripheral nerves (for example, vincristine, D-penicillamine, and perhexiline).

Skeletal-muscle channelopathies

The term 'channelopathy' has come into common usage since the last edition of this textbook. Ion channels may be ligand-gated or voltage-gated. In the field of muscle diseases, the most important ligand-gated channel is the skeletal-muscle nicotinic acetylcholine receptor, at the neuromuscular junction. Antibody-mediated destruction underlies acquired myasthenia gravis, whereas inherited mutations of genes coding for the subunits of the receptor are the basis of several forms of congenital myasthenic syndrome. Acquired neuromyotonia and Lambert–Eaton myasthenic syndrome are caused by antibody-mediated damage to the voltage-gated potassium and calcium channels, respectively, of the terminal axon, and are discussed, together with myasthenia gravis and the myasthenic syndromes, in Chapter 24.17.

The following section is concerned with inherited disorders of skeletal-muscle voltage-gated sodium, calcium, and chloride channels. In passing, it should be noted that channelopathies are not confined to muscle, and note was made above of two neuronal channelopathies. Other disorders caused by an inherited channel defect include certain forms of epilepsy (nocturnal frontal lobe epilepsy, benign neonatal convulsions), episodic ataxia, hemiplegic migraine, deafness, night-blindness, cardiac long-QT syndromes, and nephrolithiasis.

Periodic paralyses

Marked hypokalaemia and hyperkalaemia from whatever cause may produce weakness or paralysis (secondary periodic paralysis). The primary periodic paralyses are familial, dominantly inherited disorders characterized by recurrent attacks of paralysis. These have previously been subdivided into hyperkalaemic, hypokalaemic, and normokalaemic forms on the basis of changes in the serum potassium level during attacks. Recent evidence has shown that the primary abnormality in the hyperkalaemic and normokalaemic forms is a mutation affecting the adult skeletal-muscle sodium channel, whereas the hypokalaemic form is caused by a mutation affecting the skeletal-muscle calcium channel.

Hypokalaemic periodic paralysis

Attacks usually start during the second decade of life and then vary in frequency from daily to years between episodes. Weakness may be present on waking or develop during the day, typically in response to a heavy carbohydrate meal or during rest after strenuous exercise. The weakness involves the legs more than the arms, proximal muscles more than distal, and it may be asymmetrical. Bulbar and respiratory muscle weakness is rare. Attacks last from hours to several days. The tendon reflexes may be depressed or lost during an attack. Permanent and progressive proximal weakness often develops by middle age. The serum potassium level typically falls during an attack, but not necessarily outside the normal range.

The disorder is caused by a mutation in the *CACNA1S* gene (on chromosome 1) encoding the dihydropyridine receptor (**DHPR**) component of the skeletal-muscle calcium channel. The DHPR is located within the transverse tubular system, and acts as a voltage-sensor for the ryanodine receptor (RYR1) component of the calcium channel, which is located in the sarcoplasmic reticulum and is responsible for triggering calcium release and thus muscle contraction. Different mutations in the same gene, and mutations in the *RYR1* gene, are associated with malignant hyperthermia (see below).

Acetazolamide is the treatment of choice to prevent attacks. Acute attacks respond to oral potassium, given as an unsweetened aqueous solution.

Apparently-identical attacks may occur in association with thyrotoxicosis and resolve when the patient is rendered euthyroid.

Hyperkalaemic periodic paralysis

Attacks tend to start at an earlier age than in the hypokalaemic form, and do not last as long. Precipitants include cold, fasting, rest after exercise, pregnancy, alcohol intake, and potassium loading. Readily utilized carbohydrate sources, such as a sweet drink, may abort an attack. A progressive proximal myopathy may also develop. Myotonia is present in some patients (see below). The serum potassium level may rise during an attack, but the change is often slight.

The underlying abnormality is a mutation within the *SCNA4* gene (on chromosome 17) encoding the a-subunit of the skeletal-muscle sodium channel.

Mild attacks respond to carbohydrate ingestion. Kaliuretic diuretics usually prevent attacks.

Paramyotonia congenita

Paramyotonia congenita describes a dominantly inherited condition characterized by cold-induced weakness and muscle stiffness (paramyotonia), and which is sometimes accompanied by periodic paralysis. The relationship between this disorder and primary hyperkalaemic periodic paralysis had been much debated, but recent evidence has shown that hyperkalaemic periodic paralysis, hyperkalaemic periodic paralysis with myotonia, paramyotonia congenita, and paramyotonia congenita with periodic paralysis are allelic disorders involving the *SCNA4* gene (on chromosome 17) encoding the a-subunit of the skeletal-muscle sodium channel.

Myotonia congenita

Autosomal dominant (Thomsen's disease) and recessive (Becker-type) forms of this condition are recognized, with the recessive type being much commoner. Onset tends to be earlier in the dominant form but both usually become apparent in childhood. There is muscle stiffness, worse after rest and exacerbated by cold; minimal or no weakness, readily demonstrable percussion myotonia; and muscle hypertrophy, which tends to be more marked in the recessive form.

Both the recessive and dominant forms are caused by mutations in the *CLCN1* gene (on chromosome 7) encoding the skeletal-muscle chloride channel.

Malignant hyperthermia (MH)

The main features of this autosomal dominant disorder are a rapidly rising body temperature and generalized muscular rigidity during anaesthesia. Additional features include skin mottling, cyanosis, tachypnoea, tachycardia, cardiac dysrhythmias, and autonomic instability. Attacks in susceptible individuals may be triggered by suxamethonium and anaesthetic agents (halothane, cyclopropane, enflurane, ketamine). A similar, but probably different, disorder may be associated with heavy exercise in very hot conditions (for example, recruits undergoing route marches on mountains during a hot summer).

Attacks are life-threatening. Treatment consists of withdrawing the offending agent and providing general supportive measures and intravenous dantrolene (2 mg/kg body weight).

Disturbed calcium homeostasis underlies the attacks, with excessive calcium-ion influx into the sarcoplasmic reticulum. The disorder is genetically heterogeneous. In many families the underlying abnormality affects the skeletal-muscle calcium channel with either a mutation in the ryanodine receptor (*RYR1*) gene (on chromosome 19), or in the *CACNA1S* gene (on chromosome 1). *RYR1* mutations may also cause central core disease (**CCD**)—CCD and MH are allelic disorders and may occur together in the same individual or independently. Other *CACNA1S* gene mutations cause hypokalaemic periodic paralysis.

Screening for MH susceptibility involves muscle biopsy and *in vitro* testing for a reduced contractile threshold to halothane and caffeine. False-positive results are common but false-negative results appear to be very rare. It is hoped that specific molecular biological tests will become available. A significant practical problem is the management of family members who fear they may be at risk. As with those patients who have suffered hyperpyrexia under anaesthesia (even in whom repeated exposure has not led to a consistent re-occurrence), it is advisable for those individuals of proven or suspected risk to wear at all times some form of bracelet or locket giving details of the risk, in case they are casualties in an emergency such as a road accident.

Myoglobinuria

This important symptom and sign must be differentiated from haematuria and haemoglobinuria. Red cells are visible on microscopy in the former but not in the latter. In all three conditions, the haemoperoxidase stick test is positive.

Myoglobin is a protein that acts as an oxygen store within skeletal-muscle fibres. Myoglobinuria causes a dark-brown/red discoloration of the urine, the main concern being that the protein can cause renal tubular necrosis and thus renal failure. Numerous disorders are known to be associated with myoglobinuria (Table 3). In the metabolic disorders, the presumed mechanism is failure of substrate utilization or supply when energy demands increase during exercise or starvation. In other disorders, there is disruption of the plasma membrane. Apparently idiopathic cases are probably due to an unidentified metabolic defect or infection.

Rhabdomyolysis is considered further in Section 28.

24.22.5 Mitochondrial encephalomyopathies

P. F. Chinnery and D. M. Turnbull

Introduction

Mitochondria are ubiquitous intracellular organelles that are involved in many different metabolic pathways. Disorders of intermediary metabolism (such as fatty acid b-oxidation or tricarboxylic acid cycle defects) involve mitochondrial enzymes, but the term 'mitochondrial encephalomyopathy' usually means a disease which is due to an abnormality of the final common pathway of energy metabolism—the mitochondrial respiratory chain. The respiratory chain is essential for aerobic metabolism, and respiratory chain defects characteristically affect tissues and organs that are heavily dependent upon oxidative metabolism (such as the central nervous system, the eye, skeletal muscle, myocardium, and endocrine organs).

Recent studies have demonstrated the central role of the mitochondrion in the pathophysiology of well-established diseases such as Friedreich's ataxia and Wilson's disease, but these are not primarily disorders of the mitochondrial respiratory chain and are not considered here.

Biochemistry and genetics of the respiratory chain

The intermediary metabolism of carbohydrates, amino acids, and fatty acids generates the reduced cofactors NADH, NADPH, and $FADH_2$. These cofactors transfer electrons to the mitochondrial respiratory chain. As the electrons are passed through complexes I to IV of the respiratory chain along the inner mitochondrial membrane, protons are pumped out of the mitochondrial matrix into the intermembrane space. This creates an electrochemical gradient that is harnessed by complex V (ATP synthase) to generate ATP from ADP. Each respiratory chain complex contains many polypeptide subunits, some of which are coded by genes within the nucleus and some of which are encoded by the mitochondrial genome. Although all of the polypeptides encoded in mitochondrial DNA (**mtDNA**) have been known for over a decade, many nuclear genes involved in mitochondrial biogenesis have yet to be characterized.

The mitochondrial genome encodes seven complex I subunits (NADH-ubiquinone oxidoreductase), one of the complex III subunits (ubiquinol-cytochrome *c* oxidoreductase), three of the complex IV (cytochrome *c* oxidase, or **COX**) subunits, and the ATPase 6 and ATPase 8 subunits of complex V. Interspaced between the protein-encoding genes are two ribosomal RNA genes (12S and 16S rRNA), and 22 transfer RNA genes that provide the necessary RNA components for the mitochondrial translation machinery. The remaining polypeptides, including all of the complex II subunits, are synthesized from nuclear gene transcripts within the cytosol. These are subsequently imported into the mitochondria through the inner and outer membrane translocation complexes. There are many additional proteins that are essential for the normal assembly and function of the mitochondrial respiratory chain. As a result, mitochondrial respiratory chain disorders can be due to mutations affecting both nuclear and mitochondrial genes.

The classification and investigation of mitochondrial respiratory chain disorders has been revolutionized by the recent advances in our understanding of the underlying genetic defects. By the year 2000, over 70 different point mutations and over 100 different deletions of mtDNA had been associated with a wide variety of different diseases. One factor that contributes to the frequency of mitochondrial mutations is the absence in mitochondrial DNA polymerase of the 'proof-reading' property of nuclear DNA polymerase where exonuclease activity greatly enhances the fidelity of replication. Very recently a number of nuclear genetic defects have been identified in some patients with respiratory chain defects (Table 1).

Basic mitochondrial genetics

There are two main differences between nuclear DNA and mtDNA that are important for the expression and transmission of mitochondrial genetic disease, as follows.

Heteroplasmy and the threshold effect

Each mammalian cell contains over 1000 copies of the small (16.5 kb) mitochondrial genome; there are on average 5 to 15 mtDNA molecules in each organelle. Individuals with mtDNA disease often harbour a mixture of mutated and wild-type (normal) mtDNA—a situation known as heteroplasmy. Single cells only express a respiratory chain defect when the proportion of mutated mtDNA exceeds a critical threshold. Different organs, and even adjacent cells within the same organ, may contain different amounts of mutated mtDNA. This variability, coupled with tissue-specific differences in the threshold and the varied dependence of different organs on oxidative metabolism, explains in part why certain tissues are preferentially affected in patients with mtDNA disease. In general, postmitotic (non-dividing) tissues such as neurones, skeletal and cardiac muscle, and endocrine organs harbour much higher levels of mutated mtDNA and are often clinically involved. In contrast, rapidly dividing tissues such as the bone marrow are only rarely clinically affected (one example is Pearson's syndrome—see below).

Maternal inheritance and the transmission of heteroplasmy

After fertilization of the oocyte, sperm mtDNA is actively degraded. As a consequence, mtDNA is transmitted exclusively down the maternal line. This means that affected males with mtDNA disease cannot transmit the genetic defect. Deleted molecules are rarely, if ever, transmitted from clinically affected females to their offspring. By contrast, a female harbouring a heteroplasmic mtDNA point mutation, or mtDNA duplications, may transmit a variable amount of mutated mtDNA to her children. Early during development of the female germ line, the number of mtDNA molecules within each oocyte is reduced before being subsequently amplified to reach a final number of around 100 000 in each mature oocyte. This restriction and amplification (also called the mitochondrial 'genetic bottleneck') contributes to the variability between individual oocytes, and the different levels of mutant mtDNA seen in the offspring of a single female.

Clinical presentation of respiratory chain disorders

Mitochondrial encephalomyopathies are highly variable both clinically and at the genetic level. The same clinical syndrome can be caused by different genetic defects (which may be within nuclear or mitochondrial genes), but the same genetic defect may present in a variety of different ways. In general, adults who present with mitochondrial disease are often found to have a defect of mtDNA. Children often present with different clinical features and are more likely to have a nuclear genetic defect. It is often possible to identify well-defined clinical syndromes, but many patients present with a collection of clinical features that are highly suggestive of respiratory chain disease but do not fit into a discrete clinical category.

Defined clinical syndromes (Table 2)

Large-scale deletions can cause chronic progressive external ophthalmoplegia and bilateral ptosis. Some of these patients have minimal disability and may have limited skeletal muscle involvement. In contrast, similar deletions may also cause chronic progressive external ophthalmoplegia with bilateral sensorineural deafness, cerebellar ataxia, pigmentary retinopathy, diabetes mellitus, and cardiac conduction defects leading to complete heart block. When this begins in teenage years and is associated with a raised cerebrospinal fluid protein, it is called the Kearns–Sayre syndrome, which is a progressive neurological disorder associated with severe disability. Hypopara-thyroidism and hypothyroidism are well-recognized features of Kearns–Sayre syndrome. The vast majority of cases of chronic progressive external ophthalmoplegia and Kearns–Sayre syndrome are sporadic. These two syndromes are the extremes of a spectrum of disease and many individuals lie somewhere between the pure extraocular muscle and severe central neurological phenotypes.

Pearson's syndrome of exocrine pancreatic failure, sideroblastic anaemia, and marrow panhypoplasia is usually due to a mtDNA deletion. Pearson's syndrome usually presents in infancy and a number of individuals who have survived into later childhood subsequently developed the Kearns–Sayre phenotype.

Pathogenic point mutations of mtDNA are more common than rearrangements. This is partly because mtDNA deletions cause sporadic disease, whereas many mtDNA point mutations are transmitted down the maternal line. The A3243G mutation in the leucine (UUR) tRNA gene was first described in a patient with mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS). Different families harbouring the same genetic defect may have different phenotypes. For example, some families harbouring A3243G have predominantly diabetes and deafness, some families have chronic progressive external ophthalmoplegia, and some present with a cardiomyopathy. It is currently not known why this is the case but it is likely that additional nuclear genetic factors play an important role in modifying the expression of the primary mtDNA defect. This single mutation is important since it has been estimated that between 0.5 and 1.5 per cent of cases of diabetes mellitus in the general population are associated with the A3243G mutation.

Patients may present with myoclonic epilepsy, ataxia, optic atrophy, and have ragged-red fibres in skeletal muscle (MERRF) and this may also be due to a point mutation of mtDNA (for example A8344G).

mtDNA mutations are the major cause of visual loss in young adult males. About half of all males who harbour one of three point mutations of mtDNA (G11778A, T14484C, G3460A) develop bilateral sequential visual loss in the second or third decade—a disorder known as Leber's hereditary optic neuropathy (LHON). The majority of individuals with these mutations are homoplasmic—harbouring only mutated mtDNA. It is not clear why the disease only affects approximately half of the males and 10 per cent of females who inherit the primary mtDNA defect. Environmental factors, such as alcohol and tobacco, partly explain the variable penetrance of this disorder; however, additional, as yet unknown, nuclear genetic factors may also be important.

Leigh syndrome (subacute necrotizing encephalomyopathy) is a relapsing encephalopathy with prominent cerebellar and brainstem signs that usually presents in childhood and is associated with characteristic neuroimaging abnormalities involving the basal ganglia. Leigh syndrome can be due to an X-linked pyruvate dehydrogenase deficiency or a defect of the mitochondrial respiratory chain. Complex I deficiency or COX deficiency are common findings in Leigh syndrome. In these patients it may be possible to identify recessive mutations in nuclear complex I genes, or genes involved in the assembly of the respiratory chain complexes (for example *SURF 1*). Point mutations at position 8993 in the ATPase 6 gene of mtDNA may cause neurogenic weakness with ataxia and retinitis pigmentosa. These particular mutations are also associated with some forms of childhood Leigh syndrome.

COX deficiency may also present in childhood with an infantile myopathy and a severe lactic acidosis, which may also be associated with a cardiomyopathy and the Toni–Fanconi–Debre syndrome. Despite maximal supportive intervention, this is usually a fatal disorder and a severe depletion of mtDNA occurs in a proportion of these cases. It is important to recognize that isolated myopathy and lactic acidosis may be self-limiting, often with a significant improvement by 1 year of age and complete resolution by the age of 3 years.

Non-specific clinical presentations

Although the foregoing diseases and numerous other syndromes may strongly suggest a mitochondrial aetiology (Fig. 1 and Table 2), many patients do not present with a characteristic phenotype. Children may present in the neonatal period with a metabolic encephalopathy and systemic lactic acidosis, often associated with hepatic and cardiac failure. This may be associated with a depletion in the total amount of mtDNA within affected tissues. Although this syndrome may be fatal, in some it is a self-limiting disorder. Childhood presentations may be even less specific, with neonatal hypotonia, feeding and respiratory difficulties, and failure to thrive. A respiratory chain defect should be considered in any patient who has a disease with multiple organ involvement, particularly if there are central neurological features (such as seizures and dementia), a myopathy, cardiomyopathy, and endocrine abnormalities such as diabetes mellitus (Fig. 1). Bilateral sensorineural deafness and ocular features (retinopathy, optic atrophy, ptosis, and ophthalmoparesis) are common. Renal tubular defects, gastrointestinal hypomotility, cervical lipomatosis, and psychiatric features are also well described in patients with respiratory chain disease.

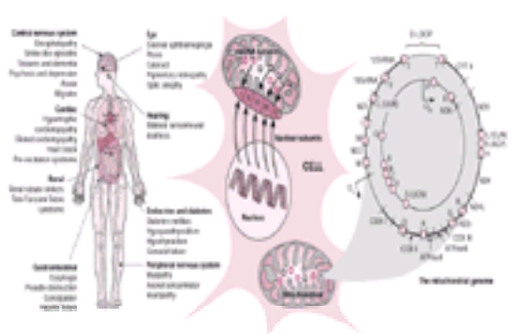

Fig. 1 The clinical features and biochemical and molecular genetic basis of mitochondrial encephalomyopathies.

Investigation of respiratory chain disease

The investigation of patients with a suspected mitochondrial encephalomyopathy involves the careful assimilation of clinical and laboratory data. In a significant proportion of cases (such as Leber's hereditary optic neuropathy), it is possible to identify a specific clinical syndrome with a clear maternal family history. Under these circumstances it is appropriate to carry out a molecular genetic test on a blood sample. In many situations, particularly in sporadic cases, this is not appropriate because the clinical features overlap with those of many other disorders. Even if the patient has a mitochondrial disorder, numerous different genetic defects may be responsible, some of which will not be detectable by analysis of blood samples.

Investigations fall into two main groups: clinical investigations used to characterize the pattern and nature of the different organs involved, and specific investigations to identify the biochemical or genetic abnormality.

General clinical investigations

It is essential to search for the more common features of respiratory chain disease. This includes cardiac assessment (ECG and echocardiography) and endocrine assessment (oral glucose tolerance test, thyroid function tests, alkaline phosphatase, fasting calcium, and parathyroid hormone levels). The organic and amino acids in urine may be abnormal even in the absence of overt tubular disease. Measuring blood and cerebrospinal fluid lactate levels is more helpful in the investigation of children than adults. These measurements must be interpreted with caution because there are many causes of blood and cerebrospinal fluid lactic acidosis, including fever, sepsis, dehydration, seizures, and stroke. The cerebrospinal fluid protein may be elevated. The serum creatine kinase level may be raised but is often normal. Neurophysiological studies may identify a myopathy or neuropathy. Electroencephalography may reveal diffuse slow-wave activity consistent with a subacute encephalopathy, or evidence of seizure activity. Cerebral imaging may be abnormal, showing lesions of the basal ganglia, high signal in the white matter on MRI, or generalized cerebral atrophy.

Specific investigations

A skeletal muscle biopsy is invaluable in the investigation of respiratory chain disease. Histochemical and biochemical investigations, in conjunction with the clinical assessment, often indicate where the underlying genetic abnormality must lie.

Histochemistry and biochemistry

Histochemical analysis may reveal subsarcolemmal accumulation of mitochondria (so-called 'ragged-red' fibres), or COX deficiency. A mosaic of COX-positive and COX-negative muscle fibres suggests an underlying mtDNA defect. Patients who have COX deficiency due to a nuclear genetic defect usually have a global deficiency of COX affecting all muscle fibres. Electron microscopy may identify paracrystalline inclusions in the intermembrane space, but these are non-specific and may be seen in other non-mitochondrial disorders. Respiratory chain complex assays can be carried out on various tissues. Skeletal muscle is preferable, but cultured fibroblasts are useful in the investigation of childhood mitochondrial disease. Measurement of the individual respiratory chain complexes determines whether an individual has multiple complex defects that would suggest an underlying mtDNA defect, involving either a tRNA gene or a large deletion. Isolated complex defects may be due to mutations in either mitochondrial or nuclear genes.

Molecular genetic investigations

Under certain circumstances, the clinical and biochemical features may point towards a specific genetic defect, and it may be possible to detect this abnormality in a blood sample. Children presenting with Leigh syndrome and who have an isolated deficiency of one of the respiratory chain subunits may have a point mutation within the nuclear-encoded respiratory chain subunit or assembly genes. These have been identified by direct sequencing of the appropriate exons.

For some mtDNA defects (particularly mtDNA deletions) the abnormality is not detectable in a DNA sample extracted from blood, and the analysis of DNA extracted from muscle is essential to establish the diagnosis. The first stage is to look for mtDNA rearrangements or mtDNA depletion by Southern blot analysis and long-range polymerase chain reaction (**PCR**). This is followed by PCR or restriction fragment length polymorphism analysis for common point mutations. Many patients with mitochondrial disease have a previously unrecognized mtDNA defect and it is necessary to sequence directly the mitochondrial genome. Interpretation of the sequence data can be extremely difficult. mtDNA is highly polymorphic and any two normal individuals may differ by up to 60 base pairs. In the strictest sense, a mutation can only be considered to be pathogenic if it has arisen independently several times in the population, it is not seen in controls, and it is associated with a potential disease mechanism. These stringent criteria depend upon a good knowledge of polymorphic sites in the background population. If a novel base change is heteroplasmic, this suggests that it is of relatively recent onset. Family, tissue segregation, and single cell studies may show that higher levels of the mutation are associated with mitochondrial dysfunction and disease, which strongly suggests that the mutation is causing the disease.

Management

There is currently no definitive treatment for patients with mitochondrial disease. Management is aimed at minimizing disability, preventing complications, and genetic counselling.

Supportive care and surveillance

Many patients with mitochondrial disorders require follow-up over many decades. An integrated approach is essential involving the primary physician, other specialist physicians (ophthalmology, diabetes, and cardiology), specialist nurses, physiotherapists, and speech therapists. Vigilant clinical monitoring over many years can prevent the development of complications, such as those secondary to cardiac and endocrine involvement. Specific procedures may be indicated at various stages of disease. These include cardiac pacing, ptosis correction, cataract surgery, and percutaneous gastrostomy.

Genetic counselling

The detailed investigation of patients with respiratory chain disease usually leads to a specific molecular genetic diagnosis, particularly in adults. This has profound implications on the counselling given to patients and their families. Most children with respiratory chain disease are compound heterozygotes with recessive nuclear gene mutations. If it is possible to identify the causative mutations in both the offspring and parents, then this will allow confident genetic counselling for the whole family. If, as in many cases, it is not possible to identify the underlying gene defect, or the genetic defect in the affected child cannot be traced back to the parents, then counselling is less straightforward.

If a causative mtDNA defect is identified, then the implications for counselling are distinctly different. Males cannot transmit pathogenic mtDNA defects. Patients who carry mtDNA deletions rarely have a family history suggestive of mtDNA disease, and there is no significant risk that they will transmit the mtDNA defect to any offspring. There are a few rare exceptions to this rule where the propensity to develop mtDNA deletions is transmitted as an autosomal dominant or autosomal recessive trait. By contrast, women harbouring pathogenic mtDNA point mutations may transmit the genetic defect to their offspring. The mitochondrial genetic 'bottleneck' leads to a variation in the proportion of mutated mtDNA that is transmitted to any offspring (see above). It is therefore possible for a female to have mildly affected as well as severely affected children. The risk of having affected offspring varies from mutation to mutation, and although there does appear to be a relationship between the level of mutated mtDNA in the mother and the risk of affected offspring, there are insufficient data from prospective studies to allow accurate risk prediction.

Prognosis

In general the prognosis depends upon the extent of central neurological involvement. Patients with Leber's hereditary optic neuropathy rarely have significant central neurological features and have a normal lifespan. The prospect for visual recovery varies. After the initial nadir, individuals harbouring the G11778A mutation are the least likely to regain functional vision, whilst those harbouring the T14484C mutation are the most likely to regain their sight.

Children presenting with an encephalopathy have a poor prognosis. Although residual neurological deficits are common after repeated childhood encephalopathic episodes, the disease may enter a more stable 'chronic' phase during teenage years and adulthood. A similar course may be seen in adults presenting with a relapsing encephalopathy. In contrast, a large proportion of adults with mtDNA defects and chronic progressive external ophthalmoplegia have very mild disease that may remain limited to the extraocular muscles for many decades. For certain mutations, there also appears to be a relationship between the proportion of mutated mtDNA in skeletal muscle and the severity of the disease. Although the proportion of mutated mtDNA in muscle may give some guide to prognosis, there is insufficient information available to allow accurate prognostic counselling based upon these determinations. A significant proportion of patients have distinct phenotypes associated with unique genetic defects and the prognosis must be guarded in these families.

Pharmacological treatments and novel approaches under development

Standard doses of vitamin C and K, thiamine, riboflavin, and ubiquinone (coenzyme Q10) may be of some benefit. These treatments have no significant side-effects and are relatively cheap, but their efficacy is largely based upon anecdotal reports. Novel treatments are, however, under development. Dichloracetate can be used to reduce lactic acid levels but may cause an irreversible toxic neuropathy. The efficacy of dichloracetate is currently being assessed in clinical trials. Exercise is important for patients with mtDNA disease, and isometric muscle contraction may lead to an improvement in muscle strength. Drug-induced muscle necrosis followed by proliferation of myoblasts may also be important for the treatment of mitochondrial myopathy and ptosis, but this approach is only at the experimental stage. Finally, several centres are investigating methods for correcting the underlying mtDNA defect by gene therapy.

24.22.6 Tropical pyomyositis (tropical myositis)

D. A. Warrell

Definition

The term 'tropical pyomyositis' should be restricted to primary muscle abscesses arising within skeletal muscles. This condition must be distinguished from abscesses extending into muscle either from subcutaneous sites following infection through the skin, or from osteomyelitis or suppuration originating in tissues other than muscle.

Geographical occurrence

Tropical myositis has been reported from most parts of tropical Africa, Malaysia, Thailand, India, Indonesia, Oceania, Central and South America, and the Caribbean. It is common in many tropical countries, accounting for 4 per cent of admissions to a hospital in Uganda and for 2.2 per cent of all surgical admissions to a hospital in eastern Ecuador. In temperate climates, pyomyositis was extremely rare, but is becoming more common in patients immunosuppressed due to the human immunodeficiency virus (**HIV**), lymphomas, chemotherapy of malignant diseases, asplenia, Felty's syndrome, and other conditions.

Aetiology

Staphylococcus aureus is the organism most commonly cultured from the abscesses. *Streptococcus pyogenes* (usually group A) is responsible for a few cases, but tropical pyomyositis must be distinguished from streptococcal necrotizing myositis (also known as peracute streptococcal pyomyositis or spontaneous streptococcal gangrenous myositis) which is more fulminant and diffuse and has a very high mortality. Other isolates have included *S. pneumoniae*, *Haemophilus influenzae*, *Escherichia coli*, *Pseudomonas* species, and anaerobes. In Thailand, most cases of pyomyositis are caused by *Burkholderia pseudomallei*. The strikingly different incidence of pyomyositis in tropical and temperate countries has not been explained. In Africa and South America, the condition appears to be relatively more common in indigenous peoples. A history of preceding trauma to the affected muscle is obtained from more than 20 per cent of patients in most series. It has been suggested that, by analogy with osteomyelitis, a muscle haematoma provides a nidus for blood-borne infection. A number of predisposing causes has been suggested: preceding viral infection (for example, an arbovirus), general debilitation, and nematode infections—particularly toxocariasis, *Lagochilascaris minor*, and filariasis. None has been supported by convincing evidence, but sickle-cell disease may be a genuine predisposing cause in a minority of cases. Most of the abscesses associated with helminth infections should not be termed 'pyomyositis' as they are inter- rather than intramuscular. For example, *Dracunculus medinensis* can give rise to deep intermuscular abscesses secondarily infected with *Staphylococcus aureus*.

Pathology

The abscesses may be large, are usually loculated, and are situated within skeletal muscles beneath the deep fascia. Histologically, there is focal muscle necrosis with an infiltration of mononuclear cells and inflammatory oedema.

Clinical features

Tropical pyomyositis can occur at any age but its highest incidence is in the second decade. It is commoner in males. The earliest symptom is pain and tenderness of the affected muscle. Any of the skeletal muscles may be involved, but those of the trunk and lower limbs are the most commonly affected. Usually there is a single localized abscess, but multiple abscesses in distantly separated muscles can occur. At an early stage, an ill-defined tender and thickened area may be palpable in the muscle. Later, a localized, very tender, and hot swelling is palpable. There may be redness and oedema of the overlying skin, but the skin is not primarily involved. The swelling is usually non-fluctuant and there is no local lymphadenopathy. Symptoms and signs usually develop over a few days. Peripheral leucocytosis is not invariable. Eosinophilia is frequently described but is usually common in the populations most affected by tropical pyomyositis. In spite of considerable muscle destruction at the site of the abscess, serum concentrations of muscle enzymes may not be elevated, but in some cases there is myoglobinaemia, myoglobinuria, and acute renal failure. Complications are uncommon, but consist of spread of infection from the affected muscle to other structures such as joints resulting in septic arthritis, to the pleural cavity resulting in empyema, or by haematogenous spread to the heart valves. Mortality in inpatients is said to be less than 1.5 per cent.

Diagnosis

The differential diagnosis is from pus tracking from abscesses in other organs and tissues, muscle haematomas, torn muscles, certain highly vascular or necrotic tumours of connective tissue or muscle (such as rhabdomyosarcoma), and the inflammatory and allergic swellings resulting from the migration of helminths such as *Loa loa* and *Gnathostoma*, *Paragonimus*, and sparganum spp. *Staphylococcus aureus* is usually cultured from the pus, but blood cultures are positive in less than 5 per cent of cases. Ultrasound, computed tomography (**CT**), and especially magnetic resonance imaging (**MRI**) scans are useful for localizing abscesses and guiding needles for diagnostic and therapeutic aspiration.

Treatment

Full surgical exploration, debridement, and drainage are essential. Because the abscesses are usually loculated, needle aspiration is inadequate. Parenteral treatment with a b-lactamase-resistant penicillin (flucloxacillin) should be started immediately, but if group A *Streptococcus* is cultured, benzyl penicillin or clindamycin are the drugs of choice.

25 The eye in general medicine

Peggy Frith

The significance of disorders of the eye in general medicine

Because the eye may be involved in so many diseases, it is essential that clinicians are familiar with ocular manifestations, learn how to examine the eye, and in particular, are proficient with the ophthalmoscope. Ocular findings may point to the diagnosis of a particular systemic disorder and in some cases an eye complication may need urgent and specific treatment.

Red eye

The pattern of redness suggests a possible diagnosis and other features help to confirm this, as shown in Table 1. The slit lamp shows specific features found in some types of conjunctivitis, the staining pattern of corneal lesions, cells diagnostic of uveitis within the eye chambers, and raised eye pressure of glaucoma. Iritis is described with ankylosing spondylitis, and scleritis with rheumatoid arthritis.

Dry eye

Lack of tears may have a systemic cause, particularly if there is also dryness of the mouth—sicca syndrome. Sicca with an identifiable systemic association is known as Sjögren's syndrome (as with rheumatoid arthritis, systemic sclerosis, mixed connective tissue disease), graft-versus-host disease, or sarcoidosis. The eyes feel gritty and are red or sticky (see rheumatoid arthritis below). Artificial tear drops can help, but severely dry eyes are a miserable problem which can be very difficult to manage.

Loss of vision

A clear history of the visual loss is important. Visual acuity should be measured in each eye, using glasses or a pinhole to correct for any error of focus. Major impairment of vision in one eye gives an asymmetrical pupil response to a bright light. There is a limited number of important causes within the retina or optic nerve (see Table 2).

The Ophthalmoscope

The optic nerve head is usually visible through an undilated pupil, but it is impossible to assess the retina reliably without using a mydriatic. Short-acting drops, such as tropicamide 1 per cent, work within 15 min and last about 2 h, with no risk of causing acute glaucoma. The pupil should not be dilated if the patient has a suspected subarachnoid haemorrhage, coma, or recent head injury. The central fovea is seen if the patient looks directly into the light, and in patients with diabetes the area temporal to the fovea should also be examined. A clouded view suggests opacity in the lens or vitreous, best seen by adjusting focus on to the pupil margin to give a red reflection against which opacities stand out as black shadows, especially if the pupil is dilated. The peripheral retina, for example in sickle-cell retinopathy, is best seen with the indirect ophthalmoscope.

Superficial flame-shaped haemorrhages, though not unique to hypertension, demand measurement of blood pressure. Deeper dot and blot haemorrhages temporal to the macula suggest diabetes, vein occlusion if unilateral or localized, or a haematological disorder if bilateral. Subhyaloid haemorrhage, confined in front of the retina and behind the vitreous, forms a dense focus which may sediment into a characteristic flat-topped shape, typical of bleeding from new vessels—as in diabetes or after retinal vascular occlusion—or secondary to a bleeding diathesis or trauma, including non-accidental injury. Most haemorrhages are asymptomatic and will resolve, but vision falls if the fovea is involved or if blood leaks into the vitreous itself, causing floaters.

Shiny hard exudates consist of protein and lipid; if in circles (circinate), focal vascular leakage may be associated with diabetes, whereas a star around the fovea forms with resolving retinal oedema, as in treated hypertension or papilloedema. Commonly confused with exudates are retinal drusen, which are more uniform and discrete, usually scattered around the retina or congregated close to the fovea. Cotton wool spots are fluffy pale patches indicating swollen nerve fibre axons at sites of microvascular closure. They are always significant (see Table 3). Retinal infiltrates look like cotton wool spots but consist of cells spilled into the vitreous. These are visible with the slit lamp, as in active toxoplasmosis, cytomegalovirus retinitis, sarcoidosis, Behçet's syndrome, or ocular lymphoma. Discrete punched-out scars suggest healed foci of inflammation of the retina and underlying choroid, of which the most common cause is toxoplasmosis.

Fluorescein angiography

This can define the type and severity of retinal vascular disorders. The dye, injected intravenously, demonstrates patterns of perfusion both in the retina and underlying choroidal circulation, outlines abnormalities of the vessels such as microaneurysms, and identifies sites of leakage indicating damage to retinal vessels or the formation of new vessels. Angiography is valuable diagnostically and indicates where laser treatment is needed. Anaphylactic reactions and even fatalities have been reported, so patients must be carefully selected.

Visual fields

The visual fields should be examined in patients with visual loss. Even large defects may go unnoticed. A unilateral central or altitudinal (top or bottom of field) defect suggests an anterior lesion, in retina or optic nerve; a bitemporal defect implicates the optic chiasm; and a homonymous defect the visual path posterior to the chiasm. With bilateral occipital infarction, visual loss may be difficult to define and pupil reactions are normal. A CT scan may be advisable. If there is unaccountably poor vision in one eye, a defect of focus or an amblyopic (lazy) eye resulting from a squint or refractive error in childhood may be responsible: the first should improve with a pinhole device but the second will not.

Eye changes in diabetes (Plate 1, Plate 2, Plate 3, Plate 4 and Plate 5)

Retinopathy, the most common serious eye complication in diabetes, is the principal reason for blind registration of younger adults from industrial countries. Annual retinal screening is essential, as early treatment can prevent blindness and patients with sight-threatening changes are often asymptomatic.

Older patients especially may have cataract, glaucoma, retinal vein occlusion, and occasionally ischaemic optic neuropathy. Diabetic eye disease is discussed fully in Chapter 12.11.1.

The eye in hypertension

In the hypertensive patient retinal changes will help determine if treatment is necessary, if it is adequate, or if it is needed urgently. Description of individual features is preferable to grading. Unless the pupil is dilated, it is easy to miss or to underestimate retinal changes. A bright halogen bulb and a green or 'red-free' filter helps accentuate vessels and haemorrhages. Haemorrhages or cotton wool spots, indicating acute changes, are most likely to be seen temporal and nasal to the optic nerve head, around the major vessels. Blurring of the margins of the optic nerve head, indicating disc oedema, must be excluded.

Long-standing hypertension and ageing produce similar changes. Arterioles are narrowed, irregular, or tortuous and the wall may be thickened, showing an increase in reflected light described as copper or silver wiring. There may be nipping at the arteriovenous crossings so that the underlying vein appears to be constricted. Long-standing changes often persist with treatment of hypertension but may be reversed in younger patients.

Classification of hypertensive retinopathy

Perhaps the best known grading of hypertensive retinopathy is the Keith–Wagner classification:

- Grade 1, mild narrowing or sclerosis of retinal arteries;
- Grade 2, moderate to marked narrowing or sclerosis with light reflex and arteriovenous crossing changes;
- Grade 3, in addition, haemorrhages or cotton wool spots; and
- Grade 4, in addition, swelling of the optic nerve head (papilloedema).

Grades 3 and 4 indicate severe, accelerated, or 'malignant' retinopathy, but disc swelling is no longer regarded as a reliable feature in assessing urgency for treatment—the prognosis is similar for grades 3 and 4.

Blood pressure high enough to damage the renal and cerebral circulation is best recognized by inspecting retinal vessels, even in the absence of visual symptoms. Diastolic pressure likely to be associated with severe retinal changes is usually 110 mmHg or higher at some stage. Proteinuria is almost invariable.

Acute, severe retinal changes indicate either leakage or closure of smaller vessels. Flame haemorrhages are seen particularly around the vessel trunks above and below the macula, temporal to the optic disc (Plate 6). These indicate leakage of blood from fine superficial capillary branches supplying the nerve fibre layer. Bleeding deeper in the retina forms blot-like haemorrhages which, if widespread or in a wedge shape from an arteriovenous crossing, indicate occlusion of the central or a branch retinal vein. Haemorrhages resolve with treatment of hypertension. Only foveal haemorrhage causes visual impairment.

Cotton wool spots indicate closure of capillaries supplying the nerve fibres. Microinfarcts cause stasis of axoplasmic flow and intra-axonal contents accumulate, distending and opacifying the fibres and producing the pale fluffy appearance. Spots gradually resolve with treatment. In the absence of hypertension, an

inflammatory vasculitis such as systemic lupus erythematosus should be suspected.

Hypertensive damage causes disruption of endothelial tight junctions in retinal vessels so that fluid, protein, and lipid leak into the extracellular spaces within the retina. These are removed by macrophages and processed into shiny hard exudates which may persist for many months. Hard exudates imply leakage for more than a matter of days. They are common in resolving hypertensive retinopathy, forming a characteristic star around the fovea. In hypertension, exudate rarely forms in the ring-shaped circinate pattern typical of diabetes.

Papilloedema implies hypertensive damage to the disc capillaries or cerebral oedema with raised intracranial pressure, attributable to hypertension. Sudden reduction of blood pressure may cause acute, sometimes irreversible, loss of vision also with a risk of stroke.

Histopathology

In the early phases of severe retinopathy there is disruption of endothelial cells or tight junctions followed by vessel wall damage leading to occlusion, sometimes with fibrinoid necrosis or frank thrombosis.

Non-retinal eye changes in hypertension

Occasional patients with severe hypertension, especially those with eclampsia or renal failure, may suffer pronounced visual loss secondary to occlusive changes in the vessels supplying the optic nerve head or in the choroid underlying the retina itself. The tissues become swollen and pale and the retina may even become detached by fluid. Rarely, patients with secondary hypertension may have eye manifestations of genetic disorders such as neurofibromatosis type 1, von Hippel-Lindau, or Sipple's syndrome (see below).

Ocular vascular occlusion

Retinal vascular occlusion is a common cause of blindness, especially in elderly patients. This can be a valuable warning of vascular disease elsewhere, particularly affecting the cerebral circulation.

Retinal artery occlusion

Occlusions of central retinal arteries or their branches, are almost always embolic, arising in the carotid system in the neck, or intracranially, or in the heart. Usually, they start abruptly with permanent loss of function once the retina has infarcted. Central artery occlusion results in profound loss of vision. Branch occlusion causes a visual field defect that often has a horizontal (altitudinal) edge which the patient may be able to define. Recovery of vision is unlikely but prognosis for the other eye is good, especially if an underlying cause can be corrected (Table 4).

Amaurosis fugax

Transient retinal ischaemia causes brief episodes of blindness limited to one eye (amaurosis fugax), usually lasting for a few seconds, some for up to a few minutes, rarely longer. Loss of vision may be total or partial, affecting the upper or lower half of the field like a blind moving up or down. Recovery is usually complete. Most attacks are painless and associated symptoms rare. There may be a history of cerebral transient ischaemic attacks on other occasions. Emboli have been seen passing through the retinal circulation during an attack, moving from central to branch arterioles where they may disperse or become permanently trapped.

Clinical findings

Initially, the infarcted retina swells and becomes opaque leaving a 'cherry' red spot at the fovea where the intact underlying choroidal circulation shows through. The territory of an occluded branch artery may become whitened for several days or a few weeks (Plate 7), then subside to leave thinned retina and narrowed, often sheathed, vessels. The optic nerve head may atrophy over ensuing months as the nerve fibres die. If much of the retina is infarcted, there is a defect in the afferent pupil response which persists when other signs have subsided. Emboli may be visible at any stage, in the central or branch vessels, often at a bifurcation. Most emboli are small, glistening white or yellow pieces of cholesterol from atheromatous plaque. Larger, round, solid white emboli, which usually lodge proximally within or near the disc in the larger vessels, may have come from a calcified heart valve, whereas fibrin and platelet emboli from thrombosed plaque or cardiac thrombus may look dark or grey.

Associated findings include an ipsilateral carotid bruit, heart murmur, or dysrhythmia (particularly atrial fibrillation), absent pulses or bruits at other sites, and hypertension.

Investigation and management

No treatment is worthwhile acutely, apart from firm ocular massage which might dislodge an unstable central embolus. Fluorescein angiography is necessary only if the clinical picture is not typical. Risk factors are assessed by measuring blood pressure, full blood count, blood sugar, lipids, and renal function. Even in the absence of a bruit, carotid Doppler ultrasonography is useful for detecting atheromatous plaque at the bifurcation, with a view to carotid surgery.

Management involves reducing risk factors such as smoking, hypertension, obesity, or other abnormalities. Patients unsuitable for surgery are given long-term aspirin.

Retinal vein occlusion

Retinal venous occlusion usually occurs *in situ*. Risk factors include age, hypertension, diabetes, haematological disorders, and glaucoma (Table 5). Symptoms develop less abruptly than with arterial occlusion. Commonly the patient wakes with blurred vision. With a central vein occlusion, haemorrhages are scattered throughout the fundus, the characteristic 'bloodstorm' pattern (Plate 8), often with cotton wool spots. Less complete block causes sparse scattered haemorrhages, but foveal oedema may impair vision. Branch vein occlusion, usually at an arteriovenous crossing, causes a wedge-shaped sector of haemorrhage in the area of drainage, its apex towards the optic disc. Vision may improve, depending on the state of the fovea, and the outlook for the opposite eye is good if risk factors are minimized. If the retina is ischaemic, the risk of retinal new vessel formation may be prevented by laser treatment. Acute signs of occlusion may persist for many weeks or months. Curly collateral vessels may develop at the disc or peripheral retina.

Investigation and management

Blood pressure, blood sugar, full blood count, and erythrocyte sedimentation rate should be measured. Ocular pressure is checked as glaucoma is a treatable risk factor. Plasma protein electrophoresis, viscosity, and blood coagulation (including antiphospholipid antibodies or lupus anticoagulant) are tested in younger patients, particularly if the changes are recurrent, bilateral, or associated with thrombosis elsewhere. Other possibilities include sarcoidosis or Behçet's syndrome, particularly if the patient describes floaters or the slit lamp shows inflammatory cells within the eye. Risk factors such as blood pressure, smoking, and obesity must be addressed. The benefit of long-term aspirin in patients with venous occlusion is unproven.

Chronic ocular ischaemia

Eye ischaemia is associated with arterial disease anywhere from the aortic arch to the ophthalmic artery. The eye is often painful and red with impaired vision. On slit lamp examination, intraocular pressure is low and there are dilated vessels on the iris with protein flare in the anterior chamber. Cataract may obscure dilated and tortuous retinal vessels, often with scattered haemorrhages. New vessels may form. In younger patients this syndrome may suggest congenital or acquired proximal arterial occlusion, particularly Takayasu's arteritis. In older patients, surgical relief of stenosis may save and even improve vision.

Occlusion of vessels supplying the optic nerve

Giant cell arteritis is associated with occlusion of ciliary (rather than the central retinal branches of the ophthalmic artery) causing acute ischaemia of the optic nerve

(see below). Some patients have non-inflammatory occlusion from atheroma. Rarely, acute optic nerve ischaemia, sometimes bilateral, is associated with catastrophic postpartum or gastrointestinal haemorrhage; prognosis for recovery of vision is poor.

The eye in systemic inflammatory diseases

Sarcoidosis

External eye

Asymptomatic sarcoid granulomas may occur in the eyelids or conjunctiva. They are solid, raised, of variable size, often clustered, and characteristically yellowish in colour. Biopsies may be made of them at slit lamp examination. 'Blind' biopsy of normal-looking conjunctiva is not fruitful. Dry eye is common causing grittiness, reduced Schirmer's test, fluorescein staining of the cornea, perhaps with enlarged lacrimal glands.

Uveitis

Iritis (anterior uveitis) is common. It is usually bilateral and recurrent; sometimes severe and damaging. Acutely, the eye is red, painful, and photophobic. Large, greasy precipitates, said to resemble mutton fat, are seen on the internal surface of the cornea by slit lamp. Granulomas may be visible; Busacca's (in the iris), Koeppe's (at the pupil margin). Repeated attacks of iritis cause cataract, glaucoma, or particularly if there is also hypercalcaemia, calcified corneal band keratopathy.

Posterior uveitis causes cells to appear in the vitreous, noticed by the patient as floaters. These may obscure the view of the fundus and may aggregate into characteristic strands or 'snowballs'. Granulomas in retina or choroid are visible as pale foci behind a haze of cells. Vision may be further impaired by fluid leaking from inflamed retinal vessels and collecting around the fovea. Inflamed retinal branch veins look dilated, irregular, later sheathed, and may be surrounded by inflammatory cells; fluorescein angiography shows a segmental pattern of leakage. Occlusive retinal phlebitis of branch veins, causing focal retinal haemorrhages, strongly suggests sarcoidosis. Differential diagnoses are Behçet's syndrome or 'idiopathic' retinal vasculitis without systemic features.

Sarcoid can also cause an optic neuropathy. Sarcoid granulomas behind the eye may cause exophthalmos or cranial nerve palsy.

Corticosteroids are given topically for anterior and systemically for posterior lesions.

Behçet's syndrome (see also Chapter 18.10.5)

Uveitis (iritis and retinal vasculitis) is a defining feature of Behçet's syndrome. Recurrent attacks progressively damage the eye with risk of blindness. In Japan and Turkey, Behçet's syndrome is the commonest cause of uveitis. The incidence in northern Japan is about 1 per 10 000 population, of whom roughly 75 per cent have ocular inflammation at some stage. Untreated, blindness results in 50 per cent of eyes within 5 years of the first ocular attack. Males with the HLA B5 haplotype, particularly the BW51 subtype, are at highest risk of eye disease.

Ocular inflammation is usually bilateral, sometimes with a gap of many years between involvement of each eye. Iritis is typically acute with pain, redness, and photophobia. Hypopyon is characteristic but not unique to Behçet's syndrome (Plate 9). Attacks may settle spontaneously, but the eye may be damaged so short intensive courses of corticosteroid drops and mydriatics are recommended.

Retinal vasculitis particularly involves capillaries and branch veins. Inflammatory cells spill into the vitreous giving rise to floaters. Inflamed vessels leak, causing foveal oedema and an increase in visual impairment with distortion of central vision and risk of permanent foveal damage. Occlusion of inflamed branch veins causes haemorrhages and cotton wool spots (Plate 10). Vision is permanently affected if occlusion involves the fovea. Fluorescein angiography indicates severity of leakage and closure. With recurrent attacks, the retina gradually dies, vessels become sheathed, and the optic nerve head atrophies. Neovascularization may cause vitreous haemorrhage. Acute retinal infiltration with polymorphonuclear leucocytes causes white fluffy patches which indicate active inflammation, strongly suggestive of Behçet's syndrome.

Management is difficult. No regime of immunosuppression tolerable in the long term will prevent all inflammation. Systemic corticosteroids limit acute damage. Longer-term agents such as azathiaprine, clorambucil, colchicine, or cyclosporin A seem to be helpful but their impact on blindness is uncertain.

In a patient dying of cerebral involvement 10 years after the onset of treated eye disease there were collections of T_4 lymphocytes within and around walls of retinal vessels. Many cells were positive for interleukin 2, and HLA DR-positive cells were found in eye tissue, despite heavy immunosuppression.

Giant cell arteritis

Ischaemic, irretrievable visual loss is a feared complication. On systemic corticosteroid treatment the risk of visual loss and blindness falls, provided initial doses are adequate. Patients presenting with visual loss are at high risk of further loss in that eye or of rapid involvement of the second eye; they should be started on high doses until the symptoms, erythrocyte sedimentation rate, and C-reactive protein are controlled. This usually takes days rather than weeks. In patients presenting with bilateral involvement, intravenous methylprednisolone is justified. Temporal artery biopsy is val-uable and helps to confirm the diagnosis and the need for continued treatment in patients with visual loss.

Vision may be lost overnight or during the daytime. Patients may have experienced episodes of transient visual loss in the preceding weeks or days. Initially loss may be partial involving either the top or bottom half of the visual field, but often becomes total. The optic nerve head is characteristically pale and swollen (Plate 11). The afferent pupil response is usually decreased compared with the normal eye. Occlusion of the central retinal artery, producing a pale retina and cherry-red foveal spot, is uncommon.

Takayasu's arteritis

This is an inflammatory disorder involving large arteries which can cause an aortic arch syndrome with raised erythrocyte sedimentation rate and C-reactive protein, typically in younger patients. There may be amaurosis fugax or retinal vascular changes of chronic ocular ischaemia, sometimes with anastomoses at the optic nerve head, or scleritis or iritis.

Wegener's granulomatosis

Episcleritis is very common in the active stages and many patients notice that their eyes become red when the disease flares. Occasionally there is a more severe painful scleritis involving the cornea with the risk of corneal thinning and even perforation. Acutely the eye is red and the slit lamp may reveal infiltrates of inflammatory cells in the peripheral cornea. Scleritis and sight-threatening sclerokeratitis respond poorly to topical treatment and require systemic immunosuppression. A pulsed intravenous regime may be needed for initial control.

In patients with 'limited' Wegener's granulomatosis of the upper airway, the orbit may be involved, usually secondarily to disease in the adjacent sinuses but sometimes in isolation. Retro-orbital granuloma produces proptosis, usually painful, and may involve cranial nerves including the optic nerve, with an acute threat to vision (Plate 12). Some patients have a positive antineutrophil cytoplasmic antibody (ANCA) test, although the titres may be low. Many respond to immunosuppression, but high doses may be required for local control.

Polyarteritis nodosa

Inflammation of the eye coat, similar to Wegener's granulomatosis, may produce episcleritis, scleritis, or keratitis. Complications may be severe, requiring systemic immunosuppression. The retinal vessels may be involved, with or without hypertensive changes, and branch arteriolar closure is characteristic. Uveitis is not a

feature.

Relapsing polychondritis

This systemic inflammatory disorder involving cartilage is associated with inflammation of the eye coat, similar to rheumatoid arthritis. Half the patients will have eye features at some stage. Episcleritis and scleritis are most common, sometimes with severe corneal features similar to Wegener's granulomatosis and polyarteritis nodosa. Uveitis, retinitis, Sjögren's syndrome, and ischaemic optic neuropathy also occur.

Systemic lupus erythematosus

Episcleritis may occur with exacerbations in systemic lupus activity; the more serious scleritis is uncommon. Retinal vascular occlusions—particularly venous but sometimes branch arterial—may be linked with the antiphospholipid syndrome. Retinopathy with cotton wool spots is associated with active vasculitis, anaemia, and perhaps, moderate hypertension. Ischaemic optic neuropathy with acute irretrievable loss of vision is unusual. Some patients, particularly those with mixed connective tissue disease, have Sjögren's syndrome. Uveitis is not a feature of systemic lupus. Cutaneous lupus may involve the eyelids with oedema and the lid margins may develop scarring inflammatory plaques.

Dermatomyositis

Purple coloration of the eyelids and oedema of the lids and conjunctiva are typical findings. Less common is retinal ischaemia with microinfarcts.

Kawasaki's disease

Bilateral conjunctivitis without discharge is a cardinal feature of Kawasaki's syndrome, characteristically found in young children. Other features are fever, rash, lymphadenopathy, and changes in the other mucosa and nails. Cells may be found in the anterior chamber (mild iritis) and cornea (keratitis) using the slit lamp. The eyes do not need specific treatment.

Multiple sclerosis

Uveitis can occur in multiple sclerosis. Low-grade subtle changes, such as sheathing of the peripheral retinal veins with inflammatory cells within the vitreous, are common in patients with optic neuritis. Fluorescein angiography reveals inflammation and leakage of the retinal veins even though the retina itself does not usually contain myelin. Association of ocular and neurological features also occurs in sarcoidosis and Behçet's syndrome, but in these conditions eye inflammation is usually more pronounced.

Vogt–Koyanagi–Harada syndrome

This curious and uncommon clinical syndrome comprises deafness or meningoencephalitis with cerebrospinal fluid lymphocytosis in the acute stages and bilateral pan uveitis, almost exclusively in patients of Asian origin. There are HLA associations. Inflammatory cells collect within the retinal pigment epithelium and may cause fluid detachment of the retina or deeper layers, associated with decreased vision. There is a response to systemic corticosteroids, with relapses if the dose is reduced. In the chronic phase of the disease there is depigmentation of skin, hair, or eyelashes (poliosis).

Cogan's syndrome

In young adults, especially males, eye inflammation may be associated with deafness or vestibular dysfunction and proximal aortitis or inflammation of medium-sized arteries. Keratitis with patchy cell infiltration in the corneal stroma may lead to corneal vascularization, as in syphilitic keratitis. Some patients have anterior uveitis, scleritis, inflammation of the eye coat, or retinitis. The disorder responds to systemic corticosteroid, which may prevent total deafness if given early enough.

Inflammatory bowel disease

About 10 per cent of patients with Crohn's disease have episcleritis, scleritis, or iritis. Corneal or retinal inflammation is uncommon. Episodes of episcleritis may be associated with exacerbation of the bowel disorder. Eye problems are less common in ulcerative colitis.

Pancreatitis

Ischaemic retinopathy and acute visual loss may occur. There is retinal oedema with cotton wool spots. Fluorescein angiography shows closure of branch retinal arterioles and capillaries, with patches of retinal non-perfusion.

Whipple's disease

This rare disorder is suggested by the association of a malabsorbing enteropathy with arthritis, ocular inflammation, or particular neurological features. There are retinal haemorrhages, diffuse retinal and choroidal vasculitis with cells in the vitreous, or keratitis. Central nervous system features include cranial nerve palsies, papilloedema, and brainstem involvement. The diagnosis is confirmed by small bowel biopsy (see Chapter 14.9.6).

Rheumatoid arthritis

The commonest problem is keratoconjunctivitis sicca, apparently due to autoimmune damage to lacrimal tissue with lymphocytic infiltration and destructive fibrosis. The eyes are uncomfortable, gritty, and often sticky due to low-grade lid infection and poor flushing of the eye surface. Signs include reduced Schirmer's test and staining of the conjunctiva with fluorescein where epithelial cells are shed, particularly of the surface exposed between the eyelids. Symptoms may respond to topical tear substitutes containing methylcellulose: most common is hypromellose. In some patients filaments of adherent mucus may disperse with topical acetyl cysteine treatment (Ilube). Severe dry eye is best managed by a specialist who will watch for complications, particularly corneal ulceration. Other systemic conditions associated with Sjögren's syndrome include systemic sclerosis, mixed connective tissue disease, lupus erythematosus, and sarcoidosis.

Episcleritis is common and may indicate an exacerbation of systemic activity. It rarely needs treatment, but may respond to oral non-steroidal anti-inflammatory agents.

Scleritis, usually found in patients with active vasculitis, is more serious. The eye is usually painful, red, and boggy. The inflammatory process may spread from the posterior eye into the internal eye or to the orbit. Any patient with rheumatism and a painful eye should be referred for specialist assessment, even if the eye is white. Scleritis is an ischaemic vasculitic process involving the vessels which supply the sclera. It responds best to systemic immunosuppression with corticosteroids, sometimes with a cytotoxic agent. Pulsed intravenous treatment may be needed to control the acute attack. Untreated scleritis may cause scleral thinning (Plate 13), corneal ulceration, and perforation of the eyeball. Patients are rarely suitable for corneal grafting.

Ankylosing spondylitis

Ankylosing spondylitis is the most common association with iritis in young patients, particularly men, who should be asked about pain and stiffness of the spine or sacroiliac joints. Radiographs of lumbar spine or sacroiliac joints, or HLA B27 haplotype may be positive. One-third of patients with ankylosing spondylitis will develop eye features at some stage.

The eye is painful, aching, photophobic, and red. The slit lamp shows the cells diagnostic of iritis floating in the anterior chamber and sedimented on the back surface of the cornea as keratic precipitates (Plate 14). Posterior synechias may form, often with the iris constricted: a mydriatic may break these adhesions. This treatment should be continued until inflammation has settled so that the pupil remains large and the iris mobile. Inflammatory cells usually clear quite rapidly with 1 to 2 weeks of topical corticosteroids. Patients with ankylosing spondylitis should be warned that recurrent iritis should be treated early and effectively; there is a 50 per cent chance

of recurrence.

Reiter's syndrome

Arthritis, urethritis, cervicitis, or colitis together suggests Reiter's syndrome, especially in HLA B27-positive patients. A self-limiting sterile conjunctivitis is common in the early stages, causing a red sticky eye. Later, iritis may be the dominant recurrent feature. Features and management are similar to ankylosing spondylitis. Other differential diagnoses of arthritis with iritis include sarcoidosis, Behçet's syndrome, psoriasis, and gonorrhoea, with intestinal involvement, inflammatory bowel disease, or Whipple's disease. Sometimes, posterior uveitis, scleritis, or keratitis develop.

Juvenile chronic arthritis

Children most at risk have chronic, seronegative, pauciarticular disease, perhaps involving only one digit or an ankle, especially younger girls positive for antinuclear antibody. The picture is usually one of a low-grade recurrent iritis over several months or years. There may be no symptoms or redness of the eye in the early stages; slit lamp examination is essential. Cells appear in the anterior chamber when inflammation is active. Untreated inflammation can damage the cornea, lens, and aqueous drainage causing band keratopathy, cataract, glaucoma, and risk of blindness. Topical treatment may prevent secondary problems, but some patients will lose useful vision in both eyes. Other causes of iritis in children include sarcoidosis, ankylosing spondylitis, toxocariasis, leukaemia, and retinoblastoma.

Ocular features of blood disorders

Retinal changes are common in haematological disorders even if vision is normal. Bilateral changes result from anaemia, hyperviscosity, and haemostatic abnormalities. The signs are easily missed unless the pupils are dilated.

Hypoxia or hyperviscosity cause retinal vein enlargement, scattered retinal haemorrhages, and cotton wool spots: 'slow flow' or 'stasis' retinopathy. If blood pressure and blood sugar are normal, bilateral retinal haemorrhages suggest a blood disorder. Full blood count, erythrocyte sedimentation rate, and plasma protein electrophoresis should be checked. Roth spots, haemorrhages with a white centre, occur in leukaemia and hyperviscosity. Blood may leak in front of the retina to form a dense, rounded, often boat-shaped, subhyaloid blotch; leakage into the vitreous will cause floaters or clouding of vision.

Leukaemias

Although retinopathy is common in acute and chronic leukaemias, visual symptoms are unusual. The retinal haemorrhages are non-specific, though Roth spots represent focal collections of white cells (Plate 15). If the white cell count is very high, frank infiltration of the retina or optic nerve head causes pale fluffy areas. Leukaemic cells may spill into the vitreous. Chronic leukaemias may cause a slow-flow picture from chronic retinal hypoxia. Retinopathy may improve with chemotherapy. In acute lymphoblastic leukaemia, collections of cells may form a mass retro-orbitally (causing proptosis), or on the iris masquerading as iritis. Ocular infiltrations may respond to radiotherapy. Associated infections (such as orbital mucormycosis), chemotherapy, or radiotherapy may affect the eye. Bone marrow transplantation is associated with cataract and dry eye whilst graft-versus-host disease may cause conjunctival scarring and severe dry eye.

Lymphomas

Lymphoma may occur around or inside one or both eyes, in isolation, in disseminated disease, or in relapse; usually non-Hodgkin, low-grade, B-cell lymphomas. Externally, they form firm swellings in the eyelid or conjunctiva, resembling smoked salmon. In the orbit lymphomas may cause neuro-ophthalmic signs. T-cell tumours may infiltrate the internal eye, particularly iris or choroid. The rare ocular reticulum cell sarcoma ('histiocytic' lymphoma), can masquerade as uveitis, but with a pale mass in the choroid or retina visible through a cloudy vitreous. The monoclonal cells may spread from or to the brain, often the frontal or temporal lobes, so repeated cranial scanning is necessary. Immunocytochemistry of cells obtained by vitreous biopsy is diagnostic. Ocular lymphomas usually respond to local radiotherapy.

Bleeding tendencies

Pronounced or repeated subconjunctival haemorrhage, hyphaema, or vitreous haemorrhage suggests a bleeding diathesis. Bleeding may be spontaneous or follow minor trauma or eye surgery. In haemophilia, bleeding around or inside the orbit may compress the optic or other cranial nerves.

Clotting tendencies

Thrombophilias, including factor V Leiden, protein S, protein C, or antithrombin III deficiencies, are associated with retinal vascular occlusion, especially in the veins. Closure of choroidal vessels affects vision if fluid exudes to detach the retina; this pattern suggests thrombotic thrombocytopenic purpura or disseminated intravascular coagulation. Retinal venous or arterial occlusions occur in systemic lupus erythematosus with lupus anticoagulant or antiphospholipid antibodies. The optic nerve head may be involved, causing amaurosis fugax or ischaemic optic neuropathy. A full clotting screen is indicated in patients with retinal vein thrombosis if another site is involved, episodes are multiple, or there is a family history of juvenile thrombosis at any site.

Sickling disorders

Minor eye features are common in the sickling haemoglobinopathies and may assist diagnosis. Major eye features occur in less than half the patients. They are more common with haemoglobin SC and sickle-cell thalassaemia (**SThal)** than in haemoglobin S homozygotes (**SS**). Unilateral blindness is uncommon, even in SC patients; bilateral blindness is rare. As early treatment improves prognosis, screening the retina of high-risk patients is important. The risk of acute painful or chronic painless glaucoma is increased. Orbital infarction or pneumococcal ophthalmitis are rare. Patients may suffer a stroke affecting the visual field.

Conjunctival signs are more marked in haemoglobin SS than SC. Small conjunctival vessels develop linear, saccular, or comma-shaped dilatations, more prominent in children and after topical phenylephrine drops.

Bleeding into the retina causes a round 'salmon patch'. After resolution over several weeks, haemosiderin is left as iridescent spots in the superficial retina. Deeper haemorrhages damage the underlying retinal pigment layer leaving a permanent black 'sunburst' scar. Bleeds are usually asymptomatic and do not threaten vision.

Sickling in terminal branches of retinal arterioles produces signs in about half the patients. Their prevalence is related to age as most new vessels form between the ages of 10 and 25 years, rarely after 40. In SC patients blindness usually occurs between the ages of 20 and 30 years. Severe retinal ischaemia with new vessel formation is twice as common in haemoglobin SC and SThal as in SS. The risk of sight-threatening vitreous haemorrhage is related to the number and size of new vessels.

After their pupils are dilated, patients must be screened using the indirect ophthalmoscope or an accessory lens at the slit lamp. The earliest sign of peripheral ischaemia is closure of arterioles in the superior temporal sector (stage I) with a paler background and narrow white vessels. If these areas extend and become confluent, anastomotic loops form (stage II), then tufts of new vessels (stage III). As the tufts grow forwards into the vitreous they often look like coral 'seafans'. Fluorescein angiography reveals profusely leaking new vessels whose size can be assessed before or after treatment. Many new vessel tufts will autoinfarct from sickling in the feeder arteriole; they will not then bleed but others may form, so the patient must still be observed.

There are no symptoms until vitreous haemorrhage occurs (stage IV). Small haemorrhages produce a sudden shower of many small floaters, like 'midges'. Large haemorrhages cause sudden marked cloudiness with reduced red reflex. If the retina is distorted or detached (stage V) there may be flashes of light and a visual field defect. Some patients lose central vision, gradually with macular ischaemia or suddenly with foveal haemorrhage or central retinal artery occlusion. Retinal vein occlusion is not associated with sickling.

Screening and treatment

Annual retinal screening is recommended for patients aged 20 to 30 years, especially for SC and SThal diseases. New vessels should be reassessed every few months. If they do not autoinfarct and their size increases or vitreous haemorrhage occurs, laser treatment should cause regression and reduce the risk of early

blindness.

Infectious diseases and the eye

Organisms on the surface of the eye can be identified from swabs. Those inside the eye are identified from their pattern of involvement; it is rarely necessary to aspirate material from inside the eye. Treatment for superficial eye infections is by topical antimicrobial drops or ointments, whereas internal infections demand systemic therapy; the choice is partly dictated by penetration into the eye cavities. Rarely, drugs are injected directly into the vitreous to supplement systemic treatment in achieving high intraocular levels.

Bacterial infections

The commonest bacterial eye infection is conjunctivitis caused by *Staphylococcus aureus*, *Haemophilus* spp., or the pneumococcus. Topical chloramphenicol is effective as drops (hourly for the first 24 h then three times daily for several days) with ointment at night. Cellulitis is usually caused by the same organisms; *Haemophilus* is common in children; systemic amoxycillin is the regimen of choice. Retro-orbital spread is an ophthalmic emergency requiring admission to hospital for investigation. If the patient is systemically ill or has orbital signs (proptosis, double vision, or loss of vision), intravenous treatment is warranted.

Metastatic endophthalmitis results when bloodborne bacteria seed to the internal eye (Plate 16). The commonest sources are meningeal, urinary, and endocardial; the most likely organisms are staphylococci, *Neisseria* spp., or streptococci. *Bacillus cereus* and fungi (see below) may complicate intravenous drug abuse and unusual opportunistic organisms must also be considered in immunosuppressed patients. There is visual impairment with pain. Cells and debris within the eye chambers blur the ophthalmoscopic view, though a pale chorioretinal focus of infection may be visible. Blood, urine, and cerebrospinal fluid cultures are necessary. Tapping of the internal eye for vitreous microscopy and culture is justified in some cases. In infective endocarditis, retinal haemorrhages and microembolic infarcts are common, classically in the form of Roth spots.

Tuberculosis can cause indolent granulomatous uveitis, either of the iris or choroid. The eye is frequently involved in leprosy with a risk of blindness; specific iritis and cataracts occur in the lepromatous form. Corneal scarring complicates facial palsy and/or reduced corneal sensation.

In syphilis, uveitis or neuroretinitis occur in the secondary stage and optic neuropathy or Argyll Robertson pupils in the tertiary stage. Congenital syphilis is associated with interstitial keratitis and a salt-and-pepper retinopathy. *Leptospira icterohaemorrhagiae* commonly causes an early conjunctivitis with subconjuctival haemorrhages and a late uveitis. Late Lyme disease may cause ocular inflammation.

The gonococcus causes a marked purulent conjunctivitis in the newborn baby or in those sexually exposed. Tularaemia is associated with a severe granulomatous conjunctivitis with local lymph node enlargement. Botulism causes paralysis of the ocular muscles, sometimes with autonomic signs, with diphtheria as a differential diagnosis. Brucellosis can cause optic neuritis or uveitis—consider this especially in slaughterhouse or farm workers. Actinomycetes can infect the tear canaliculi. Rarely, *Nocardia* spp. can infect the internal eye with a focal chorioretinitis.

Chlamydial eye infection (see also Chapter 7.11.40)

Trachoma is the most common cause of chronic conjunctivitis and worldwide a preventable cause of blindness. At least 600 million people are infected, and about 6 million blinded. *Chlamydia trachomatis* serotypes A to C cause a chronic conjunctivitis with follicles which look like pale grains of rice in the conjunctiva. Scarring of the lids associated with inturning of eyelashes may accelerate corneal scarring. The diagnosis is confirmed by seeing inclusions in conjunctival scrapes or by culturing the organism from swabs. World Health Organization recommendations for control are topical tetracycline ointment twice daily for 7 days six times a year, or six doses of oral doxycycline at 5 mg/kg given monthly.

The genital serotypes of chlamydia cause acute conjunctivitis. The eye is red and sticky, and lymphoid follicles are found in the conjunctiva lining the eyelids. Infection is persistent, responding only partially to topical chloramphenicol. Systemic tetracycline (or erythromycin) with topical tetracycline is effective.

Viral infections and the eye

Adenovirus conjunctivitis is the most common viral infection. It is usually caused by highly contagious, potentially epidemic types 3, 4, 7, 8, or 19. The eye is acutely red and uncomfortable with scanty discharge. Lymphoid follicles may be visible in the conjunctiva lining the eyelids and the preauricular node may be enlarged. Symptoms may continue for some weeks, but recovery is usually uneventful and treatment rarely necessary. The most important differential diagnosis is chlamydial infection, in which eye discharge is more profuse.

In systemically ill patients with fever, rash, and red eyes, measles, meningococcal, or disseminated gonococcal infection may be implicated and in some parts of the world, relapsing fevers (borreliosis) or rickettsoses. Conjunctivitis with marked local lymphadenopathy (oculoglandular syndrome) may be attributable to adenovirus, chlamydia, mumps, or other rarer causes.

Primary herpes simplex can cause conjunctivitis. Secondary herpes infection is associated with recurrent attacks of dendritic corneal ulceration which can result in corneal scarring and poor vision, especially if treated with topical corticosteroid. Herpes zoster can cause corneal ulceration, iritis, glaucoma, and delayed cranial nerve palsies including optic neuropathy. Patients with ophthalmic shingles should be referred for slit lamp examination if there is red eye or visual impairment. All herpes viruses can cause retinal infection, particularly in the immunosuppressed patient; simplex and zoster can cause potentially blinding necrotizing retinitis, which progresses rapidly and may respond poorly to systemic antiviral therapy.

Cytomegalovirus causes progressive retinitis with characteristic haemorrhages and patchy retinal necrosis (see below). In transplant recipients, cytomegalovirus infection may respond to reduction of immunosuppression.

Measles may cause a scarring corneal inflammation, an important cause of blindness in undernourished children. Inflammation of the internal eye is less common. Neuro-ophthalmic associations occur in subacute sclerosing panencephalitis. Congenital rubella and varicella are associated with cataract and retinopathy in infancy. Iritis is characteristic of mumps. Molluscum contagiosum, cowpox, and orf can cause lid infection.

Fungal infections

Indolent fungal keratitis is associated with contact lens wear, diabetes, exposure to inoculation in the garden or field, and intravenous opiate abuse. Metastatic endophthalmitis is usually caused by *Candida albicans* in association with immunosuppression, irradiation, intravenous drug use/abuse, and poorly controlled diabetes. Small, dense, white 'snowballs' are seen in the vitreous with white foci of infection visible in the choroid and overlying retina (Plate 17). Retinal haemorrhage is uncommon. Diagnosis can be confirmed by vitreous biopsy which provides the opportunity to inject antifungals into the eye. The differential diagnosis of a white focus with hazy vitreous full of cells includes purulent endophthalmitis, toxoplasmosis, intraocular lymphoma, sarcoid, or tuberculosis.

Peri- and retro-orbital infection is characteristic of invasive mucormycosis in the same groups at risk of candida, especially debilitated patients receiving treatment for haemtological malignancies and in severe diabetic ketoacidosis. The infection spreads rapidly, often involving the vascular supply and producing tissue necrosis, particularly blackening of the hard palate. Medical treatment is combined with surgical debridement.

In endemic areas such as the Mississippi basin, *Histoplasma capsulatum* produces a multifocal scarring chorioretinitis described as 'histo spots'.

Rickettsial infection

There are petechial haemorrhages of the bulbar conjunctiva with marked redness. Retinal haemorrhages also occur.

Protozoal infections

Toxoplasma gondii causes congenital infection of the retina and underlying choroid, if the mother acquired a primary infection in pregnancy. This is especially common in France and Brazil. The primary scarring focus in the eye may involve the macula or optic nerve head resulting in congenitally poor vision. More commonly, an asymptomatic scar reactivates later in life, releasing cells into the vitreous (Plate 18). An inactive scar may be visible in the other eye. Patients presents with visual blurring, often describing 'floaters'. Presumptive diagnosis is based on clinical findings and positive blood serology. Acute attacks are best treated promptly by an ophthalmologist with several weeks of combined systemic clindamycin or co-trimoxazole and corticosteroid. Some infants have associated cerebral toxoplasmosis.

Retinal haemorrhages are commonly found in patients with cerebral malaria (see Chapter 7.13.2). Retinal toxicity has not been reported with standard use of antimalarials, but has been reported with chloroquine abuse.

Ulcers and nodules of cutaneous leishmaniasis may be seen on the eyelids in endemic areas. Retinal haemorrhages are common in kala-azar, particularly when there is associated anaemia.

Keratosis may occur in African trypanosomiasis (Chapter 7.13.10). In Latin America, oedema of the eyelids, lacrimal gland, and local lymph nodes (Romaña's sign) develops in the weeks following a periocular bite by a reduviid ('kissing') bug transmitting *Trypanosoma cruzi*, the causatial agent of Chagas disease (Chapter 7.13.11).

Acanthamoeba can cause an indolent and potentially blinding keratitis in contact lens wearers or after corneal abrasion.

Pneumocystis choroiditis is discussed in Chapter 7.10.21 and Chapter 7.12.6.

Helminth infections

Onchocerciasis ('river blindness') (see Chapter 7.14.1) is a common cause of blindness, particularly in Africa. Microfilarias lodge particularly in the choroid causing insidiously progressive destructive and scarring chorioretinitis. Lymphatic filariasis rarely affects the eye.

Nematode worms of *Toxocara canis* (see Chapter 7.14.7) form a visible mass beneath the retina with uveitis and sometimes whitening of the pupil. The differential diagnosis is a tumour such as retinoblastoma.

Some adult worms invade the eye surface. *Loa loa* (see Chapter 7.14.1) may be felt by the patient and be visible to an observer beneath the bulbar conjunctiva; it may be removed surgically. In Japan, the fly-transmitted 'oriental eye worm' *Thelazia* occurs in the conjunctival sac. In South-East Asia, *Gnathostoma* infects the eyelids or internal eye where the larvas may be visible with the slit lamp.

When pork is eaten, trichinosis (*Trichinella spiralis* infection) affects extraocular muscles, causing pain, periorbital oedema, proptosis, and defective eye movements. There may be internal eye involvement.

Sparganosis (see Chapter 7.15.4) can cause conjunctivitis, swelling, itching, proptosis, and blindness.

The larval form of cysticercosis may be visible inside the eye in either chamber, looking like a motile pearl or toxocara-like mass. Posterior uveitis and retinitis may occur. Orbital involvement is rare. Orbital cysts, perhaps calcified, may occur in patients with hydatid disease.

In schistosomatasis an urticarial conjunctivitis is associated with egg deposition, but the interior of the eye is rarely involved.

Myiasis can involve the eye and orbit (ophthalmomyiasis externa) (Chapter 7.17).

Human immunodeficiency virus infection and AIDS (see also Chapter 7.10.21)

Eye signs are common, particularly in the later stages of AIDS. The retina and optic nerve head are most commonly involved. In patients with coexisting central nervous system infection, eye features may prove an important clue. Definitive diagnosis in life is possible only by retinal biopsy, which is rarely if ever justified. The cellular response within the eye is much scantier than usual. Opportunistic pathogens tend to be facultative intracellular parasites. Cytomegalovirus retinitis is the most common problem in patients with AIDS in the United Kingdom and United States, but is rarely seen in patients with haemophilia or in Africa where non-specific retinopathy and herpes zoster ophthalmicus are more common.

Retinal microvascular disease is common. Cotton wool spots (Plate 19) are commonly seen in relatively early HIV infection with haemorrhages, Roth spots, and microaneurysms. There may be closure and sheathing of the peripheral retinal venous branches and occasional microvascular closure around the fovea producing visual loss; this retinal pattern is common in patients in Africa, particularly children.

Cytomegalovirus retinitis

This was the most common ocular complication in sexually acquired HIV infection in the United Kingdom and United States, affecting about one in three of such patients in the later stages of AIDS when the CD4 T-cell count fell below 100. The incidence has fallen and the prognosis improved strikingly since the introduction of highly active antiretroviral therapy (**HAART**) (see Chapter 7.10.21).

The typical appearance is of patchy areas of pale crumbled-looking retina with associated scattered haemorrhages (sometimes said to look like pizza), most commonly around branch vessels (Plate 20). These are areas of cytomegalovirus replication with oedematous and necrotic retina and some cells, mostly neutrophils and macrophages, although the cell response within the eye cavity is usually scanty. The patches spread contiguously from their borders and, untreated, may enlarge over the course of several weeks. Retinal death results eventually in blindness. Before HAART, the average life expectancy of patients with AIDS in conjunction with cytomegalovirus retinitis was about 9 months.

Differential diagnoses of these appearances include branch retinal vein occlusion, toxoplasmosis, early acute retinal necrosis, candida, or cryptococcus. Definitive diagnosis is difficult. Culture and serology discourage a diagnosis only if they are repeatedly negative.

Adequate doses of virustatic (cidofovir, ganciclovir, or foscarnet) damp down the infection. The lesions become atrophic with resolution of the pale and haemorrhagic features and arrest of spread. Ganciclovir treatment is initiated with 2 weeks of twice daily intravenous doses of 5 mg/kg. The dose is reduced if there is renal impairment. The daily maintenance dose is 5 mg/kg intravenously or 3 g orally. The most important complication is bone marrow suppression. To avoid toxicity, ganciclovir may be given by direct injection into the eye (vitreous), but this is rarely justified as the treatment must be repeated perhaps weekly and the infection is usually bilateral and elsewhere in the body. If the CD4 cell count remains low, breakthrough of retinitis is common and is treated by repeating the induction course of ganciclovir, or by switching to foscarnet or cidofovir.

Spread of retinitis will occur if treatment is interrupted and will often smoulder on during the treatment course; breakthroughs after several weeks are treated by increasing the dose or changing to another agent. Ophthalmic supervision is important as it is more accurate to assess the lesions by indirect ophthalmoscopy, preferably with serial retinal photographs to document progression at the edges of lesions.

In patients with cytomegalovirus retinits, the low CD4 cell count must be improved with HAART and once the count is securely above 100/µl, maintenance therapy for cytomegalovirus may usually be suspended.

Other infections

Especially in non-industrial countries, HIV infection is a common cause of herpes zoster ophthalmicus. Retinal infection with herpes zoster or simplex may also cause rapidly spreading retinal death, as acute retinal necrosis (**ARN**) with pale oedematous areas lacking the crumbled texture and haemorrhages characteristic of

cytomegalovirus retinitis. Often there is involvement of the optic nerve with optic neuritis and sometimes there may be encephalitis. Vision can be lost bilaterally, within days if untreated. Intravenous acyclovir may halt spread within the retina.

Syphilis in HIV infection may cause iritis or optic neuritis, often bilateral. There may be retinitis with a vitreous cell reaction, abnormal cerebrospinal fluid, or other signs of central nervous system involvement. Non-specific treponemal serology may be negative, so specific tests must be done. Eye complications are treated with benzathine penicillin, using a regime suitable for central nervous system infection.

Toxoplasmal choroidoretinitis in HIV-infected patients may show a fluffy focal retinal lesion with cells in both chambers. These signs may explain accompanying optic neuritis or encephalitis. Treatment is with clindamycin, without corticosteroids.

Pneumocystis pneumoniae may occasionally cause a multifocal choroidoretinitis with multiple, pale, rounded patches visible beneath the retina, and cryptococcus an acute optic neuropathy associated with meningitis.

Disorders of the thyroid and parathyroid

Eye signs result either from imbalance of thyroid hormones or from an immunological disorder of both the thyroid (Graves' disease) and retro-orbital tissues; the most common cause of proptosis/exophthalmos, referred to as 'Graves' ophthalmopathy' or 'ophthalmic Graves' disease'.

Cosmetic problems and eye discomfort are common, but a threat to vision may be an acute emergency. Evolution of eye signs is often independent of current thyroid status; the patient may be euthyroid, hyperthyroid, or hypothyroid, and correction of hormone imbalance may not affect eye features. Commonly, orbital disease appears in patients who have become hypothyroid after treatment for hyperthyroidism.

Orbital disorders result from infiltration of orbital tissues by T cells, stimulated by autoantibodies which cross-react with adipocytes. Initially, fibroblasts are stimulated to produce mucinous material and oedema within muscle or fat; later this leads to fibrosis and atrophy.

Werner's classification is as follows.

- Class 0, signs and symptoms both absent;
- Class 1, signs without symptoms;
- Class 2, both symptoms and signs of soft tissue involvement;
- Class 3, proptosis indicating orbital involvement;
- Class 4, eye muscle involvement with double vision;
- Class 5, secondary corneal involvement; and
- Class 6, optic nerve involvement with loss of vision.

The eyelids may be swollen in both hyper- and hypothyroidism, especially on waking. In hyperthyroidism, upper lid retraction reveals white sclera above the upper cornea and there is lid lag. Raised orbital pressure causes congestion and redness of the eye, particularly over the visible tendon insertions of the lateral rectus muscles and conjunctival swelling (chemosis) (Plate 21). Diplopia is common; it is usually vertical, worse on waking and looking upwards.

Proptosis causes white sclera to appear, often asymmetrically, below the lower corneal margin. This can be measured from the bony rim of the orbit using an exophthalmometer, which gives a useful impression of progression. Thyroid function and autoantibody tests may be normal in patients with typical eye disease. Scans, especially coronal MRI views, can show enlargement of ocular muscles. Severe protrusion with upper lid retraction exposes the cornea to damage; corneal abrasion, ulceration, and perforation can develop rapidly and so patients with a protruding eye, impaired blinking, pain, or fluorescein staining of the cornea are an ophthalmic emergency.

Orbital pressure may be highest in patients without much proptosis as protrusion has a decompressing effect. Optic nerve compression causes visual blurring, perhaps with a central scotoma, loss of colour definition, or relative afferent pupillary defect. The optic nerve head may be swollen. Scanning shows enlarged extraocular muscles. Urgent management is necessary.

Cosmetic orbital surgery is rarely justified, but upper lid surgery is sometimes worthwhile. Discomfort is difficult to treat; simple artificial tears may be tried. Immunosuppression seems justified for active inflammation. Initially, diplopia is best managed with a plastic Fresnel prism stuck on to a spectacle lens. Stable diplopia may need a permanent spectacle prism, surgery, or botulinum toxin injection. Corneal exposure demands lateral tarsorrhaphy or temporarily taping the lids or single lid suture under local anaesthesia.

Optic nerve compression needs urgent orbital decompression; medically, using high-dose systemic corticosteroid; surgically, by removing bone from the orbital walls, or by orbital radiotherapy in severe cases.

Another cause of a congested protuberant eye is an orbital mass, usually unilateral. Few conditions mimic thyroid eye disease in having bilateral if asymmetrical signs. Upper lid signs are particularly helpful in suggesting this diagnosis. Orbital pseudotumour or myositis is characteristically more painful and a caroticocavernous arteriovenous fistula may cause a frontotemporal bruit. The conditions are differentiated neuroradiologically.

Parathyroid disorders

Hyperparathyroidism producing hypercalcaemia may cause calcium deposition (band keratopathy), a lacy opacity spreading horizontally from the margins inwards. The eyes may be red and feel gritty.

In hypoparathyroidism and pseudohypoparathyroidism, hypocalcaemia causes lens opacities. Small white or coloured crystals beneath the lens capsule may not impair vision. Papilloedema from intracranial hypertension is rare and reversible by correcting hypocalcaemia.

Multiple endocrine neoplasia syndrome

In type IIb of this rare autosomal dominant condition, prominent corneal nerves are easily detected by slit lamp. Conjunctival neuromas or thickened eyelids may occur.

The eye in diagnosis of inherited conditions Table 6)

Marfan's syndrome (see Chapter 19.1)

Most patients have reduced vision, commonly due to myopia and astigmatism which may be inferred from their spectacle lenses. Slit lamp reveals lens dislocation upwards (Plate 22). The iris trembles with eye movement (iridodonesis), because it is poorly supported by an abnormally mobile lens. The dislocated lenses are best retained. Careful correction of focus can improve vision dramatically in early childhood, preventing permanent amblyopia. Differential diagnoses of dislocated lenses are isolated ectopia lentis (without other marfanoid features) and homocystinuria (with marfanoid habitus).

Neurofibromatosis type 1 (see Chapter 24.6.1)

Most patients have raised, yellowish/brown, multiple, Lisch nodules of the iris visible by slit lamp which must be distinguished from common, simple, flat iris freckles. Corneal, retinal, or orbital neurofibromas/schwannomas may be found. There is an increased incidence of glaucoma. Screening and management of intracranial tumours associated with neurofibromatosis type 1, including optic nerve or chiasmal gliomas, is controversial. Neurofibromatosis type 2 is associated with posterior

subcapsular cataracts.

von Hippel–Lindau disease

Retinal angiomas may be the presenting and sole features. They are usually bilateral and multiple in the mid-peripheral retina, so indirect ophthalmoscopy is advised. They start as a very small lesion no bigger than a microaneurysm which enlarge, later developing dilated, tortuous feeder and draining retinal vessels. Early peripheral angiomas may be destroyed by laser, preferably before they bleed or cause retinal detachment. Juxtapapillary angiomas at the optic nerve head may affect vision early in their development and are difficult to treat (Plate 23). Prolonged eye follow-up is needed.

The eye in diagnosis of inherited premalignant conditions

Gardner's syndrome is deep retinal pigmentation with polyposis coli; the dark retinal patches, multiple and usually bilateral, are best seen by indirect ophthalmoscopy. Absence of the iris (aniridia) is associated with renal Wilm's tumour, especially if there is a chromosome 11p deletion. Retinoblastoma, when associated with deletion of chromosome 13q, is inheritable as a dominant trait with high penetrance, together with other tumours such as osteosarcomas. In multiple endocrine neoplasia syndrome type IIB, associated especially with thyroid malignancy, there are enlarged corneal nerves and other ocular abnormalities (see above). von Hippel–Lindau disease is also associated with malignant renal tumours.

Ocular drug toxicity

Few drugs require ophthalmic screening but visual loss can result from poisoning.

Antimalarials

The risks of chloroquine are discussed in Chapter 7.13.2. Patients may develop a dose-dependent retinal toxicity of the 'bull's eye' type with permanent reduction in central vision (Plate 24).

Hydroxychloroquine (Plaquenil) carries a lower risk of retinal damage. Monitoring is recommended only in patients taking more than the standard dose of up to 400 mg daily.

Ethambutol (see Chapter 7.11.22)

Toxicity, rare at doses of 15 mg/kg or less, is usually related to total dose, and is therefore least likely in the first 6 months of treatment. However, idiosyncratic toxicity in the first few weeks has been reported. Patients with symptoms of optic neuropathy should stop taking the drug immediately and should be warned to report any change in visual clarity or colour vision. Visual acuity, colour vision (100 Hue test), and optic disc appearance are monitored 3-monthly during treatment. Previous optic nerve damage or renal failure increase the risk. The early changes usually recover if the drug is stopped.

Corticosteroids

Lens opacities, typically posterior subcapsular, producing light scatter and glare, are visible by slit lamp or the ophthalmoscope set to catch the red reflex in focus, particularly if the pupil is dilated. Surgery may be necessary.

Eye signs in poisonings (see Chapter 8.2)

Quinine poisoning can blind by damaging the retina and optic nerve head. Ethyl alcohol (antifreeze) damages the optic nerve. Cyanide in raw cassava can blind.

Organophosphate pesticides and other anticholinesterases constrict the pupil by parasympathetic stimulation. Vision is not affected. Opiates also constrict the pupil. Atropine-like compounds, including nightshade berries, dilate the pupils ('gardeners's mydriasis') (see Chapter 8.3).

The external eye is vulnerable to ammonia, alkalis (including lime, cement, and plaster), acids, and some riot control agents. Primary treatment is prolonged irrigation for up to 20 min, using tap water (or even milk if necessary), followed by specialist referral.

Blindness worldwide

The World Health Organization defines blindness as binocular vision of Snellen 6/60 or less. More than 45 million people are estimated to be blind worldwide; perhaps two-thirds of these have visual impairment that prevents self-sufficiency.

Trauma

Physical or chemical eye injuries are a common cause of visual loss where prevention and treatment are poor. Emergency eye surgery and antibiotics can save vision.

Cataract

There is no known method of preventing cataract, which remains the most common cause of blindness in populations with limited surgical services. As the lens ages, its protein structure changes and the lens opacifies. Malnutrition, dehydration, diabetes, and perhaps sunlight accelerate lens ageing. In some populations, primitive surgical 'couching' or dislodging of the lens within the eye makes matters worse. Implanting artificial lenses is impracticable in many countries and, even if surgery is successful, correction by spectacles needed afterwards is often unsatisfactory. In poorer countries attention is focused on organizing the training and deployment of mobile surgical teams to carry out as many effective operations as possible.

Glaucoma

Nerve fibres within the rim of the optic nerve head are damaged by relatively high intraocular pressure and impaired blood supply. The central cup of the nerve head enlarges and visual field is irretrievably lost long before central acuity is affected, so the early stages are usually asymptomatic and painless. Even in wealthy populations, screening for early glaucoma is difficult and some patients progress to blindness despite all efforts. Those most at risk have a first-degree relative with glaucoma.

Age-related macular degeneration

The central retina around the fovea has an extraordinarily high metabolic turnover. In some patients, the efficiency of recycling metabolic products fails, abnormal material is deposited in the retina, and tissue integrity breaks down. Drusen may form around the fovea. They do not impair vision themselves but may herald formation of aberrant vessels which grow into the fovea from the choroid beneath, and may leak and may leak or bleed to form a scar with an irregular 'disciform' shape. This permanently damages the fovea. The patient loses detailed central vision, although peripheral vision allows them to navigate independently. Only a few patients at an early stage are ever likely to benefit from laser coagulation.

Diabetic retinopathy

This remains an important cause of blindness in younger patients. Major problems are organization of effective screening programmes and deployment of laser treatment. Over 50 per cent of blindness is preventable if laser treatment is given early enough.

Trachoma

Blindness occurs in populations who have poor eye hygiene and repeated fly-borne infection. Vaccination is not feasible. The only effective means of control is intermittent topical or systemic tetracycline treatment. Surgery for established scarring is less effective on a mass scale.

Vitamin A deficiency (xerophthalmia)

This most commonly affects young children and may destroy the whole eye. Lack of vitamin A causes conjunctival and corneal dryness and keratinization (xerosis) with Bitot's spots. The cornea softens (keratomalacia), ulcerates, and may perforate and become infected, resulting in endophthalmitis. Vitamin A is found in many green leafy vegetables and palm oil. Measles keratitis increases the risk of corneal scarring in malnourished children.

Onchocerciasis (river blindness)

This is estimated to cause blindness in 1 million people. Recently the disease has been largely controlled, thanks to vector control and the widespread use of ivermectin.

26.1 General introduction

Michael Sharpe

Further reading

Modern psychiatric medicine represents a substantial body of knowledge and skills, much of which is of potential value to the physician. It is therefore unfortunate that psychiatry and medicine have become so divorced from one another. Based on the questionable intellectual foundations of mind–body dualism, this separation has shaped research, planning, and services. In recent years, the split seems to have widened as medicine has focused increasingly on the basic biology of disease and psychiatric services have tended to make psychoses such as schizophrenia their central concern. Despite this, there is much evidence to show that physicians are faced every day with diagnostic and management problems for which the larger body of psychiatric knowledge and skills are relevant. Indeed, it could be argued that much of the criticism of clinical medicine in recent years reflects a lack of attention to the non-biological aspects of patient's illnesses. Examples include failures to establish therapeutic relationships with patients, to properly manage distress, and to effectively understand and manage complaints that are medically unexplained.

Psychiatric knowledge of relevance to medicine includes a practically useful, if imperfect, classification system, with an increasingly sophisticated psychological and neurobiological underpinning, and a range of pharmacological and psychological treatments, each with a substantial evidence base. Skills of relevance to the physician include the ability to assess the patient's mental as well as physical state, the detection of symptoms of depressive and anxiety disorders, and the eliciting of the patient's own understanding of their illness. These factors can be of substantial importance in the patient's management. Attitudes are also important, it being no secret that some physicians are dismissive toward patients who are perceived as 'psychiatric'. The acceptance of patients' concerns, even if apparently illogical, the tolerance of difficult behaviours, and a degree of reflectiveness in moderating one's own response; all are valuable in all medical settings.

Although physicians do a great deal of 'psychiatry' themselves, specialist help is not infrequently required, but psychiatric and psychological services can be problematic for the hospital physician to access because of the separation of psychiatric and medical services. In recent years, however, there has been a slow but steady growth of general hospital-based psychiatry and psychology services dedicated to the needs of medical patients, often termed 'liaison psychiatry' or 'health psychology', respectively. Such services offer improved integration of medical and psychiatric practice.

The sections that follow hopefully provide a practical and accessible summary of those aspects of assessment and management conventionally deemed 'psychiatric', but which are in fact central to the practice of medicine: They include:

- guidance on taking a psychiatric history from a medical patient in a way that is manageable within a medical setting;
- information about relevant psychiatric diagnoses, including organic mental disorder, depression and anxiety, reactions to stress, somatoform disorders and eating disorders, as well as basic coverage of the less commonly encountered but important psychiatric diagnosis of bipolar disorder, schizophrenia, and obsessive–compulsive disorder;
- practical advice on the management of depression and anxiety when it coexists with disease, somatic symptoms that are unexplained by disease, deliberate self-harm, and on how to cope with acute behavioural emergencies;
- a substantial section on the highly prevalent and clinically significant problem of alcohol and substance misuse.

Some might regard this section as an 'add on' that is of questionable relevance to the practising physician. Rather, it is better considered as a more detailed look at some aspects of medicine that are of relevance to the management of many of the medical conditions described in this book. It therefore forms part of an integrated approach to illness in which biological, psychological, and social strands of patient assessment and management run in parallel.

For the interested reader who wishes to find out more about psychiatry in general or liaison psychiatry in particular standard texts are listed below.

26.2 Taking a psychiatric history from a medical patient

Eleanor Feldman

> Listen to the patient, he is telling you what is wrong
>
> William Osler

This chapter covers issues that physicians and surgeons need to know about concerning psychiatric history-taking in general hospital patients. It would not be appropriate for a non-psychiatrist to attempt to take a full psychiatric history, involving as it does at least one hour's discussion covering relationships in the family of origin and a detailed biography to establish premorbid personality and aetiological factors, plus further discussion with at least one other informant. However, all patients should be screened for the most common problems: cognitive dysfunction, mood disorder, anxiety states, and alcohol and substance misuse. The assessment of cognitive dysfunction is predominantly a matter of mental state examination rather than taking a history and is covered in Chapter 26.4 and Chapter 30.2. Substance misuse is covered in some detail in Section 26.7. Chapter 26.5.2 covers how to assess a patient following attempted suicide, and the diagnostic features of patients with eating disorders are discussed in Chapter 26.5.5.

It is not necessary to screen routinely for psychotic symptoms as functional psychosis rarely presents for the first time in general hospital cases. If hallucinations and delusions do emerge during an inpatient's stay, then the most likely cause is an acute organic brain syndrome, and careful testing of orientation in time and observation for fluctuations in conscious level will usually confirm delirium. If in doubt, psychiatric advice should be sought.

Screening questions in routine assessment

Depression and anxiety

Significant proportions of general hospital patients will have diagnosable mental health problems. (Table 1 and Table 2) Frequently these will impinge on the physical health and well being of the patient. Stress affects the immune response; depression and anxiety are often comorbid with physical illness, either preceding it, or arising largely as a result of it; depressed and anxious people frequently have increased worry about physical health and experience minor physical symptoms as severe and intolerable. Antidepressants may help.

Screening for depression and anxiety need not take much time in itself (Box 1). However, if the patient gives positive answers it is helpful for these to be explored in more depth when time allows and in a private interview room. Patients will be aware when you are under pressure or in a rush, and this will inhibit them from telling you important things and you from wanting to hear about them. Therefore, indicating that you think something is important and will come back to them when you can set aside more time is very helpful and reassuring to the patient.

Questions about mood disorder are best construed as part of an enquiry into general health and the 'person as a whole', and most patients are pleased to discover that their physician takes an interest in their general well being. Starting with a non-directive enquiry about sleep **before** coming into hospital (most patients have sleep disturbance **in** hospital) is a natural way to link physical and emotional health: difficulty sleeping is a common denominator in stress, anxiety, and depression and a description of a disturbed sleep pattern may also assist you in distinguishing endogenous depression characterized by early morning wakening and diurnal mood variation. The reasons for any sleep disturbance, whatever they may be, are important in general health and will often reveal what troubles and worries a patient. Again ask this non-directively; do not be tempted to offer the patient a multiple choice of explanations. By open questioning, you will guide the patient into revealing what difficulties they are facing and most will find it a relief to tell you. At this stage, it is best to listen empathically and let the patient tell you their story. It may seem to you that you are doing nothing, but the patient gains great relief by being heard and understood, and you are gaining their trust and eliciting valuable information Box 1.

Box 1 Screening and probing questions for mood and anxiety disorder

- **Screening for current problems**
- How have you been sleeping (before you came into hospital)?
- **Probing: sleep, worry, and mood**
- *If not sleeping well, ask about the pattern of, and perceived reason for, sleep disturbance:*
- Is it difficulty getting off to sleep?—If Yes: how long before you fall asleep?
- Are you woken intermittently? Why? (may be due to physical symptoms)—Do you get back to sleep easily?
- Do you wake early and find you can't get back to sleep?—If Yes: how early?
- *If they have good nights and bad nights:*
- What proportion are good or bad; is it 50:50 or better or worse than that?
- *If sleeping badly:*
- Why do you think you are sleeping badly? (This is a natural opportunity for patients to reveal what is worrying them)
- Are you kept awake with worries going round and round your mind?
- At this point you will find out what is bothering the patient—after they have confided this in you, it is then empathic to ask:
- How have you been feeling in your spirits?
- If a patient reveals problems, it is appropriate now to ask about their previous mental health.
- **Screening for past mental health problems:-**
- Have you ever had trouble with your nerves?
- Ever seen a doctor about your nerves?
- Ever taken tablets for your nerves or to help you sleep?

The rare patient who objects to a sensitive enquiry intended to be helpful will have a reason to be defensive, and a history from the family practitioner or another informant will usually explain all. If you find the patient defensive and there always seem to be reasons why there is no-one else you can talk to, so that you cannot even confirm the patient's identity, then this is characteristic of those with factitious disorder using a false identity.

It is also advisable to screen for a past history of mental disorder, either when screening for the patient's past medical history, or if you have already elicited current mental health problems. Use the vernacular language of the culture of that patient; for example, in my own culture it would be: 'Have you ever had any troubles with your nerves or had to see a doctor about your nerves?'. Positive answers should then be explored non-directively by saying something like: 'Tell me more about that'. Hence, there need be only a few screening questions to lead effectively into a discussion of most mood disorders, worries, and stress. As important as the questions themselves will be, the way in which they are asked, the time available for discussion, and the physician's own willingness to listen and take note, are equally—if not more—important.

The importance of the alcohol use history

Insomnia and mood and anxiety disorders may be associated with heavy alcohol use. This alone may depress mood and give rise to early morning wakening, appetite changes, and weight loss. For this reason, a diagnosis of depressive illness cannot be made until the patient has been through alcohol withdrawal and been dry for a few weeks. If the alcohol problem is missed, incorrect advice and treatment will be given.

Patients are often defensive and evasive when they have an alcohol problem and persistent probing is needed to elicit the precise amount. Questions need to be asked as a routine and in a non-judgemental friendly way (Box 2). It is important to know the average intake in terms of units, rather than a vague qualitative response such as 'social drinking' or 'moderate drinking'. The CAGE questions may also be asked as a routine in anyone who drinks excessively (also in Box 2).

Box 2 Screening for alcohol problems

- **Routine questions**
- On an average week, how much alcohol do you drink?
- What do you like to have (spirits, wine, beer, etc.)?
- How many measures/glasses/pints?
- How often do you drink that much?
- Did you used to drink much more than that?
- If so, when and how much?
- **CAGE questions**:
- Do you feel you should **C**ut down on your drinking?
- Does anyone **A**nnoy you or get on your nerves by telling you to cut down your drinking?
- Do you feel bad or **G**uilty about your drinking?
- Do you have a drink first thing in the morning to steady your nerves or get rid of a hangover (**E**ye-opener)?
- *A positive answer to one or more questions is indicative of problems*

Recognizing and dealing with somatized anxiety and depression

Stress, anxiety, and depression can also be the main reasons for physical symptoms (Table 3). When patients experience the unpleasant physical symptoms that arise from their bodily reactions to emotional states, it is natural for them to complain of these to their medical attendants rather than present their primary complaint as an emotional disorder, which they will often regard as secondary to their physical symptoms, or make no connection at all. This is the common phenomenon known as somatization.

Misinterpretation by patients and their doctors of the symptoms of chronic tension, as well as sympathetic hyperarousal and hyperventilation in panic disorder, may lead to inappropriate extensive searches for organic abnormalities and provide no relief from suffering for the patient. Indeed, the patient's suffering increases as they are left with continuing uncertainty as to the cause of very distressing symptoms, and they become sensitive to the increasing scepticism and exasperation displayed by their doctors. In a study at a cardiac clinic in London, 50 to 60 per cent of patients had normal cardiac function on investigation, and many of these were experiencing the palpitations, dyspnoea, and chest discomfort of anxiety; 21 per cent showed evidence of hyperventilation. The common physical effects of hyperarousal and hyperventilation affect most organ systems and parts of the body from head (ache) to toe (tingling) (see Table 3), and so these patients find their way into every specialist clinic in the hospital.

If you have patients with such unexplained physical symptoms, then the most acceptable way of exploring the possibility of these syndromes is to enquire systematically about all the common symptoms listed in Table 3. Patients often have a few more symptoms that are not on the list and are usually not bothered by all. Once organic causes have been excluded, the diagnosis of panic disorder can be made on the history of physical symptoms alone, and an explanation can be given to the patient in terms of the physiological effects of adrenaline plus overbreathing. It is particularly important that the physician makes it clear that the symptoms are genuine, and that the tests only show that nothing is wrong because we do not use tests for the transient physiological changes accounting for the symptoms.

Treatments for panic disorder include low doses of antidepressants and cognitive–behavioural therapy, and give very good results. The majority of patients will accept psychiatric referral if it is made clear: that you **do** believe their symptoms are real (which they are); you are **not** saying that they are mad, or making it up, or it is all in their minds; and that there **is** a treatment that is effective and not addictive or harmful. It helps if you know the psychiatrist and know what the patient is likely to experience. Left untreated these patients may become severely disabled and continue to undergo expensive and unnecessary medical investigation.

Recognizing depression in someone with good reasons to be unhappy

To be ill and in discomfort is generally to be unhappy, and the more serious the illness, the greater the pain, the greater the loss and the tragedy, so much more the misery. Worry about health and fears for the future are to be expected. How can a doctor tell when an ill person's unhappiness amounts to a depressive illness requiring specific intervention, and when is it an appropriate adjustment reaction to grievous circumstance? Some of the cardinal diagnostic features of depressive illness much emphasized in general psychiatric practice are of little use in these circumstances, so that in patients with physical reasons for poor appetite and weight loss, and sleep disturbed by pain or other physical symptoms, we must look for other indicators of mood disorder. Endicott has thus suggested modifications to the diagnostic criteria for depression (see Box 3).

Box 3 Endicott's criteria for depression in the medically ill

- Presence of five out of these nine symptoms for at least 2 weeks:
- *Fearful or depressed appearance*
- Social withdrawal or decreased talkativeness
- Psychomotor retardation or agitation
- Depressed mood, subjective or observed
- Marked diminished interest or pleasure in most of the activities, most of the day
- *Brooding self-pity or pessimism*
- Feelings of worthlessness or excessive or inappropriate guilt
- Recurrent thoughts of death or suicide
- *Mood is non-reactive to environmental events*
- Symptoms in italics replace DSM-III-R* symptoms as follows:
- weight change
- sleep disturbance
- fatigue or energy loss
- diminished ability to think, concentrate; indecisiveness
- **Diagnostic and statistical manual of mental disorder, third edition, revised* (1987).

The emphasis is placed on the predominantly negative thinking style that is pervasive. A depressed person cannot be cheered up when nice things happen, will not be interested in things he/she used to enjoy, will be excessively pessimistic, and have an exaggerated sense of guilt and worthlessness.

Final comment

It is important to screen for mental health problems: they are common in general medical patients and failure to recognize and deal with them will often interfere with the management of the physical health of the patient. Moreover, depression itself can kill, and if by screening you identify depression, you should ask about hopelessness and suicidal ideation. How to do this sensitively is covered in Chapter 26.5.2.

26.3 Neuropsychiatric disorders

Laurence John Reed, Tom Stevens, and Michael D. Kopelman

Introduction

'Neuropsychiatry' is concerned with disorders of affect, cognition, and behaviour that arise from overt disorder in cerebral function, or from indirect effects of extracerebral disease. The term has largely replaced the earlier expression 'organic psychiatry', which originated in the classification of mental disorders as either 'organic' or 'functional' on the basis of the presence or absence of pathological changes in the brain. The latter distinction has become increasingly ambiguous as a result of the development of new methods for detecting abnormal brain pathology and pathophysiology in so-called 'functional' disorders such as depression and schizophrenia. Indeed, the most recent version of the *Diagnostic and statistical manual of mental disorders, fourth edition* (DSM-IV, American Psychiatric Association) states, 'the term organic mental disorder is no longer used in DSM-IV because it incorrectly implies that 'non-organic' mental disorders do not have a biological basis'. Nevertheless, a creative conflict has always pertained between neurological and psychological theories of behaviour and, in the absence of satisfactory alternatives, these terms have retained a place in clinical practice. In part, this serves to demarcate the uneasy and shifting boundary between disorders predominantly diagnosed and managed by physicians and psychiatrists, respectively.

This chapter is divided into two parts. First, we provide a consideration of practical issues related to the assessment, investigation, and management of patients manifesting cognitive and behavioural change. Second, we discuss specific cerebral and extracerebral disorders that commonly involve or are accompanied by cognitive or behavioural change. This bipartite organization is intended to help in the identification of possible diagnoses causing particular behavioural features, and also to alert clinicians to the likely neuropsychiatric sequelae of specific medical disorders.

Assessment, investigation, and management of patients with cognitive and behavioural change

The assessment and classification of mental and behavioural disorders is a frequent source of misunderstanding and confusion for clinicians, the process being undermined by the absence of robust clinical and laboratory markers for these conditions. Moreover, the clinical terminology used to describe certain symptoms and signs (such as 'confusion') is often unsatisfactory and unreliable. Although the major systems of classification are broadly similar, they continue to use different terminology: for instance, the World Health Organization's *International classification of diseases, tenth edition* (ICD-10) retains the term 'organic disorders', whereas DSM-IV uses the broad grouping 'delirium, dementia, amnesic and other cognitive disorders'. In addition, some of the operational diagnoses may have little validity in assisting the clinician to determine the appropriate investigation and treatment, for example the ICD-10 'unspecified organic personality and behavioural disorders due to brain disease, damage and dysfunction'. Nevertheless, there is consensus on the essential clinical features of these disorders, and in this section we shall describe their assessment on the basis of a number of core features underpinning the differential diagnosis.

Differential diagnoses

Acute versus chronic disorder

The differentiation of acute and chronic cognitive disorder essentially determines the boundary between delirium and dementia. This distinction should be apparent from the history and mode of presentation, although difficulties may arise where a clear history is lacking due to disturbed communication or the absence of an adequate informant. However, they can usually be distinguished on the basis of the characteristic clinical features described below. Essentially, a conspicuous impairment of attention is typical of an acute disorder, together with a fluctuating course and prominent perceptual disturbance. However, the 'acute on chronic' disorder, where there is a delirium superimposed on a chronic cognitive disorder, should not be overlooked.

Cognitive versus psychiatric disorder

This distinction between a cognitive and a psychiatric disorder is not always easy. It is important to recognize that an apparent cognitive abnormality may be seen in psychiatric disorders such as schizophrenia and depression. In depression, impairment of memory and concentration together with somatic complaints may lead to a misleading impression of dementia, so-called 'pseudodementia' or 'reversible dementia'. Likewise, the distinction between acute psychotic disorders and delirium can be difficult where both conditions show behavioural disturbance and disturbed communication. The risks associated with the wrongful categorization of delirium as psychosis are high: delirium is a medical emergency with high morbidity and mortality, and it is potentially reversible. Likewise, the attribution of a psychiatric disorder as delirium or dementia bears costs in terms of performing unnecessary investigations and pursuing the wrong therapy in an inappropriate setting, thereby compounding any illness behaviour.

Specific versus generalized cognitive impairment

If cognitive impairment is identified, it needs to be determined whether this is generalized to many cognitive functions or affects a specific function such as memory, planning, perception, language, or attention. Identification of a specific impairment, such as the amnesic syndrome, offers important clues as to the aetiology and management and is more likely to result from a focal brain lesion (as opposed to an extracerebral disorder).

Reversible versus irreversible

The range of causes of any cognitive impairment needs to be fully assessed. In particular, it is essential that those conditions that can be reversed or arrested should be specifically considered, for example human immunodeficiency virus (HIV) infection and cerebral neoplasms. It is equally important that any treatable psychiatric disorder is identified.

Acute cognitive and behavioural change

Assessment

A wide range of disorders may cause acute emotional and behavioural disturbance (Table 1). One of the most problematic aspects of assessment is the distinction between an acute psychotic episode and delirium. The clinical features of delirium (also known as 'acute organic brain syndrome' or 'acute confusional state') and of the 'functional' psychoses typical of schizophrenia or affective disorder share a number of characteristics. First, both involve a pervasive disruption of thought, cognition, communication, and behaviour in the patient, hence presenting particular difficulties in assessment. Second, both conditions may involve abnormalities of

perception in the form of hallucinations or illusions; abnormalities of belief, in the form of delusions or overvalued ideas; psychomotor abnormalities, including hypo- or hyperactivity; disturbance of the sleep–wake cycle; and emotional disturbance encompassing the range from depression to irritability and euphoria. These similarities cause practical difficulties in diagnostic differentiation, and they also hint that an absolute distinction between 'functional' psychosis and 'medical' delirium is probably untenable.

Delirium

A thorough history of the antecedents and onset of any behavioural and mental disturbance, as well as details of any past medical or psychiatric contact, will yield important clues as to the likelihood of an organic aetiology to behavioural change. The unco-operative or mute patient presents a particular challenge as important historical details may not be forthcoming, such as head injury, substance misuse, foreign travel, diabetes, or other medical disorders. Furthermore, accurately eliciting a mental and cognitive state is problematic, and it is in this group that a history from an informant, ward staff, or relatives is especially important. The diagnosis of delirium should be suspected where the history of behavioural disturbance is of recent onset, fluctuating, and there is evidence of deterioration at night. Difficulty in communicating with a patient is frequently the first indication of an underlying delirium.

The elderly and general hospital inpatients are particularly vulnerable to delirium. Any change of environment such as a recent admission to residential care or pre-existing cognitive impairment will heighten this vulnerability. Visual and hearing impairments are also more frequently observed in this group. Amongst inpatients the problem is compounded by inadequate information, impersonal environments, and confusing exposure to a myriad of different professionals. It is common for the diagnosis to be missed where there is no overt agitation or antisocial behaviour.

Behavioural changes seen with delirium include irritability, repetitive purposeless movements, and disorganization or difficulty performing routine tasks such as undressing. It is important to recognize that patients may be both overactive and noisy or inactive and slow.

The predominant clinical feature of delirium has been described as 'clouding of consciousness' or 'clouding of the sensorium'. These terms lack consensus definitions or clarity in practice, but have traditionally been used to describe a combination of orientation, attention, and memory deficits. Consequently, deficits of attention are stressed in diagnostic criteria, which in the delirious patient may range from distractibility and inability to follow complicated conversations, through an almost complete inability to register information or to concentrate, progressing in the extreme case to diminished consciousness and coma. Furthermore, such attentional difficulties tend to have a sudden onset and to fluctuate over time. Thinking tends to be muddled and speech may show considerable perseveration. The illusions and hallucinations associated with delirium tend to include a strong visual component, although auditory hallucinations and misperceptions are common. Delusions are usually simple, persecutory in nature, fluctuating, and transient.

It should be noted that if delirium and cognitive impairment are simply assessed by orientation in time, place, and person, then 'mild' or 'early' delirium may be missed, and it is therefore important to use additional tests of concentration and memory. All patients should be screened with a small battery of bedside cognitive tests that include specific tests of concentration such as serial subtractions and an assessment of memory for recent events and new information. The Mini-Mental State Examination (**MMSE**), supplemented with a few additional memory tests, is often used.

Psychiatric disorder

The characteristic clinical features of psychiatric disorders are covered in Chapter 26.5.6. Here we will discuss the features of acute behavioural disturbance that are suggestive of a psychotic illness or other psychiatric disorder. This issue is especially important in the emergency medical setting where such patients may be perceived as 'time-wasting' and 'not medical', and their medical needs may be crucially neglected.

A past history of psychiatric contact or treatment should be sought in all those with behavioural disturbance, as this is an indicator of putative psychiatric causation. In those with an underlying psychiatric disorder there is usually a background of insidious behavioural disturbance or personality change, and this will often become apparent from any informant. Delusions in psychotic disorders tend to be complex, bizarre, and consistently held, but this may not be so in early cases. Visual hallucinations are rare in psychosis. Marked attentional and memory deficits are not typical of psychosis, although more subtle attentional problems and a range of other cognitive deficits may be present. Distractibility as a consequence of internal experiences may give the impression of confusion and attentional impairment, although careful cognitive assessment will usually indicate preserved function.

Delirium in those with psychiatric disorder

The diagnosis of delirium is particularly difficult in those with a history of severe psychiatric disorder and/or learning disability. Difficulty in communicating with and examining such patients, who may have baseline cognitive impairment, means that delirium is particularly likely to be overlooked. Patients with severe mental illness will often attend for emergency consultations where the initial impression is of deterioration in their mental state, often coupled with a recent history of failing to comply with prescribed treatment or a disengagement from services provided. It should always be remembered that there is a high rate of undiagnosed physical illnesses in this population, and their risk of delirium is also raised because of serious side-effects from psychotropic medication, including neuroleptic malignant syndrome and lithium toxicity that can result in a deteriorating mental state. In addition, other aspects of these patients' behaviour place them at risk of physical illness, such as coexisting substance and alcohol dependency.

Investigation

It is necessary to exclude the wide range of medical conditions (Table 2) that may lead to delirium. A history of alcohol and/or illicit substance misuse may offer important indicators of aetiology. Although not always easy, a thorough physical examination with particular attention to neurological examination is essential in the assessment of all patients with acute disturbance. In addition, a routine screen—including blood count, electrolytes, liver and thyroid function, and C-reactive protein (**CRP**)/erythrocyte sedimentation rate (**ESR**)—is required, as this might indicate delirium where the diagnosis is in doubt. Infection is implicated in around one-third of hospital inpatients who are delirious, and a mid-stream urine sample (**MSU**) and chest radiograph are usually warranted in addition to routine blood testing in these patients. Relevant history and findings on physical examination usually guide more specific investigation. Encephalitis and intracerebral haemorrhage sometimes present with acute disturbance and cognitive impairment with no additional abnormalities in the history and clinical examination. An urgent computed tomography (**CT**) head scan or magnetic resonance imaging (**MRI**) is indicated where the immediate cause of acute cognitive impairment is not apparent or there are focal neurological signs. Appropriate tests for infectious diseases such as malaria, trypanosomiasis, typhoid fever, and typhus will also need to be considered when there is a history of foreign travel. An electroencephalogram with evidence of progressive cortical slowing may suggest a delirium and the need for a more extensive investigation where the diagnosis is in doubt.

Management

The management of delirium essentially consists of treating the underlying cause. Containment of any behavioural disturbance should involve general measures in the first instance, rather than psychotropic drug treatment, although sedation is necessary in some cases. Careful and repeated explanation of the diagnosis, investigations, and treatment to the patient and relatives is important. The patient should be nursed in a bright, simple room with minimal changes in staff and good lighting at night to reduce perceptual disturbance. Drugs, especially psychoactive and anticholinergic agents that may exacerbate confusion, should be reduced to a minimum. Where sedation is required then a regular oral antipsychotic such as haloperidol or chlorpromazine can be administered, although the clinician should be alert to the powerful antidopaminergic side-effects of these drugs. (See Chapter 26.4 for further discussion of these issues.)

Behavioural disturbance in patients with alcohol and substance misuse

This group of patients often present considerable demands on clinicians due to the wide range of associated physical morbidity that follows from substance and alcohol misuse. Approximately one-quarter of all male medical admissions have been found to have a current or previous alcohol problem. Such individuals commonly attend accident and emergency departments in a state of withdrawal or intoxication that engender negative attitudes from clinical staff. Often there is an expectation that the behavioural disturbance is due to intoxication or a withdrawal syndrome, without adequate assessment of any other physical pathology. Alternatively, such patients may attempt to minimize their alcohol and drug history so that the contribution of these to their complaints may not be immediately apparent.

Patients with a history of excessive alcohol consumption are vulnerable to a large number of complications that may precipitate a delirium (see Table 3) and care is needed to assess all of these possibilities. The onset of hallucinations may be mistakenly labelled as a consequence of delirium tremens without consideration of

other 'organic' or 'functional' disorders.

Delirium tremens carries a mortality risk of approximately 5 per cent and, furthermore, there is the danger that a withdrawal or intoxication syndrome may mask the emergence of other complications of alcohol and substance misuse. A history of recent blackouts or seizures should alert the physician to the possibility of hypoglycaemia or epilepsy. A careful assessment of the mental state is needed to differentiate 'functional' disorders, such as alcoholic hallucinosis, from schizophrenia as treatment of a mental disorder may be overlooked. Physical examination should include a careful assessment for signs of cirrhosis or acute hepatic encephalopathy. Investigation is essential to distinguish underlying conditions such as hepatic encephalopathy and hypoglycaemia from delirium tremens and should include full blood count, liver function tests, electrolyte and g-glutamyl transferase (**GGT**) measurements, glucose estimation, chest radiographs, and a CT or MRI scan of the brain where there is a suspicion of head trauma contributing to the disturbance. In particular, Wernicke's encephalopathy should be considered since it may be seen in up to 3 per cent of all admissions for alcohol complications. (See Chapter 26.7.1, Chapter 26.7.2, and Chapter 26.7.3 for further discussion of these issues.)

Chronic and subacute cognitive and behavioural disturbance

Assessment

In the assessment of patients with a more insidious onset of cognitive or psychiatric disturbance there can again be uncertainty as to the relative aetiological roles of organic or psychiatric factors. This may lead to unnecessary investigations at both considerable expense and discomfort to the patient, with attention diverted from appropriate management. Moreover, failure to consider a treatable cerebral disorder such as a space-occupying lesion may lead to avoidable and irreversible brain damage. Table 4 outlines a list of cognitive and psychiatric disorders that may exhibit evidence of cognitive impairment. The diagnostic uncertainty pertaining to the assessment of chronic cognitive impairment is highlighted by the somewhat misleading term 'pseudodementia' used to denote a psychological aetiology.

The diagnostic challenges in this group of patients are exemplified by the complex differentiation between dementia and depression or 'depressive pseudodementia', where there are changes in behaviour, mood, intellectual functioning, and cognitive performance. Differentiation is complicated by the fact that depressed mood is a frequent prodrome (and possibly even a risk factor) for an emerging dementia such as Alzheimer's. Furthermore, depression is a common complication or consequence of Alzheimer's and other dementias. It is therefore essential in the clinical setting that the relative contributions of psychiatric and pathological factors in any given case are considered, and that assessment includes a thorough physical, neurological, and psychiatric examination.

Dementia

Dementia is a syndrome involving a pervasive impairment of higher cortical functions and resulting from widespread brain pathology. The aetiology and characteristic clinical features of dementia are described in detail in Chapter 24.13.8 and Chapter 30.2, summarized in Table 5, and the most important causes are shown in Table 6. In the investigation of dementia it is essential to identify or exclude reversible causes: this should therefore include a complete blood count, electrolyte and metabolic screen, thyroid screen, vitamin B_{12} and folate levels, syphilis serology, urinalysis, chest radiography, and electrocardiography, and head CT or MRI scan. These investigations are sufficient to diagnose most treatable dementias. Any uncertainty about the extent of cognitive impairment necessitates formal neuropsychological assessment using instruments such as the Weschler Adult Intelligence Scale (**WAIS**-R or WAIS-111), as well as standard memory and executive tests.

The presence of a family history of early-onset cognitive impairment may indicate the need for genetic screening for Alzheimer's and Huntington's disease after appropriate counselling. Other potential evaluations include MRI, electroencephalography, cerebrospinal fluid examination, and possibly cerebral blood flow and metabolism measures (single-photon emission computed tomography (**SPECT**) and positron-emission tomography (**PET**)). Brain biopsy can be of additional assistance in diagnosing the cause of the dementia when justified by the clinical setting. For example, any suggestion of Creutzfeldt–Jakob disease would make an electroencephalogram (**EEG**) essential, and focal neurological signs would indicate the need for neuroimaging to exclude a space-occupying lesion. A known history of HIV infection would warrant a lumbar puncture. Evidence of extrapyramidal disturbance should alert the clinician to the possibility of Wilson's disease, necessitating serum copper and caeruloplasmin level investigation and slit-lamp examination for Kayser–Fleischer rings. These issues are discussed more completely in Chapter 24.13.8.

New cases of psychotic disorder

Missing an underlying 'organic' diagnosis remains a continuing concern of clinicians responsible for the assessment and treatment of new cases of an apparent psychosis. Clinical experience and numerous case reports attest to the wide range of disorders that may emerge following the initial diagnosis of a 'functional' psychosis. One follow-up study of a sample of patients with first-episode schizophrenia found that 15 out of 268 cases studied had 'organic' disorders that appeared relevant to the mental state: 13 patients out of these 15 had salient features in the medical history or neurological signs that could have alerted the clinician to the underlying disorder, the two exceptions both having a diagnosis of neurosyphilis. HIV is increasingly prevalent in this population and one recent cohort identified a known diagnosis of HIV in 4 per cent, with many subjects not tested. An assessment of risk factors for HIV is therefore required in all new cases of psychotic disorder. Overall, the literature suggests that the risks of missing organic illness are low, provided that a thorough clinical assessment is performed.

Some debate remains over the degree of investigation appropriate for the onset of psychosis. Certainly patients with cognitive impairment, abnormal neurological signs, atypical illnesses not responding to treatment, or other indications from the history, warrant further investigation. Where appropriate, this should include neuroimaging, electroencephalography, syphilis serology, and other investigations indicated by the clinical picture. Increasingly, neuroimaging provides important information relevant to the management of a particular case, although in the absence of specific indications the identification of treatable neurological disease is low.

Focal cognitive disorders

A variety of neuropsychiatric syndromes may arise from regional cerebral impairments of diverse cause in the absence of generalized cognitive impairment.

Clinical features

Amnesic disorders

The essential clinical feature of an amnesic disorder is a profound impairment in new learning relative to any generalized cognitive impairment. The impairment in recent memory is usually associated with disorientation in time and the patient is unable to retain information for more than a few seconds. A common cause of the amnesic syndrome is the Wernicke–Korsakoff syndrome resulting from thiamine deficiency in association with chronic alcoholism or, occasionally, malnutrition or malabsorption. The Wernicke phase of this disorder is characterized by confusion, nystagmus, abducent and conjugate gaze palsies (ophthalmoplegia), and ataxia. These features are commonly accompanied by peripheral neuropathy. Prompt treatment with thiamine replacement is vital in order to avert a chronic and disabling amnesic disorder (the Korsakoff syndrome).

The neuropathology of amnesic disorders usually involves lesions within the limbic system, including the thalamus and posterior hypothalamus, medial temporal lobes, and mamillary bodies. The crucial pathology in Korsakoff's syndrome is thought to involve neuronal loss, gliosis, and microhaemorrhages that produce disruption of mammilothalamic circuits. Pathology elsewhere in the paraventricular and periaqueductal grey matter, the frontal lobes, and in white matter pathways traversing the diencephalons, are common accompanying features. Amnesia can also be seen in herpes simplex encephalitis, carbon monoxide poisoning, other causes of cerebral anoxia, thalamic infarction, subarachnoid haemorrhage, head injury, deep midline space-occupying lesions, or tuberculous meningitis.

Frontal lobe syndromes

Particular neuropsychiatric interest is attached to the consequences of damage to the anterior regions of the brain. These are frequently neurologically 'silent', but they can also result in remarkable alterations in behaviour and personality, with preservation of cognitive functions such as memory and intelligence. Thus, psychiatric manifestations may be the only signs of frontal brain disease, and psychiatric disturbance may be an impediment to medical management. Two clinical pictures that frequently coexist are recognized. The first is characterized by a loss of initiative, indifference, lack of motivation, with impoverished speech and communication to the extreme of mutism. The second is characterized by disinhibition, impulsivity (occasionally with aggression), lack of ability to sustain attention and concentration, and loss of sensitivity to social cues: in general, such patients are excessively talkative and they may confabulate spontaneously. Both such syndromes have been

subsumed under the term 'dysexecutive syndrome' (also known as 'strategy application disorder'), which attempts a unitary cognitive psychological perspective on the condition. Interesting parallels have been drawn between the clinical frontal lobe syndrome and the features of neurological conditions such as Parkinson's disease and psychiatric disorders such as the negative syndrome in schizophrenia: in both these examples it is thought that impaired dopaminergic neurotransmission in prefrontal brain regions gives rise to the particular symptomatology.

Temporal lobe syndromes

A variety of syndromes, depending upon the particular area affected, are recognized following temporal lobe damage. Personality disturbance may be seen, although usually with neurological impairments. A particular variant of this is the Kluver–Bucy syndrome following bilateral lesions to the medial and lateral temporal lobes: this results in irresistible impulses to touch objects and place them in the mouth, combined with a lack of initiative, placidity, and visual agnosia. Dominant lobe lesions may produce aphasia, 'surface' dyslexia, and/or dysgraphia, frequently accompanied by neurological impairments on the contralateral side. Non-dominant lesions may particularly affect facial, spatial, or autobiographical memory, or may appear to be cognitively 'silent'. There is a recognized association between temporal lobe lesions, particularly those giving rise to epileptic activity, and psychosis, which may bear striking similarities with that seen in schizophrenia or affective disorder. Last, severe bilateral medial temporal lobe damage usually gives rise to a profound amnesic syndrome, with an almost complete loss of the ability to learn new material (anterograde amnesia) and a variable degree of retrograde loss of memory, whilst pathology in the left inferior temporal gyrus can produce severe deficits in semantic memory.

Parietal lobe syndromes

Parietal lobe lesions are associated with two particular sets of higher cognitive impairments: first, loss of visuospatial abilities, resulting in apraxias and spatial disorientation including left–right disorientation; second, loss of higher sensory perception, resulting in astereognosis and body image disturbance, which may be of such severity that there is a denial of disability, anosognosia, and visuospatial neglect. There may also be involvement of the occipital lobe, which can produce additional homonymous field defects, occasionally associated with visual hallucinations.

Diencephalic syndromes

Lesions to the deep midline structures of the thalamus, hypothalamus, and brainstem are associated with an amnesic syndrome, particularly exemplified by the Wernicke–Korsakoff syndrome. Deep midline tumours can produce a similar picture. More posterior brainstem lesions are associated with hypersomnia and placidity, which may be insidious: this was memorably described in a patient with 'akinetic mutism' due to a juxtapituitary meningioma.

Investigation of focal cognitive disorders

Cognitive assessment

Neuropsychological tests require the patient's co-operation and may fail to discriminate reliably between a cognitive and psychiatric disorder. However, they may furnish important indications of localized cerebral dysfunction and assist the clinician in monitoring the progress of any cognitive impairment. A wide range of tests is available to evaluate the pattern of disability, and these may also contribute important information to assist rehabilitation.

Brain imaging

The most useful range of investigations in suspected neuropsychiatric disorders comprise brain imaging techniques, the technology and application of which has expanded greatly in recent years. The most widely available, computed tomography (CT), is able to visualize most cerebral lesions, but should nowadays be reserved for the investigation of acute progressive cerebral damage such as stroke or subarachnoid haemorrhage, where time is of the essence and management decisions must be made rapidly. In more insidious, less acute contexts, the brain imaging of choice is magnetic resonance imaging (MRI), which allows both a higher spatial resolution with fine anatomical detail and a choice of endogenous/exogenous tissue-contrast modalities, producing greater diagnostic yield. MRI is more sensitive than CT in identifying small vascular lesions or demyelination, but less sensitive in detecting calcified lesions. Sequential assessments of cerebral atrophy and quantitative approaches can facilitate the accurate assessment of disease progression.

The EEG is frequently employed in the investigation of neuropsychiatric disorder as it is both widely available and a sensitive, if relatively non-specific, indicator of cerebral dysfunction. Focal abnormalities are characteristic of epilepsy that may, in turn, reflect vascular change. Diffuse slowing (that is to say, a shift to lower frequency ranges) is a sensitive indicator of brain dysfunction arising from metabolic and degenerative processes that correlates with the degree of cognitive impairment, although with relatively little specificity. Characteristic EEG changes are associated with Huntington's disease (pronounced flattening of traces), sporadic Creutzfeldt–Jakob disease (repetitive and triphasic spike discharges), and in association with specific drugs. Medial temporal slowing can be suggestive of early Alzheimer dementia.

The imaging of cerebral metabolism, blood flow, and receptor density, using techniques such as SPECT and PET, provide an alternative perspective on cerebral dysfunction. These are proving increasingly valuable in neuropsychiatry, although more for research than clinical purposes.

The past decade has seen an enormous expansion in functional brain imaging that allows assessment of brain regional engagement during cognitive processing. Changes in regional cerebral blood flow using PET, or in regional haemoglobin oxygenation status using blood oxygenation level-dependent (**BOLD**) functional MRI (**fMRI**), can be measured during cognitive performance. Such dynamic assessments remain essentially research techniques, allowing measurement of regional brain function and functional connectivity between linked brain areas. However, they may well offer clinical value in diagnosis and disease stratification in the future.

Neuropsychiatric causes of psychiatric disorders

Neuropsychiatric causes of psychiatric disorder are shown in Table 7.

'Organic mood disorder'

A variety of medical conditions are associated with prominent affective disorder, including anxiety, elation, and depressive symptoms. In many of these there appears to be a direct relationship between the presence of brain disease and depression, and the latter does not just seem to reflect the disabling social consequences of chronic disease, although the 'psychological reaction' to the disablement may still be an important contributory factor. In this connection, the severity of the depression is poorly correlated with the 'objective' disability or the prognosis of the disorder, and some disorders, such as multiple sclerosis, can be associated with either euphoria or depression or mood swings between the two extremes.

'Organic personality disorder'

'Organic personality disorder' is an unhappy term employed in ICD-10 to denote acute or (more typically) insidious changes in personality, defined as a significant alteration in the habitual disposition and behaviour of a patient from their premorbid state. The syndrome is increasingly well recognized, although often in retrospect. Most prominently affected is the degree of emotional expression and levels of activity, in the absence of pronounced cognitive alterations, except where 'higher level' functions such as planning complex actions or anticipation of social and emotional consequences are affected. Causes comprise intracerebral insults and consequent damage, most commonly to the frontal, temporal, or subcortical regions, or a range of rare degenerative conditions (Table 8).

Specific conditions giving rise to acute, subacute, or insidious cognitive and behavioural change

This section attempts to address two aspects of psychiatric problems associated with medical conditions: (1) to prompt the recognition and exploration of psychiatric abnormality in 'high-risk' conditions where such associations are well recognized; and (2) to encourage appropriate medical examination and investigation in the presence of outwardly psychiatric abnormality.

Psychological or psychiatric disorder may become manifest as an adjustment reaction to medical disability, malaise, and handicap, and this can affect not only the

patient, but also family members, who often bear the practical burden of care. Psychological disorder may also result from a specific compromise of cerebral function, either directly or systemically mediated. For example, postoperative psychiatric disturbance is common and usually the result of infective, metabolic, or drug-induced delirium. However, the simple circumstances of operation may lead to the precipitation of disorientation in the presence of an insidious dementia, or a withdrawal syndrome in an alcohol-dependent individual. Furthermore, the emotional reaction in response to life-threatening and life-altering circumstances may be profound following major surgery. These factors interact, and the ultimate expression of mental disturbance depends upon a particular patient's premorbid disposition and social circumstances, as well as specific illness factors. Nevertheless, the recognition and specific ascertainment of the presence of mental disturbance in certain conditions has profound diagnostic and prognostic importance.

Neurological disorders

Cerebrovascular disorders

The psychiatric complications associated with stroke have illustrated the relevance of a neuropsychiatric perspective. Early studies recognized distinct emotional reactions associated with cerebral damage. These included the catastrophic reaction (often extreme or disproportionate emotional outburst to small demands); the indifference reaction (associated with fatuous mood, indifference to failures, and unilateral neglect and anosognosia); and pathological laughter/crying (also known rather pejoratively as emotional incontinence, where emotional displays occur seemingly spontaneously or to trivial provocation). More recent and carefully controlled studies have revealed that, contrary to expectation, the mood consequences of stroke are disproportionate to the objective disability and show a consistent relationship with the location of the lesion, with anterior lesions being strongly associated with depression.

Cerebral tumours

Cerebral tumours are frequently associated with psychiatric disability, ranging from 'understandable' reactions to the diagnosis to frank syndromes resulting from impaired brain function. Minor psychological disturbance including anxiety, depression, and occasionally hysterical symptoms may be seen before the medical diagnosis is made, and specific signs of cerebral pathology need to be excluded in this group of patients. The regional syndromes outlined above are notable in cases of primary or secondary cerebral tumours, in particular when the tumour is rapidly progressive or where multiple brain regions are involved with metastases. The most common adult-onset primary tumour is the ostensibly 'benign' meningioma, which is notoriously slow growing (estimates of growth indicate that tumours at diagnosis have often been present for some 10 to 15 years), and thus cerebral function is only slowly compromised. Coupled with their propensity for a frontal location, in which there may be few frank neurological signs, this can lead to tragic cases of progressive personality deterioration being overlooked. More dramatic impairments of cerebral function are particularly associated with rapidly progressive tumours in which raised intracranial pressure, irritative epileptic phenomena, and an overall distortion in brain structure may combine to produce delirium and dementia. There can be remote effects of malignant disease on cerebral function: hypercalcaemia may present with an acute confusional state or with other psychological/psychiatric manifestations, and some forms of lung carcinoma (in particular) secrete growth factor/endocrine hormones that result in neurodegenerative changes and a dementia-like picture. Last, both episodic and prolonged confusional states have been reported in malignant disease in the absence of a clear metabolic disturbance or focal brain involvement, for example in diffuse leptomeningeal disease.

Head injury

The most prominent group suffering head injury are young men who have sustained a motor vehicle injury. Recent neuropsychiatric interest in the condition stems from recognition that the problems suffered involve impairment in personality, affect, and social/occupational function more prominently than the objective dysfunction would suggest should be the case. The wide range of neuropsychiatric sequelae recognized after head injury are outlined in Table 9. The most disabling and distressing problems for both patients and carers are the emotional and behavioural effects and, in particular, the personality change.

Impairment of consciousness is characteristic after all but the most mild head injuries and features of delirium are often seen after severe injuries. The period of post-traumatic amnesia (**PTA**), representing the time that elapses between the moment of injury and the restoration of memory for everyday events, is an important predictor of outcome. This is correlated with personality change as well as intellectual impairment and neurological disorder. By contrast, memory loss for the events of the trauma itself appears to protect against the development of post-traumatic stress disorder.

Cognitive impairment following head injury is usually more apparent after a PTA exceeding 24 h, and testing reveals that performance and non-verbal intelligence are more vulnerable to the effects of trauma than verbal and vocabulary-based intelligence. Penetrating and localized injuries tend to result in more focal cognitive deficits dependent on the site of injury. Dysexecutive syndrome and short-term memory impairment are commonly seen.

Personality change is particularly common after severe head injury and frontal lobe damage and includes irritability, impatience, apathy, and lability of mood. There is an inability to learn from experience, with poor judgement and lack of initiative. Aggression and sexual disinhibition may necessitate high levels of subsequent care. Delusional disorders are frequently observed in the early stages of recovery and may reflect the persistence of disordered cognition; mood and anxiety disorders are also often seen. Premorbid alcohol misuse may have predisposed to the trauma and alcohol tolerance can decline markedly after severe injury. Problems with heavy drinking are not uncommon in this group, which may reflect poor insight and drinking in response to stressful circumstances. Caution is needed to exclude chronic subdural haematoma and post-traumatic epilepsy before ascribing emotional and behavioural change to a psychiatric diagnosis.

Complex rehabilitation strategies are often needed to manage this group of patients and novel pharmacological management are being assessed.

Epilepsy

In assessing epilepsy it is important to establish the extent of underlying cerebral damage giving rise to the epileptic discharge, as well as the nature and severity of any cognitive impairment. While compatible with normal intelligence, epilepsy is more common in patients with a learning disability, and is related to its severity, presumably as both epilepsy and a learning difficulty arise from underlying cerebral dysfunction. Thus the capacity of individuals to manage their epilepsy is highly variable and poses an important problem for management. Furthermore, there is a relationship between emotional state and definite epileptic seizures, indicating an interesting brain–mind relationship.

The neuropsychiatric consequences of epilepsy are best considered in terms of peri-ictal and interictal disorders, which are outlined in Table 10. Further information is available in Chapter 24.13.3.

Intracranial infections

Subacute encephalopathies

A well-recognized manifestation of acute cerebral infection is dramatic behavioural disturbance, which may involve violence and delirium—this forms a relatively common diagnostic problem, with particular value placed on a correct diagnosis. Of note are, first, that the groups relatively predisposed to the development of encephalitis are alcohol and drug misusers, where attitudes of medical staff may exert a pejorative effect; second, that the disordered behaviour may be sufficiently extreme to render medical examination and management difficult. While not rigorously studied, herpes simplex encephalitis is particularly implicated in such presentations, perhaps as the most common encephalitis and also because of tropism of the virus to frontal and temporal regions. Damage in these areas can lead to impairment of behaviour and language, and occasionally to acute psychotic features such as auditory hallucinations. Other forms of encephalitis can also produce striking behavioural change.

Neurosyphilis

In historical terms syphilitic infection is considered an archetype for neuropsychiatric disorder. It was formerly called the 'great mimic' in that a large variety of presentations were recognized, including frank neurological features, insidious cognitive deterioration, affective disturbance (particularly grandiose mania), and personality coarsening. Whilst its incidence is low, particular groups such as immigrants and those with coexistent HIV infection are at increased risk. More recently, partially treated neurosyphilis means that atypical presentations have become the norm. Although neurological features, such as the Argyll–Robertson pupil, may raise suspicions, these are rare; in practice, possible exposure needs to be elicited and routine laboratory testing carried out on a regular basis.

HIV and AIDS

Human immunodeficiency virus and the acquired immunodeficiency syndrome (**AIDS**) now form the most common infection 'cluster' associated with prominent psychiatric features. Primarily, the most common reactions are to the psychological impact of the diagnosis and its prognosis, which can result in profound depression or anxiety states and needs careful management. It is now recognized that HIV has a direct tropism for neuronal tissue and may result in a frank encephalopathy, producing progressive cognitive impairment in a so-called AIDS–dementia complex. The encephalopathy is also associated with features of mania. Gathering evidence suggests that this may be reversible using antiretroviral combination therapy.

New-variant Creutzfeldt–Jakob disease

New-variant Creutzfeldt–Jakob disease (**nvCJD**) commonly presents with neuropsychiatric problems, particularly with subtle memory disturbances (which may result from the disproportionate tropism of prions for the thalamus and diencephalon), intermittent delirium with violent outbursts, auditory hallucinations, and mutism. It is rapidly progressive, and while thalamic involvement can be recognized at an early stage on neuroimaging, the diagnosis can only be confirmed by brain biopsy with immunostaining for prion precursor protein. Less invasive tonsillar biopsy methods, which require specialist referral, have also been developed for diagnosis.

Neurodegenerative conditions

Multiple sclerosis and demyelinating disorders

A strong association with cognitive impairment (between 40 and 60 per cent) and mood disorder is recognized in multiple sclerosis. The cognitive deficits seem to subtend from disturbed 'frontal' or executive function, as does depressed mood, and both show little relationship with motor disability or with demonstrable lesion load.

Parkinson's disease and movement disorders

There are four particular aspects of neuropsychiatric disturbance relevant to the consideration of idiopathic and atypical parkinsonian syndromes, including multisystem atrophy:

1. A prodromal period without frank movement disorder is well recognized and may be typified by depression, personality change, and sensory changes, reflecting the onset of nigrostriatal degeneration. This must proceed to about 80 per cent loss before the development of motor signs relatively late in the disease process.
2. Dopaminergic replacement therapy, whether with cholinergic antagonists, dopamine agonists, or L-levodopa (**l-DOPA**), is associated with a substantial incidence of psychosis and delirium.
3. There is a strong association between Parkinson's disease and depression, with estimates of prevalence in community samples of about 7.5 per cent for major depressive disorder and 45 per cent for mild depressive symptoms. This association is widely divergent from objective disability, and probably reflects a prominent dopaminergic influence on mood and motivation.
4. A substantial proportion of sufferers develop 'diffuse' (extranigrostriatal) Lewy-body disease leading to focal and general cognitive deficits and dementia.

Particular mention should be made here of iatrogenic movement disorder attendant upon antipsychotic medication. All currently available antipsychotic agents have dopamine D2-antagonist activity and provoke parkinsonism, dyskinesias, and dystonia, although newer agents, in particular clozapine, have a lower propensity for this effect. Tardive dyskinesias and provoked parkinsonian syndromes do not necessarily remit on cessation of the antipsychotic agent.

Mental retardation

Although beyond the immediate scope of this chapter, the diverse conditions that give rise to learning disorders have been the subject of intense recent interest. In particular, their strong associations with attention-deficit hyperactivity disorder (**ADHD**), fetal alcohol syndrome, and autism have underscored a probable neuropsychiatric basis. From a neurodevelopmental perspective, attention deficit in children is strongly linked to conduct disorder and may have diverse consequences in adulthood, providing an archetype for the understanding of personality disorder, traditionally not viewed in neuropsychiatric terms. (See Chapter 24.21 for further discussion of some of these issues.)

Another relevant area of interest is the concept of behavioural phenotypes, where consistent behavioural abnormalities are associated with distinct genotypic abnormalities. For example, the frequently occurring chromosomal disorders of Down's syndrome, Turner's syndrome, and Klinefelter's syndrome have distinct and consistent neuropsychiatric aspects, albeit of variable degree. In Turner's syndrome, while overall IQ is variable, distinct difficulties in visuospatial function give rise to large verbal-performance IQ deficits.

Extracerebral disorders

Endocrine disorder

Endocrine disorder has an important influence on mental function and characteristic associations with neuropsychiatric disorder are found. The use of 'routine' blood tests of endocrine function has resulted in the earlier detection of problems, such that florid states are rarely seen. The focus of clinical interest in this area is upon 'preclinical' endocrine dysfunction, the complications arising from the disorder, and their treatment.

Diabetes mellitus

The neuropsychiatric aspects of diabetes mellitus, both insulin-dependent (**IDDM**) and non-insulin dependent (**NIDDM**) forms, may be considered in four areas:

1. The syndrome itself and the constraints of optimal management have a considerable impact on the lives of sufferers. The disorder is stigmatizing, especially in the young, and has significant associated morbidity and increased mortality, both factors that confer the risk of impaired psychological development, personality difficulties, and affective disorder. There is clear evidence of a relationship between 'stress', emotional disturbance, and impaired glycaemic control, although whether this is directly or indirectly (through neglect of diet and treatment) mediated is unclear.
2. Hypoglycaemic episodes are associated with frank behavioural disturbance and automatisms, as described below.
3. A series of studies have identified significant intellectual impairments in a subset of sufferers of diabetes, an attribute particularly associated with an earlier age of onset, and the frequency and severity of hypoglycaemic episodes. While this strongly suggests that episodic hypoglycaemia results in brain damage in this subgroup, the so-called 'hypoglycaemic encephalopathy', an alternative possibility is that these patients are less able to manage their diabetes. This is of particular importance for those suffering 'brittle' diabetes, whose dietary and insulin requirements prove unpredictable, and who manage only poor glycaemic control; also for those suffering hypoglycaemia-unawareness, where incipient hypoglycaemia fails to trigger counter-regulatory neuroendocrine responses, thereby resulting in unpredictable hypoglycaemic episodes.
4. Later complications of diabetes, particularly if the diabetes is suboptimally controlled, include cerebral atherosclerosis and an increased risk of stroke, focal neuropsychological syndromes, and multi-infarct dementia.

Thyroid disorder

It is rare for classical presentations of thyroid disease to be missed in clinical practice, but interesting to note that surveys reveal that more than 5 per cent of attendees at psychiatric consultations have an abnormality in thyroid function. While not all of this group would benefit from treatment for thyroid disease, it underscores the insidious nature of thyroid dysfunction, and the rule should be to exclude this whenever suspicions are aroused. In particular, hypothyroidism may commonly manifest as apathy, depression, memory impairment, and dementia, with prominent cognitive slowing. If recognized and treated early, the condition may be reversible, although in long-lasting cases of hypothyroidism it is rarely so. Neonatal hypothyroidism or 'cretinism' is now rare as a result of routine screening, but again this indicates the importance of adequate thyroid function for cerebral development. Occasionally, adult hypothyroidism may be associated with psychosis (most commonly a delirium with prominent agitation), famously termed 'myxoedema madness'.

Hyperthyroidism is almost ubiquitously associated with a subjective feeling of tension, irritability, and high arousal. Initially this may be confused with anxiety, but in more severe cases behaviour can be frankly disturbed, although the individual concerned generally retains insight. Hypomania has been reported, as has a paradoxical apathetic state—both are rare. Thyroid 'crises' with delirium are occasionally seen following radioiodine treatment.

It should be noted that both hypo- and hyperthyroidism are common consequences of lithium treatment of bipolar affective disorder. This introduces the possibility of confusing a thyroid disorder with the recurrence of affective disorder, although it should be effectively excluded by the routine monitoring of lithium treatment.

Cushing's syndrome

The excess endogenous corticosteroid production in Cushing's syndrome appears to give rise to apathy and depression, with irritability and occasionally frank behavioural disturbance. The depression is often marked and may progress to stupor. Interestingly, exogenous steroids can give rise not only to anxiety and irritability, but also to hypomania and euphoria, which are rarely seen in Cushing's syndrome itself.

Phaeochromocytoma

The episodic release of adrenergic hormones from phaeochromocytoma classically gives rise to dizziness, tremulousness, palpitations, and the subjective feeling of intense fear, leading to confusion with anxiety and panic attacks. The diagnostic feature is the elevation of blood pressure during an attack, and if such attacks are reported, routine testing for adrenergic metabolites should be conducted. Attacks are occasionally of sufficient intensity to lead to confusion and delirium.

Pituitary disorder

Panhypopituitarism with consequent adrenal failure produces a characteristic neuropsychiatric picture with apathy, fatigue, weight loss, inability to attend and concentrate, and memory impairment. The disorder may therefore be confused with chronic fatigue, depression, or even dementia. The weight loss has been confused with anorexia nervosa, although neither appetite disturbance nor distorted body image is usually found with panhypopituitarism. Acromegaly can also result in a rather characteristic apathy and lack of concern, with occasional depression and irritability, perhaps reflecting a degree of global hypopituitrism.

There are two other particular neuropsychiatric issues that arise in consideration of a pituitary disorder. First, cerebral irradiation of pituitary tumours may give rise to collateral damage to adjacent brain structures, and there are reports of memory impairment, perhaps reflecting diencephalic and/or hippocampal damage. Second, endocrine replacement therapy following pituitary ablation may be suboptimal; indeed, replacement of sex steroids is occasionally omitted because of their propensity to release sexual drive, which may be inappropriate.

Gonadal dysfunction

Considerable attention has been devoted to the influence of the menopause and the consequent fall in oestrogen and progesterone on the development of depressive disorders in women. However, given the association with changing social role, this is a complex area. The consensus is that a lack of these hormones does play a significant part in the development of minor depressive disorders, which are significantly ameliorated by hormone replacement therapy. As a corollary, recent studies of testosterone deficiency in men have identified an association with depression, anxiety, irritability, insomnia, weakness, fatigue, diminished libido, impotence, and poor memory. Given the significant confound with ageing, this remains a controversial area.

26.4 Acute behavioural emergencies

Eleanor Feldman

This chapter covers the assessment and management of patients with acute behavioural disturbance in the general hospital.

Compromised cerebral function can lead to acute behavioural problems in any unit in a general hospital, but behavioural emergencies are most frequently encountered in accident and emergency departments and on wards to which deliberate self-harm patients have been admitted. The physician needs to be able to evaluate the causes of disturbance, understand how to calm the situation before resorting to sedation, know what emergency medication may safely be used if required, and have a confident understanding of his own, and other hospital staff's, legal rights and duties under local jurisdiction. Whilst all hospitals should have specialist help available from a psychiatrist, in many circumstances a physician will be the first doctor on the scene and may need to take immediate action to prevent harm.

Evaluating the causes of disturbance

A priority is to discover whether or not the patient is severely physically ill with compromised cerebral function and suffering from delirium. 'Delirium' is a term often used interchangeably with such phrases as 'toxic confusional state', 'acute confusional state', and 'acute organic brain syndrome'. It accounts for the majority of acute behavioural disturbances arising in patients in a general hospital who have no previous history of mental or behavioural disorder. Delirium in a young adult may signal severe life-threatening illness, but most patients will be elderly, many with a degree of dementia on to which the delirium is superimposed.

Delirium is a reversible organic mental syndrome with an acute or subacute onset, typically fluctuating in severity and often worse at night. Patients will have disturbed attention and concentration and no clear memory of events once they recover. They may be somnolent and have decreased psychomotor activity, or have the opposite with agitation and aggression. Mood changes occur, as do delusions (usually fleeting) and hallucinations, with the latter being in any sensory modality, commonly visual. Clinical features present in delirium are listed in Table 1.

Where mood disorder, delusions, and hallucinations are prominent, the patient's history and cognitive function are particularly helpful in distinguishing delirium from acute functional psychoses such as schizophrenia, mania, or psychotic depression. The most sensitive indicator of generalized cognitive dysfunction is disorientation in time, which may be subtle (see Table 1). The underlying cause of the delirium must be found and treated, but in the meantime any behavioural disturbance needs to be managed. Table 2 lists the causes of delirium.

It is worth noting that a patient who appears disorientated in person but shows no sign of other cognitive impairment is not delirious, but may be in a dissociative state or possibly be presenting with a factitious disorder.

How to calm the situation before resorting to sedation

Whatever the cause of a behavioural disturbance, there are general principles in the management of all such patients.

Staff behaviour

Disorientated and psychotic patients are often in a state of nightmarish terror, whilst patients disinhibited by drugs or alcohol are less in control of their aggressive tendencies. In all cases, staff need to remain calm and polite in their dealings with patients, as anxiety and hostility on the part of staff will only serve to escalate fear and aggression in the patient. Speech should be gentle, calm, and soft spoken, but also clear, confident, and honest. The patient should be treated with normal respect and staff should not forget to introduce themselves and explain what is happening at every point. The same few staff should have contact with a disorientated patient and, for inpatients, catering staff and cleaners should be kept away. Disorientated patients need to be reminded repeatedly where they are and what is happening. Non-verbal communication should mirror this calm and gentle approach. Touching the patient without permission or getting too close may be misinterpreted as an attack. An unpredictable patient should never be seen without support staff being present in the background and within earshot. Furthermore, the patient should not be backed into a corner of the room, and staff should remain close to the door. No attempts to control and restrain the patient should be made unless staff are trained in these techniques.

Facilities in an accident and emergency department

Accident and emergency (**A&E**) departments need an interview room designed for use with behaviourally disturbed patients. The room should be situated within sight and hearing of A&E staff, not isolated in an inaccessible part of the department, nor at the end of a corridor. It should be well lit, in a good state of decoration in quiet calming colours. No furniture or fittings should be usable as weapons. In the interests of safety the room should have more than one outwardly opening door and an observation window so that the occupants can be seen from outside. There should be an easily accessible 'panic button' with connection to the staff area nearby.

Facilities on an inpatient unit

Acutely disturbed inpatients are best managed in a well-lit, single-bedded room: delirious patients are more prone to visual misperceptions in the shadows of half light. The room should be sparsely furnished with no objects that can be used as weapons. The door should have an observational glass panel. If the room is not on the ground floor, the window in the room should be made safe, with reinforced glass and a means of preventing the window from being fully opened. The room should be fitted with an appropriate alarm system.

What emergency medication may be safely used if required?

It may be necessary to sedate a patient when all other efforts to calm them and make the situation safe have failed. The reality is that there is usually much less capacity to contain behavioural disturbance in a general hospital than would be the case on a psychiatric unit: there are usually no specialist psychiatric nurses available, ward layout is not designed for patients with disturbed behaviour, and other ill patients in the vicinity may be placed at risk. If non-drug calming measures fail, early intervention is desirable to bring disturbed behaviour under control as soon as possible. None the less, the decision to restrain and sedate a patient is not to be undertaken lightly. Whilst this experience may not be recalled by someone with delirium, it is very traumatic for a fully orientated and aware person, and this includes someone with psychosis. That person could develop post-traumatic stress disorder, and the experience may seriously compromise their future cooperation with the required medical and psychiatric treatment. The intervention must be carried out with kindness and as gently as possible. The general principles whereby medication can be used as safely as possible are summarized in Table 3.

Recommended drugs

Major tranquillizers

There are three major tranquillizers in common usage in emergencies: chlorpromazine, haloperidol, and droperidol. These are generally safe and effective for rapid tranquillization. All lower the seizure threshold and should be avoided in patients at risk of seizures, including those in alcohol withdrawal. They are also to be avoided in patients with pre-existing parkinsonism and they have proved dangerous in dementia with Lewy bodies. Hypotension is the most common of the potentially serious side-effects and is most frequent with chlorpromazine. Extrapyramidal side-effects are also relatively frequent, making the use of an antiparkinsonian drug such as procyclidine advisable prophylactically, especially in patients with organic brain syndromes. Acute dystonic reactions may be confused with the severe neck stiffness of meningitis or a spastic posture, thereby adding to diagnostic difficulty in organic brain syndromes of unknown cause. For a patient in spinal traction a dystonic reaction would be very dangerous. The most hazardous complication overall is cardiorespiratory arrest: the true incidence of this is unknown, but it is less of a risk with haloperidol than with chlorpromazine.

Haloperidol has been widely studied with regard to its rapidity of action: intramuscular injection brings about a quicker improvement than oral administration, with significant improvement within 30 min at minimum, although 1 to 2 h is more usual. The usual intramuscular dose is 5 to 10 mg, repeated every 60 min, to a maximum dose over 24 h of around 18 mg. Doses in the elderly should be much lower: Jacoby recommends a single small dose of no more than 2 mg oral haloperidol, with effect assessed after an hour, and in general no more than 6 to 9 mg given orally over 24 h. The patient should be assessed between doses, rather than given a regular regimen, since individual response is unpredictable and doses need careful titration to avoid oversedation and severe extrapyramidal effects.

Chlorpromazine is the least rapidly effective of the two commonly used major tranquillizers and carries the greatest risk of cardiovascular side-effects; it need not be used where haloperidol is available. If it is all that is available, then a dose of 50 to 100 mg chlorpromazine would be appropriate for a first dose to assess the patient's response. The oral route should always be offered first, but where this fails, the intramuscular route is generally preferred over the intravenous on grounds of safety and ease of access. A reasonable general assumption is about a 2:1 oral:parenteral equivalent dose.

In summary, haloperidol is the most rapidly effective major tranquillizer by the safe and convenient intramuscular route. Small doses of haloperidol should be preferred in the elderly.

Minor tranquillizers

The benzodiazepines are sedative drugs with low toxicity. The principal adverse effect is respiratory depression, and prolonged use results in tolerance and dependence. They raise the seizure threshold and may be used as anticonvulsants, so are helpful in cases where there is a risk of seizures and in other conditions where major tranquillizers are contraindicated. Flumazenil allows rapid reversal of respiratory depression. Its short half-life (1 h) means repeated administration may be necessary. There have been concerns about paradoxical disinhibition and release of aggression with benzodiazepines, but these have been overstated in the past and at less than 1 per cent are no greater than placebo.

In general, intramuscular lorazepam appears as effective as a sedative as intramuscular haloperidol, even in mania, and has fewer adverse effects. In a small study in patients with mania the peak reduction in agitation occurred 60 to 120 min after oral administration, but 45 to 75 min after intramuscular and 5 to 10 min after intravenous injection. It appeared more effective than haloperidol during the first 2 h if patients were already receiving antipsychotic drugs: 10 patients who received lorazepam on one occasion and haloperidol on another spent less time in seclusion after lorazepam medication. Doses reported in studies have ranged from 2 to 10 mg every 1 to 2 h. The maximum single dose reported is 40 mg and maximum daily doses from about 20 to 40 mg. No serious adverse effects have been reported with lorazepam use over 1 to 2 weeks. Ataxia has occurred above 10 mg/day, with nausea and confusion at the highest doses. When given by intramuscular injection lorazepam should be diluted with an equal volume of water or saline for injection.

Diazepam is poorly and erratically absorbed after intramuscular injection, making it less suitable for emergency sedation than lorazepam. It has a long half-life and accumulation is likely with repeated doses. Intravenous diazepam is effective in calming behavioural disturbance within 15 min, the diazemuls preparation causing less venous inflammation.

It is often useful to combine an antipsychotic with a benzodiazepine for the most effective safe sedation. The most studied combination has been parenteral haloperidol with lorazepam. It has been claimed that this reduces the total dose of antipsychotic required, but there are case reports where an intravenous combination of these drugs has caused cardiorespiratory arrest. In an open trial the combination of haloperidol and lorazepam given intramuscularly was effective more rapidly than either drug alone, occurring within 30 min in most patients, compared to nearing 60 min for most receiving a single drug.

The management of different syndromes

Psychosis

If a non-organic psychotic illness such as schizophrenia, mania, or psychotic depression is suspected, a psychiatrist should be contacted as soon as possible. Where disturbance is extreme and the patient represents a risk to themselves or others the recommended drug is haloperidol 5 to 10 mg orally or intramuscularly. Further doses can be given hourly according to response. Lorazepam 2 to 4 mg orally or intramuscularly can be added to treat patients who are extremely disturbed. The benzodiazepine antagonist, flumazenil, should be available in case of respiratory depression. Evidence from the notes of known psychiatric patients may suggest that higher doses may be required. The elderly should be treated with half the normal adult doses. Acute dystonic reactions to major tranquillizers respond to procyclidine 5 mg intramuscularly or orally.

Alcohol and drug states

Patients with alcohol withdrawal and disturbed behaviour should be treated acutely with diazepam 10 mg orally or lorazepam 2 mg intramuscularly. They should then be placed on an alcohol withdrawal regime including thiamine to prevent Wernicke's encephalopathy.

Patients suffering from acute drug or alcohol intoxication or drug withdrawal (but **not** alcohol withdrawal) should be treated with haloperidol 5 mg orally or intramuscularly, and continuing disturbance should be treated as for psychosis.

Care following tranquillization

Patients should not be left unattended in the hours following rapid tranquillization. Observations should be recorded every 15 min for 1 hour on a form detailing the following information:

1. Conscious level:
   a. awake and active,
   b. awake and calm,
   c. asleep but rousable,
   d. asleep and unrousable.
2. Respiratory rate, blood pressure, and oxygen saturation in patients in conscious levels 1(c) and 1(d)—arterial gases should be measured if oxygen saturation is less than 92 per cent.
3. Blood pressure should always be measured if antipsychotic drugs have been given.
4. Reassessment at 1 h to look for evidence of dystonia.

When the acute situation has been calmed, a decision should be made as to whether parenteral or oral medication should be used to keep things under control, also regarding the need for specialist advice. There should be further consideration of the overall treatment plan and levels of nursing and medical observation. There

should be a daily reassessment of mental state, and specialist advice should be sought if the patient remains disturbed after 3 days.

Drug interactions

Pharmaceutical formularies contain further information on drug interactions and these should be consulted for patients taking other drugs including alcohol, antiepileptic drugs, levodopa, and lithium.

Legal rights and duties under local jurisdiction

Unlike clinical matters, legal issues are limited by state and national boundaries. Most states and countries will have statute laws covering the treatment of mental disorder in situations of non-consent, but these laws may not allow treatment for coexisting medical disorders where the treatment of the latter is not a recognized treatment of the mental disorder. Clinicians require an understanding of local statute law and common law covering circumstances where patients have a diminished capacity to give meaningful consent to medical intervention in their best interests. This aspect of clinicians' training has often been neglected and the law in this area may be confusing for clinicians who must apply it in an emergency situation. Whilst psychiatrists may have a good understanding of statute law in relation to the treatment of mental disorder, they may not be so conversant with the legal issues surrounding non-consent for the treatment of physical illness. Hospital managers can assist their staff by drawing up guidance in conjunction with their legal advisors, the professions concerned, and any standing body or commission involved in the monitoring and regulation of statutory powers relevant to these circumstances. The author has discussed the legal situation in England and Wales in detail elsewhere (Feldman, in press).

26.5.1 Grief, stress, and post-traumatic stress disorder

Jenny Yiend and Tim Dalgleish

Grief

Introduction

- Grief could be described as a natural response to an objectively significant loss, most commonly the death of a loved one, although whether the boundaries defining a 'significant loss' should be stretched further (and if so, how far) remains controversial. It involves primarily psychological reactions, although it may also lead to social and physical responses. 'Normal grief', which requires no clinical intervention, can be distinguished from 'pathological grief', also variously called 'atypical, traumatic, neurotic, morbid, complicated, or unresolved grief'. However, it should be stated clearly at the outset that the concept of an abnormal form of grief is not represented in current official diagnostic manuals, and as such is not an established clinical condition. Indeed, the lack of consensus over terminology in the literature illustrates the urgent need for quality research to establish clear and universally accepted diagnostic criteria. Despite this confusion, many professionals now recognize some form of abnormal grief response as an appropriate target for active intervention, the key features being: (1) an excessive intensity of the grief reaction (inappropriate within the culture); and (2) of an unusually prolonged duration.

Epidemiology

Considering the ubiquity of bereavement, the consequences of grief are of global importance. Incidence rates for pathological grief are not available; estimates of prevalence vary from 14 to 34 per cent, based primarily on samples drawn from the United States and Europe. In geographical areas prone to natural disasters and places engaged in active military conflict these rates will obviously rise significantly in line with death rates, and in such cases particular attention should be paid to the concurrent trauma that will have accompanied the loss (see under Stress, below).

Mortality

Much evidence shows that the bereaved in general (irrespective of whether a pathological response develops) are at greater risk of dying themselves than would be expected given mortality rates in the population at large. Mortality is elevated by a factor of two to three, applying not only to spousal loss, but also to parental, sibling, and child loss. These findings have proven robust across cultures and generations. The point of highest risk is the weeks and months immediately following the loss, although the data suggest it remains elevated for several years. This evidence should alert the clinician to pay particular attention to all forms of presenting grief, whether normal or pathological.

Within a bereaved population additional factors moderate this mortality risk, although it remains elevated for all subgroups. Thus, the younger bereaved are at a higher relative risk of death themselves than the older, as are widowers compared to widows (although remarriage selectively reduces the risk in widowers). The cause of bereavement is also important, mortality risk being particularly elevated for bereavements involving suicide, accidents, liver cirrhosis, and heart disease.

Hard evidence concerning the underlying reason for reduced longevity following bereavement is scarce, but factors both directly and indirectly related to the loss may be involved. For example, psychological consequences such as the loss of the will to live might directly lead to increased suicides and carelessness. Indirectly, the change in lifestyle necessitated by bereavement may lead to the adoption of health-impairing behaviours (neglect of diet, exercise, general well being) or may create psychological stress, which in turn could have serious negative consequences for health (see ' Stress' below).

Psychiatric comorbidity

Acute bereavement is associated with an increased risk for a range of psychiatric disorders, including major depression, panic disorder, generalized anxiety disorder (**GAD**), and post-traumatic stress disorder (**PTSD**). Any of these may occur comorbidly with pathological grief, when between 17 and 31 per cent will also meet criteria for major depression, 13 per cent panic disorder, 39 per cent GAD, and 9 per cent PTSD. However, these figures should be treated with caution since the criteria for 'pathological' and the timing and consistency of assessment can greatly affect the results. What is clear though, is that the rate of comorbidity following bereavement is significant, with estimates suggesting more than half of the bereaved suffer from two disorders. Hence, having diagnosed one disorder in the bereaved patient (be it psychiatric or pathological grief), the clinician should be particularly alert to the possible presence of additional, complicating disorders. It is unclear whether this comorbidity is best conceived as the presence of one disorder predisposing the patient to additional pathology, or simply the presence of two coexisting disorders whose symptoms may or may not aggravate each other. Whichever, it is essential that both domains of symptoms are separately monitored and, to the extent that it differs, treatment for both disorders is given.

Clinical features

Normal grief

The literature on normal grief reveals that we have yet to achieve a precise characterization of the process and a clear demarcation of its boundaries. Many theorists propose that there are distinct 'stages' of grief, and while opinions vary about the precise number and nature of stages, it is common to consider at least three. These are:

- an initial period of shock, including emotional numbing and disbelief. This stage may last from hours to weeks.
- a subsequent phase of acute mourning, involving an acknowledgement of the death together with intense emotional states that typically engulf the individual in periodic 'waves' of feeling. Somatic discomfort, social withdrawal, and preoccupation with thoughts of the deceased may accompany this. There may also be 'identification' with the deceased, in which the individual adopts characteristic behaviours, mannerisms or habits of the loved one, and may even experience physical symptoms associated with the cause of death ('grief facsimile symptoms'). This phase may last for several months.
- a period of restoration of normal function during which the characteristics of acute mourning are gradually replaced by feeling able to continue with life. A shift in focus occurs away from the deceased and towards the future. While memories and a sense of loss may remain, there is recognition of having grieved and a will

to move on.

More recent theories have placed less emphasis on chronological stages, preferring instead to consider particular domains or clusters of symptoms that may fluctuate in intensity throughout the period of grieving. Table 1 summarizes some of these symptoms of grief.

Pathological grief

As stated earlier, the concept of 'abnormal' grief superseding what might be construed as normal and therefore requiring medical intervention, is not currently an officially acknowledged pathology. However, many workers are calling for a set of universally accepted diagnostic criteria to be developed, and in the meantime Jacobs has proposed a preliminary set that should prove helpful to the practising clinician. These represent a consensus opinion drawn up at a recent conference of experts, and as such incorporate a variety of perspectives on grief and its manifestations. They are formulated in the American Psychiatric Association's *Diagnostic and statistical manual of mental disorders* (**DSM**) style and are reproduced in Table 2.

Several features are worth noting.

- First, diagnosis requires the actual death of a significant other, thereby excluding any other forms of loss (physical separation, loss of non-human objects: animals, body parts, material possessions). This remains controversial.
- Second, observable psychological distress in response to the death is essential, although it may be delayed. Thus a total non-response (the absence of any observable or reported signs of grief), which may be of concern to the practising clinician, would not warrant a positive diagnosis. In such cases the best approach may be close monitoring of the patient over time, together with probing for signs of intrusive thoughts or behaviours relating to the deceased, despite emotional numbing.
- Third, criterion B represents symptoms of particular severity. They fall into four broad categories: avoidance and numbing (1, 3, 4, 5); disorganized behaviour or experience (2, 6, 7, 9); identification symptoms (10); and anger (11). The recommendation is that at least four of these should be present for a positive diagnosis, in addition to the core response of distressing preoccupation listed under A.
- Fourth, criteria D and C are central to distinguishing normal from pathological grief. They embody the notion, described earlier and consistent throughout DSM-IV, that there must be significant impairment of functioning together with an abnormally long duration of symptoms. The latter is set, somewhat arbitrarily, at 2 months.

The core domains for positive diagnosis can therefore be summarized as severity, duration, and functioning.

Differential diagnosis

Bereavement and comorbid psychiatric disorder

DSM-IV criteria for the diagnosis of major depression include specific guidelines for the circumstances of bereavement. In effect, this acknowledges that depressive-like symptoms will be fairly ubiquitous following bereavement and criteria are therefore more stringent. Specifically, either a 2-month (rather than a 2-week) duration of symptoms is required, or alternatively the presence of particular symptoms such as marked functional impairment, psychotic symptoms, or suicidal ideation is necessary. Although no specific guidelines for other comorbid psychiatric disorders are given, the clinician would be well advised to apply similar principles of increased severity or extended duration before making a positive diagnosis.

Pathological grief and comorbid psychiatric disorder

Pathological grief, by the working definition given above, occurs exclusively in the circumstances of the death of a significant other. While this objective criterion helpfully restricts diagnosis, it remains necessary to distinguish between this and other possible psychiatric disorders that may follow bereavement.

- *Major depressive episode*—is distinguished by a pervasive and general depressed mood disturbance, in contrast to the episodic pangs of grief focused around the absence of the deceased. Other characteristic symptoms of pathological grief are absent (e.g. Criterion B: 1, 4, 5, 7, 8, 9, 10, 11)
- *Panic disorder and GAD*—are distinguished primarily by the absence of characteristic symptoms of pathological grief, and in the former by the presence of acute episodes of severe anxiety or panic attacks.
- *PTSD*—this is perhaps the most problematic differential diagnosis. Could pathological grief be construed as a specific example of PTSD? Only further research will resolve this question. For the present, we suggest that the following features be considered: pathological grief, in contrast to PTSD, does not require exposure to an objectively traumatic event (although this may occur in cases of violent death). In pathological grief, symptoms of avoidance and hyperarousal are less prominent than in PTSD. Symptoms of pathological grief are centred on the deceased person (pining, searching for them, sensitivity for signs of them in the environment), whereas those of PTSD centre around the traumatic event itself (re-experiencing the trauma, intrusive thoughts about the trauma, general hypervigilance). Finally, where both disorders are suspected, it is advisable to focus treatment initially on PTSD.

Treatment

Normal grief will resolve spontaneously over time. Treatment options for pathological grief fall into the categories of pharmacology, psychotherapies, cognitive/behavioural therapies, and self-help strategies. In common with other psychological disorders, maximum benefit may often be obtained by the prudent combination of drugs with psychological treatments. In practice, individual circumstances and the local availability of treatments will inevitably impose restrictions.

Pharmacology

The few studies available looking specifically at drug treatments following bereavement suggest that both tricyclic antidepressants and selective serotonin-reuptake inhibitors (**SSRIs**) may provide effective relief of symptoms. The tricyclics appear to be more confined in their effects, influencing primarily depressive symptoms, whereas the SSRIs may have a broader action, additionally counteracting symptoms reflecting trauma, such as avoidance and emotional numbing. SSRIs have the additional advantage of more tolerable side-effects, as well as being safer in overdose. Individual circumstances, side-effect profiles, and any known personal or family history of response to treatment can act as a guide in the selection of therapy.

Psychotherapies

Psychodynamic forms of psychotherapy tend to be favoured nowadays over those of a psychoanalytical persuasion. The former centre around the developing relationship between therapist and client, and focus on ongoing changes in the presenting psychological processes observed in the client. Current opinion suggests that this form of psychotherapy may yield more effective results within a shorter time frame than psychoanalytical techniques, which tend to focus more on a re-evaluation of personal history as the means to personal change.

Psychotherapies that have been used specifically to treat the bereaved include crisis intervention and brief dynamic psychotherapy. One study of crisis intervention psychotherapy, given immediately after the loss, lasted for several months and involved reviewing aspects of the lost relationship within the context of the psychodynamic relationship. A significant reduction in symptoms was noted. By contrast, in a study of a psychodynamic therapy starting several months after the loss, only a marginal symptom improvement was found.

Cognitive/behavioural therapies

Cognitive–behaviour therapy (**CBT**) is a popular form of treatment for many psychological disorders. It combines behavioural techniques, such as relaxation and exposure, with cognitive restructuring in which the patient is encouraged to identify and alter maladaptive styles of thinking that are thought to maintain ongoing psychological distress. While there is no data specifically considering the efficacy of this treatment for bereavement, it is likely to confer similar benefits to those noted elsewhere. In relation to separation anxiety disorder, which could be considered as a childhood analogue of pathological grief, a 60 per cent recovery to normal functioning has been reported, sustained over a follow-up year.

Exclusively behavioural techniques have also been used. These involve exposure to feared or avoided stimuli in order to produce habituation, and may also incorporate relaxation techniques to aid this process. Guided mourning and trauma desensitization are two such treatments. Both appear to selectively reduce somatic and avoidance symptoms, having less of an effect on depressive symptoms and preoccupations with the deceased.

Self-help

Self help groups should not be overlooked as a possible supplement to treatment, either to aid transition following successful treatment, or in a preventive capacity. Some evidence suggests that, with appropriately trained group leaders, benefits conferred may be equivalent to some of the more formal treatments discussed above.

Finally, the reader is referred to an excellent text by Jacobs, an expert in the area, which outlines one possible practical approach to treatment endorsed by the author (see p 81 therein), as well as a diagnosis/treatment algorithm (see p 76 therein).

Prognosis

Pathological grief responses may be chronic and unremitting without medical intervention, and a prolonged course of 2 years or more is likely where symptoms persist beyond the first year. In the case of normal grief, most of the acute symptoms of mourning may be expected to dissipate within several months to a year, but some level of emotional involvement may persist indefinitely. Those at higher risk of a pathological grief response may include the young, women, those who suffer multiple losses, and those who have suffered childhood loss. The risk is increased following sudden, unexpected, violent, or suicidal death. An ambivalent or insecure relationship to the deceased ('attachment disturbance') also increases risk, as do personality traits such as neuroticism, dependency, and schizoid personality. Finally, transient features displayed in an individual, such as the inability to accept an imminent death, or severe distress during a terminal illness, increase that individual's risk for pathological grief.

Prevention

Primary measures fall largely in the domain of social policy, such as gun control, safe driving practice, or healthy living styles. These can directly reduce deaths due to unnatural causes. However, the clinician may also play a role by moderating the impact of death, particularly when it is sudden or unexpected. This would include allowing ample time to be spent with a dying or indeed a deceased patient in a quiet and supportive atmosphere, which can enable associated others to more effectively assimilate their loss.

Secondary prevention might include screening bereaved populations at high risk. At the level of the individual this would involve ascertaining the risk profile of a recently bereaved patient and, where this is high, maintaining contact, monitoring progress, and providing early intervention where appropriate.

Tertiary prevention, to moderate the extent of disability, can be implemented by considering appropriate medium- to long-term treatments. Patients may well present late in the course of pathological grief, prompted only by severe functional impairment or social pressure. Although early intervention is preferable, an appropriate selection from the treatment options discussed above is still likely to confer some benefit.

Areas of controversy needing further research

Perhaps the major controversy of concern to clinicians is whether the concept of 'pathological grief' warrants a distinct diagnostic category, or whether it is best subsumed under existing pathologies such as PTSD or major depression. The high comorbidities and the question of the differential diagnosis support the latter view; factor analysis of symptom clusters, their differential response to drugs, and the distinct risk profiles support the former. However, the question of labelling becomes clinically unimportant, to the extent that the treatment for these pathologies overlaps.

Other controversies are:

- the model of distinct 'stages of grief', which some advocate more than others;
- the extent to which the absence of grief might be considered pathological;
- the duration of normal grief, which some argue is indefinite;
- the nature of the grief object, which some restrict to the death of an intimate, while others extend far more broadly to include non-death and non-human loss.

The following issues also warrant investigation:

- cultural differences in the expression and experience of grief;
- the factors responsible for the relationship between bereavement and increased health and mortality risks.

Stress and post-traumatic stress disorder

Introduction

Stress often refers to an external object, event, or situation that causes physical and psychological effects on an individual as a result of increased levels of arousal. These effects are usually experienced as unpleasant and undesirable, although there is a close correspondence with the excitement that occurs when a positive, desirable interpretation is adopted, for example during dangerous sports. The term 'stress' is perhaps more appropriately used to refer to the subjective experience of these effects, and the agent causing them is more accurately termed 'the stressor'.

Societal and lifestyle changes in developed nations, as well as media coverage, have given prominence to the role of stressors and their adverse effects, although in practice these are prevalent universally. While a moderate degree of stress can be helpful to enhance performance, chronic stress is indeed associated with negative outcomes. Stress can be a risk factor for various physical health problems, most notably coronary heart disease, infectious diseases, immune function, and cancer. In addition 'background stress' (the presence of low-level chronic stressors) is known to potentiate an individual's negative response to acute stressors, and thus can be considered a vulnerability factor for negative outcome. Within psychiatry the effect of stressors has been extensively studied. They are known to raise the probability of relapse and, more controversially, are believed to play a part in triggering the onset of some disorders. Examples include schizophrenia, where interventions developed to reduce the levels of interpersonal stress within families ('expressed emotion') have proved effective. Similarly, in major depression much research has been conducted on the role of 'life events' (for example, death of a spouse, loss of a job, going on holiday).

For the non-psychiatric patient the adverse effects of stressors can usually be addressed through lifestyle changes such as increased exercise, improved diet, relaxation techniques, reduction of working hours, and delegation of responsibilities. All these measures require an adjustment of personal priorities, which some may be unwilling to do. Where stress arises from unavoidable personal circumstances (for example, care-giving, financial or relationship problems), the role of the clinician includes referral to appropriate support services to enable the stressors to be addressed at their source.

An additional option, provided within the DSM-IV system, is a diagnosis of adjustment disorder. This may be appropriate where a discrete, identifiable stressor exists and causes either significant impairment in functioning, or distress beyond that which would normally be expected given the nature of the stress. However, this disorder (by definition) is time-limited by and closely coupled to the external stressor itself, although it may be classed as chronic where the stressor or its consequences persist indefinitely. Specifically, symptoms must commence within 3 months of the onset of the stressor and cease within 6 months of its termination. It is also of note that bereavement is specifically excluded as a qualifying stressor. Nevertheless, where these criteria are fulfilled and other psychiatric diagnoses have been excluded, the clinician may wish to offer appropriate psychological interventions as described below.

We will use the term 'trauma' where extreme stress occurs in response to an acute, intense episode brought about by a specific, objectively identifiable, external event. A trauma (defined under Clinical features, below) may be distinguished from a stressor primarily in terms of the objective intensity and severity of the experience or incident. It is now recognized that a proportion of people exposed to such a trauma go on to develop a clinical pathology, post-traumatic stress disorder (PTSD). PTSD, the subject of the rest of this section, was first introduced into the diagnostic nomenclature in 1980 with the publication of DSM-III, and it subsequently

appeared in the World Health Organization's *International classification of disease* (**ICD**) system in 1992.

Epidemiology

Traumatic events are common, estimates suggesting that most Americans will experience at least 1 trauma over a lifetime. The lifetime prevalence of PTSD in the general population is between 1 and 14 per cent according to DSM-IV, with a recent review suggesting this level is higher in women (10 to 12 per cent) than men (5 per cent). Estimates of lifetime prevalence among trauma victims vary widely according to the criteria and populations sampled, but somewhere between 3 and 58 per cent of people who experience a trauma will go on to develop PTSD at some time in their lives, although more recent reviews put the figure as high as 60 to 80 per cent. Clearly geographical factors will influence these figures, leading to significant increases in areas prone to natural disasters or human conflict. In common with most psychiatric disorders there appears to be high comorbidity in PTSD, with 80 per cent of sufferers meeting the criteria for at least one other psychiatric disorder.

Clinical features

The primary, essential feature for a positive diagnosis of PTSD is the prior experience of an objectively traumatic event. DSM-IV distinguishes two components: first, the nature of the event itself, which should involve an 'actual or perceived threat to life or physical integrity'—typical events including active combat, rape or other assault, natural disasters, and serious accidents. Witnessing such events is also included within the concept of 'experiencing'. Second, individuals should have an extreme emotional response to the event, which DSM-IV describes as intense fear, helplessness, or horror.

A pathological reaction to such a trauma is characterized by symptoms that fall into three clinically observed domains: re-experiencing, avoidance/numbing, and hyperarousal. Avoidance and numbing may be better considered separately, although DSM-IV does not do so. Typical examples of these symptoms are as follows.

- *Re-experiencing*—including nightmares, flashbacks, intrusive thoughts, and images relating to the trauma. Such symptoms have often been considered to be the hallmark of PTSD.
- *Avoidance*—typically anything that could remind the individual of or be associated with the trauma is avoided. This can include people, places, activities, and conversations.
- *Numbing*—emotional responsiveness is generally reduced. This may include an inability to experience certain feelings and feelings of detachment or other dissociative symptoms (e.g. depersonalization, dissociative amnesia, derealization).
- *Hyperarousal*—this includes insomnia, anger, irritability, hypervigilance, problems with concentration, exaggerated startle.

DSM-IV requires at least one symptom of re-experiencing, three of avoidance/numbing, and two of hyperarousal to be present for a positive diagnosis. It also currently specifies three subtypes of PTSD—acute, chronic (where symptoms have lasted under or over 3 months, respectively), and delayed onset (where 6 months or more has elapsed after the stressor before the emergence of symptoms).

Finally, DSM-IV introduced a new, related diagnostic category—acute stress disorder (ASD)—which essentially is an acute form of PTSD. The symptoms are identical, but the diagnosis can be made as early as 2 days' post-trauma, thereby encouraging earlier intervention. Persistence of symptoms beyond 1 month results in the diagnosis reverting to PTSD. For ASD three of five dissociative/numbing symptoms are required, reflecting the belief that these are predictive of longer term psychopathology. Although the diagnosis remains controversial, it does provide the clinician with a clear indication for early intervention in certain cases.

Differential diagnosis

Normal reactions to trauma

As with grief, the key features that distinguish PTSD from non-pathological reactions to trauma are intensity, duration, and functioning. The intensity of the pathological reaction is captured by the nature of the symptoms themselves, with the presence of numbing symptoms thought to be the most effective distinguisher of victims with PTSD from those without. In addition, symptoms must have been present for at least 1 month and must be causing clinically significant distress or impairment in functioning.

Other psychiatric conditions

Subsets of the features of PTSD often overlap with other psychiatric conditions, but distinguishing characteristics are usually present. First, in PTSD there is an instigating traumatic event, which is not required for any of the other anxiety disorders. Second, the symptoms of nightmares and flashbacks are specific for PTSD and do not characterize other anxiety disorders. Third, emotional numbing, which occurs in the place of the normally expected emotional reactions, is strongly and uniquely characteristic to PTSD.

PTSD, considered to be an anxiety disorder, shares several anxiety-related symptoms, particularly from the hyperarousal cluster. Hypervigilance, sleep disturbance, irritability, and concentration problems are all common to GAD. Similarly, fear and avoidance are common to the phobias. Intrusive thoughts may also occur in obsessive–compulsive disorder (**OCD**), major depression, and GAD. Conversely, PTSD sufferers may exhibit compulsive behaviours of the type associated with OCD, such as repetitive cleansing procedures, or continual checking of locks and security devices, perhaps following rape or other kinds of assault. Although rates of comorbidity are indeed high (see above), dual diagnoses should only be made where the full criteria for both disorders are met.

Treatment

Crisis intervention

This approach, also called 'psychological debriefing', aims to treat all survivors of a trauma in the hope of reducing subsequent pathology. It takes place in a single session, within days of the incident, most forms of treatment being given individually or in small groups. Typically, there are several structured phases including each individual sharing their own general perspective ('recreating the event'), their thoughts at the time, the worst aspect of the event, and their reactions to it. There is usually also a teaching element, covering common reactions to trauma and how to deal with them.

Without doubt participants subjectively feel this type of intervention to be helpful and valuable. However, the research findings on its efficacy are mixed: a recent review revealed that there have been few randomized controlled trials, but that these show little observable benefit, some even reporting a negative outcome. One current view holds that benefits are greater if the treatment is delayed for a week or so, until the initial shock subsides. Unless and until future empirical data supports their worth, clinicians should be cautious about the use of indiscriminatory immediate intervention. The treatment options discussed below are suitable for individuals who go on to develop PTSD following trauma.

Pharmacology

The main difficulty regarding drug treatment is the current dearth of clinical trials, hence what follows cannot be more than tentative advice, based primarily on clinical experience.

Antiadrenergic agents

Agents such as b-blockers are effective in the short term in reducing symptoms of hyperarousal and re-experiencing. Patients respond quickly, although tolerance is likely to develop. They are perhaps most appropriate for those whose individual prognosis is good, or where immediate symptom relief is required, before pursuing other treatment options.

Antidepressants

Most antidepressants provide at least some symptom relief, but the benefits are generally considered to be modest for classes such as tricyclics and monoamine oxidase inhibitors (**MAOIs**), and issues of side-effect profiles and overdose safety mean that SSRIs tend to be preferred. Recent data suggests that SSRIs may be

effective in reducing symptoms from all symptom domains, and therefore they are currently the preferred option for the long-term drug treatment of PTSD. Two additional points are worth noting. First, uncertainty persists about the speed of action of these drugs, with estimates for the onset of beneficial effects varying between 2 weeks and 1 month. Patients should therefore be prepared for some delay. Second, some SSRI side-effects, such as arousal and insomnia, although usually short-lived, will be particularly difficult for the patient with PTSD to tolerate.

Psychological treatments

Many different types of psychological therapy have been used to treat patients with PTSD, most appearing to impart some benefit in terms of symptom relief and improved psychological and social functioning, but longer term benefits remain unclear. Similarly, the potential for additional gains to be made by combining psychological treatments with each other or with drugs remains largely unexplored. Some of the commoner therapies are given below.

Cognitive–behavioural therapies

These are the psychological treatments of first choice for patients with PTSD because most are relatively brief and have a well-established efficacy, both from clinical experience and empirical research. Treatments are similar to those used for other anxiety disorders, such as specific phobia, but they focus specifically on trauma-related material. Therapies may differ in the particular components included, but generally they fall into one of two groups, exposure treatments or anxiety management.

Exposure treatments

Exposure treatments involve repeated exposure to trauma-related material on the basis that this will reduce undesirable responses, either through simple habituation or as a result of concurrent cognitive reprocessing. Treatments vary in the type of exposure used. Imaginal techniques involve the patient reliving (describing verbally, writing down, or role playing) the trauma within the treatment room. *In vivo* exposure involves confronting, in real-life but safe situations, places or objects that provide reminders of the trauma. Other variables include the length of exposure (brief or prolonged) and the level of arousal induced (high or low). Prolonged imaginal exposure is currently the favoured technique of many therapists for the treatment of PTSD because of its relative efficacy and time-efficiency.

Some forms of exposure treatment, for example systematic desensitization, adopt a hierarchical approach in which exposure is graded in difficulty, starting with least feared stimuli and progressing in tandem with patient improvement. Relaxation procedures may also be employed: these are known to be unnecessary for treatment efficacy, but may help to encourage patient participation in an initially unpleasant procedure.

Exposure techniques are time-efficient and easy for patients to learn. Good quality, consistent data supports their efficacy. However, as noted, compliance may be a genuine problem, particularly in those with prominent avoidance symptoms.

Anxiety management

Anxiety management training aims to teach patients to control and cope with heir symptoms, rather than focusing on elimination or cure. Stress inoculation training is one such technique that has been commonly used for PTSD. Treatment usually involves components of both education and skills training. The latter may include deep relaxation, quick relaxation, breathing control, thought stopping, and role play. Anxiety management programmes are more complex to administer and more intellectually demanding for patients than other treatment options. However, they are likely to be particularly appropriate for PTSD patients with symptoms of chronic, general arousal. In addition, they may be indicated at later stages, for example where maximal benefit has been achieved from other treatment options and the patient is left with residual symptoms.

Psychotherapies

Both psychodynamic and psychoanalytical techniques (see 'Grief' above) have been used to treat PTSD. Such therapies tend to vary enormously in nature, encompassing individual and group approaches and lasting anywhere from a few sessions to over a year. The available data reveals improvements following treatment, but methodological flaws preclude any clear conclusions. Where alternatives exist, it may well be advisable to pursue these options first.

Hypnotherapy

Hypnosis has reportedly been used with some success. However, there is a lack of sound published data to confirm this, although one controlled study suggests that hypnosis is effective and may be particularly suitable for reducing intrusive symptoms (re-experiencing cluster).

Eye-movement desensitization and reprocessing (EMDR)

This is a controversial treatment, largely because of the surprising claims made by its originator, the lack of rigorous scientific testing to confirm its supposed efficacy, and the lack of any obvious theoretical basis or justification for its beneficial effects. Treatment involves focusing on a disturbing trauma-related thought or image, while visually tracking a movement, for example the therapist's finger. The primary components are therefore production of saccadic eye movements and exposure. Until methodologically sound data is available, clinicians are advised to consider this technique with caution.

Prognosis

The evidence suggests that most treatments are effective in reducing symptoms and improving quality of life, but it seems that the magnitude of these benefits is limited. Many sufferers retain some symptoms despite having received optimal treatment. Although little data exists on the efficacy of combining treatment options (for example, drugs alongside psychological techniques), it may be appropriate to consider this in resistant cases. In addition, where residual symptoms persist, it may be appropriate to shift goals towards rehabilitation and the successful management of symptoms.

What factors influence the chance of recovery following exposure to trauma? Known risk factors for the development of PTSD include the following: the severity of (including proximity to) the trauma; bereavement as a result of the trauma; presence of a pre- or comorbid psychiatric disorder; certain personality traits, for example neuroticism; and the absence of adequate social and psychological support. All appear to be predictors of poor outcome. Recent reviews suggest that neither age nor ethnic group interacts with pathological response to trauma and that PTSD-symptom expression is similar across age groups and cultures.

Areas of controversy needing further research

Controversial issues largely overlap with those requiring further research in this relatively newly recognized area. Particular attention should be paid to:

- SSRIs as a drug treatment of first choice;
- combined treatment approaches;
- crisis intervention as an immediate, unselective, post-trauma intervention;
- the eye-movement desensitization and reprocessing technique;
- long-term outcomes;
- the new diagnostic category, acute stress disorder;
- postconcussional disorder—a category provided for further study (Appendix B, DSM-IV). Symptoms occur following a closed head injury with concussion and include cognitive (specifically, attention and memory), emotional (anxiety, depression, irritability), and physical (sleep problems, fatigue, headache) problems.

26.5.2 The patient who has attempted suicide

Keith Hawton

Introduction

The term 'attempted suicide' is usually applied to all acts of deliberate self-harm, in other words deliberate self-poisoning or self-injury. In many ways this is a misleading term since the primary motivation for, or aim of, deliberate self-harm is often not death but some other purpose, such as communication of distress, blotting out an unbearable state of mind, or trying to change the behaviour of other people. Such 'non-suicidal' aims, however, often involve the use of the suicidal message to enhance the impact of such intentions. Because of this and the popularity of the term 'attempted suicide' among physicians, this terminology will be used throughout this chapter.

Attempted suicide is a major and increasing healthcare problem in most developed, and some developing, countries. In the United Kingdom, for example, there are approximately 170 000 general hospital presentations for self-poisoning or self-injury each year. Attempts occur in older children, but the behaviour becomes more common in adolescence, increasing rapidly in frequency in females from the age of 12 years, with peak rates in the late teens and early twenties. The increase with age occurs more slowly in males, rates peaking in the mid- to late twenties. In recent years there has been an increase in attempts by young males, which parallels the trend for completed suicide.

The vast majority of hospital-referred attempts involve self-poisoning. In the United Kingdom the substances most frequently involved are non-opiate analgesics, particularly paracetamol and paracetamol-containing compounds, and psychotropic agents, especially antidepressants and minor tranquillizers. Most self-injuries involve patients cutting themselves.

A wide variety of patient characteristics and problems can lead to attempted suicide. These include psychiatric disorders (especially depression, substance abuse, and anxiety disorders), personality difficulties, and poor coping resources. The more common life difficulties experienced by patients include interpersonal problems and broken relationships (especially in the young), employment difficulties, legal problems, and alcohol and drug misuse.

An important feature of attempted suicide is that it is often repeated, with at least 12 to 25 per cent of people repeating the act within a year. In the United Kingdom between 1 and 2 per cent die by suicide within a year and 3 to 5 per cent within 8 to 10 years. In settings where the patient population tends to be older the risk of suicide within a year of an attempt may be as high as 6 to 10 per cent.

This chapter focuses on the management of those who attempt suicide in the general hospital. It is imperative that patients should not only receive adequate physical care but that their psychiatric and psychosocial problems and needs are assessed.

Arrival of patients at the general hospital

In addition to the immediate assessment of the medical consequences of self-poisoning or self-injury, accident and emergency department staff should be capable of conducting a brief assessment of a patient's psychiatric status and risk. In particular, they need to determine whether a patient has a serious psychiatric disorder (for example, psychosis or severe depression) and/or is actively suicidal such that urgent attention by the psychiatric service is required. Dangerous tablets or other potential methods of self-harm should be removed.

Staff should be aware that a large number of patients leave hospital accident and emergency departments before a psychiatric assessment can be conducted. Such patients often have substance abuse disorders and a history of previous attempts, and may show behavioural disturbance in the department. Many have features associated with suicide risk, and tend to present to hospital with further repeat attempts more often than patients who are assessed in the accident and emergency department. These facts highlight the need for accident and emergency staff to have basic skills in assessment, and for them to be able to readily obtain urgent psychiatric assessment when they judge it to be necessary. Where a patient is thought to be at serious risk but wanting to leave hospital, medical staff can, in the United Kingdom at least, restrain the patient under common law until a psychiatric opinion can be obtained and, if necessary, a Mental Health Act order completed.

Medical care

Management of the medical complications of suicide attempts is dealt with in Chapter 26.6.1, but an obvious difficulty for physicians can arise with those patients who have attempted suicide and refuse potentially life-saving treatment for the physical consequences of their acts. The dilemma is whether to instigate such treatment against a patient's will. This problem most often presents in those who have poisoned themselves, such as with large overdoses of paracetamol, in which early treatment can prevent the development of potentially fatal liver damage.

In the United Kingdom the issue primarily comes down to one of mental capacity. To show that patients have the capacity to refuse treatment, they:

1. must be able to understand and retain information on the treatment proposed, its indications, and its main benefits, as well as possible risks and the consequences of non-treatment;
2. must be shown to believe that information; and
3. must be capable of weighing up the information in order to arrive at a conclusion.

If a clinician instigates treatment against a patient's wishes in spite of the patient appearing to have capacity, then the clinician is at risk of being accused of battery. Where the patient is judged as lacking capacity, essential treatment can either be instigated: (1) directly by a physician, or (2) after the patient has been placed on a Mental Health Order because of the degree of mental illness, in which case the treatment for the physical condition is given because the overdose is judged to be the result of mental illness.

In situations of dire emergency most clinicians would instigate essential treatment to save the patient's life and then try to sort out the legal issues afterwards. Such understandable action is unlikely to lead to successful litigation if the clinician acted in a way that he/she judged at the time to be in the patient's best interest.

Psychiatric assessment

Psychiatric assessment should not usually take place until a patient has recovered from any acute medical effects of an attempt. Clearly, more urgent assessment is indicated if the patient is severely disturbed or regarded as being at acute risk. In some centres, general medical and nursing staff may have to carry out these assessments, either because this is local policy or because of inadequacy of the local psychiatric service. General hospital staff should in any case be familiar with

how to conduct an assessment so that they can do this at times of emergency.

A semi-structured assessment procedure is recommended. The main factors that should be covered are listed in Table 1. A useful way of assessing the events and the patient's problems that preceded the act, the nature of the attempt, possible motivation, and suicidal intent, is to obtain a very detailed account of the few days leading up to the act. Whenever possible the patient's account should be supplemented by enquiry of other informants such as a partner, relatives, and friends. Information should also be sought from professionals and others involved in the patient's care, including the general practitioner.

Suicidal intent and other motives

Suicidal intent (that is to say, the extent to which the patient wished to die at the time of the attempt) can usefully be assessed by examining the circumstances of the act and the explanation given by the patient and by the relatives or friends. Circumstances suggesting high suicidal intent include:

- act carried out in isolation;
- act timed so that intervention unlikely;
- precautions taken to avoid discovery;
- preparations made in anticipation of death (e.g. making will, organizing insurance);
- preparations made for the act (e.g. purchasing means, saving up tablets);
- communicating intent to others beforehand;
- extensive premeditation;
- leaving a note;
- not alerting potential helpers after the act.

It is also important to take account of what the patient and others say about the purpose of the act. Approximately one-third of patients will say that they definitely wanted to die, although in some cases the circumstances of the act will suggest otherwise. There is a small but important group of patients who will claim they did not wish to die when the circumstances strongly suggest high suicidal intent—such patients may be at increased risk of making a repeat attempt, which has a high chance of being fatal. A useful questionnaire which can assist in the assessment of suicidal intent is the Beck Suicidal Intent Scale.

It is extremely important to recognize that the apparent physical danger of an overdose is a poor and potentially misleading measure of the extent to which a patient may have wanted to die. Many patients are ignorant of the relative dangers of substances taken in overdose, although increasing attention to suicidal behaviour by the media may be changing this. Thus a small overdose of a benzodiazepine hypnotic or even an antibiotic may represent a serious attempt at suicide for some patients, whereas a large overdose of a highly dangerous analgesic might be taken with low intent by others. People in the medical and allied professions represent an exception, and usually the danger of their acts is a good measure of intent. Very dangerous self-injuries are often associated with high suicidal intent, but this is not always so.

Assessment of the motives for deliberate self-poisoning and self-injury should be based on the precedents, circumstances of the act, the patient's account, that of other informants, and deduction by the clinician. Motivational reasons that frequently underly this behaviour include:

- to die;
- to escape from unbearable anguish;
- to get relief;
- to change the behaviour of others;
- to escape from a situation;
- to show desperation to others;
- to get back at other people/make them feel guilty;
- to get help.

Risk of a repeated attempt and of suicide

Estimation of the risk of repetition and of suicide following attempted suicide, both short-term and long-term, is a very important part of the assessment. Factors associated with an increased risk of a repeat include:

- previous attempt(s);
- personality disorder;
- alcohol or drug abuse;
- previous psychiatric treatment;
- unemployment;
- lower social class;
- criminal record;
- history of violence;
- age between 25 and 54 years;
- single, divorced, or separated.

Factors associated with an increased risk of suicide in this population include:

- older age;
- male gender;
- unemployed or retired;
- separated, divorced, or widowed;
- living alone;
- poor physical health;
- psychiatric disorder (particularly depression, alcoholism, schizophrenia, and 'sociopathic' personality disorder);
- high suicidal intent in current episode;
- violent method involved in current attempt (e.g. attempted hanging, jumping);
- leaving a suicide note;
- previous attempt(s).

It is essential, however, to recognize that such predictive measures are notoriously imprecise. For repetition, this is because the predictive factors are relatively crude and, whilst those patients who show the risk factors have a high risk of repeating, a substantial proportion of repeaters, possibly more than half, do not demonstrate many risk factors.

Coping resources and supports

Assessment of coping resources and supports should be based on past behaviour under stress and the patient's account of whom they can turn to for support. It is particularly important to assess whether the patient has specific difficulties in problem-solving as these can be an important target for psychosocial therapy. The best evidence for such difficulties will be a description of the methods used to solve problems in the past. It is always important to determine whether current problem-solving is impaired by depression or other psychiatric disorders.

Care after attempted suicide

Patients who have attempted suicide are frequently ambivalent about accepting help, or even frankly dismissive of it. However, this may be understandable in the context of acts that often represent attempts at interpersonal communication or have other functions unconnected with help-seeking. Furthermore, many patients

come from socioeconomic backgrounds in which help-seeking for emotional problems is rarely considered. Therefore clinicians may have to work hard in some cases to explain to patients how treatment might be of benefit. These factors also mean that a brief intervention, such as problem-solving, is likely to be more acceptable to a sizeable proportion of patients than more lengthy therapeutic approaches.

The assessment procedure can itself be highly therapeutic. Patients may be provided with their first opportunity to discuss their difficulties with a clinician. Joint interviews with family members can help highlight issues that need addressing and assist with communication problems.

Some patients thought to be at high risk of suicide refuse psychiatric treatment when this is judged to be essential. Management comes down to a judgement of whether the patient is suffering, or likely to be suffering, from a mental illness that necessitates hospital assessment and/or treatment. In most countries, if a patient thought to be at serious risk and/or mentally ill has presented to a general hospital following attempted suicide but is refusing to stay for a psychiatric assessment, accident and emergency department staff would be judged to be acting reasonably if they restrained the patient under 'common law' until a psychiatric opinion could be obtained.

Currently, there is inadequate evidence for the efficacy of treatments for patients who have attempted suicide, at least with regard to the prevention of repetition of attempts. This is partly to do with methodological flaws in the design of studies, and also because most studies have included too few patients. In one trial, repetition of attempts was reduced in multiple repeaters who received the depot neuroleptic flupentixol, compared with patients who received a placebo. Intensive and prolonged psychological therapy has been associated with promising results in female patients with a history of multiple acts of self-harm and borderline personality disorder. There are also promising results for brief problem-solving therapy.

Clinical services for patients who have attempted suicide

At one time the assessment of patients who attempted suicide was regarded as primarily the responsibility of psychiatrists. Increases in the clinical responsibilities of non-medical clinical staff and findings from research have resulted in a major change in the pattern of services in many places. In the United Kingdom it has been demonstrated that nurses, social workers, and other clinicians can assess these patients reliably, make effective aftercare arrangements, and provide effective therapy. This has resulted in official guidelines that reflect these findings.

It is imperative that staff of whatever discipline who are involved in this work have reasonable background experience and skills in the management of patients with emotional and psychiatric disorders, and that they be properly trained in the assessment and treatment of patients who have attempted suicide. They must also have support from senior psychiatrists, especially for patients with severe psychiatric disorders and where compulsory admission to hospital may be required. They must also be highly motivated and have good support systems in place, because working with such patients can be extremely demanding.

The functioning of a service for patients who have attempted suicide but do not require physical treatment in specialized settings (for example, in an intensive care unit) can be improved if they are admitted to one short-stay medical ward, rather than to a large number of wards. The attitudes of general medical and nursing staff to these patients can be negative, especially towards patients whose acts they perceive as having a low suicidal intent. Clinical experience shows that attitudes are far more favourable when admission to a single ward is possible. General medical and nursing staff in such wards acquire experience in managing these patients, and also develop closer working relationships with members of the service for attempted suicide.

The development of high-quality general hospital services for patients who attempt suicide should be a major element in any national or local suicide-prevention strategy.

Specific subgroups of patients

Alcohol and drug abusers

Many patients who attempt suicide have problems related to alcohol and drug abuse, and these factors, especially alcohol abuse, increase the risk of both repetition and eventual suicide. All attempters should be screened for substance abuse. Recognition of such problems in the general hospital may provide a special opportunity for treatment, which may be an important factor in preventing further suicidal behaviour as well as reducing physical and social harm.

Children and very young adolescents

Very young patients are usually admitted to a paediatric ward where this is available in the general hospital. It is advisable that all very young attempters be admitted to hospital rather than be dealt with in the accident and emergency department, since they require particularly careful and often prolonged assessment, including interviews with their families and the possible involvement of community statutory services (for example, social services).

The elderly

Attempted suicide in the elderly, while less common than in younger people, very often involves high suicidal intent. Routine admission to a medical bed is therefore also recommended for this group. Close links should be established with the local psychogeriatric service (if one exists) so that clinicians from the service can provide assessment and make arrangements for their aftercare.

26.5.3 Medically unexplained symptoms in patients attending medical clinics

Christopher Bass and Michael Sharpe

Historical background

Throughout history, patients have presented with subjective somatic complaints that their doctors could not explain in terms of objectively identifiable disease. Medical advances have improved the precision with which disease can be identified, but has not solved the problem. Many complaints remain unexplained and continue to present a challenge to doctors.

The proposed explanations for medically unexplained symptoms have changed over the last 300 years; early ideas located their cause in a disturbance of a bodily organ, often the uterus. Attention then focused on the peripheral nervous system, later the central nervous system, and more recently the cause has been assumed to be in the patient's mental functioning. These changing aetiological theories have been reflected in the varied terms used for such complaints: the organ theory gave rise to hysterical and hypochondriacal; the nervous system theory to nervous, functional nervous illness, and neurasthenic; and the mental theory to psychological, psychogenic, and somatization.

Changes in theory led to changing approaches to management. Early treatments were focused on the organ believed to be giving rise to the symptoms. Consequently manipulations of, and even removal of, the female reproductive organs was practised. When the proposed explanation shifted to the peripheral nervous system the preferred treatments became tonics, electrical stimulation, and other means to regenerate nervous energy. As interest shifted to the central nervous system, hypnosis became a favoured treatment and was used by famous physicians such as Charcot. By the end of the nineteenth century many physicians came to consider hypnosis unnecessary and explanation and advice to be sufficient. It was only in the twentieth century that, with the rise in popularity of psychoanalysis, medically unexplained symptoms began to be seen as a 'mental' problem requiring psychiatric treatment. Much subsequent thinking has emphasized psychological and psychiatric theories and treatments.

At the beginning of the twenty-first century many doctors continue to regard medically unexplained symptoms as psychological in origin because there is no abnormality on standard investigation. However, it has become increasingly obvious that patients dislike the psychological approach, which they see as dismissive and stigmatizing. As a result of these conflicting views patients often seem to be left in a 'no man's land' between a psychiatric conceptualization, which they reject, and a biomedical approach that they see as rejecting them. Recent developments in neuroscience have suggested that many unexplained symptoms do have a basis in the functioning of the nervous system, as hypothesized more than 100 years ago. An approach that recognizes this, whilst also drawing on evidence-based psychological and psychiatric treatment, appears to be the most productive.

Introduction

Definition and terminology

Various terms have been used to describe symptoms that are unexplained by identifiable disease processes. These include:

- *Medically unexplained*—A simple operational term, but with the potential disadvantage of suggesting that psychophysiological explanations are not 'medical'.
- *Functional*—Originally meaning a disturbance of bodily function rather then structure, it is unfortunately used pejoratively to mean 'all in the mind'.
- *Somatization*—A widely used term implying a psychological problem expressed somatically. It should arguably be restricted to cases where the somatic symptoms are plausibly understood as an expression of identifiable emotional disorder.
- *Conversion*—Used specifically to refer to loss of function such as weakness of a limb. Implies (as does somatization) that the symptoms are due to a 'conversion' of psychological problems, usually without good evidence.
- *Somatoform*—A diagnostic category in the psychiatric classifications. Intended to be atheoretical but obviously linked to the idea of somatization.

In conclusion, there is no entirely satisfactory term: the best term scientifically is probably 'medically unexplained', or perhaps 'unexplained by identifiable disease', but many textbooks and computer databases use the term 'somatoform'.

Symptoms

Almost any symptoms can be medically unexplained. Common examples include:

- pain (including back pain, chest pain, abdominal pain, and headache);
- fatigue;
- dizziness;

- 'fits', funny turns, and feelings of weakness.

Syndromes

Unexplained symptoms have been grouped into various 'functional' syndromes. Each medical specialty has at least one (Table 1): for rheumatologists, prominent muscle pain and tenderness is fibromyalgia; for gastroenterologists, abdominal pain with altered bowel habit is irritable bowel syndrome; and for infectious-disease specialists, chronic fatigue and myalgia is a postviral or chronic fatigue syndrome.

It has been argued that these syndromes do not necessarily reflect separate conditions, but merely reflect the tendency of specialists to focus only on those symptoms most pertinent to their specialty. The research literature offers support for this hypothesis by revealing substantial overlap between syndromes in their constituent symptoms, proposed aetiological factors, and response to treatment.

The significance of medically unexplained symptoms and syndromes

Medically unexplained somatic complaints are a common and important but relatively neglected medical problem, constituting a major part of the work of most doctors. Whilst sometimes regarded as merely 'worried well', patients with medically unexplained complaints often suffer disability and distress at least as severe as that of those whose symptoms are explained by disease. Their doctors often find them difficult to help. They are also expensive to the healthcare system because they attend multiple specialist services and receive extensive, but unproductive, investigation and treatment. Many not surprisingly turn to unconventional treatments that are of unproven effectiveness. Some are financially exploited. This situation is clearly unsatisfactory.

Aetiology

The precise aetiology of many medically unexplained symptoms is unknown, but there is evidence that biological, psychological, and social factors all play a role. The degree to which each of these contributes probably varies from case to case. Rather than seeking a single factor, it is helpful to consider multiple factors and to distinguish between those that predispose to the development of medically unexplained symptoms, those that precipitate them, and those that act to perpetuate them. Table 2 provides a summary of possible aetiological factors, perpetuating factors being especially important since they are targets for treatment. For example, a person may be predisposed by virtue of genetics or childhood experience to develop irritable bowel syndrome. This may have been precipitated by a combination of infection and psychological stress. The factors that perpetuate it may include neurophysiological mechanisms, fear of gastrointestinal disease, social stress, chronic anxiety, and iatrogenic factors such as overinvestigation.

Epidemiology and classification

Epidemiology

Medically unexplained somatic symptoms are extremely common in the general population in all countries, some of whom will visit doctors, usually because of concern about the cause or because of severe discomfort and disability.

- *Primary care*—Medically unexplained symptoms are the principal reason for 25 to 50 per cent of all consultations in primary care. A minority are referred for a specialist opinion.
- *Hospital outpatient care*—At specialist outpatient clinics between one-quarter and one-third of new patients have symptoms that remain unexplained by disease. A small number of such patients are admitted to hospital.
- *Hospital inpatient care*—The proportion of medical inpatients with unexplained complaints is lower than amongst outpatients, but these patients can be particularly costly to the service. One Scandinavian study found that a relatively small number of patients with recurrent multiple medically unexplained symptoms (referred to as somatization disorder as described below) were consuming a significant proportion of the country's hospital inpatient budget.

Classification

There are, rather confusingly, parallel medical and psychiatric classification schemes for medically unexplained complaints. The former emphasizes the type of symptom and lists functional syndromes by organ system as in Table 1; the latter emphasizes the number of symptoms and associated psychological factors, with the main categories as listed in Table 3. The implication of these parallel classifications is that most patients will qualify for both a medical and a psychiatric diagnosis. Both may be useful in guiding management and prognostication, hence a combined medical/psychiatric diagnosis such 'irritable bowel syndrome/anxiety disorder' is probably more useful than either alone.

An alternative multidimensional classification system that combines both the medical and psychiatric approach has been suggested and may have additional clinical value. An example is shown in Table 4.

Pathogenesis and pathophysiology

Although the physiological mechanisms of symptom production are not fully understood in many cases, some physiological abnormalities and putative mechanisms have been identified, for example the effect of overbreathing in causing non-cardiac chest pain. These physiological mechanisms interact with psychological and social factors to perpetuate the illness. Hence, overbreathing gives rise to chest pain and paraesthesias, which is interpreted by the patient as a cardiac problem, leading to anxiety and the seeking of medical care. Medical investigation increases the anxiety, leading to further hyperventilation, and so on. Some suggested physiological mechanisms are listed in Table 5.

General clinical features

Pointers to a patient having medically unexplained complaints may be apparent before the initial consultation. The referral letter and medical notes may reveal frequent attendance at medical services, numerous negative (and often repeated) investigations, and a previous history of unsuccessful surgery.

At the consultation multiple symptoms are suggestive. However, the only way of confidently diagnosing complaints as medically unexplained is when the appropriate history, examination, and investigation reveal one or more somatic symptoms that remain unexplained by disease. It should be remembered that patients often have both symptoms that are explained by disease and others that are unexplained. An example is the frequent co-occurrence of epilepsy and non-epileptic attacks. Several general points are worth noting:

- Many (but not all) unexplained medical complaints are simply somatic symptoms of depression or anxiety.
- Most medically unexplained complaints reflect genuine suffering. The deliberate manufacturing of complaints with the intent to mislead is uncommon in ordinary medical practice. However, some degree of exaggeration and even frank deception in order to obtain financial gain is not uncommonly encountered in medicolegal practice.
- Although management may be based on general principles, psychiatric diagnosis may indicate additional specific and evidence-based treatment strategies.

Differential diagnosis

The main medical differential diagnosis is from symptoms due to disease. Difficulties are likely to involve unusual presentations of common diseases and rare diseases. Missed disease is always a concern, but once a patient has been carefully assessed the emergence of a 'missed' disease is the exception rather than the rule.

Management

The general principles of management are outlined in Table 6.

Patient assessment

When assessing the patient the main tasks are to:

- Understand the nature of the presenting symptoms. For example, what does the patient mean by their complaint of fatigue? Is it lack of energy (non-specific), sleepiness (suggesting a sleep problem), or lack of motivation (suggesting depression)?
- Find out what other symptoms the patient has. It is worth asking for an exhaustive list: the more symptoms, the more likely it is that they will be medically unexplained.
- Ask the patient what they think or fear is wrong with them. This can reveal the reason they are worried about the symptoms (for example, 'it could be cancer') and allow appropriately targeted education and reassurance to be given.
- Seek evidence of 'stress'. Life stresses may be a contributory factor. Furthermore, most patients find 'stress' to be a more acceptable explanation than psychiatric diagnoses such as depression or anxiety.
- Systematically seek evidence of depression and anxiety. This is often best done toward the end of the consultation so that the patient does not feel they are being dismissed as 'just psychiatric'. A useful approach is to empathize with the understandable distress resulting from the symptoms, thereby avoiding antagonizing the patient by giving the impression that the doctor believes that the cause of the symptoms is psychological.
- Physically examine the patient. This may reveal unsuspected signs of disease and also helps to convince the patient that they have been taken seriously and properly assessed.
- Perform appropriate investigations. It should be noted that misdiagnosis is relatively uncommon, and a balance needs to be struck between the risk of missing disease and the potential iatrogenic harm resulting from excessive investigation.

Giving reassurance explanation and advice

As well as being reassured that there is no evidence they have an unpleasant disease, patients benefit from being given a positive and credible explanation for their symptoms and practical advice on what to do next.

Reassurance

Giving appropriate reassurance is an important part of the medical consultation. This is most effective if based on the patient's actual concerns, so it is important to ask them what they are worried about before reassuring them. Many patients report that having a physical examination is particularly reassuring. A detailed explanation of what the tests that they have had do and don't show can also help. Clearly, it may be unwise to state categorically that the patient has no disease. However, it can be explained that it is not possible to do this, whilst emphasizing as unambiguously as possible that the probability they have the disease they fear is very low. Beware of the patient who repeatedly asks for reassurance about the same issue—they may have hypochondriasis (see below).

Explanation

Patients also need a positive explanation for their symptoms. It is nearly always unhelpful to explain that the symptoms are 'just psychological' or 'all in the mind'. Such statements are likely to reduce confidence in the doctor and may paradoxically increase the patient's concern about missed disease. It is also potentially harmful to suggest that the patient has a disease when they do not, or to collude with their idea that they do so. This may lead to inappropriate coping behaviour, for example obtaining a wheelchair rather than seeking rehabilitation. Rather, it is useful to describe a plausible physiological mechanism for the symptom that emphasizes the link with psychosocial factors and helps the patient to see their symptoms as reversible. For example, it can be explained that in irritable bowel syndrome psychological stress results in increased activation of the autonomic nervous system, leading to constriction of smooth muscle in the gut wall, which in turn causes pain. The symptoms may therefore be perpetuated by a vicious circle in which pain leads to anxiety, and anxiety leads to further pain. It can then be explained (perhaps using a diagram) that this mechanism is reversible by targeting these perpetuating factors. It is helpful to offer an optimistic prognosis, but an unrealistically precise prediction ('you will be better next week') is unwise as it is likely to lead to loss of faith in the doctor if not fulfilled.

Advice

A positive plan of action that specifies both what the patient can change and what the doctor can do is helpful. The patient can be advised how to overcome probable perpetuating factors, for example by resolving stress causing social problems or by practising relaxation. The doctor can offer to review progress, to prescribe (for instance, an 'antidepressant' drugs) and if appropriate to refer, for example, to physiotherapy or psychology. Action by the doctor gives the patient a sense that they are being taken seriously and not (as they may have experienced before) being dismissed. Writing to the patient as well as to the general practitioner to summarize the conclusions of the medical assessment and the proposed plan reinforces messages that may otherwise be easily forgotten.

'Antidepressant' drugs

Antidepressant drugs are most useful when the patient is depressed, but they can also be tried when he or she is not. A specific explanation of why they are being prescribed is needed if they are to be acceptable to the patient. Depending on the circumstances, one of the following two approaches is suggested. The first is to explain that the term 'antidepressant' is a misnomer: in fact the drugs are broad-spectrum 'nervous tonics' of proven value for sleep and pain as well as for depression. The second is to be explicit that they are being prescribed for depression, but emphasize that depression is understandable given the somatic symptoms the patient is suffering. Both these explanations minimize blame and stigma.

A systematic review of antidepressants for medically unexplained symptoms found them to be moderately effective overall. The odds ratio (**OR**) for improvement with antidepressant treatment compared with placebo was 3.4, with the size of effect similar across the different functional syndromes. However, there was a high dropout rate from treatment, emphasizing the need for careful explanation and follow-up to ensure adherence.

Psychological therapies

Explanation, reassurance, and advice are important psychological therapies. Where insufficient they can be reinforced by a formal psychological treatment. The most widely used are behavioural or cognitive–behavioural treatment (**CBT**), although other psychological treatments may have a role. CBT aims to help the patient to improve by examining their way of thinking about and coping with their symptoms. The treatment works by changing potentially illness-perpetuating beliefs and coping behaviours.

A systematic review of CBT for medically unexplained symptoms found that it was significantly superior to non-specific treatment in 70 per cent of trials. Individual behavioural components of CBT, such as graded exercise, have also been studied and are of value, but are probably less effective. Overall research supports the use of specialist CBT and other behavioural therapies in the management of patients with medically unexplained symptoms.

Referral for psychological or psychiatric management

The decision to refer will be based on the physician's assessment of the patient and an appraisal of the available services. Ideally, all medical clinics would have dedicated specialist psychiatric or psychology services: this is rarely the case in practice. It is wise to find out who is willing and interested in receiving referrals in the immediate locality. If the options are few, however, the healthcare team may wish to make the case for the provision of better services.

Reasons to refer include:

- very severe disability;
- suspected somatization disorder;
- specific service available, e.g. for chronic pain or chronic fatigue syndrome (**CFS**);

- patient remains distressed despite explanation and reassurance;
- suicide risk.

When explaining the referral to the patient it is wise to:

- Emphasize the reality of the patient's symptoms.
- Be positive about the service you are referring to.
- Do not prematurely imply you think the origin of their complaint is psychological.

A patient is more likely to attend for a referral if you have said: 'I see you have real and troublesome symptoms. I am pleased to tell you that they do not indicate a disease but am sorry to say that I do not have a simple cure I can prescribe. However, I can recommend and refer you to a specialist service for your problem', than if you have said: 'there is clearly nothing wrong with you; it must all be in your mind. There is nothing to do now but to refer you to the shrinks.'

What happens in practice?

In practice the ideal management described above is inconsistently applied and iatrogenic psychological and physical damage is probably common. The specific evidence-based treatments of antidepressants and CBT are rarely offered and frequently refused by patients. We could do better.

Prognosis

The prognosis for those patients whose symptoms are sufficiently severe and persistent for them to be referred to a specialist service is often poor. It is not uncommon for persistent symptoms and disability to persist for years, especially if untreated The prognosis is best for those patients who were well before the onset of the complaint and whose symptoms are expressions of uncomplicated depressive and anxiety disorders. It is worst for those patients with long-standing multiple symptoms.

Prevention

We do not know enough about the aetiology of medically unexplained complaints to implement primary prevention. Parenting behaviour and social factors such as the stigma associated with psychiatric illness and the nature of benefit and litigation systems appear to play a role.

Secondary prevention is important, as effective early management probably reduces the risk of chronicity, whereas poor explanation and overinvestigation probably perpetuates it.

Tertiary prevention is the effective management of chronic somatization and requires a proactive management plan as described above.

Quality of life and psychological aspects

Patients with medically unexplained symptoms may have considerable functional impairment and a markedly reduced quality of life. Two disorders in particular, fibromyalgia and chronic fatigue syndrome, are associated with marked functional impairment and can have important consequences on a person's ability to work. Some patients may become involved in medicolegal claims, especially if the symptoms were temporally related to an accident or injury.

Areas of uncertainty and controversy

Many aspects of medically unexplained somatic complaints are controversial. Perhaps the most controversial issue is whether they are best regarded as a psychiatric/psychological or as a medical problem. This issue has been particularly prominent in controversy over chronic fatigue syndrome/myalgic encephalomyelitis (**ME**).

Any clinician who sees patients with medically unexplained symptoms (and most do) is likely to agree that they are difficult to manage effectively. Furthermore, the core of this problem is frequently a clash between the physician and the patient in how the illness is viewed. A consideration of the changes in medical fashion for explaining such symptoms over the last few hundred years should encourage humility. Further study that integrates psychosocial and physiological perspectives is required, both to improve our understanding and to help us to explain these problems effectively to our patients.

Common syndromes

This section will cover specific aspects of the main psychiatric categories of medically unexplained symptoms listed in Table 3.

Predominant worry about disease—hypochondriasis

The central feature of hypochondriasis is a persistent preoccupation with the possibility that one has a serious and progressive physical disease. These fears have persisted despite the fact that repeated investigations and examinations have identified no adequate physical cause, and appropriate reassurance that there is no physical disease has been given.

Example

The patient is a young woman. Her urgent referral is faxed by her general practitioner (**GP**). She has attended the general practice clinic daily for the last 2 weeks. Her history is of headache. On enquiry her main concern is that she has developed a brain tumour. The background history reveals that her father died of a brain tumour 2 years ago; he was told it was only a 'tension headache' by the GP. Examination is normal but she is very anxious indeed and repeatedly asks for a brain scan and for your reassurance that she doesn't have a tumour.

Management and prognosis

Assessment should elicit the patient's specific fears. A useful question is: 'what is your worst fear?' The patient's catastrophic fear leads understandably to their behaviour and anxiety. For example, a patient with headache who thinks, 'I have a brain tumour' will be anxious and seek urgent medical attention. That is to say the somatic symptoms (headache) leads to thoughts (brain tumour) that in turn lead to anxiety and to certain behaviours (visiting doctors). It also causes muscular tension that leads to further pain and so on. Eliciting this causal sequence from the patient, and describing it to them, perhaps with a diagram, aids explanation. Reassurance that they do not have a tumour is appropriate. However, repeated reassurance can worsen concern about disease and should be avoided. Depressive disorder should be treated. CBT can be effective. Many acute cases resolve, but the condition can become chronic.

Somatic presentation of depression and anxiety

One of the commonest causes of medically unexplained somatic complaints is undiagnosed depression. Because depression is (erroneously) thought of as a purely 'mental illness', it is readily forgotten that it has somatic symptoms. These include:

- fatigue;
- increased pain complaints;
- loss of weight and appetite;
- loss of libido;
- in severe forms there may be negative ruminations on health that in rare cases can be delusional.

Another very common cause of unexplained symptoms is anxiety in a generalized form (generalized anxiety disorder) or episodic severe form (panic disorder). Somatic symptoms of anxiety include:

- fatigue;
- dizziness;
- paraesthesias;
- chest pain and palpitations;
- shortness of breath (especially 'getting enough breath in').

Example

A 50-year-old man presents to the Accident and Emergency department with chest pain and fatigue. Investigations are negative. Only after admission to hospital does a junior doctor examine the patient's mental state and find a persistent low mood, loss of interest, and negative thinking, with episodic anxiety associated with overbreathing and many somatic symptoms. The diagnosis is panic disorder and depressive disorder.

Management and prognosis

Treatment is by reassurance, explanation, and treating the depression and anxiety. This can be achieved by prescribing an antidepressant agent combined with explanation and active follow-up to ensure adherence. In some cases psychological treatment may also be required. The prognosis for recovery within 6 months is good, although there is a risk of relapse. Patients should continue to take the antidepressant drug for at least 6 months to prevent early relapse.

Simple somatoform disorders

This presentation refers to the patient with a single or small number of somatic complaints that do not appear to be simply expressions of depression or anxiety. This diagnosis includes undifferentiated somatoform disorder and somatoform pain disorder. The most common type of clinical problem in this group is the patient with chronic persistent pain in one site, for example chronic back pain or chronic headache. The physical symptoms may have commenced after a trivial injury or accident, but the subsequent disability is usually out of proportion to the organic findings. A medicolegal case may be pending, which often makes management more difficult.

Example

A middle-aged man presents with widespread pain. He believes that his symptoms are a result of occupational exposure to printing ink. He is medically retired. There is a history of depression some 12 months ago, but no evidence of current depressive or anxiety disorder. Examination is normal. The patient walks with a stick and seems concerned to demonstrate to you how ill he is.

Management and prognosis

Explanation and symptomatic treatment including cognitive–behavioural therapy is appropriate. Antidepressants may be tried on an empirical basis. The prognosis for chronic complaints is fairly poor, although improvement often occurs over many months. Physical rehabilitation may be useful.

Somatization disorder (Briquet's syndrome)—patients with chronic multiple complaints

'Somatization disorder', or Briquet's syndrome, is a term used to describe patients—mostly women—who have a lifelong history of multiple recurrent somatic complaints, which usually include conversion symptoms. If looked for, such patients are relatively easy to identify. Although the patient's current presenting complaint may be of only one or two symptoms, for example chest pain or shortness of breath, scrutiny of the past medical notes reveals numerous outpatient visits to different clinics with symptoms such as abdominal pain and bloating, diffuse muscular pains and tenderness, and chronic lassitude over previous years. A history of childhood abuse is common.

Example

The patient is a middle-aged woman, referred to as a 'heart sink' patient by the GP. She presents with dizziness, bloating of her stomach, and generalized weakness. She has three volumes of medical notes documenting presentations with a range of symptoms including pain in a number of sites, irritable bowel symptoms, menstrual problems, and transient loss of sight. She has had many investigations, a hysterectomy and three laparotomies, and she is taking many medications including oral opiates. However, review of her notes does not reveal any convincing evidence of any proven disease and examination reveals only a number of operation scars.

Management and prognosis

If possible, it is sensible to review the case notes before the patient arrives in the clinic. It is worth asking why the patient has been referred now: the GP may have become frustrated or angry, or helpless in the face of repeated complaints, or unable to cope with or contain the patient's distress. Management requires a reduction in the patient's and their general practitioner's expectation of medical 'cure', and a shift toward the development of coping strategies. Further investigation should be strictly limited to that which is clearly indicated, but may be difficult to avoid. Practical management strategies are listed in Table 7.

Depression is common in such patients, may give rise to some of the symptoms, and should be treated. Long-term follow-up by a hospital doctor, general practitioner, psychiatrist or a combination of these is desirable. A realistic aim is for limited improvement and prevention of iatrogenic harm. The condition is very likely to persist.

Conversion disorder

The presentation is loss of function of a body part, most often a limb, or abnormal body movements. This is not thought to be produced intentionally, as with factitious disorder and malingering, but rather 'subconsciously'. In reality this distinction is difficult. Persistence of the symptom even when the patient believes they are unobserved helps to differentiate intentional and non-intentional symptom production. Other oft-quoted signs such as 'belle indifference' are unreliable. In acute cases the symptoms may have arisen in the context of severe interpersonal stress or conflict. The patient may have experienced a family member with similar symptoms.

Example

A young woman is referred for unexplained weakness of her left side. She reports being unable to move her left arm and leg following a bang on the head. Enquiry reveals that she was sexually assaulted the week before her symptoms began. She has no explanation for the symptoms and seems unconcerned about them. On examination her left arm and leg appear weak, with a 'collapsing' pattern of weakness, but there are no abnormalities of reflexes. A magnetic resonance imaging (**MR**I) brain scan is normal.

Management and prognosis

For the acute case an early return to function should be encouraged. Physiotherapy may be useful. Depression should be sought and treated if present. The patient should also be offered an opportunity to talk about stressors. In chronic cases treatment is more difficult and may best be achieved via referral to a physical rehabilitation service. In chronic cases there may be long-term invalidism with dependence on state benefits.

Body dysmorphic disorder—requests for surgery to a body part in the absence of a conspicuous abnormality or deformity

Patients who are dissatisfied with some aspect of their bodily appearance or shape may find their way into the clinics of physicians and surgeons. Some of these patients are preoccupied with an imagined defect in appearance, such as a large nose. Others have more substantial concerns, such as disliking a limb sufficiently to

desire its amputation. Even in the presence of a physical abnormality, the person's concern appears to be markedly excessive.

Example

A 30-year-old woman complains about the shape of her nose and blames this for many failures in her life. She requests plastic surgery.

Management and prognosis

In the absence of a conspicuous physical abnormality or deformity, it is usually prudent to seek a psychiatric opinion. There is some evidence for the effectiveness of CBT. Surgery sometimes helps, but should only be carried out after careful consideration.

Other unusual presentations

Atypical eating disorders

Some patients who attend with symptoms of abdominal pain after food, vomiting, anorexia, or constipation may have a covert eating disorder. Judicious enquiry about weight loss, amenorrhoea, and laxative use may help to establish the correct diagnosis, which may have been present for many years. See Chapter 26.5.5 for further discussion.

Chronic constipation that has not responded to conventional treatment

Patients may report constipation for two or three decades that has proved unresponsive to appropriate treatment. There is often no identifiable organic cause, and some are referred to surgeons for colectomy. All such patients require a thorough psychiatric assessment before major decisions about treatment are implemented. Biofeedback has been shown to benefit some patients, but resources for this treatment are scarce.

Loin-pain haematuria syndrome

This is a rare syndrome that is poorly understood. Patients may abuse opiate analgesics, and a proportion is thought to simulate their pain. It is unwise to carry out renal autotransplantation, because the pain can recur on the opposite side of the body.

Factitious disorders

Patients with factitious disorder deliberately feign or simulate illness, which is in contrast to the disorders described above. The term 'factitious disorder' is preferable to the eponym Munchausen's syndrome, because this stereotype is often misleading—Munchausen's syndrome generally being applied to wandering, untreatable, male sociopaths. Over three-quarters of patients with factitious disorders are women, over half of whom work in medically related occupations. They often report a large number of childhood illnesses and operations. High rates of substance abuse, mood disorder, and personality disorder have been reported. Some patients exploit genuine disease (usually chronic) to create dramatic medical emergencies.

Example

A young man is repeatedly admitted with breakdown of an abdominal surgical wound. He is observed rubbing dirt into the wound. When confronted with this he discharges himself immediately.

Management and prognosis

A supportive confrontation is required. This means presenting the patient with the evidence that they have been manufacturing symptoms, together with the acknowledgement that they have an emotional problem and an offer of psychological help. Ideally, the physician and psychiatrist do this jointly. There is some evidence that psychological support following hospital discharge may be associated with an improved outcome. Patients with more stable social networks have a better prognosis than wanderers.

Malingering

Malingering is the deliberate simulation or exaggeration of physical or psychiatric symptoms for obvious and understandable gain, for example monetary compensation, disabled status, and avoidance of criminal prosecution or conscription. Doctors are often reluctant to diagnose malingering lest it adversely affect the individual's healthcare, occupation, or legal case. However, it does occur, especially in medicolegal contexts. Common examples include malingered cognitive deficit and postinjury back/neck pain in patients seeking compensation or disability payment. The initial physical injury may be established, but the length and severity of symptoms, disability, and distress are disproportionate. There is probably a continuum from minor embellishment of symptoms to frank malingering.

Example

A 30-year-old man is seen in order to produce a legal report for the purpose of claiming compensation. He reports severe back pain following a car accident 2 years ago and is in a wheelchair. There are no neurological signs and no muscle wasting. He is later seen lifting his wheelchair into the boot of his car.

Management and prognosis

Assessment of suspected malingering requires the methodical use of all sources of information. It may only be possible to make the diagnosis positively when covert surveillance reveals behaviour clearly at odds with the reported disability. If management is required it is by confrontation, although it is more common that the identification of malingering ends the behaviour (and the legal case).

26.5.4 Anxiety and depression

L. Chwastiak and W. Katon

Introduction

Depression and anxiety are more commonly seen in primary care than any other condition except hypertension. Over half of all patients with mental health disorders are cared for solely by a primary care provider, and many seek help from their physician because they attribute symptoms of depression and anxiety to a physical problem. Physicians fail to make an accurate diagnosis in at least 50 per cent of those with depressive or anxiety disorders. This failure occurs because of time limitations, lack of knowledge, focus on presenting physical symptoms, fear of opening 'Pandora's box', and the stigma associated with psychiatric illness. As a result, only about half of those patients with major depression receive the dose and duration of treatment with antidepressants that meets United States Agency for Health Care Policy and Research (**AHCPR**) guidelines. Fewer than half of patients with anxiety disorders in primary care are treated with specific medications or psychotherapy.

Early recognition of depressive and anxiety disorders is important because they can be treated effectively, often in primary care. The detection and treatment of anxiety and depression can prevent patient discomfort and unnecessary expensive diagnostic investigations, which are often ordered to investigate unexplained physical symptoms. More serious complications may also be prevented, such as the progression of psychiatric illness, loss of employment and impairment of social roles, decreased adherence to medical treatment, and suicide.

Epidemiology

Depression and anxiety are very common and frequently follow a chronic course. The National Comorbidity Survey (**NCS**) found, through a structured psychiatric interview, that almost 50 per cent of community respondents in the United States had at least one lifetime DSM-III-R (*Diagnostic and statistical manual of mental disorders, third edition, revised*) psychiatric disorder. Major depression was the most common disorder with a lifetime prevalence of 17.3 per cent and a 12-month prevalence rate of 10.3 per cent. The point prevalence of depression in Western industrialized nations is from 2.3 to 3.2 per cent for men and 4.5 to 9.3 per cent for women; lifetime risk is 7 to 12 per cent for men and 20 to 25 per cent women. The reasons for gender differences are poorly understood, but are thought to include endocrine, biological, and sociocultural factors: women have been found to have experience higher rates of childhood (especially sexual) abuse.

The prevalence rates of depression are higher for medical patients than for the general population: 6 to 10 per cent of primary care patients; and 10 to 14 per cent medical inpatients meet the criteria for major depression. In patients with at least two chronic physical illnesses, the 12-month prevalence rate of major depression was 12.5 per cent. Major depression is commonly associated with cardiovascular disease (prevalence rate of 25 per cent), cancer (20 to 45 per cent), cerebrovascular accidents (26 to 34 per cent), chronic pain (33 to 35 per cent), and Parkinson's disease (40 per cent). Depression and panic disorder are also common in 'medically unexplained' syndromes (Table 1, and see Chapter 26.5.3).

Some 16 per cent of people experience an anxiety disorder sometime during their lifetime. These disorders are commoner in women, with a 12-month prevalence of panic disorder in community samples of 3.2 per cent in women and 1.3 per cent in men, and a lifetime prevalence of 5 per cent and 2 per cent, respectively. Infrequent panic attacks occur in up to one-third of individuals. Only 26 per cent of patients with panic disorder present to a mental health setting: one-third present to an emergency room, and over a third to their primary physician.

About 80 per cent of psychiatric disorders are comorbid disorders: almost half the cases of depression and anxiety occur in the same patients at the same time. About 25 per cent of patients with major depression, dysthymia, and anxiety disorders also have a history of substance abuse.

Costs

Worldwide, depression is the leading cause of years lived with disability. In the United States in 1990, the estimated total annual cost of major depression was $44 billion, and for anxiety disorders it was $42.3 billion, of which $23 billion was attributed to non-psychiatric medical costs, reflecting the high degree of medically unexplained symptoms these patients experience. Patients with anxiety and depression make more emergency visits, primary care visits, and more telephone calls to their physicians, have more medical tests and evaluations, take more medications, and are more likely to be admitted to hospital for a medical disorder than patients who do not have these disorders. As many as 50 per cent of 'high utilizers' of medical care services have a current depressive or anxiety disorder. Even after controlling for age and pre-existing medical comorbidity, patients with depression receive two to four times as much non-psychiatric medical care as patients without depression, and those with panic disorder use three times as many services as other primary care patients.

In patients with chronic medical illness, depressive and anxiety disorders are associated with an amplification of physical symptoms, additional functional impairment, and a decreased ability to adhere to medication and important lifestyle changes (exercise and diet). Depression reduces the effectiveness of rehabilitation in older patients with stroke, Parkinson's disease, heart disease, fractures, and pulmonary disease. Effective treatment of major depression reduces physical symptoms and functional impairment in patients with chronic medical illness.

The indirect costs of depression and anxiety include mortality, absenteeism from work, and adverse effects on family roles. In the WHO study in primary care, depression was associated with 6.1 disability days per month—as much or more than eight chronic illnesses, including coronary artery disease and arthritis. Anxiety disorders usually strike people at the beginning of their working lives, and may last for many years. Some studies reported that over half of those with panic disorder were not working, and others were forced to take lower-paying or part-time jobs near their homes. The lost economic productivity is easier to quantify than the other indirect costs: lost earning time of family or friends bringing patients to treatment, decreased efficiency at work, the toll on families, the future costs to society of children reared by an unemployed or housebound parent. The role functioning of patients with panic disorder is substantially lower than that of patients with chronic medical illnesses, but higher than that of depressed patients.

Pathophysiology

Depressive and anxiety disorders are complex syndromes that are diagnosed based on clinical criteria. No clear anatomical, physiological, or biochemical explanation has been found. Pathophysiological hypotheses for these disorders involve endocrine characteristics, abnormalities in levels of particular neurotransmitters, and neuroanatomical changes.

Data support an underlying genetic component for major depression, panic disorder, generalized anxiety disorder, and obsessive–compulsive disorder. There are significantly higher rates of depression and panic disorder in first-degree relatives of patients with these disorders. Twin studies have shown a higher rate of

concordance for monozygotic compared to dizygotic twins in patients with panic disorder and major depression.

Mood disorders are associated with heterogeneous dysregulation of the biogenic amines, noradrenaline (norepinephrine) and serotonin being the two neurotransmitters most implicated. In animal models, long-term treatment with virtually all antidepressants is associated with a decrease in the sensitivity of postsynaptic b-adrenergic and type-2 serotonin receptors. Anxiety disorders are associated with abnormalities of the same neurotransmitters as well as in receptors of the neurotransmitter g-aminobutyric acid (GABA), an inhibitory neurotransmitter found mainly in the cerebral cortex.

A variety of neuroendocrine abnormalities have been reported in patients with mood disorders, but it is unclear whether these are the cause of the mood disorder, or reflect an underlying brain disorder. Among the more consistent observations in patients with major depression is dysfunction of the hypothalamic–pituitary–adrenal (**HPA**) axis, presenting as elevation of basal cortisol, dexamethasone-mediated negative feedback resistance, increased cerebrospinal fluid levels of corticotropin-releasing factor (**CRF**), and an ACTH response to challenge with exogenous CRF. These features appear to be markers of state rather than trait: they usually normalize after successful treatment.

There is evidence suggesting that panic disorder is associated with specific biological abnormalities in the central nervous system. Stimulation of the locus coeruleus in the pons increases anxiety, and selective serotonin-reuptake inhibitors (**SSRIs**), tricyclic antidepressants, monoamine oxidase inhibitors (**MAOIs**), and benzodiazepines all decrease the firing rates of neurones in this area.

Diagnosis and clinical manifestations

Patients with depression or anxiety initially present with physical complaints 50 to 70 per cent of the time. They often complain of vague symptoms or report multiple somatic symptoms in a variety of anatomical locations, or experience greater dysfunction than can be attributed to their known medical disorders. Patients with panic disorder often selectively focus on the somatic components of anxiety, such as chest pain or palpitations, attributing their increased anxiety and tension to the frightening nature of somatic symptoms.

When depression or anxiety are suspected, simple screening questions may be helpful: 'Are you feeling sad, blue, or depressed?' 'Have you lost interest and pleasure in most things you usually enjoy?' 'Do you have sudden episodes or attacks where your heart beats fast, your chest is tight, it feels hard to breathe and you feel shaky?' The physician should enquire about the patient's explanatory model for his or her symptoms: 'Why do you think you get these symptoms?'

History is the single best diagnostic tool. The physician should elicit the patient's concerns and fears, current life situation, family and other support systems, and concurrent medical problems. A family history of psychiatric problems (depression, anxiety, substance use disorders) should also be obtained. Screening questions about a childhood or adult history of physical or sexual abuse or domestic violence are important and can be woven into the usual questions about family medical history. Adverse childhood and adult traumatic experiences are associated with an increased risk of anxiety and affective disorders in adulthood. Over half of the depressed women in one primary care study reported experiencing physical abuse as adults.

The physician should explain carefully that anxiety and depression reflect a biological predisposition that is provoked during a period of life stress, but major depression is not the uniform outcome of any stressful event. Risk factors that predispose patients to anxiety or depression include a personal or family history of depression or substance abuse, serious medical illness, lack of social support, or a history of early childhood trauma or neglect. Risk factors that can precipitate an acute episode or perpetuate the disorder include poor physical health, divorce, poor interpersonal relationships, illness or death in a family member, low socioeconomic status, or a stressful work situation.

Major depressive episodes last at least 2 weeks and are characterized by at least five of nine criteria, including at least one of the two primary criteria of depressed mood and loss of interest or pleasure in nearly all activities (Table 2). There are two to three times as many people with 'minor' depressive symptoms that fall short of major depression criteria: these have a higher rate of spontaneous recovery.

Physical symptoms are predictive of a good response to treatment: patients with middle insomnia (awakening between 0200 and 0400 h) or a diurnal variation in mood are more likely to respond to antidepressant medications.

Several dimensions of depression severity should be assessed: the frequency and chronicity of depressive symptoms, the impact of depression on the patient's ability to function, the potential for suicide, and the presence of psychotic or manic symptoms. Dysthymic disorder is characterized by a chronically depressed mood that occurs most of the day, more days than not, for at least 2 years. Dysthymic disorder is associated with many of features of major depression, but differs in its onset, duration, persistence, and severity of symptoms. Dysthymia is associated with impaired functioning and may not remit spontaneously.

Patients with anxiety have cognitive, affective, and somatic symptoms. The key feature distinguishing panic disorder from other anxiety disorders is the episodic nature of the attacks. Panic attacks are characterized by the sudden onset of intense apprehension, fear or terror, and by the abrupt development of at least four of the symptoms listed in Table 3, reaching a peak within 10 min. Panic disorder is diagnosed when attacks are recurrent, produce persistent fear, or become significantly disruptive to the patient's life.

Laboratory studies

An adequate diagnostic work-up for anxiety or depression may include a complete blood screen, urinalysis, and routine laboratory tests of renal and liver function. Selected patients should receive an electrocardiogram or chest radiograph. Thyroid function studies are recommended in perimenopausal or postmenopausal women. Given the sizeable differential diagnosis for a patient presenting with anxiety or depression, the extent of work-up must be tailored for each case.

Suicide

The risk of suicide should be evaluated in all patients with depressive and anxiety disorders. The risk of suicide attempts and suicidal ideation more than doubles in depressed patients with comorbid anxiety or physical illness. Other risk factors for suicide include gender (elderly White males are at highest risk), alcoholism, severe medical illness, psychosis, and lack of social support. The topic of suicidal ideation can be approached gradually with a non-specific question such as, 'Do you ever feel so discouraged that life does not seem worth living?'

Asking about suicide will not increase a patient's risk. Enquiries about suicide can reassure the patient and enable the physician and patient together to make a plan to prevent suicide, including deciding together whether emergency psychiatric consultation or hospitalization is necessary. Physicians should consider using a 'no harm contract': meaning that patients are simply asked to contract with the physician in writing that they will contact the physician if they think that they are losing control of a suicidal impulse. Although data on the effectiveness of this technique are not available, it seems sensible and is standard clinical practice in many centres.

For further discussion of these issues see Chapter 26.5.2.

Treatment

Whilst depression and anxiety are usually recurrent or chronic disorders, their clinical course can be markedly improved with timely, evidence-based treatments. Many patients can be treated successfully by primary care or general physicians. A meta-analysis of 28 randomized controlled trials found an overall efficacy rate of 54 to 65 per cent for the treatment of depression in the primary care setting, which is comparable to the response of patients seen by psychiatrists.

Physicians need to educate patients about the nature of depression or anxiety and how symptoms can be managed. They should explore background problems, define treatment goals, and dispel negative perceptions (for example, that antidepressant therapy is addictive). Patients should be reassured that they are not 'crazy', nor are their symptoms a manifestation of their own failure or shortcomings. There are several important educational points to cover. Depression and anxiety are quite common and are associated with important physiological changes. With proper treatment, these disorders almost always improve or remit; but relapses and recurrences can occur, so follow-up is essential. Physicians should enquire about the patient's concerns regarding a diagnosis of depression or anxiety, and also their

worries about medical disorders. Raising the possibility of referral to a psychiatrist or other mental health professional early may make it easier to accept later.

Patients should be educated about the types of available treatments. Identifying the patient's desires and goals for treatment can provide a focus for the management of problems that can otherwise seem to be poorly defined and overwhelming. This can also increase patients' sense of participation in their care. Successful disease management programmes developed for asthma and diabetes that have emphasized educating patients to be partners in their medical care have resulted in significant improvements in adherence to treatment and in outcomes. Similar approaches appear to be successful in managing those with depression and panic disorder.

Pharmacotherapy

The decision to prescribe antidepressant therapy should be based on the number of symptoms, the level of dysfunction, and previous episodes of depression or anxiety. Before initiating antidepressant therapy, the physician should educate the patient regarding potential side-effects, the need to take medication regularly, and the usual time period and course to recovery.

The different classes of antidepressant drugs show virtually equivalent efficacy in the treatment of outpatients with major depressive disorder. The consensus on the pharmacotherapy of panic disorder also described equivalent efficacy of tricyclic antidepressants (**TCAs**), SSRIs, MAOIs, and high-potency benzodiazepines. For other forms of anxiety (social phobia and post-traumatic stress disorder), there is more evidence of the efficacy of SSRIs and MAOIs compared to TCAs.

The choice of medication should therefore be made on issues other than efficacy, such as side-effects, cost, adherence, and physician familiarity and comfort with prescribing particular agents. Primary care providers should become familiar with one or two medications with minimal side-effects from each of the major classes of antidepressants: TCAs, heterocyclics, and SSRIs. In each case the aim is to optimize treatment benefit and lower risk. Factors to be considered include the possibility of side-effects, history of response or a failure to respond, possible drug interactions, the presence of other psychiatric or medical conditions, familial response to a specific agent, and patient age.

The SSRIs have become the first-line treatment for major depression, dysthymia, and panic disorder, primarily because their improved side-effect profiles are associated with improved adherence to treatment. In the primary care setting, patients are significantly more likely to discontinue TCAs than SSRIs, those started on an SSRI being 7.5 times more likely to have a duration and an average dose of medication consistent with treatment guideline recommendations. The initial prescription of fluoxetine results in fewer side-effects, a lower rate of medication switching, and no difference in clinical outcomes, quality of life outcomes, or overall treatment costs when compared to TCAs. Although SSRIs are more expensive, total treatment costs per depressive episode are similar for patients treated with SSRI or TCA medication.

Randomized controlled trials have failed to show efficacy for antidepressant medication in patients with minor depression, largely because the placebo response rate was so high. Watchful waiting is appropriate for these patients, although the physician should recognize that they are at a higher risk of developing a major depressive episode.

Classes of medications

For a discussion of the pharmacology, side-effects, and interactions of tricyclic antidepressants, SSRIs, MAOIs, and other agents used in the treatment of anxiety and depression, see Section 26.6.1.

Selective serotonin-reuptake inhibitors (SSRIs)

The advent of the SSRIs (fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram) and the newer atypical antidepressants (amfebutanone (buproprion), nefazodone, and venlafaxine) has significantly increased the number of patients receiving pharmacological treatment for depression and anxiety in a primary care setting. These new agents have fewer adverse side-effects and are safer for treating elderly patients and those with comorbid medical illnesses. SSRIs are also much safer than the tricyclic antidepressants if taken in overdose. They do not cause postural hypotension or cardiac conduction delay.

These agents have the advantage that the starting dose may also be an effective treating dose. This is most clearly the case for fluoxetine (20 mg), but may also be true for paroxetine (20 mg), sertraline (50 mg), and citalopram (20 mg). The frail elderly and those with liver disease require smaller starting doses (generally one-half of the recommended starting dose). Fluoxetine has the longest half-life (24–27 h) and a long-acting active metabolite (half-life of 7 days). This medication can be taken every other day, and the doses can eventually be given once or twice weekly to allow for smooth tapering when the drug is being withdrawn. The other SSRIs have half-lives of about 24 h and have no active metabolites with longer half-lives. This allows once-daily dosing and rapid washout. Amfebutanone (buproprion), venlafaxine, and nefazodone have shorter half-lives (14 h), so must be given at least twice a day; sustained release forms of amfebutanone and venlafaxine can be taken once daily.

Table 4 describes common side-effects of these medications: those such as anxiety, insomnia, nausea, headache, and agitation occur in fewer than 20 per cent of patients. When they do occur, they are usually mild and may respond to a reduction in the dose of medication. Sexual dysfunction (decreased libido and anorgasmia) may occur in up to one-third of patients treated with SSRIs; the addition of amfebutanone (buproprion) (75 to 150 mg a day in divided doses) or buspirone (20–40 mg) may alleviate these sexual side-effects. Strategies for the management of other common side-effects are listed in Table 5.

Patients with anxiety disorders are especially sensitive to the SSRI side-effects of jitteriness, restlessness, agitation, and insomnia. Low doses should be prescribed initially (5–10 mg paroxetine; 12.5–25 mg of sertraline; 25 mg fluvoxamine; 5 mg fluoxetine) for approximately 1 week, then gradually increasing to full therapeutic doses. To completely alleviate panic attacks in most cases requires: 20 to 50 mg paroxetine, citalopram, or fluoxetine; 50 to 200 mg of sertraline; and 100 to 300 mg of fluvoxamine. Similar schedules and dosages are used to treat patients with social phobia, post-traumatic stress disorder, and generalized anxiety disorder.

The SSRIs (but not amfebutanone (buproprion)) have all been shown to inhibit the cytochrome P-450 system in the liver, thus potentially leading to drug interactions (see Chapter 26.6.1). Amfebutanone is an effective antidepressant that may be especially useful because it does not cause the sexual side-effects common to the SSRIs, but it has been associated with a 1.5 per cent increase in prevalence of seizures compared to other antidepressants. The medication should not be given to individuals at risk for seizures (those with a history of seizures or head injury), and should never be administered in a single dose greater than 150 mg. Patients with a history of bulimia also have an increased risk of seizures on amfebutanone, and should not be prescribed this medication. The starting dose of 75 mg twice per day should be increased every week to achieve a therapeutic level of between 300 and 450 mg/day.

Tricyclic antidepressants

The heterocyclic medications include the tricyclic antidepressants and several other agents that are similar in structure, including maprotiline, amoxapine, and trazodone. These medications are similar in their side-effects and dosing strategies (see Chapter 26.6.1).

Low starting doses are required, with a gradual increase to a therapeutic level. For treating depression, generalized anxiety disorder, or panic disorder, physicians should begin at 10 to 25 of imipramine, gradually increasing the dose by 10 to 25 mg every 4 or 5 days. The ultimate dosage is variable, with some patient responding at a low dosage (50–100 mg), and others needing up to 300 mg.

Plasma levels can be measured, but these function primarily as crude indicators of whether or not the patient is taking the medication. Clinicians should treat the patient, and not the blood level, since many with high or low blood levels may do very well clinically. Nortriptyline is an exception, as it has a therapeutic window (50–150 ng/ml): levels below or above this are less likely to lead to remission of depression.

Other agents

For the small subgroup of patients with anxiety disorders who do not tolerate SSRIs or TCAs, high-potency benzodiazepines may be an effective second-line treatment. Alprazolam, lorazepam, and clonazepam have all been shown to be more effective than placebo for the treatment of panic disorder. Patients can be started at 0.25 mg clonazepam three times per day, with a gradual increase by 0.25 mg every 2 to 3 days until the attacks stop. Symptoms of generalized anxiety disorder can

be alleviated in most cases with a clonazepam dose between 0.25 to 0.5 mg twice daily and 1 mg two or three times daily, or lorazepam 0.5 to 1 mg three times daily. These agents are best used in conjunction with an SSRI or TCA at the beginning of treatment. After 6 to 8 weeks, when the antidepressant begins to have its optimal effects in treating anxiety symptoms, the benzodiazepine can usually be tapered with a 10 per cent dose reduction per week.

Buspirone is an azapirone with affinity for 5-HT1A and dopamine receptors that has been approved for the treatment of patients with generalized anxiety disorder. It is non-sedating, and there are no withdrawal symptoms with abrupt discontinuation. There are also no synergistic effects with alcohol. Buspirone is typically effective at doses of 30 to 60 mg, divided two or three times daily. Common side-effects include dizziness, nausea, headache, and nervousness. These can be reduced by using lower starting doses of 5 mg two or three times daily and advancing as tolerated.

Beta-adrenergic blockers may be useful for treating performance anxiety. Propranolol is used at doses of 10 to 80 mg per day (ideally taken 2 h before the anticipated exposure). Atenolol at 30 to 100 mg may be preferred since it has fewer CNS side-effects (exacerbating depression).

MAOIs are potentially the most effective class of medication for panic or certain types of depression. However, their regular use in primary care or by general physicians is precluded by the lack of familiarity with these agents, and the potential for hypertensive crisis that can ensue from not following a low-tyramine diet or taking an over-the-counter stimulant medication (like pseudoephedrine).

St John's Wort

Clinicians need to ask patients in a routine and non-judgemental manner about their use of alternative treatments, and should know enough about the more common ones to assess for deleterious effects or interactions. St John's wort has been widely used in Europe. A recent meta-analysis found it to be more effective than placebo and of similar effectiveness to low-dose TCAs in the short-term treatment of mild depression. However, a recent study comparing treatment with an SSRI versus St John's wort found that St John's wort was less effective in treating major depression. Gastrointestinal effects, including nausea, pain, loss of appetite, and diarrhoea occurred at a rate of 0.55 per cent in a German study of 3250 patients taking 300 mg three times a day. It may cause a sunburn-like reaction, mucosal inflammation, pruritis, and can lead to significant depression of the blood level of ciclosporin in organ transplant recipients, even leading to rejection.

Special issues in pregnancy

Mild postpartum 'blues' occur in 30 to 75 per cent of women immediately after delivery. Symptoms include labile mood, tearfulness, irritability, anxiety, and sleep and appetite disturbances lasting 4 to 10 days. If physical symptoms and depressed mood persist for 2 weeks, patients should be evaluated for postpartum major depression, which is relatively common, having a prevalence rate of approximately 10 per cent. Symptoms usually begin during the third trimester. A history of depression, limited social support, marital conflict, and ambivalence about the pregnancy increase the risk of depression during pregnancy and in the postpartum period.

Pharmacotherapy for depression during pregnancy requires an assessment of the risks and benefits of treatment for both mother and fetus. The risks of not treating depression may include suicide, poor maternal and fetal nutrition, an obstetric complication, and the continuation of depression into the postpartum period, with effects on mother and child bonding. Psychotherapy can be helpful in resolving interpersonal and psychosocial conflicts without exposing the mother or fetus to medications. Although psychotherapy is the first-line treatment for mild to moderate depression during pregnancy or after the birth of a child, antidepressant treatment may be warranted in severe major depression.

SSRIs are considered the first-line pharmacotherapy for depression during pregnancy. The Fluoxetine Pregnancy Database, based on 1103 prospectively reported pregnancies, reported rates of fetal malformation and spontaneous abortion similar to rates in pregnancies not exposed to fluoxetine. A prospective, controlled multicentre study to assess fetal safety and risks of the SSRIs (fluvoxamine, paroxetine, and sertraline) found that exposure to SSRIs was not associated with an increased risk for major malformations or higher rates of miscarriage, stillbirth, or prematurity. There do not appear to be adverse effects on global intelligence quotient, or language or behavioural development in preschool children exposed *in utero* to either tricyclic antidepressants or fluoxetine.

Data regarding the excretion of antidepressants in breast milk are limited. The American Academy of Pediatrics Committee on Drugs concluded: 'antidepressants are drugs whose effect on nursing infants is unknown but may be of concern'. Several studies have shown only small amounts of SSRIs in breast milk and infant serum samples. Children have been followed through their enrolment in kindergarten with no evidence of negative effects on global intelligence, language, or behaviour.

Monitoring

Regular visits are essential for patients with depression and anxiety. Brief visits every 2 weeks are usually indicated during the first 6 weeks of treatment to evaluate the dosage and side-effects of medications, and any changes in the patient's condition. With appropriate counselling beforehand and a regular discussion of side-effects, patients are more likely to adhere to a full medication trial, and this can also be encouraged by telephone monitoring. The physician should record the main symptoms that the patient presents at the beginning of treatment, and review these at each follow-up visit. After they have been on a therapeutic dose of medication for 4 weeks, the treatment response should be evaluated. Simply asking the patient to note the degree of progress on a scale of 1 to 5 can be helpful in assessing either an improvement or worsening of the target symptoms. Empirically validated, self-rating scales, such as the Patient Health Questionnaire, administered at initial diagnosis and at follow-up, can be useful in assessing treatment response. A 25 per cent or greater reduction in baseline symptoms constitutes a reasonable basis for extending the initial treatment. If there has been no response or only a partial response in symptoms, the dose of the medication should be increased to the upper therapeutic range.

Some two-thirds of patients with major depression respond to an antidepressant within 3 weeks after reaching a therapeutic plasma level. This success rate can be increased to 90 per cent by switching initial non-responders to another class of antidepressant, or by augmentation strategies using additional medication or psychotherapy. However, if a patient fails to improve adequately with first-line therapy, the diagnosis and the treatment plan must be reassessed. There may be unrecognized comorbid anxiety or substance abuse, and treatment failure is commonly due to inadequate dosing or lack of adherence to medication.

Once the patient is stabilized on a medication (usually 6–12 weeks), monthly visits are important for support. If chronic prophylactic treatment is necessary, visits every 3 months are usually appropriate. Consensus statements recommend a treatment period of between 6 and 9 months for a major depressive episode. Pharmacotherapy should be discontinued slowly over a period of 7 to 21 days. If tapered too quickly, almost all antidepressants (except fluoxetine) can produce withdrawal syndromes that include sleep disturbance, mood changes, anxiety, sensory disturbance, malaise, muscle aches, vertigo, sweating, fatigue, and gastrointestinal upset.

Patients who have remitted during the acute phase of pharmacotherapy for anxiety and depressive disorders remain at substantial risk of relapse during the subsequent 12 months: 37.1 per cent of depressed primary care patients experience further depressive symptoms during this time. There are three main risk factors are associated with relapse: (1) persistence of subthreshold depressive symptoms 7 months after the initiation of antidepressant therapy; (2) history of three or more previous episodes of major depression; and (3) chronic mood symptoms for more than 2 years. Patients with two of these risk factors are approximately three times more likely to relapse than those without. Between 50 and 60 per cent of patients who have had a single major depressive episode will have a second one; 70 per cent of those who have two episodes will have a third; and 90 per cent of those who have had three episodes will have a fourth. For patients with three or more depressive episodes or dysthymia and major depression, the AHCPR guidelines recommend treatment for 2 years or more.

The optimal duration of treatment for anxiety disorders has not been as well established by controlled studies. Treatment is recommended for 6 to 9 months after the first episode. Maintenance therapy should be considered for those with either a chronic history since adolescence, or three or more recurrences. Panic disorder is a recurrent or chronic disease in the majority of cases. In a review of 16 studies, most patients had improvement in symptoms with treatment, but few experienced complete resolution. As panic disorder progresses, attacks become more frequent, and are preceded by anticipatory anxiety. Patients may begin to associate environmental events with anxiety, leading to avoidance behaviour. The disorder may culminate in agoraphobia: being afraid to leave the house because of the association with panic attacks.

Electroconvulsive therapy (ECT)

ECT is still the most effective treatment available for the treatment of depression: it can be life-saving in some cases, and in the frail elderly it may be safer than antidepressants. Some reversible short-term memory loss is a common side-effect, but this reverts to normal in almost all cases. Patients with recurrent depression

who receive effective ECT treatment should be treated with prophylactic medication or maintenance ECT once the acute course of the treatment has finished.

Psychotherapy

Randomized controlled trials support the efficacy of psychosocial interventions provided to ambulatory medical patients with psychiatric disorders. Problem-solving skills and other behavioural techniques, most of which can be provided as simple self-help materials, are part of the psychosocial support that general physicians can provide in a disease management programme for depressive or anxiety disorders. As in all chronic illnesses, lifestyle changes should be reinforced: good sleep habits, adequate exercise, and minimization of caffeine and alcohol intake.

There are three short-term psychotherapies used to specifically target the symptoms of major depression: cognitive–behavioural therapy (**CBT**), interpersonal psychotherapy (**IPT**), and problem-solving therapy (**PST**). CBT is directed at the negative and distorted thinking patterns and subsequent maladaptive behaviours that often accompany depressive episodes. IPT helps the patient learn to manage the current interpersonal relationship difficulties that are sometimes related to the development and maintenance of depressive symptoms. PST helps activate patients to break down global problems to smaller units that they can begin to attempt to solve.

Patients with major depression treated with CBT and IPT experience as much relief from symptoms by 16 weeks and those with PST by 11 weeks as those taking medication alone. Given these findings, physicians need not rely as heavily on drug treatments as they typically have, and should consider psychosocial interventions if the patient prefers them and they are available.

In a meta-analysis of studies on panic disorder, psychological coping strategies involving relaxation training, cognitive restructuring, and exposure worked comparably with both antidepressant and benzodiazepine medications. The combined somatic exposure and cognitive therapy used by Barlow and Clark helps patients confront and alter maladaptive cognitions (for example, thoughts of a heart attack or stroke when experiencing a rapid heartbeat). A meta-analysis of the treatment of generalized anxiety disorder concluded that CBT is more efficacious than control treatments and at least equal in efficacy to anxiolytics.

Specialty referral

Referral to a psychiatrist should be considered when the physician is confused about the primary diagnosis, as in distinguishing an anxiety disorder from depression with anxiety or substance abuse disorder. Referrals should also be made when adequate treatment does not lead to an improvement in symptoms within 10 to 12 weeks**,** or several medication trials have failed. Patients with suicidal behaviour require specialty care (see Chapter 26.5.2).

Other disorders

Generalized anxiety disorder is characterized by constant, non-episodic anxiety that affects the patient for more than 6 months and interferes with normal function. In community samples, lifetime prevalence rates are 5.1 per cent. Medical problems such as hyperthyroidism should be ruled out as the cause of the symptoms of motor tension and autonomic hyperactivity. This disorder can be treated effectively with SSRIs, TCAs, buspirone, and benzodiazepines; the first three classes should be tried first, given their lower potential for habituation and dependence.

Post-traumatic stress disorder (**PTSD**) is a syndrome that can occur after a person experiences trauma outside the range of normal human experience (accidents, abuse, rape, and natural disasters). The lifetime prevalence in the general population is between 1 and 9 per cent. The most frequent traumas in civilian cases involve adult domestic violence and childhood abuse. Symptoms include flashbacks, nightmares, and/or severe distress (or numbness) to stimuli that concretely or symbolically resemble the event—or to many stimuli (generalization), hypervigilance, or other persisting signs and symptoms of autonomic arousal, and secondary depression. Cases of PTSD are occasionally seen in primary care or by general physicians, with these patients often having a combination of symptoms of PTSD, panic, major depression, and an increased risk of alcohol and drug abuse. The alcohol and drugs are often taken to try to blunt excessive anxiety symptoms. Treatment of PTSD usually includes medication and psychotherapy, recent trials showed SSRIs to be more effective than placebo.

Specific phobias are characterized by episodic anxiety in response to a specific precipitant: intense excessive fear makes patients avoid the situation. Examples of stimuli for simple phobias are airplanes, heights, and insects, although most patients with simple phobias do not seek care for the condition. Social phobia is the fear of humiliation or failure in public situations (such as public speaking, meeting strangers, and eating in restaurants), and many with this condition also have major depression (58.3 per cent of cases of social phobia), or other anxiety disorders in (panic disorder, 27.8 per cent; generalized anxiety disorder, 30.6 per cent). Since social phobia is often present from childhood or adolescence, patients often consider the marked social anxiety and avoidance as part of their personality. Recent studies have shown that SSRIs are more effective than placebo in the treatment of social phobia; effective cognitive–behavioural techniques have also been developed. Propranolol (10–80 mg) may be useful for treating non-generalized social phobia that occurs in one situation, such as public speaking.

Obsessive–compulsive disorder (**OCD**) is characterized by regular intrusive thoughts or obsessions about aggression, sex, religion, theft, or loss—or other covering mental rituals such as counting objects or letters. Patients may also have persistent rituals or compulsions that are so frequent or complex that they interfere with normal function. They experience these obsessions and compulsions as intrusive, silly, and upsetting. Most patients with OCD have experienced major depressive episodes. Pharmacological treatment is indicated: although clomipramine had been the first-line treatment for many years, recent randomized controlled trials have shown SSRIs to be as effective. Treatment with SSRIs should continue for at least 10 weeks before it is considered ineffective. Randomized trials have shown behavioural treatments to be effective; these focus on exposure to feared activities and prevention of compulsive responses.

Conclusions

The healthcare problems of depression and anxiety are as common, and as treatable, as asthma and hypertension. If a patient does not improve with initial management, he or she should be referred to a mental health specialist. Routine follow-up is essential: these disorders follow a relapsing and remitting course in 70 to 80 per cent of patients, and become chronic disorders in up to 20 per cent. Lifelong monitoring of symptoms with the patient and his or her family is required.

26.5.5Eating disorders

Christopher G. Fairburn

Introduction

The term 'eating disorder' refers to a persistent and severe disturbance of eating habits which results in impaired physical health or psychosocial functioning. The disturbance should not be secondary to any general medical disorder or to any other psychiatric condition. Anorexia nervosa and bulimia nervosa are the best characterized of the eating disorders. Anorexia nervosa has been recognized for many years, with physicians in the 19th century providing particularly good accounts of the disorder. By contrast, bulimia nervosa was first described in 1979. Anorexia nervosa and bulimia nervosa are closely related, in that they have many features in common and some patients move from one disorder to the other. Other eating disorders are encountered, most of which appear to be variants of anorexia nervosa or bulimia nervosa. These disorders are classified as 'atypical eating disorders'.

Eating disorders should not be confused with obesity—a general medical condition in which there is excess body fat (see Chapter 10.5). Eating disorders may coexist with obesity, although in practice most people with an eating disorder have a normal or low body weight.

Anorexia nervosa and bulimia nervosa

Definition of anorexia nervosa

To make a diagnosis of anorexia nervosa, three features need to be present:

1. *A characteristic set of attitudes to shape and weight in which self-worth is judged largely, or even exclusively, in terms of shape and weight*—Whereas most people evaluate themselves on the basis of their perceived performance in a variety of domains (such as their relationships, work, sport, artistic ability, etc.), in anorexia nervosa shape and weight dominate self-evaluation. This overevaluation of shape and weight may be regarded as the core psychopathology of the disorder since most other features appear to be secondary to it.
2. *The active maintenance of an unduly low body weight*—This is the principal behavioural expression of the extreme concerns about shape and weight. For diagnostic purposes, an 'unduly low body weight' may be defined as a weight at least 15 per cent below that expected for the person's age, height, and sex, or as a body mass index below 17.5.
3. *Amenorrhoea* (in postmenarchal females who are not taking an oral contraceptive)—Although required for official diagnostic purposes, the symptom of amenorrhoea has little discriminatory value. A clinical diagnosis of anorexia nervosa may be made in its absence.

Definition of bulimia nervosa

Bulimia nervosa also has three necessary diagnostic features:

1. *The same core psychopathology as that seen in anorexia nervosa, with self-worth being judged in terms of shape and weight*.
2. *Repeated episodes of uncontrolled overeating*—These bulimic episodes (commonly referred to as 'binges') involve the consumption of unusually large amounts of food, given the circumstances, and a sense of loss of control at the time. It is this latter feature that distinguishes binge-eating from simple overeating.
3. *The regular practice of extreme weight-control behaviour*—People with bulimia nervosa diet intensely, they may overexercise, and many engage in self-induced vomiting and the misuse of laxatives or diuretics. This behaviour is an expression of their extreme concerns about shape and weight, although it is further encouraged by the episodes of loss of control over eating.

It should be noted that there is no weight criterion for bulimia nervosa. In practice, body weight is generally unremarkable. This is because the overeating and weight-control behaviour tend to cancel each other out. There are some patients with anorexia nervosa who have binges like those seen in patients with bulimia nervosa, and who could therefore be eligible for both diagnoses. In practice, both diagnoses are not given: instead, the convention is that the diagnosis of anorexia nervosa takes precedence over that of bulimia nervosa.

Epidemiology

Anorexia nervosa is largely confined to females aged between 10 and 30 years and to Western societies. Estimates of the incidence of the disorder range from 0.10 to 8.2 per l00 000 population per annum, the higher figure being likely to be the more accurate. Estimates of its prevalence amongst adolescent girls, the group most at risk, range from 0.2 per cent to 0.8 per cent. The disorder is uncommon among men with about 10 per cent of patients being male. The social class distribution seems to be uneven with an over-representation of cases from upper socioeconomic groups, but the extent to which this is a result of referral bias is not known. It has been suggested that the disorder has become more common over recent decades, but other explanations for the apparent increase cannot be ruled out. These include alterations in diagnostic practice, better detection, increased help-seeking, and changes in the demographic structure of the population. Irrespective of whether the incidence has increased, anorexia nervosa is a major cause for concern. The disorder has one of the highest mortality rates of any psychiatric illness and it can be extremely difficult to treat.

Bulimia nervosa affects a slightly older age group than anorexia nervosa, with most cases being in their twenties. It also appears to have a broader social class distribution. The disorder is considerably more common than anorexia nervosa, the prevalence rate among young women (15 to 40 years) being between 1 per cent and 2 per cent, most of whom are not in treatment. Whilst there are no satisfactory data on the incidence of bulimia nervosa, it seems that the disorder has become much more common since the early 1970s. From being viewed as an unusual variant of anorexia nervosa, bulimia nervosa is now the most common eating disorder seen in clinical practice. It rarely occurs among men and, like anorexia nervosa, it appears to be largely confined to Western societies.

General clinical features

Anorexia nervosa

In anorexia nervosa the overevaluation of shape and weight results in a pursuit of weight loss and thinness. To the extent that this is successful, the disorder is 'egosyntonic'; that is, it is not viewed by the person as a problem—indeed, it has been noted that patients view it more as an achievement than as an affliction. As a

consequence, there is little motivation to change or seek help.

The low weight is primarily the result of the strict and self-imposed restriction of food intake. Typically, the range of foods eaten is limited with those foods viewed as fattening being avoided. Except in long-standing cases, appetite persists and for this reason the term 'anorexia' is misleading. Restlessness and frequent intense exercising are common, and contribute to the low weight. Self-induced vomiting and the misuse of laxative and diuretics are practised by a subgroup, and some have occasional binges.

Driving the disturbed eating habits is the so-called 'body image disturbance'. This has several aspects. There is the core psychopathology, already mentioned, in which self-worth is judged largely in terms of shape and weight. In addition, there is sometimes a perceptual component involving overestimation of body size. This may be a consequence of the patients' frequent checking of their own body, and in some this becomes so distressing that it is abandoned, although the concerns about shape and weight persist. In almost every case there is preoccupation with thoughts about food, eating, shape, and weight, which may be expressed as an avid interest in cooking, nutrition, fitness, and health.

Depression, anxiety, irritability, lability of mood, and obsessional features are all common concomitants of anorexia nervosa. Typically, they get worse as weight is lost and improve with weight regain. Outside interests also decline and there may be marked social withdrawal. Suicidal thoughts may be present and the risk of suicide should always be kept in mind when assessing patients.

Bulimia nervosa

The clinical features of bulimia nervosa are similar to those of anorexia nervosa. There is the same over-evaluation of shape and weight, and this also leads to body checking and extreme methods of weight control. The main differences lie in the frequent bulimic episodes and the fact that body weight is generally unremarkable. The other important difference is that, as a consequence of the loss of control over eating, the disorder is 'egodystonic'; that is, it is viewed by the patient as a problem. This makes treatment much easier.

The binges involve the consumption of sizeable amounts on food (typically over 2000 kcal per episode) and they are a source of distress and shame. Typically, they are kept secret. In most cases, they are followed by self-induced vomiting or the taking of laxatives or diuretics, although there is a subgroup of patients who do not 'purge'. Between the binges, food intake is severely restricted. Depressive and anxiety symptoms are prominent in bulimia nervosa, more so than in anorexia nervosa, and some patients have problems with alcohol or drug misuse.

Physical and laboratory features

The physical abnormalities seen in anorexia nervosa have been the subject of much interest. They used to be viewed as evidence of a primary pituitary or hypothalamic disorder, but it is now thought that they are secondary to the disturbed eating habits and the patient's state of starvation. The physical abnormalities encountered in bulimia nervosa resemble those seen in anorexia nervosa except that they are less severe.

Symptoms and signs in anorexia nervosa

Many patients with anorexia nervosa have no physical complaints. However, systematic enquiry often reveals a heightened sensitivity to the cold and a variety of gastrointestinal symptoms such as constipation, fullness after eating, bloatedness, and vague abdominal pains. Other symptoms include restlessness, low sexual appetite, and poor sleep with early morning wakening. In females who are not taking an oral contraceptive, amenorrhoea is, by definition, present. Occasional patients complain of infertility.

On examination, the degree of emaciation may be striking. Growth may be stunted in those with a prepubertal onset and there may be failure of breast development. Unlike patients with hypopituitarism, axillary and pubic hair are preserved and there is no breast atrophy. A fine downy hair (lanugo) is commonly present on the back, arms, and side of the face. Typically, the skin is dry and the hands and feet are cold. There may be hypothermia. Blood pressure and pulse are low and some patients have dependent oedema.

Abnormalities on investigation in anorexia nervosa

Endocrine abnormalities

Many of the abnormalities encountered have been reproduced in studies of the physiological effects of dieting and starvation, and are reversed by the restoration of healthy eating habits and a normal weight. Luteinizing hormone-releasing hormone (**LHRH**) secretion is impaired and, as a result, levels of luteinizing hormone (**LH**), follicle-stimulating hormone (**FSH**), and oestradiol are low. There is an immature pattern of LH release. The LH response to LHRH is reduced, but the FSH response is normal or exaggerated.

Hypothalamic disturbance is also evident in a delayed thyroid-stimulating hormone (**TSH**) response to thyrotropin-releasing hormone (**TRH**). In addition, there is reduced peripheral conversion of thyroxine (T4) to triiodothyronine (T3), and an increased conversion of T4 to inactive reverse T3. These changes are seen in other chronic illnesses. T4 levels are in the low-normal range, whereas T3 levels are depressed. Clinical evidence of hypothyroidism includes sensitivity to cold, constipation, dry skin, and bradycardia.

Plasma cortisol levels are raised and the normal diurnal variation is lost. These changes are due in part to the increased half-life of cortisol seen in starvation, and in part to a relative increase in cortisol production. Growth-hormone levels are also increased, another secondary effect of starvation. Prolactin secretion is normal. Leptin levels are low.

Haematological changes

A normocytic normochromic anaemia is found in a minority of patients and is sometimes attributable to a low intake of iron or folate. Mild neutropenia is common. The erythrocyte sedimentation rate (**ESR**) is generally low.

Other metabolic abnormalities

Hypercholesterolaemia is frequently present. The mechanism is not understood. Increased serum beta-carotene may also be found and reflects increased dietary intake. Life-threatening hypoglycaemia very occasionally occurs, but may not present typically due to impaired sympathetic response. Dehydration is not uncommon, and electrolyte disturbance is found in those who vomit frequently or misuse large quantities of laxatives or diuretics.

Other abnormalities

Brain imaging studies have revealed enlargement of the cortical sulci and cisternes and dilatation of the ventricles. This appears to be reversible and has been termed 'pseudoatrophy'.

There is delayed gastric emptying and a prolonged gastrointestinal transit time. This may account for the common complaints of fullness after eating, bloatedness, and constipation. Acute gastric dilatation is a rare complication which can be provoked by episodes of extreme overeating or attempts at refeeding that are too vigorous.

In more long-standing cases bone mineral density is reduced, probably as a result of oestrogen deficiency and low weight. There is a heightened risk of fractures, particularly of the lumbar vertebrae. The bone loss appears to reverse with weight regain and the resumption of regular menstruation.

Symptoms and signs in bulimia nervosa

There are few physical complaints in bulimia nervosa. Those most commonly encountered are irregular or absent menstruation, weakness and lethargy, vague abdominal pains, and toothache. On examination, appearance is usually unremarkable. Salivary gland enlargement may be present: typically, this involves the parotids and gives the patient's face a slightly rounded appearance. Sometimes it is associated with a raised serum amylase level, the increase being in the salivary isoenzyme. The underlying pathophysiology is not understood. In those who vomit there may be calluses on the dorsum of the dominant hand (Russell's sign) due to the fingers being used to stimulate the gag reflex. Also, there may be significant erosion of the dental enamel particularly on the lingual surface of the upper front teeth. A minority of patients, particularly those who take large quantities of laxatives or diuretics, have intermittent peripheral or facial oedema.

Abnormalities on investigation in bulimia nervosa

Of most importance is the electrolyte disturbance which is encountered in about half of those who vomit or take laxatives or diuretics. Metabolic alkalosis, hypochloraemia, and hypokalaemia are the most common abnormalities and may account for the weakness and tiredness (and in rare instances hypokalaemic paralysis) experienced by some patients. The overall picture may resemble Bartter's syndrome. Severe electrolyte disturbance is occasionally encountered, particularly low potassium levels, but even when it is long-standing there may be surprisingly few accompanying symptoms. Despite concern about possible cardiac arrhythmias, nephrogenic diabetes insipidus, and the suggestion that chronic hypokalaemia may induce changes in the renal proximal tubular cells, aggressive treatment of this type of chronic electrolyte disturbance is rarely appropriate: instead, it should be monitored while treatment is focused on the eating disorder itself.

Endocrine abnormalities are also encountered in bulimia nervosa. They resemble those seen in anorexia nervosa, but are not as severe. They are thought to be secondary to the strict dieting and are probably reversible, given that the menstrual disturbance responds to the correction of the eating disorder.

Aetiology

It is generally accepted that anorexia nervosa and bulimia nervosa are the result of a complex interplay of physiological, psychological, and social processes. These have different influences at different stages in the development and subsequent course of the disorder. The understanding of the exact nature of these processes is limited, although there is increasing convergence between the findings of biological and psychosocial studies.

Development of anorexia nervosa and bulimia nervosa

Anorexia nervosa generally starts in mid-adolescence with a period of voluntary dietary restriction that proceeds to get out of control. Whereas everyday adolescent dieting is neither persistent nor extreme, in anorexia nervosa it becomes unremitting and intense. As a result body weight falls and a state of semi-starvation eventually develops. Concerns about shape and weight may pre-date the onset of the dieting or develop as weight is lost.

Bulimia nervosa starts in a similar way, although the age of onset is typically some years later. There is dietary restriction and it too leads to weight loss (sufficient to result in a period of anorexia nervosa in about 25 per cent of cases), but instead of dietary control being maintained, it becomes punctuated by episodes of binge-eating. This breakdown in control generally occurs within 2 years of onset. At first the episodes of overeating may be both modest in size and intermittent, but gradually they become larger and more frequent. As a result, the lost weight is regained and body weight returns to about the level at which the dieting first began. By this point the disorder tends to be self-perpetuating. At some stage in this sequence of events self-induced vomiting or laxative misuse may be adopted to compensate for the episodes of overeating. In practice they have the opposite effect, because these patients' belief in their effectiveness at preventing energy absorption undermines their attempts to control their eating.

Risk factors and processes

Epidemiological studies have implicated a variety of risk factors in the development of anorexia nervosa. These may be divided into four classes:

1. Being female, adolescent, and living in a Western society. These individuals are under social pressure to diet.
2. Being exposed to a microenvironment that further encourages dieting. This includes being brought up in a family in which there is intense interest in shape, weight, or eating, sometimes as a result of one or more family members having a frank eating disorder. Social or occupational pressures to diet are another example.
3. Being exposed to factors that increase the risk of psychiatric disturbance in general and depression in particular. These include a family history of psychiatric disorder, especially depression, and exposure to adverse childhood experiences such as parenting deficits and sexual and physical abuse.
4. The presence of the psychological traits of perfectionism, inflexibility, and low self-esteem.

A similar set of risk factors has been implicated in bulimia nervosa, although it seems that there is more exposure to social factors that encourage dieting. For example, there are strikingly raised rates of parental and childhood obesity (antedating the eating disorder), both of which are likely to sensitize individuals to their appearance and weight, and thereby make them prone to diet. The risk factors for psychiatric disturbance are also prominent, whereas the traits of perfectionism and inflexibility are less pronounced. One additional class of risk factor is parental substance abuse. How this might operate is not clear, although it does seem that those who develop bulimia nervosa are prone to mood fluctuations and that some may learn to modulate them by consuming large quantities of food, alcohol, or psychoactive drugs.

An important question is why people with bulimia nervosa have repeated episodes of loss of control over eating, whereas those with anorexia nervosa do not. Several factors appear to be relevant. First, the traits of perfectionism and inflexibility are less prominent, which may result in the person being less able to maintain strict self-control. Second, the mood fluctuations may interfere with dietary restraint. Third, the vulnerability to obesity, and perhaps therefore overeating, may also be relevant.

Genetic factors and neurobiological mechanisms

Family-genetic studies have demonstrated that eating disorders run in families, with familial aggregation being particularly evident in anorexia nervosa. The relative extent of genetic and environmental contributions is unclear: the findings of the few twin studies have been inconsistent and there have been no adoption studies.

The nature of any inherited vulnerability is not known. The liability appears not to be shared with that for other psychiatric disorders. However, there is some evidence of shared familial transmission between the various eating disorders, and between anorexia nervosa and 'obsessive–compulsive personality disorder', a personality construct that overlaps with certain of the traits mentioned earlier. Thus anorexia nervosa and obsessive–compulsive personality disorder may be common phenotypic expressions of a similar genotype. Clearly there may also be genetically determined abnormalities in the regulation of weight and eating habits.

Attempts to identify susceptibility genes have focused on those implicated in serotonin (5-hydroxytryptamine, **5-HT**) neurotransmission. This transmitter is of particular interest for a number of reasons: (1) it is known to have an important role in the control of both eating and mood; (2) there is some evidence of trait-related abnormalities in brain 5-HT function in both anorexia nervosa and bulimia nervosa; and (3) it has been found that dieting influences brain 5-HT function in women. There is some evidence, albeit inconsistent, that anorexia nervosa is associated with a polymorphism of the 5-HT $_{2A}$ receptor.

Maintaining factors and processes

Several processes maintain the dietary restriction that is central to anorexia nervosa. One is the potent and strongly reinforcing sense of self-control that these people get from restricting their eating. Another is the resulting weight loss, given the overevaluation of shape and weight. A third is the effect on others of refusing to eat, which can be of special significance when there are dysfunctional relationships. A fourth is secondary to certain aspects of the starvation state. For example, the social withdrawal and preoccupation with food and eating both narrow the focus of the person's interests, and the delayed gastric emptying produces feelings of fullness even after eating modest amounts of food.

In bulimia nervosa similar maintaining processes operate. For example, the periods of successful dietary control are strongly reinforcing, as is the initial weight loss. However, there are also important differences. First, since the disorder is usually kept secret, there may be no reinforcing effects on others. Second, since body weight is generally unremarkable, starvation-related mechanisms are less relevant. Third, the repeated binges, while being aversive and a stimulus to change,

strongly encourage further dieting as they undermine the sense of being in control and magnify fears of weight gain.

Treatment

Patients with eating disorders vary in the severity of their presenting symptoms and in their response to treatment. Some have a brief period of disturbance which spontaneously remits and does not recur; in others treatment is needed, but there is full and lasting recovery; while in others the disorder persists and may prove intractable.

The treatment of bulimia nervosa has been the subject of numerous randomized controlled trials. The most effective treatment is a specific form of cognitive–behaviour therapy. This is a psychological treatment which directly addresses both the disturbed eating habits and the abnormal attitudes to shape and weight. It involves about 20 sessions over 5 months and generally results in substantial improvement, with about half the patients making a complete and lasting recovery. Antidepressant drugs are the only pharmacological treatment to have shown promise. They result in a decline in the frequency of binge-eating and associated compensatory behaviour, and an improvement in mood, but their effect is not as great as that obtained with cognitive–behaviour therapy and, more importantly, it is often not maintained. Some patients respond to simple and brief forms of cognitive–behaviour therapy. These may be implemented in primary care. Indeed, a 'stepped care' management strategy has been advocated in which a simple treatment (such as cognitive–behavioural self-help) is used first, with more intensive and specialized treatments (such as full cognitive–behaviour therapy) being reserved for those who do not respond.

There has been relatively little research on the treatment of anorexia nervosa. This is for a number of reasons, including the low prevalence of the disorder and the fact that treatment may take a year or more. Another barrier to research and, indeed treatment, is the egosyntonic character of the disorder.

In principle, there are three aspects to the management of anorexia nervosa. The first is persuading patients that they need help, and maintaining their motivation thereafter, which is crucial given their reluctance to change. The second is weight restoration. The third is addressing the patient's overevaluation of shape and weight, eating habits, and general psychosocial functioning.

Weight restoration is needed to reverse the effects of starvation and of itself usually leads to substantial improvement in the patient's physical and psychological state. Weight restoration may be achieved on an outpatient, day-patient, or inpatient basis. Indications for hospital admission include risk of suicide, adverse home circumstances, and failure of outpatient treatment. Physical indications include a body mass index below 13.5, rapid weight loss, and the presence of medical complications such as marked oedema, severe electrolyte disturbance, hypoglycaemia, or significant intercurrent infection. Under such circumstances admission should be to a general medical ward or a psychiatric unit with good access to general medical help. Weight restoration may be achieved in either setting, but it is a great advantage if the staff are experienced in the management of patients with anorexia nervosa, and in a psychiatric unit it is generally easier to arrange the other aspects of treatment. Inpatient care should always be regarded as a preliminary to outpatient treatment.

There is no single way of addressing overevaluation of shape and weight, eating habits, and general psychosocial functioning. Leading approaches include various forms of family therapy, primarily for younger patients, and adaptations of cognitive–behaviour therapy. Training is needed to deliver these treatments, and they are best conducted on an outpatient basis.

Drug treatment has almost no role, although occasionally it is appropriate to use drugs to stimulate the resumption of regular menstruation, so long as body weight has reached a reasonable level and the patient is eating healthily.

Prognosis

Whilst at least half of those with anorexia nervosa recover in terms of their weight and menstrual function, sensitivity about shape and weight often persists and eating habits may remain disturbed. Up to one-quarter develop bulimia nervosa. The standardized mortality ratio is significantly raised, deaths being either a direct result of medical complications or due to suicide. The outcome in males appears to be similar to that in females. Few consistent predictors of outcome have been identified, exceptions being a long history and late onset, both of which are associated with a worse prognosis.

The outcome in bulimia nervosa is also varied, although it is substantially improved by cognitive–behaviour therapy. The mortality rate does not appear to be raised. No consistent predictors of outcome have been identified. Both anorexia nervosa and bulimia nervosa 'breed true', in that they do not seem to evolve into any other disorder.

Prevention

Programmes for the primary and secondary prevention of anorexia nervosa and bulimia nervosa have been developed, but none has been satisfactorily evaluated. The primary prevention programmes tend to focus on schoolgirls, the group most at risk. However, two specific difficulties have been encountered: first, there is a danger of magnifying concerns about shape and weight rather than reducing them; and second, there is potential for conflict between the content of these programmes and those directed at the prevention of obesity.

Pregnancy and childrearing

This topic has come to the fore with the emergence of bulimia nervosa, since pregnancy does not often occur in the course of anorexia nervosa. It is now clear that eating disorders can have untoward effects. They generally improve during pregnancy, but the amount of weight gained may be abnormally low or high. The effects on the fetus have yet to be established, although there have been reports of intrauterine growth retardation and low birth weight. Childrearing is impaired in some cases with adverse effects on the child's feeding and growth.

Atypical eating disorders

More than one-third of those who present for the treatment of an eating disorder do not meet the diagnostic criteria for anorexia nervosa or bulimia nervosa. Such patients have an 'atypical eating disorder', the equivalent North American term being an 'eating disorder not otherwise specified'. These eating disorders have received little attention. Many are similar in form to anorexia nervosa or bulimia nervosa and respond similarly to treatment.

Binge-eating disorder

The one atypical eating disorder to have been delineated is termed 'binge-eating disorder'. It is characterized by recurrent binge-eating in the absence of the extreme weight-control behaviour seen in anorexia nervosa and bulimia nervosa. The binge-eating occurs against the background of a general tendency to overeat. It seems to be more an habitual response to negative mood states than an intermittent breakdown of dietary restraint as occurs in bulimia nervosa. Not surprisingly, many of these patients are overweight or obese.

Little is known about the distribution of binge-eating disorder. It appears to affect an older age group than anorexia nervosa and bulimia nervosa, and cases among men are not uncommon. About 10 per cent of those attending obesity clinics have the disorder. The treatment that shows most promise is conventional behavioural weight control. As in bulimia nervosa, cognitive–behavioural self-help programmes help a subgroup of cases. The value of drug treatment is unclear.

26.5.6 Schizophrenia, bipolar disorder, obsessive–compulsive disorder, and personality disorder

S. Lawrie

Recent research, using reliable diagnostic criteria based on clinical features since diagnostic laboratory tests are not available, has established that all of these conditions have both biomedical and psychosocial components. The *Diagnostic and statistical manual of mental disorders, 4th edition* (**DSM-IV**) has been most rigorously developed and is used here.

Schizophrenia

Schizophrenia and bipolar disorder are psychoses, that is to say they include phenomena that qualitatively differ from everyday experience. Schizophrenia is characterized by delusions, hallucinations, disorganized speech/behaviour, and negative symptoms.

Onset is in early adulthood (median age 25 years). The sex incidence is equal, but women tend to be affected later than men. The incidence is only 15 in 100 000 of the population per year, but the prevalence is about 5 in 1000 due to chronicity, and the lifetime risk is 1 per cent.

Aetiology

Genetic factors account for 80 per cent of the liability to schizophrenia, but no major genes have been identified. Having an affected relative increases the risk 5 to 50 times, depending on the relationship. Other risk factors include obstetric complications, developmental problems, and cannabis use, but these only double the risk. Stressful life events can be precipitants, but only in those otherwise predisposed.

There are subtle abnormalities of brain structure and function (particularly of the temporal and frontal lobes) in both chronic and first episode cases. Developmental changes in brain structure (for example, synaptic pruning) and function (for example, dopamine sensitivity) are thought to disrupt frontotemporal integration and bring on symptoms, but direct evidence is lacking.

Clinical features

Hallucinations and delusions are 'positive symptoms', that is, abnormal by their presence. Hallucinations are perceptions in the absence of stimuli. They are usually auditory 'voices' speaking the patients' thoughts or commenting on their actions. Hallucinations in other senses can occur but suggest a neurological disorder. Delusions are unshakeable false beliefs. Persecutory ('paranoid') delusions are common but occur in all psychoses. Delusions of passivity (actions or feelings 'made' by external forces) and other bizarre beliefs are more specific. The other positive symptom is 'thought disorder'—an illogical sequence of thoughts (as revealed in speech).

'Negative symptoms' are features that are abnormal by their absence. Common symptoms include a loss of emotion ('flat affect'), apathy, self-neglect, and social withdrawal. These may be prodromal, but are more common in chronic patients, and can be confused with depression or parkinsonism.

Differential diagnosis

Prodromal symptoms can be similar to depression. Delusions of passivity can be confused with obsessional ideas, but the latter are recognized as one's own. Drug intoxication can cause positive symptoms, but also disorientation. Neurological causes, for example temporal lobe epilepsy or brain tumours, are rare. The distinction of schizophrenia from bipolar disorder is based on whether psychotic or affective features predominate. Rarely, if both are present equally, a diagnosis of schizoaffective disorder is appropriate.

Management

Acute positive symptoms generally respond well to any antipsychotic drug (Table 1). These work by dopamine-receptor blockade. The main adverse effects are sedation, weight gain, and extrapyramidal syndromes (acute dystonia, akathisia, parkinsonism, tardive dyskinesia). These are best avoided by minimizing dosage, but dystonias and parkinsonism respond to anticholinergics. Medication should be continued for at least 2 years to reduce relapse rates.

Patients often refuse medication, due to adverse effects or lack of insight. Some are suitable for depot medication (intramuscular injections of esterified antipsychotics, see Table 1). The new 'atypical' antipsychotics have fewer adverse effects, but this is primarily because they are prescribed in relatively low doses. It is claimed that they are effective in those with negative and treatment-resistant positive symptoms, but clozapine is the only proven such treatment. Clozapine is the definitive atypical antipsychotic, with relatively high serotonin:dopamine-receptor blockade, but carries a considerable risk of neutropenia and agranulocytosis. These treatments are not contraindicated in pregnancy, as they confer only a small increased risk of teratogenicity and an untreated psychosis is more dangerous.

There are few effective non-drug treatments. Cognitive therapy may reduce symptoms and improve drug compliance. Illness education reduces relapse rates, as does teaching social skills, but these may primarily work by improving drug compliance.

Primary prevention is not a realistic prospect until better understanding of the pathogenesis of schizophrenia allows early detection. There is, however, some

evidence that earlier treatment with antipsychotics may be associated with a better prognosis.

Prognosis

The prognosis is generally poor. About 25 per cent of patients will only have one or two episodes, but most will suffer chronic symptoms, numerous relapses, unemployment, and social isolation. Most patients smoke heavily, and many abuse alcohol/drugs, resulting in a high premature mortality rate. Suicide is all too common, at 10 to 15 per cent over a lifetime.

Bipolar disorder (BPD)

The key features of bipolar disorder ('manic depression') are episodic increases or decreases in mood, thoughts, and activity, lasting at least 1 week. The prevalence, incidence, and lifetime risk of BPD are similar to schizophrenia (at 0.5 per cent, 0.01 per cent, and 1 per cent, respectively) and the sex incidence is also equal, but the mean age at onset is 21 years in both sexes in BPD.

Aetiology

The risk factors for BPD are similar to those for schizophrenia. Genetic influences are equally strong, but other associations are weaker in BPD. There may be specific abnormalities in monoamine metabolism and neuroendocrine function in BPD, for example a first 'high' may be precipitated by antidepressants, stimulants, steroids, or childbirth.

Clinical features

If 'hypomanic', such patients feel 'high', report rapid thoughts, have limitless energy, require little sleep, and are 'disinhibited', that is they are overfamiliar and take risks. They speak quickly ('pressure of speech') and jump between topics ('flight of ideas'), but with logical connections between thoughts. If psychotic ('manic'), their delusions and hallucinations are usually 'mood congruent', for example 'grandiose delusions' of special abilities.

If depressed, their mood is low, activities are not enjoyed ('anhedonia'), interests are diminished, energy is low, sleep is disturbed, appetite is reduced, and weight may fall. Patients typically think they are worthless, the future is hopeless, and they may be suicidal. Severe 'melancholic' depression is accompanied by early morning wakening, 'diurnal mood variation' (feeling worst in the morning), and 'psychomotor retardation' (head down, expressionless face, little spontaneous activity). Any psychotic symptoms are again mood-congruent, for example delusions of sin or guilt, 'voices' criticizing the patient.

Occasionally, one encounters 'mixed states', where patients have some features of (hypo)mania and depression simultaneously.

Differential diagnosis

Some one-third of patients will have several depressive episodes before their first 'high'. With no previous history, especially if old, (hypo)mania may rarely be attributable to thyroid disease or dementia. In established cases, the main differential is schizophrenia as individual symptoms can be similar (e.g. low mood and flat affect, thought disorder, and flight of ideas) but the key is that BPD is an episodic disturbance of mood.

Management

The treatment of depression is discussed elsewhere. 'High' patients may reject treatment, but most will later report feeling out of control and gratitude for being treated. (Hypo)mania generally responds well to antipsychotic drugs (see Table 1). Lithium is also effective, particularly with high serum levels (of about 1.0 mmol/l). Carbamazepine and sodium valproate are alternative 'mood stabilizers', with fewer adverse effects, but may be less effective. Valproate is the best treatment in 'rapid cycling disorder' (four or more illness episodes annually). Acute mixed episodes are probably best treated with mood stabilizers alone.

Prophylaxis is required if patients have two or more episodes in 5 years. Lithium (maintained at 0.5–1.0 mmol/l) is the treatment of choice as it reduces both (hypo)manic and depressive relapses, and may reduce suicide rates. Common adverse effects are dose-related and include diarrhoea, tremor, thirst, polyuria, and weight gain. Long-term effects can include hypothyroidism and renal impairment. Lithium is excreted in competition with sodium, so thiazide diuretics, non-steroidal agents, and dehydration can precipitate toxicity. Sudden vomiting, coarse tremor, sedation, or dysarthria require urgent medical treatment to avoid seizures, renal failure, and death.

Lithium is contraindicated in pregnancy and breast feeding, as it increases the rate of Fallot's tetralogy 10- to 20-fold and can cause neonatal toxicity. Carbamazepine and sodium valproate are associated with spina bifida. Best practice is therefore to use antipsychotics for symptom control until after delivery. Mood stabilizers should then be reinstituted, and bottle feeding commended, as relapse is very common postnatally.

Early diagnosis and self-medication can minimize relapses in established cases, but primary prevention is not presently possible.

Prognosis

Acute episodes generally respond to treatment, but 10 per cent of patients will be ill for a year and 50 per cent of (hypo)manic patients immediately become depressed. Recurrence is the norm, and becomes more frequent with age. Many patients have chronic symptoms between episodes, such that only 25 per cent of patients fully recover. Employment and social difficulties are common. Before treatment was possible, the annual mortality from cardiovascular collapse or suicide was 10 per cent. This is now the lifetime rate of suicide.

Obsessive compulsive disorder (OCD)

OCD is characterized by recurrent, unwanted thoughts that are recognized as one's own and/or repeated acts ('rituals') to relieve tension. Originally viewed as a neurosis, DSM-IV does not use this ambiguous term and classifies OCD as an anxiety state. OCD is common, with a prevalence of 1 per cent and lifetime risk of 2 to 3 per cent. The peak prevalence is in the fourth decade, with an earlier onset and slight excess in women.

Aetiology

OCD runs in families but twin studies are inconclusive. Obsessional personality is a risk factor, as are other personality disorders, childhood conduct disorder, and Tourette's syndrome. OCD can arise after lesions of the frontal lobes and basal ganglia; regions also implicated by studies of brain structure and function in patients. Follow-up functional imaging has found recovery is associated with normalized metabolism in these areas of the brain. Effective drugs all inhibit serotonin (5-hydroxytryptamine, **5-HT**) reuptake, and neurochemical evidence also suggests postsynaptic serotoninergic hypersensitivity and/or low synaptic 5-HT concentrations.

Clinical features

Patients are commonly ill for years before they come to medical attention. Obsessions are thoughts that are recurrent, resisted, and unwanted, but regarded as one's own. The thought may be a fear of contamination, excessive doubt, a somatic concern, a desire for precision, or an aggressive or sexual impulse. Usually, several obsessions coexist. Obsessional slowness and precision are more common in men.

Compulsions are obsessional acts, based on these thoughts and usually performed as a means to reduce anxiety, that are not in themselves pleasurable. Checking, cleaning, and counting are the most common acts. Most are performed in private as they are recognized as senseless.

Differential diagnosis

Rituals and superstitions are common in childhood, but are only pathological if they cause distress. Distinguishing OCD from depression/anxiety can be difficult, as secondary depression is frequent in OCD, and thoughts in depression and anxiety can have an obsessional quality. Obsessions can also be similar to phobias, but obsessives actually seek out anxiety-provoking stimuli whereas phobics avoid them.

Management

Both drugs and psychotherapy are effective in OCD. The tricyclic antidepressant clomipramine and the 'selective' serotonin-reuptake inhibitors (**SSRIs**) work, but high doses may be required. Clomipramine is probably most effective, particularly in treating patients with comorbid depression, but has unpleasant adverse effects (sedation, weight gain, anticholinergic). Maintaining drug treatment for 1 year reduces relapse rates.

The most effective psychotherapeutic techniques are behavioural. 'Exposure' to anxiety-provoking stimuli (with or without therapist 'modelling') and 'response prevention' (avoiding rituals by persuasion, monitoring, or adopting alternative behaviours) should also involve family members. This is more effective against compulsions than obsessions. Recent trials suggest that the combination of antidepressants and exposure may be best of all.

Prognosis

Response to treatment may take months and symptoms tend to recur if drugs are stopped. About 10 per cent of cases progressively deteriorate, particularly men with an early-onset OCD. Suicide was regarded as rare in OCD but recent studies challenge this view.

Personality disorder (PD)

PD is commonly seen as distinct from psychiatric 'illness' and untreatable. It is ironic that many PDs were originally described because they had links to particular psychiatric disorders, and that recent research has rediscovered these and found possible treatments.

PD is defined as culturally abnormal experience or behaviour, with onset in early adulthood, that is pervasive and inflexible, leading to distress or impairment. Only a brief description of subtypes (Table 2) and specific points is possible here.

Aetiology

Paranoid and borderline traits are clearly heritable, and schizotypy is genetically and biologically linked to schizophrenia. Paranoid and antisocial PDs are more common in men; borderline, histrionic, and dependent PDs in women. Childhood adversity is a general risk factor but specific effects are difficult to identify. Child sexual abuse, for example, may be linked to self-harm and substance abuse rather than any particular PD. Psychopaths have mild frontal lobe deficits—and similar head trauma related changes in personality have been described.

Clinical features

Many patients meet more than one set of PD criteria. Some borderline patients report auditory and visual hallucinations. Dysthymia (formerly depressive PD) and cyclothymia (also formerly a PD) are now seen as mild depression and bipolar disorder, respectively. Paranoid, schizotypal, obsessional, and avoidant PDs may be similarly reclassified in the future.

Differential diagnosis

The main differential is with the associated psychiatric disorder and other PDs. As a rule, the eccentric cluster can present similarly to schizophrenia, the emotional cluster-like bipolar disorder, and the anxious cluster with anxiety states. Borderline PD can cause diagnostic difficulties with both schizophrenia and BPD.

Management

Clinical management has conservative aims, but pressure is being put on psychiatrists to do more. Few treatments have been evaluated for PD *per se*. Cognitive therapy may generally reduce the frequency of deliberate self-harm. Dysthymia responds to antidepressants; paranoid, schizotypal, and borderline patients may benefit from antipsychotic drugs; and obsessional PD may respond to SSRIs.

Prognosis

Recurrent deliberate self-harm and eventual suicide is common. Patients with PDs who develop other psychiatric disorders also have a poor prognosis for that disorder.

Concluding remarks

Psychiatric disorders are common, involuntary, distressing, and disabling. Like most medical disorders, they are caused by biological, psychological, and social factors. They can be successfully treated, but are often chronic and associated with social rejection. Stigmatization remains a big problem, not least from doctors.

26.6.1 Psychopharmacology in medical practice

P. J. Cowen

Introduction

Psychotropic drugs are widely used in medical practice so that most clinicians are likely to have under their care a number of patients receiving treatment with psychoactive medication (Table 1). Practitioners therefore need to have an understanding of the uses and side-effects of psychotropic drugs, particularly of the way in which such medication can interact with drugs used to treat other medical disorders.

The majority of psychotropic drugs are prescribed for the treatment of depressive and anxiety disorders. This reflects the frequency of these conditions in both primary care and general hospital settings; accordingly, drug treatment for anxiety and depression will often be instituted both by general practitioners and hospital clinicians. Similarly, while the principal use of antipsychotic drugs is in the treatment of schizophrenia, such agents are also frequently used in general hospitals in the management of organic psychoses. Finally, while treatment with mood-stabilizing drugs, such as lithium, will generally be initiated by psychiatrists, patients receiving long-term therapy may well require treatment for coexisting medical disorders, because of which a knowledge of the effects of lithium on different body systems and its liability to produce adverse drug interactions will be required.

Drug overdose

The effects of deliberate or accidental overdose of psychotropic drugs will also involve physicians (see Chapter 8.1 and Chapter 26.5.2). Related to this is the general point that when prescribing psychotropic drugs, particularly for depressed patients, the risk of overdose should always be considered. If such a risk is present the practitioner should: (1) ensure that medication is dispensed in small amounts; (2) consider asking a close relative to supervise the medication; (3) use a relatively non-toxic drug, if possible.

Pharmacokinetic factors

Most psychotropic drugs are highly lipophilic and well absorbed from the gastrointestinal tract. They are metabolized by the liver to water-soluble derivatives which are eliminated by the kidney, hence their half-life will be prolonged in patients with hepatic or renal impairment and in the elderly. Where psychotropic medication is added to another drug treatment the possibility of drug interaction must be considered. For example, selective serotonin-reuptake inhibitors are potent inhibitors of hepatic cytochrome P-450 enzymes and can thereby increase plasma levels of coadministered drugs such as warfarin.

Withdrawal of psychotropic medication

Psychotropic and many other classes of drugs produce neuroadaptive changes during their repeated administration. Readjustment has to occur when drug treatment is stopped, and this may appear clinically as a withdrawal or abstinence syndrome. Characteristic abstinence syndromes have been described for the antidepressants and anxiolytics, while the sudden discontinuation of lithium can provoke a 'rebound' mania, hence it is prudent to withdraw psychotropic drugs slowly whenever possible. It is clearly also important to be able to distinguish withdrawal syndromes from relapse of the disorder being treated.

Compliance and concordance with treatment

In psychotropic drug prescribing, compliance is an even greater problem than in general therapeutics. Psychoactive drugs frequently have unpleasant side-effects and, while side-effects are experienced early in treatment, several days may elapse before a therapeutic response is evident. In addition, patients may not see the need for treatment or believe that it can help them. Careful explanation accompanied by written instructions can help to ensure that necessary medication is taken.

It is increasingly recognized that the successful and safe use of medication requires a collaborative relationship between patient and doctor. The term 'concordance' may therefore be preferred to 'compliance', which carries the implicit assumption that the patient's job is to obey instructions. It is therefore important to acquire an understanding of the patient's attitude to his or her illness as well its treatment. For example, discussion that helps patients to weigh the advantages and disadvantages of drug treatment ('compliance therapy') has been shown to benefit those with schizophrenia.

Antidepressant drugs

All currently employed antidepressant drugs, through one mechanism or another, increase the activity of serotoninergic (5-hydroxytryptamine, **5-HT**) and/or noradrenergic neurones in the CNS. The pharmacological actions of both noradrenaline (norepinephrine) and 5-HT in the synapse are terminated by specific reuptake pumps that draw these neurotransmitters back into the presynaptic nerve ending. Most antidepressants potentiate the action of 5-HT and noradrenaline by blocking this reuptake process.

Tricyclic antidepressants

Pharmacology

Tricyclic antidepressants inhibit the neuronal uptake of noradrenaline (norepinephrine) and 5-HT. They have numerous other pharmacological properties, but these are thought to contribute to their adverse effect profile rather than their therapeutic activity. However, some of these adverse effects, for example, sedation, can prove beneficial in certain circumstances.

Principal drugs

These are amitriptyline, clomipramine, desmethylimipramine, dothiepin, doxepin, imipramine, lofepramine, and nortriptyline.

Indications and use

Tricyclic antidepressants are still the most widely prescribed drug treatment for the management of depressive illness, but their use, particularly in less severe depressive states, is waning in favour of newer compounds that are better tolerated (see below). However, none of the newer antidepressants is more efficacious than the tricyclics and their therapeutic activity in severely ill patients is not as well established. For this reason, unless there are specific contraindications, tricyclic antidepressants should be preferred in depressed inpatients or in those with marked melancholic features.

Depressed patients with prominent sleep disturbance and anxiety should be treated with a sedating antidepressant such as amitriptyline; for other patients, less sedating compounds such as lofepramine or nortriptyline can be used. To obtain tolerance to side-effects, it is usual to begin treatment at a low dose, for example 25 to 50 mg of amitriptyline at night, and to increase the amount over about 2 to 3 weeks to the usual therapeutic dose, which ranges between 75 and 200 mg daily for amitriptyline and imipramine. Tricyclic antidepressants have long half-lives and a single daily dose taken at night is usually appropriate. Patients should be warned about side-effects because this helps to ensure compliance in the early stages of treatment. They should also be advised that a clear therapeutic response may not appear for up to 2 to 4 weeks.

If treatment is successful, it is usual to continue the antidepressant for 4 to 6 months at the original dose if tolerance allows (so called 'continuation therapy'). This reduces the risk of early relapse by about half. Some patients with recurrent depressive illness require long-term prophylactic treatment with antidepressant drugs. This should be considered in those who have had more than two episodes of depression in the previous 5 years, particularly if the episodes have been severe in terms of symptomatology and impact on work and social functioning.

Side-effects

As well as inhibiting the uptake of noradrenaline (norepinephrine) and 5-HT, tricyclic antidepressants possess antagonist properties at a variety of neurotransmitter receptors, including muscarinic cholinergic receptors, a $_1$-adrenoceptors, and H_1-histamine receptors. These receptor-antagonist effects account for much of the adverse effect profile of these agents, particularly their anticholinergic properties (Table 2). Tricyclics also possess membrane-stabilizing effects that underlie their most serious side-effect of cardiotoxicity, which can be particularly problematic in tricyclic overdose, where ingestion of less than 1 g can sometimes prove fatal. Lofepramine**,** however, is relatively safe in overdose. Tricyclics should be used with caution in patients with cardiovascular disease. They also lower the seizure threshold and can thereby aggravate pre-existing epilepsy or sometimes cause seizures *de novo*.

Drug interactions

Tricyclic antidepressants antagonize the hypotensive effects of a $_2$-adrenoceptor agonists such as clonidine, but can be safely combined with thiazides and angiotensin-converting enzyme (**ACE**) inhibitors. The ability of tricyclics to block noradrenaline (norepinephrine) reuptake can lead to hypertension with systemically administered noradrenaline and adrenaline (epinephrine). Tricyclics should not be used in conjunction with antiarrhythmic drugs, particularly amiodarone. Plasma levels of tricyclics can be increased by numerous other drugs including cimetidine, sodium valproate, calcium-channel blockers, and selective serotonin-reuptake inhibitors (**SSRIs**).

Newer antidepressants

Principal drugs

These can be classified as follows:

- *selective 5-HT reuptake inhibitors (SSRIs)*: citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline;
- *selective noradrenaline (norepinephrine)-reuptake inhibitors:* reboxetine;
- *selective noradrenaline- and serotonin-reuptake inhibitors:* venlafaxine;
- *monoamine-receptor antagonists*: mirtazapine, nefazodone, and trazodone.

Pharmacology

The actions of SSRIs are essentially confined to inhibition of 5-HT reuptake. Their use is associated with a sustained increase in brain 5-HT neurotransmission. By contrast, reboxetine inhibits only the reuptake of noradrenaline (norepinephrine). Venlafaxine is a potent blocker of 5-HT reuptake and at higher doses blocks the reuptake of noradrenaline as well. Nefazodone and trazodone have weak 5-HT-and noradrenaline-reuptake inhibiting properties. They also act as antagonists at 5-HT_2 receptors, and trazodone is a potent a $_1$-adrenoceptor antagonist. Mirtazapine is also a 5-HT $_2$-receptor antagonist, but in addition blocks inhibitory presynaptic a_2-adrenoceptors, resulting in an increased release of noradrenaline

All these compounds lack the cardiotoxicity and the anticholinergic effects of conventional tricyclic antidepressants. They are therefore safer in overdose and, in general, somewhat better tolerated. In the broad range of depressed subjects they have equal efficacy to tricyclics but, as noted above, it is not clear if this extends to the most severely ill patients.

Indications for use

The newer antidepressants should be used to treat patients in whom the use of tricyclic antidepressants is contraindicated because of their anticholinergic and cardiotoxic effects. In addition, some patients unable to tolerate a clinically effective dose of a tricyclic agent may find that one of the newer drugs causes fewer side-effects. The lack of sedation associated with SSRIs, reboxetine, venlafaxine, and nefazodone can be beneficial in outpatients striving to carry out their usual activities. Unlike tricyclic antidepressants, many of the newer drugs do not stimulate appetite and may therefore be appropriate in patients in whom weight gain would be undesirable. Finally, in patients where the risk of overdose cannot be minimized, the newer drugs may be preferred because of their lower acute toxicity.

Side-effects

The main adverse effects of the newer antidepressants are shown in Table 3. The major distinction between compounds is whether or not they are sedating. The sedating antidepressants have the advantage of improving sleep at an early stage but may impair cognitive function, while the reverse is true for SSRIs, venlafaxine, and reboxetine. Like tricyclic antidepressants, the newer compounds appear to lower seizure threshold to some extent, though this effect may be less with trazodone and SSRIs. SSRIs may increase the risk of upper gastrointestinal bleeding, particularly if given in conjunction with non-steroidal anti-inflammatory drugs (**NSAIDs**).

Drug interactions

SSRIs, with the exception of citalopram, slow the metabolism of numerous other drugs including warfarin, theophylline, anticonvulsants, antipsychotics, and tricyclic antidepressants. Dangerous interactions, characterized by 5-HT neurotoxicity, have been reported between SSRIs, venlafaxine, and monoamine oxidase inhibitors (**MAOIs**). This may be particularly problematic with fluoxetine, whose active metabolite norfluoxetine has a half-life of 7 to 10 days. At least 5 weeks should therefore elapse between stopping fluoxetine and prescribing a monoamine oxidase inhibitor. SSRIs may also produce 5-HT toxicity in combination with lithium. Trazodone and mirtazapine may increase the sedative effects of other centrally acting drugs. Nefazodone can raise plasma levels of terfenadine, causing a risk of cardiac arrhythmias. Nefazodone also elevates plasma levels of carbamazepine and digoxin. Reboxetine should not be given with other agents that might potentiate noradrenaline (norepinephrine) function (such as MAOIs) or increase blood pressure (such as ergot derivatives).

Monoamine oxidase inhibitors

Pharmacology

Monoamine oxidase inhibitors (MAOIs) block the enzyme monoamine oxidase, which deaminates the neurotransmitters, 5-HT, noradrenaline (norepinephrine), and dopamine. Monoamine oxidase exists in two forms, known as type A (which deaminates noradrenaline and 5-HT) and type B (which preferentially deaminates dopamine and tyramine). Conventional MAOIs irreversibly deactivate both type A and type B monoamine oxidase. This has two main consequences of importance for MAOI use: (1) there is a potential for serious food and drug interactions; and (2) the consequent drug and food restrictions need to be continued for 2 weeks after cessation of MAOI treatment so that new monoamine oxidase can be synthesized.

Recently a new MAOI, moclobemide**,** has been introduced. This differs from conventional MAOIs in that its inhibition of monoamine oxidase is reversible, and it selectively inhibits type A monoamine oxidase only. This leads to an increase in brain noradrenaline and 5-HT levels, but other amines such as tyramine are little affected. These factors make moclobemide much less likely than the older monoamine oxidase inhibitors to produce adverse food and drug interactions, giving it a significant safety advantage. However, while moclobemide has been shown to be effective in the treatment of moderately depressed outpatients, studies have not thus far demonstrated its efficacy in the patient groups for whom conventional MAOI treatment is currently reserved (see below).

Principal drugs

These are isocarboxazid, phenelzine, tranylcypromine, and moclobemide.

Indications and use

Conventional MAOIs are rarely used as a first choice of antidepressant, except where a patient is known to have responded to them in the past. They are usually reserved for subjects who have failed to respond to tricyclic antidepressants, newer antidepressants, or electroconvulsive therapy, where a very useful antidepressant effect can often be achieved.

Phenelzine and tranylcypromine are the two most commonly prescribed MAOIs. The usual therapeutic dose for phenelzine is between 30 and 90 mg daily. As with tricyclic antidepressants, patients should be informed about side-effects and advised that a therapeutic response from monoamine oxidase inhibitors may not be apparent for 3 to 4 weeks. Once a response is obtained, it is usually necessary to continue treatment for several months.

Side-effects

Monoamine oxidase inhibitors may cause the following side-effects:

- *central nervous system*: dizziness, muscular twitching, insomnia, confusion, mania;
- *cardiovascular:* tachycardia, postural hypotension, hypertension;
- *other:* dry mouth, blurred vision, impotence, peripheral oedema, hepatocellular damage, leucopenia.

Food and drug interactions

The major hazard of conventional MAOI treatment is through interaction with indirect sympathomimetics, that is, agents that release noradrenaline from nerve endings. The usual source of the interaction is tyramine in certain foodstuffs, especially cheese and meat extracts. Tyramine is usually metabolized by monoamine oxidase in the gut wall and liver, but in patients taking MAOIs large amounts may enter the systemic circulation, resulting in hypertension and even cerebrovascular accidents. Similar adverse effects have been reported when sympathomimetic drugs, such as amphetamines or ephedrine, are administered to patients taking monoamine oxidase inhibitors. Ephedrine or its derivatives are frequently present in cold cures: patients must therefore be warned against self-medication without seeking advice.

Hypertensive episodes resulting from the interaction of sympathomimetic drugs and monoamine oxidase inhibitors are best treated with an a_1-adrenoceptor antagonist. If one is unavailable, intramuscular chlorpromazine is an alternative.

MAOIs also produce important interactions with other commonly used drugs, including opiates, insulin, and oral hypoglycaemic agents. Except in special circumstances, combination with tricyclic antidepressants is best avoided. Combination with clomipramine, SSRIs, and venlafaxine can cause a 5-HT neurotoxicity syndrome and is contraindicated.

From the foregoing it will be apparent that conventional monoamine oxidase inhibitors should only be prescribed to patients capable of adhering to the necessary dietary restrictions. Written instructions listing prohibited foods should be provided. No additional medication should be given until the possibility of an adverse drug interaction has been excluded.

Moclobemide

Moclobemide is well tolerated, although insomnia and nausea may occur. Unlike conventional monoamine oxidase inhibitors, moclobemide does not cause significant interaction with tyramine, and adverse drug interactions also seem to be less likely. However, caution is recommended when prescribing with opiates, and combined use with SSRIs and sympathomimetic agents should be avoided. Because of the reversible nature of moclobemide's interaction with monoamine oxidase and its short half-life (about 3 h), normal monoamine oxidase activity is restored within a day of stopping treatment.

Mood-stabilizing drugs

Lithium

Pharmacology

Lithium salts have inhibitory effects on receptor-transduction systems, particularly second messengers such as cyclic-AMP and phosphoinositol. Lithium also produces marked increases in some aspects of brain 5-HT function.

Indications and use

The main uses of lithium are:

- prophylaxis of recurrent affective disorders, especially manic depressive illness;
- acute treatment of mania;
- augmentation of antidepressant medication in patients with resistant depression.

The excretion of lithium from the body is critically dependent on the kidney. Since there is little margin between the therapeutic plasma levels of lithium (0.5 to 0.8 mmol/l) and those causing toxicity (>1.2 mmol/l), the introduction of lithium therapy should be preceded by clinical and laboratory assessment of renal function. Renal function tests should include urinalysis and estimations of plasma creatinine and electrolyte levels, with measurement of creatinine clearance if there is any suggestion of impaired renal function.

Patients should initially be treated with 200 to 400 mg daily of lithium carbonate, usually as a single dose at night. Slow-release preparations of lithium are available, but their pharmacokinetics *in vivo* are very similar to those of the standard preparation. Dosage should be adjusted every 5 to 7 days on the basis of plasma lithium determinations obtained approximately 12 h after the last dose. For prophylaxis of recurrent mood disorders, plasma levels of 0.5 to 0.8 mmol/l are usually

satisfactory; but some patients—particularly those with an acute manic episode—may require higher levels (0.8 to 1.0 mmol/l). Most patients achieve adequate plasma levels with lithium carbonate dosages of between 600 and 1200 mg daily, and following this their lithium requirement is generally stable.

In the absence of clinical indications it is usually sufficient to check lithium levels every 2 to 3 months and repeat renal function tests every 6 months. Lithium can also cause hypothyroidism, so thyroid function tests should be performed prior to treatment and at 6-monthly intervals thereafter. If necessary, lithium can be combined with thyroxine replacement therapy. Sudden withdrawal of lithium in bipolar patients can cause an acute rebound mania and should be avoided if at all possible.

Side-effects

Many patients suffer from a fine tremor and nausea; diarrhoea may occur, especially at the start of treatment (Table 4). Some degree of thirst and polyuria is common, and a few patients develop nephrogenic diabetes insipidus, probably caused by lithium blocking the effect of ADH on the renal tubule. Most patients taking lithium have a demonstrable impairment of tubular concentrating ability, although this is rarely of clinical significance. Glomerular function is not usually affected by lithium, but glomerular damage and interstitial fibrosis have been reported following lithium toxicity. There are reports that long-term lithium treatment can occasionally cause long-term renal impairment. However, this risk is low provided the plasma concentrations of lithium are kept within the therapeutic range and episodes of toxicity are avoided.

Up to 80 per cent of the lithium filtered by the renal glomerulus is reabsorbed by the proximal tubule. Conditions such as diarrhoea and excessive sweating, which induce renal sodium retention, also result in increased lithium reabsorption by the kidney and elevated plasma lithium levels.

Drug interactions

Thiazide diuretics, through their effect on sodium excretion, increase lithium reabsorption and can produce lithium toxicity unless the dose of lithium is reduced and plasma concentrations carefully monitored. It is said that loop and potassium-sparing diuretics are less likely to alter lithium clearance, but it is prudent to monitor lithium levels carefully when using these drugs. Plasma lithium levels may also be increased by concomitant administration of NSAIDs, and a similar effect may be produced by metronidazole. Lithium levels may be increased by ACE inhibitors and lowered by theophylline. While the effects of lithium on cardiac conduction are usually considered benign, the effects of cardiac glycosides on conduction may be potentiated. Lithium can cause neurotoxicity (at normal plasma levels) with calcium-channel blockers and carbamazepine. Finally, lithium may increase the liability of antipsychotic drugs to cause extrapyramidal movement disorders.

Lithium toxicity

Acute lithium toxicity usually appears at plasma levels above 1.2 mmol/l. Early signs are coarse tremor, drowsiness, and dysarthria. Higher plasma concentrations (>2.0 mmol/l) can lead to seizures, coma, and death. Since lithium toxicity is potentially fatal, any suspicion of intoxication should lead to the immediate withdrawal of lithium treatment and close monitoring of serum lithium and plasma electrolyte and creatinine concentrations. Severely ill patients with high serum lithium levels may require dialysis.

Carbamazepine

Pharmacology

Like certain other anticonvulsant drugs, carbamazepine blocks neuronal sodium channels. The relationship of this effect to its therapeutic actions in affective disorder is uncertain. Similarly to lithium, carbamazepine facilitates some aspects of brain 5-HT neurotransmission.

Indications and use

Carbamazepine is effective in the acute treatment of mania and in the prophylaxis of bipolar affective disorder. It is used in patients who have difficulty tolerating or fail to respond to lithium therapy, when it may be given in combination with lithium.

The dose range of carbamazepine employed to treat patients with affective illness is similar to that used in the treatment of seizure disorders. Initial treatment should be with 100 mg of carbamazepine twice daily, with the dose increased according to tolerance over the next 2 to 4 weeks. The effective dose range in the treatment of bipolar disorder is generally between 600 and 1200 mg daily, although some patients require higher doses. Plasma level monitoring may be used to help avoid toxicity.

Side-effects

Dizziness, drowsiness, and nausea are common early in treatment, particularly with rapid dose titration, but tolerance to these effects usually develops. Persistent ataxia and diplopia may indicate plasma carbamazepine levels in the toxic range. A moderate degree of leucopenia is often seen during carbamazepine treatment and agranulocytosis can occasionally develop, such that it is prudent to monitor the white cell count as well as the carbamazepine level during treatment. Skin rashes are also quite common. Other rarer adverse effects include hyponatraemia and liver cell damage. Circulating thyroid hormone level may be lowered by carbamazepine treatment, but thyroid-stimulating hormone (**TSH**) levels generally remain in the normal range and clinical hypothyroidism is unusual. Carbamazepine can impair cardiac conduction and should be used with caution in patients with cardiovascular disease.

Drug interactions

Carbamazepine increases the metabolism of a number of other drugs, including tricyclic antidepressants, haloperidol, oral contraceptive agents, warfarin, and other anticonvulsants. A similar mechanism may underlie the decline in the plasma carbamazepine level sometimes seen during continued treatment. The carbamazepine level may be increased by erythromycin and by some calcium-channel blockers, such as diltiazem and verapamil. Reversible neurotoxicity has been reported when carbamazepine is combined with lithium.

Sodium valproate

Pharmacology

Valproate is a simple branch-chain fatty acid with a mode of action that is unclear, although there is some evidence that it can slow the breakdown of the inhibitory neurotransmitter g-aminobutyric acid (**GABA**). This action could account for its anticonvulsant properties, but whether it also underlies the psychotropic effects is unclear.

Indications and use

Like carbamazepine, sodium valproate was first introduced as an anticonvulsant. Recent studies have shown that it is clearly effective in the management of acute mania: the drug is licensed for this purpose in the United States, but not in the United Kingdom. In the United States, valproate is widely used in the longer term prophylaxis of bipolar disorder, but there is little evidence for this indication from randomized trials.

Valproate can be started at a dose of 400 to 600 mg daily, which may be increased once or twice weekly to between 1 and 2 g daily. Plasma levels of valproate do not correlate well with either its anticonvulsant or mood-stabilizing effects, but it has been suggested that efficacy in the treatment of mood disorders is usually apparent when plasma levels are above 50 µg/ml.

Side-effects

Common side-effects of valproate include gastrointestinal disturbances, tremor, sedation, weight gain, and transient hair loss. Serious side-effects are rare, but fatal hepatic toxicity has been reported, as has acute pancreatitis. Valproate may also cause thrombocytopenia and inhibit platelet aggregation, and increases in plasma

ammonia have been reported.

Drug interactions

Valproate potentiates the effects of central sedatives. It has been reported to increase the side-effects of other anticonvulsants (without necessarily improving anticonvulsant control). It may increase plasma levels of phenytoin and tricyclic antidepressants.

Antipsychotic drugs

Conventional (typical) and atypical agents

Pharmacology

Antipsychotic drugs, also known as major tranquillizers or neuroleptics, are a group of agents of varied structure that are used to treat schizophrenia and other psychoses. Conventional or typical antipsychotic agents have in common the ability to block dopamine receptors in the central nervous system, and it is likely that their antipsychotic effect is caused by blockade of dopamine D2 receptors in mesolimbic and mesocortical brain regions.

Atypical antipsychotic drugs have been developed more recently. These have a varied pharmacology, but a much lower likelihood than conventional agents of producing extrapyramidal side-effects at therapeutic doses. Some are highly selective dopamine D_2-receptor antagonists with selectivity for mesolimbic dopamine receptors, for example sulpiride and amisulpiride. Others (for example, risperidone, olanzapine, and quetiapine) have high affinities for the 5-HT_2 receptor that exceed their affinities for the D_2 receptor. Finally, clozapine is also a potent 5-HT_2-receptor antagonist but a weak D_2-receptor antagonist, which accounts for its particularly low risk of inducing extrapyramidal movement disorders.

Principal drugs

These are the:

- *conventional (typical) antipsychotic drugs*: chlorpromazine, haloperidol, flupentixol, fluphenazine, loxapine, pimozide, thioridazine, and trifluoperazine;
- *atypical antipsychotic drugs*: amisulpiride, olanzapine, quetiapine, risperidone, sulpiride.

Indications and use

Antipsychotic drugs are used mainly in the management of schizophrenia. They are also used to treat mania and are sometimes given to depressed patients who have psychotic symptoms or who are particularly agitated. Antipsychotic drugs are also used in the management of disturbed behaviour arising from other causes (for example, confusional states), but their use as non-specific tranquillizing agents should (if possible) be limited to short-term use because of potentially serious side-effects.

In the treatment of acute confusional states, haloperidol, in doses of 1.0 to 5.0 mg is often helpful. This can be administered either orally or parenterally, with the dose repeated after an hour if the patient remains disturbed. Cardiovascular and respiratory side-effects are unlikely with this drug, but acute dystonias can occur and should be treated appropriately (Table 5). Antipsychotic drugs such as risperidone are used for the treatment of confused elderly patients. It is worth noting that some groups of demented patients (particularly those with Lewy-body type dementia) may suffer severe extrapyramidal effects from comparatively low doses of antipsychotic drugs.

The treatment of patients with schizophrenia or mania with antipsychotic drugs requires careful monitoring and persistence because the full therapeutic response may be delayed for some weeks. Furthermore, the dose of antipsychotic drug required may vary considerably from patient to patient, and also within the same patient at different stages of the illness. Lower doses of conventional antipsychotic drugs are now employed for the treatment of these disorders, since positron-emission tomography (**PET**) imaging studies have revealed that an adequate blockade of dopamine D_2 receptors can be obtained with oral doses of 5 to 10 mg of haloperidol daily or 200 to 400 mg of chlorpromazine. Higher doses of these agents can produce sedation and behavioural calming, but at the expense of movement disorders and decreased compliance subsequently.

If a patient has responded to an antipsychotic drug it is usual to continue the medication for a number of months into remission. Frequently it is necessary to administer medication on a long-term basis to prevent relapse, in which case the use of long-acting intramuscular preparations will improve compliance. The decanoates of fluphenazine, flupentixol, and haloperidol are most commonly used.

Atypical antipsychotic drugs should be used when patients experience extrapyramidal movement disorders on low doses of typical agents. In addition, clozapine can be effective in up to 50 per cent of patients with schizophrenia whose symptoms have not responded to typical antipsychotic drugs. It is effective in the treatment of both positive and negative symptoms of schizophrenia; the latter often showing a poor response to typical agents. Whether the other atypical agents are effective in treatment-resistant patients is not yet fully clear. Clinical impression is that some patients can indeed show a useful response, but the frequency of a positive outcome may be less than with clozapine.

Side-effects

Movement disorders

Through their blockade of brain dopamine receptors, typical antipsychotic drugs produce a variety of extrapyramidal movement disorders that can mimic signs of basal ganglia disease (Table 5). Many patients exhibit symptoms of parkinsonism very similar to those of the idiopathic disorder, although tremor is less prominent. A side-effect that appears early in treatment is acute dystonia, which can present with abnormal postures or dramatic muscular spasms involving the face and limbs. Laryngeal spasm with respiratory distress can also occur. A history of recent antipsychotic drug use can help avoid misdiagnoses (it is not unusual, for example, for such reactions to be viewed as 'hysterical'). Another movement disorder that patients find very distressing is akathisia, which is a state of motor restlessness, often with agitation and dysphoria. Distinguishing this reaction from symptoms arising from the underlying psychiatric disorder may not be easy.

All these movement disorders may be treated by a reduction in dosage of the antipsychotic drug or by the introduction of anticholinergic medication such as benzatropine. However, anticholinergic drugs should not be prescribed routinely with antipsychotic medication because of the risk of misuse for their euphoriant effects.

Later in treatment, tardive dyskinesia may develop. This consists of involuntary repetitive movements, usually involving the tongue and lips, though other parts of the body may be involved. The condition may be associated with a supersensitivity of postsynaptic dopamine receptors in the basal ganglia. Unfortunately, this disorder cannot be treated easily, and anticholinergic medication may make it worse. If possible, the antipsychotic drug should be stopped, but this decision is often difficult because of the risk of relapse of the psychiatric disorder.

Atypical antipsychotic drugs are much less likely to cause movement disorders. Risperidone, however, is a potent D_2-receptor antagonist as well as a 5-HT_2-receptor antagonist and can produce some movement disorders at the upper end of its dose range (above 4 to 6 mg daily). Whether atypical antipsychotic drugs are generally less likely to cause tardive dyskinesia is not yet clear. The risk does appear to be less with clozapine, olanzapine, and risperidone.

Neuroleptic malignant syndrome

A rare but potentially very serious reaction to antipsychotic drugs is the neuroleptic malignant syndrome (Table 5). This is characterized by fever, rigidity, and altered consciousness, together with tachycardia and labile blood pressure. Laboratory investigations usually reveal a leucocytosis together with markedly raised levels of creatinine phosphokinase. Antipsychotic drug treatment should be withdrawn immediately if the neuroleptic malignant syndrome is suspected. Management in an

intensive care facility may be needed to deal with cardiovascular, respiratory, and renal complications. Treatment with a dopamine-receptor agonist, such as bromocriptine, and the antispasticity agent dantrolene may be beneficial.

Other side-effects of antipsychotic drugs

Antipsychotic drugs, especially chlorpromazine and thioridazine, can produce a variety of side-effects due to blockade of muscarinic receptors and a-adrenoceptors (Table 2). Other side-effects include:

- *endocrine*: elevated prolactin levels, amenorrhoea, and galactorrhoea;
- *skin*: rashes, pigmentation, and photosensitivity (especially phenothiazines);
- *other*: precipitation of seizures, hypothermia (especially chlorpromazine), cardiac arrhythmias (pimozide), weight gain, cholestatic hepatitis, leucopenia, and retinitis pigmentosa (thioridazine in doses >800 mg daily).

The most common side-effects of atypical antipsychotic drugs are shown in Table 6.

Drug interactions

Antipsychotic drugs potentiate the effects of other central sedatives. They may delay the hepatic metabolism of tricyclic antidepressants and antiepileptic drugs, leading to increased plasma levels of these agents. The hypotensive properties of chlorpromazine and thioridazine may enhance the effects of antihypertensive drugs. Antipsychotic drugs, particularly pimozide and thioridazine, can increase the Q–T interval and should not be given with other drugs likely to potentiate this effect, such as antiarrhythmics, astemizole, terfenadine, cisapride, and tricyclic antidepressants. There are also reports of an increased risk of cardiac arrhythmias when pimozide has been combined with clarithromycin and erthyromycin. Clozapine should not be given with any agent likely to potentiate its depressant effect on the white cell count such as carbamazepine, cotrimoxazole, and penicillamine. SSRIs slow the hepatic metabolism and increase blood levels of several antipsychotic drugs, including haloperidol, risperidone, and clozapine.

Antianxiety agents

Benzodiazepines

Pharmacology

Benzodiazepines enhance the action of the neurotransmitter g-aminobutyric acid (GABA) in the central nervous system by binding to a specific benzodiazepine receptor located in a complex with a GABA receptor and a chloride-ion channel. The pharmacological effects of benzodiazepines are attributed to the facilitation of GABA neurotransmission.

Principal drugs

These are alprazolam, chlordiazepoxide, diazepam, flurazepam, lorazepam, lormetazepam, nitrazepam, and temazepam.

Indications and use

The prescription of benzodiazepines is now decreasing following concern about their liability to produce dependence. Alternative therapies are available for most anxiety-related disorders, and it is recommended that the drug treatment of anxiety and insomnia should be limited to a few weeks' duration. The major indication for the use of benzodiazepines is to help patients in a crisis, when generalized anxiety and insomnia are causing functional impairment and reducing their ability to cope. Patients should be advised that the drug treatment will be of short duration to help them manage their immediate difficulties.

All benzodiazepines have hypnotic and anxiolytic properties. The major distinction of clinical importance is their length of action. Derivatives with short half-lives, such as temazepam, are suitable hypnotics because of their relative lack of a hangover effect. Other benzodiazepines, for example diazepam, have long half-lives and are metabolized to active compounds. These may be used for the treatment of anxiety, either in the form of regular dosing, or on the now preferred 'as required' basis with an agreed maximum daily dose.

Side-effects and interactions

Benzodiazepines have a low acute toxicity. Their adverse effects are extensions of their clinical effects and include the following: drowsiness, psychomotor impairment, dizziness, ataxia, and paradoxical aggression (rare). Benzodiazepines potentiate the effects of other centrally acting sedatives, particularly alcohol. The effects of benzodiazepines are potentiated by cimetidine.

Patients who have taken clinical doses of a benzodiazepine for more than a few months may show a withdrawal syndrome when the medication is stopped. In many respects this syndrome resembles an anxiety state, but perceptual disturbances and acute dysphoria may also occur. It is thus apparent that benzodiazepines can cause physical dependence, and, although the withdrawal syndrome is less severe than that seen following the cessation of barbiturates, patients frequently find it extremely difficult to stop their medication. A gradual reduction is usually best. Generally, withdrawal from a long-acting benzodiazepine is easier than from a short-acting preparation, and if patients taking short-acting benzodiazepines have difficulty withdrawing, then a switch to a long-acting preparation may be helpful.

Other drugs that increase brain GABA function

Zopiclone, zolpidem, and zaleplon

Zopiclone is a cyclopyrrolone derivative marketed for the treatment of insomnia. It binds to a site close to the benzodiazepine receptor and thereby facilitates brain GABA function. By contrast to the benzodiazepines, which reduce the amount of slow-wave (deep) sleep at night, zopiclone has little effect on sleep architecture and is relatively free from a daytime 'hangover' effect. It is claimed to be less likely than benzodiazepine hypnotics to produce tolerance and withdrawal effects, but cases have been reported. The most common adverse effects of zopiclone include bitter taste, nausea, dry mouth, irritability, and headache.

Zolpidem is an imidazopyridine derivative, which also binds to a site close to the benzodiazepine receptor. It has a very short duration of action and, like zopiclone, has little effect on sleep architecture or daytime performance. Its possible adverse effects include nausea, dizziness, headaches, and diarrhoea. Zoleplon is a pyrazolopyrimidine derivative with pharmacological properties similar to zopiclone and zolpidem. However, its half-life is only about an hour which means that it can be used to re-induce sleep after nocturnal waking.

Clomethiazole

Clomethiazole also binds at the GABA-receptor complex, but its clinical effects resemble those of barbiturates rather more than those of the benzodiazepines. It can cause serious respiratory depression in overdose, particularly in combination with alcohol. Because of its short half-life (4 to 5 h), clomethiazole is also used as a hypnotic in the elderly, where dependence has not been reported.

Drugs altering monoamine function

Buspirone

Buspirone is a 5-HT_{1A}-receptor agonist structurally unrelated to benzodiazepines. It is effective in the treatment of generalized anxiety disorder (less so in patients previously exposed to benzodiazepines) but has a slow onset of action (1 to 3 weeks). Unlike benzodiazepines, buspirone does not cause significant sedation or

cognitive impairment and appears unlikely to cause dependence. It does not have hypnotic properties. Side-effects include nervousness, dizziness, and headache.

Other drugs

Tricyclic antidepressants and SSRIs are effective in the management of patients with a range of anxiety disorders, including generalized anxiety. They are generally preferred to benzodiazepines for the treatment of agoraphobia with and without panic attacks. SSRIs are also effective in the treatment of obsessive–compulsive disorder and social phobia, but tricyclics (with the exception of clomipramine) are not.

26.6.2 Psychological treatment in medical practice

Michael Sharpe and Simon Wessely

What is psychological treatment?

Psychological treatments in medicine come in two main forms. First are formal psychological interventions, which usually have particular labels and content, such as counselling or behaviour therapy, and which are rarely delivered by physicians. Second, and arguably more important, is the doctor–patient interaction itself. This can also be regarded as a psychological treatment; an intervention that has an important and unavoidable psychological impact, whether for good or ill.

Psychological treatment and the medical consultation

The psychotherapeutic importance of the medical encounter was perhaps best acknowledged and described at a time when physicians had less to offer in terms of biological therapies, and consequently placed more emphasis on what they could achieve by talking with the patient. Hence, one less-welcome consequence of the increasing specialization and dependence on technology in modern medicine has been a relative neglect of the psychological aspects of the encounter, most particularly in hospital medicine. Despite the power of modern drug and surgical therapies, there remains a great and possible increasing need for the psychotherapeutically helpful medical consultation. This is especially the case when there is diagnostic uncertainty and when the patient is distressed.

Psychotherapeutic consultations (doing good)

The key ingredients of the psychologically helpful consultation are those described by Jerome Frank as factors common to all psychological treatments, including:

- establishing a good, confiding, and collaborative relationship with the patient;
- giving an explanation to the person of what is wrong with them;
- offering a clearly described plan of action;
- giving a positive message.

Medical encounters are often suboptimal in these general, but important, non-specific factors. The nature of the encounter and its context may not provide an opportunity for the patient to confide in the doctor. The doctor may convey verbally or non-verbally that he does not wish to hear the patient's story or concerns. A positive explanation for the person's symptoms is often lacking and there may be no clear plan of action.

Simple steps can be taken to remedy these shortcomings. It is desirable that attention be paid to the physical arrangements for the consultation. The days when patients were first told that they have cancer on an open ward round may be gone, but many consultations offer scant privacy and opportunity for the patient to ask questions. Some consultations will take time. Whilst to some extent others such as nurses can supplement the doctor's role, it is important that time and privacy are recognized and insisted on as essential therapeutic tools. Taking an interest in the patient's symptoms (even those that are not of diagnostic value) and their fears about these (even if they appear illogical) is essential. Unless this is done the patient may feel they have not been listened to and ignore subsequent advice. It is hard to give effective reassurance if one does not know what the patient fears: time spent on such matters is not therefore a distraction from the diagnostic process, but critical to the overall aim of helping the patient to feel better.

A clear explanation and plan of action is important. All too often patients complain that doctors told them what they didn't have, but not what they did have. This usually happens when the patient's symptoms are not adequately explained by identifiable disease (see Chapter 26.5.3), but even when a clear explanation cannot be given, a positive plan of action usually can. There is evidence that a positive approach has a beneficial effect on outcome.

The provision of hope and an expectation of improvement has long been an ingredient of the doctor–patient relationship. This should not be false hope, for example if the patient has a terminal condition the message should not be a false message that the condition can be cured, but rather that their symptoms will be managed and the doctor will provide ongoing help for them.

Psychological iatrogenesis (doing harm)

Iatrogenesis is not only the result of prescribing the wrong drug or doing the wrong operation: what doctors say to patients can also have powerful negative effects. These include:

- *Dismissive messages*: for example, telling a patient with medically unexplained symptoms 'there is nothing wrong with you—it's “all in the mind”, you are imagining it'. This is not only likely to damage your relationship with the patient, but may also send him or her into the arms of less scrupulous practitioners.
- *Excessively optimistic predictions*: for example, telling a patient who has not yet been adequately assessed 'I'm sure it's nothing serious'. This may lead to the patient losing faith in the doctor who made the predictions (and to legal redress) if it turns out to be incorrect.
- *Excessively negative predictions*: for example, telling a person with possible multiple sclerosis 'its probably best if you come to terms with the idea of a wheelchair'. This is likely to lead to the patient becoming unnecessarily distressed.
- *Ill-considered or unhelpful explanation for the illness*: for example, telling the person who is depressed that it's 'probably a virus'. This can set them off on the wrong track for how they should cope and what treatment they should seek.
- *Poorly thought out or ill-informed advice*: for example, telling a patient with indigestion to avoid all foods that are associated with the symptoms. For some patients this can fuel excessive dietary restriction. An elegant demonstration of this type of problem was found in a study of schoolchildren whose parents were told (sometimes incorrectly) that their children had abnormal hearts and should avoid exertion: at follow-up the children with normal hearts were as disabled as those with heart disease.

Specific psychological treatments

Specific psychological treatments may be broadly divided into simple counselling interventions, more intense but short-term psychotherapeutic interventions such as cognitive–behavioural therapy, and longer-term treatments such as long-term psychotherapy. These have a potentially important role in medical practice in improving quality of life and adherence to recommended treatments, and there is some evidence that they may even improve survival. Certainly there is empirical support for better integration of psychological therapies into standard medical care.

Counselling

Simple counselling may have a role in helping people express distress and talk through acute problems, for instance adjustment to a worrying diagnosis such as that of cancer. Whereas the provision of reassurance and emotional support is clearly important, whether or not this qualifies as a specific 'treatment' or needs to be given by a mental health professional is doubtful. Rather it should be regarded as a generic skill to be possessed by all health workers.

Short-term specific psychological therapies

Short- and medium-term specific therapies such as cognitive–behavioural therapy and interpersonal therapy are of documented effectiveness. Both are as effective as antidepressant medication in the treatment of depression. Cognitive–behavioural therapy is also of value in the treatment of patients with anxiety and panic disorders and has a specific role in those with unexplained somatic symptoms (see Chapter 26.5.3). It has been shown in randomized trials to be of benefit in patients with chronic unexplained pain, chronic fatigue syndrome, hypochondriasis, irritable bowel syndrome, non-cardiac chest pain, and other poorly understood conditions.

Cognitive–behavioural therapy is based on a collaborative relationship. The cognitive aspects refer to the patient being helped to re-evaluate and optimize their understanding of their illness. The behavioural part involves some form of target setting, activity scheduling and trying out new ways of coping. Interpersonal therapy is similar, but focuses on the person's relationships and social roles, rather than on their thoughts and behaviours.

Long-term psychotherapy

For persons with problems not amenable to brief therapy, such as ongoing difficulty in adjusting to disease and/or personality problems, there is a case for longer term psychological therapy, but the availability of such therapy is very limited.

Making a referral for specialist psychological treatment

The first requirement for making a referral for specialist psychological treatment is to ensure that there is a service available and to find out what types of referrals are accepted. The second is to make sure that the patient understands why they have been referred and to establish that they are likely to attend.

Services

Psychological treatment services will ideally be located in organizational and geographical proximity to the medical consultation. In reality they often are not. It is therefore desirable for the physician to familiarize themselves with what is available, how long the patient will have to wait, and how they will be received before the need to make a referral arises.

Making the referral

It is often helpful to discuss the referral with the service to ensure it is appropriate. For example, the psychological problems may appear obvious to the physician but regarded as untreatable personality characteristics by the service being referred to. If medical investigation or treatment is ongoing it will help if uncertainties are made explicit in the referral letter and new findings communicated as they arise.

Explanation to the patient

The first and perhaps most important aspect of explaining such a referral to the patient is to make is clear to them that you are not implying that their illness is 'all in the mind', but rather that there is a psychological aspect that deserves attention. The second is to convey a positive attitude towards psychotherapy as being a sensible approach with a realistic chance of helping them. It helps if you have some knowledge of what they can expect. Finally, it can be important, if appropriate, to indicate that you will see the patient after the psychological treatment, meaning that you do not simply regard this as a way of disposing of them.

Summary

There has been an unfortunate separation of biomedical and psychosocial aspects of patient management in our medical system. This is maintained by a number of factors, including geographical separation of services and the short time available for medical consultations. None the less, all medical interactions have an inescapable psychological component and the potential to help or harm the patient. There are basic aspects of a consultation that will maximize the opportunity of doing good; there are other ways of handling consultations that may do harm and should be avoided.

Specific psychological treatments have an important role, especially for those who are distressed in relation to a medical condition, and for those who have unexplained physical symptoms. Whilst there is a general supportive role for counselling, most of the evidence of effectiveness is in support of short- and medium-termed structured psychological treatment such as cognitive–behavioural therapy. A small number of patients, such as those with long-standing problems adjusting to an illness or personality problems, might benefit from longer term psychotherapy, although the evidence for the effectiveness of this is limited.

26.7.1 Alcohol and drug dependence

Mary E. McCaul and Gary S. Wand

Diagnosis

In the 1970s, Edwards and Gross first characterized the alcohol-dependence syndrome. Today, this syndrome is the basis of alcohol- and other drug-dependence criteria for both major diagnostic systems: the *World Health Organization international classification of diseases, tenth revision* (**ICD-10**) and the *American Psychiatric Association diagnostic and statistical manual of mental disorders, fourth edition* (**DSM-IV**). For a diagnosis of dependence, both systems require a clustering of at least three of the following symptoms during a 12-month period:

1. tolerance (i.e. increasing amounts of drug needed to achieve the desired effect);
2. characteristic physiological withdrawal;
3. difficulties in controlling onset, termination, or amount of substance use;
4. neglect of important social, occupational, or recreational activities because of substance use;
5. increased time required to obtain, use, or recover from substance use; and
6. continued use despite persistent negative physical or psychological consequences.

In DSM-IV, dependence is subtyped for the presence/absence of physiological withdrawal and tolerance, and recovery status is characterized for duration (early versus sustained remission) and symptom status (partial versus full remission). International studies have found remarkable consistency in the dependence syndrome across diverse geographical and cultural settings, suggesting that fundamental biological processes underpin the disorder.

By contrast, cross-cultural reliability has not been established for the less severe diagnoses of harmful use (ICD-10) and substance abuse (DSM-IV), defined by the negative consequences of alcohol and drug use. This may stem from the greater subjectivity of defining 'harm' within a particular social and cultural context, compared to the more physically based dependence symptoms of withdrawal and tolerance. Similarly, specific levels of hazardous alcohol consumption have not been defined: acceptable amounts vary across cultures, time, and individuals as a function of health, pregnancy, age, and gender.

It is sometimes difficult to disentangle the signs and symptoms of substance abuse and dependence from other common psychiatric and medical conditions. Given their prevalence, alcohol and other drug use should be explored carefully with every patient; there are few socioeconomic, racial/ethnic, or educational predictors of who may experience these problems. Patients should be queried for substance use versus abstention, recent, lifetime, and heaviest use patterns, and finally any problems associated with use. Particular attention should be given to those who report family members with alcohol or drug problems. Additionally, certain behaviours often suggest hazardous levels of substance use; these include cigarette smoking, missing work, neglecting family responsibilities, poor nutrition and hygiene, and high rates of injury and accidents.

This chapter focuses on the harmful use of alcohol, stimulants, and opioids because of their prevalence and severe medical and psychosocial consequences. Although of importance, marijuana, nicotine, sedative, hallucinogen, and inhalant use will not be covered (some of these are discussed in Chapter 26.7.3, and for review, see APA 1994).

Epidemiology of alcohol and drug use, abuse, and dependence

There is considerable cultural variation in alcohol- and drug-use patterns and definitions of harmful or pathological levels of consumption. In North America and Europe the use of alcohol is widespread: in a recent multinational study, approximately one-quarter of primary healthcare patients reported at least one alcohol-related problem in the last year. The North American and European lifetime prevalence of alcohol dependence is approximately 9 per cent (range: 5.5 per cent in The Netherlands to 14.3 per cent in the United States) and the prevalence of drug dependence is about 4 per cent (range: 0.7 per cent in Mexico to 7.5 per cent in the United States). Alcohol-related problems account for approximately 4 per cent of the total burden of disease and injury in the world.

In comparison to alcohol use, the prevalence of drug use in Europe and North America is considerably lower, with approximately one-third of persons reporting lifetime drug use. Globally, the use of substances other than alcohol is generally considered socially aberrant, and rates of use remain low. In the United States there was a large increase in the prevalence of cocaine use during the 1970s and 1980s, and currently about 10 per cent of people report lifetime cocaine use: 2 per cent report use in the past year and 1 per cent report current use. In the United States less than 1 per cent of the population reports heroin use in the past year. Use of most illicit drugs peaks in young adults and then declines with age.

Aetiology of alcohol and drug dependence

Many people have tried alcohol or drugs, but only a subset develop dependence, with an interplay of genetic, psychological, and environmental factors increasing dependence vulnerability. A family history of alcohol or drug dependence remains one of the strongest predictors of risk, with heritability estimates for alcohol dependence ranging from 45 to 65 per cent for men and women. Genetic factors associated with an increased risk for alcohol dependence may include inborn abnormalities in dopamine, opioid, and serotonin neurotransmitter systems.

Drugs of abuse influence several different brain neurotransmitter systems, many of these primary responses leading to secondary effects involving dopamine. For example, morphine and heroin first bind to opioid receptors, which then increase the activity of midbrain mesolimbic dopamine neurones that send projections to interconnected forebrain structures such as the prefrontal cortex and striatum. The nucleus accumbens, a region at the base of the striatum, is the key zone that mediates the rewarding effects of drugs such as amphetamine and cocaine, which act directly by increasing dopamine levels at this site, as does ethanol ingestion. Opioid antagonists block ethanol-induced release of nucleus accumbens dopamine, implicating opioidergic activity as an intermediary between ethanol exposure and dopamine release. Genetic, as well as psychological and environmental effects, on this key mesolimbic system may contribute to individual differences in dependence vulnerability.

Psychological factors also appear to increase a person's vulnerability for alcohol or drug dependence. A recent international study found strong associations between anxiety and mood disorders and substance-use disorders, despite large differences in their prevalence across study sites. Anxiety disorders were very likely to pre-date the onset of the substance-use disorders, suggesting aetiological significance. By contrast, mood disorders did not indicate as strong a temporal relationship. In a recent United States household survey, over three-quarters of alcohol-dependent persons were diagnosed with at least one additional psychiatric disorder, with anxiety disorders having the highest prevalence, 61 per cent of women and 36 per cent of men meeting lifetime diagnostic criteria. Some types of people are at increased risk for alcoholism as a result of antisocial tendencies and high excitement-seeking behaviours. Antisocial personality disorder increases the risk of alcohol dependence approximately fourfold for men and over fivefold for women. Cross-cultural consistency in patterns of comorbidity suggests that, while cultural factors may influence the availability and type of substance exposure, the associations between psychopathology as risk factors and the sequelae of substance disorders are probably independent of particular cultural norms and standards.

Finally, environmental and social processes—including marital discord, parental hostility, poor parental monitoring, and high parental tolerance of adolescent drinking—influence a person's vulnerability for alcohol and drug dependence.

Laboratory diagnosis of alcohol- and drug-use disorders

A diagnosis of alcohol or drug dependence is not based primarily on laboratory findings, but rather on the behavioural manifestations of uncontrolled substance use. None the less, laboratory assessments can be useful for confirming recent alcohol or drug use, supporting other evidence of regular use, and providing information about alcohol- and drug-related physical problems. For patients enrolled in treatment, periodic testing can be used to monitor their progress and encourage accurate verbal reports of recent use.

To confirm recent use, measurements are made of current alcohol or drug concentrations in blood, urine, or other body fluids. Blood alcohol levels are measured in milligrams of alcohol per decilitre of blood and can be readily obtained from breath or blood samples. Impairment from alcohol is common above 50 mg/dl and climbs steeply as the blood alcohol level reaches 100 mg/dl and higher: a very elevated value without significant impairment indicates high alcohol tolerance resulting from chronic, heavy drinking. Urine or blood toxicology screens are commonly effective in detecting most illicit drugs for up to 72 h following use.

Most markers (including liver enzymes—aspartate aminotransferase (**AST**), alanine aminotransferase (**ALT**), gamma-glutamyl transferase (**GGT**)—and estimation of macrocytosis, mean cell volume (**MCV**)) have not provided sufficient sensitivity and specificity for use in widespread screening for alcohol problems. Various non-alcohol-related diseases produce similar changes in these markers to those produced by excessive alcohol use. Recent findings indicate that an increase in carbohydrate-deficient transferrin (**CDT**) levels is highly specific for heavy alcohol use (>50 g ethanol/day for at least 1 week), although its usefulness in women or for screening heterogeneous populations of drinkers may be limited.

Alcohol pathology, treatment, and pregnancy complications

Alcohol-related pathology

Age-adjusted morbidity and mortality rates increase as a function of the amount and duration of alcohol consumption, and these rates are increased two- to threefold among chronic, heavy drinkers. Alcohol consumption affects virtually every major organ system. The primary causes of excess mortality include liver disease, severe respiratory infections, cancer of the upper respiratory and digestive systems, cardiovascular disease, suicides, and violence.

Gastrointestinal system

Heavy alcohol use is associated with acute abdominal pain, nausea, and vomiting. With regular, heavy alcohol use, a variety of medical complications involving the gastrointestinal tract and related organ systems can develop. Oesophageal disorders include oesophagitis, oesophageal varices, and oesophageal mucosal tears with bleeding. Common upper gastrointestinal symptoms are gastritis, duodenitis, and ulcer disease. Some of these effects result from direct mucosal irritation by alcohol.

Liver

Because the liver receives portal blood directly from the intestines and is the primary site of alcohol metabolism, liver damage is one of the most common health consequences of chronic, heavy drinking. Two main types of alcohol-related liver injury are inflammation (alcoholic hepatitis) and progressive scarring (fibrosis or cirrhosis), the mechanisms of the toxic effects being shown in Table 1. Despite multiple pathways for alcohol-induced hepatic injury, only some chronic, heavy drinkers experience serious liver damage. Vulnerability to liver injury may result from genetic variations in the enzymes that metabolize alcohol (ADH and **ALDH** (aldehyde dehydrogenase)) and in cytochrome P4502E1 activity. Women experience higher rates of hepatic injury at lower cumulative alcohol levels than men. This been attributed to a toxic interaction of female sex hormones and alcohol-metabolizing enzymes, also to lower levels of gastric ADH in women compared to men, resulting in reduced first-pass metabolism in the stomach and higher blood alcohol levels following equivalent alcohol doses. Hepatic injury is also facilitated by nutritional factors, including depletion of antioxidant vitamins and glutathione and a diet high in polyunsaturated fats or iron. Finally, other medical conditions including infection with hepatitis B and C viruses are known to increase the risk of liver damage in alcoholics. These issues are discussed in more detail in Section 14.20.

Cardiovascular

In healthy individuals, moderate alcohol use reduces mortality from atherosclerotic cardiovascular disease, due in part to alcohol's effects of decreasing low-density lipoprotein (**LDL**) and increasing high-density lipoprotein (HDL) cholesterol. By contrast, heavy drinking is associated with an increased risk for cardiac arrhythmias, cardiomyopathy, and sudden cardiac death. Heavy alcohol consumption is also associated with systolic and diastolic hypertension, significantly increasing the risk of stroke by 250 to 450 per cent. In those with established arrhythmias, hypertension, or hyperlipoproteinaemia, even moderate alcohol use may aggravate symptoms.

Pulmonary

At high doses, alcohol decreases respiratory rate, airflow, and oxygen transport, hence increasing pulmonary disease symptoms in affected patients. Alcohol also reduces key pulmonary defences against infection, including: mucociliary clearance; macrophage mobilization, killing, and clearance; and phospholipid metabolism. These actions directly contribute to the increased rates of pulmonary infections (e.g. pneumococcal and Gram-negative pneumonias) in chronic, heavy drinkers.

Neurological

Chronic, heavy alcohol consumption causes structural changes in the brain, particularly in the cerebellum, limbic system, diencephalon, and cerebral cortex. Enlargement of the ventricles and widening of the fissures and sulci over the cerebral hemispheres suggest cortical atrophy. Severely dependent patients may experience a significantly decreased blood flow in the frontal, cortical, and periventricular regions of the cerebral cortex.

A variety of cognitive deficits have been associated with regular, heavy alcohol use, including slowed information-processing, poor attention, difficulties with abstraction, solving problems, and learning new information, and reduced visuospatial abilities. Chronic irreversible damage includes ataxia and gait disturbances, polyneuropathy, dementia, and the Wernicke–Korsakoff syndrome. These are discussed further in Chapter 24.15.

Endocrine

Endocrine abnormalities result from the direct toxic effects of chronic, heavy alcohol use and indirect effects associated with alcohol-related liver disease and malnutrition. Chronic alcohol exposure is particularly damaging to the gonadal axis, resulting in impaired sex hormone production. Male alcoholics often develop gynaecomastia, impotence, and testicular atrophy. Alcohol-dependent women often develop menstrual abnormalities. Both sexes have a higher incidence of osteoporosis resulting in part from reduced sex hormone levels.

Chronic, heavy alcohol use is also associated with activation of the hypothalamic–pituitary–adrenal axis (**HPA**), especially during acute alcohol withdrawal. Some

alcoholics develop clinical and biochemical features of Cushing's syndrome or 'the psuedo-Cushing syndrome'. By contrast, HPA responsiveness is temporarily dampened following alcohol withdrawal. As alcohol-dependent individuals cycle through periods of intoxication and withdrawal, the HPA cycles through hyper- and hypoactivity. This alcohol-induced cyclical pattern of corticotropin-releasing factor (**CRF**) and cortisol secretion may induce various pathological states, for instance episodes of sustained hypercortisolism may exacerbate osteoporosis, diabetes mellitus, and hypertension, as well as impairing growth, reproductive ability, and immune function. Further, hypercortisolism accompanying alcohol withdrawal increases excitatory amino acid levels within the central nervous system, resulting in neurotoxicity and worsening withdrawal symptoms such as seizures.

Other alcohol-related endocrine abnormalities are shown in Table 2.

Cancers

Heavy alcohol consumption significantly increases the risk of oesophageal cancers through the local actions of alcohol-metabolizing enzymes on oesophageal cells, and by the increased production of cytochrome P4502E1 in the oesophageal mucosa. This risk is considerably increased by smoking, which has a strikingly high prevalence in heavy drinkers. Other cancers increased by chronic heavy alcohol use include breast, thyroid, skin, laryngeal, and nasopharyngeal. Compromised immune function associated with heavy drinking may contribute to these elevated cancer rates.

Injury

Accidental injuries are a major cause of increased morbidity and mortality among chronic, heavy drinkers. Alcohol use has been implicated in 15 to 63 per cent of fall fatalities, 33 to 61 per cent of burn fatalities, and 44 per cent of fatal traffic accidents. In a study of emergency-room patients admitted for blunt or penetrating trauma, almost half had a positive blood alcohol level (as do half of all those who die from unintentional injuries).

Treatment of alcohol disorders

Inpatient settings have traditionally been used for the early phases of treatment, particularly acute detoxification and short-term residential programmes. Outpatient settings have provided longer term, abstinence-maintenance treatment. With growing concern over the cost-effectiveness of services, outpatient utilization has increased across all treatment phases.

Alcohol-withdrawal management

Alcohol withdrawal is potentially life-threatening. However, fewer than 10 per cent of alcohol-dependent patients are at risk for severe withdrawal symptoms, which: appear within the first 24 h after drinking cessation; intensify; and then decrease over 2 to 3 days. Symptoms generally result from disinhibition of the g-aminobutyrate (**GABAergic**) system and the resulting overactivation of the autonomic nervous system. Primary symptoms include tremor, sweating, headache, restlessness, anxiety, nausea, vomiting, disorientation, hallucinations, and seizures. The level of alcohol consumption typically determines symptom severity, but comorbid medical conditions can exacerbate the problem and complicate its management.

Repeated, unmedicated withdrawal episodes may increase the risk of future alcohol withdrawal seizures (kindling), and hence withdrawal management using benzodiazepines is recommended for most patients. Symptom-driven protocols that base medication frequency and dosage on regular withdrawal severity assessments are increasingly preferred over traditional fixed-dose regimens. These decrease the total amount and duration of medication and withdrawal-symptom severity. For most patients, alcohol withdrawal can be successfully treated on an outpatient basis. (See Chapter 26.7.3 for further discussion.)

Pharmacotherapy for alcohol dependence

There is considerable interest in developing medications to use in conjunction with psychosocial therapies to improve treatment retention and reduce relapse. Until recently, the only pharmacotherapy for alcoholism was disulfiram (Antabuse), an alcohol-sensitizing medication that produces flushing, nausea, vomiting, increased blood pressure, and heart rate when combined with alcohol. However, there is limited empirical support for the effectiveness of disulfiram because of poor patient acceptance and compliance.

As described above, various neurotransmitter systems contribute to alcohol reward, tolerance, and dependence, so providing an empirical basis for the development of pharmacotherapies to treat alcohol craving or reduce alcohol reward or intoxication. If persistent and intrusive thoughts about drinking (in other words, craving) and within-treatment 'slips' could be effectively treated, this would improve patients' retention in psychosocial services and decrease their risk of relapse. In clinical trials, opioid receptor antagonists (such as naltrexone) have decreased craving and alcohol consumption, whilst improving objective markers of drinking such as liver function test results. Of particular interest, placebo-treated subjects who drank were far more likely to progress to persistent heavy drinking than naltrexone-treated subjects who drank. Acamprosate, an *N*-methyl-D-aspartate (**NMDA**)-receptor antagonist, also increases abstinence and improves treatment retention; it is widely marketed in Europe and is currently under a Food and Drug Administration (**FDA**) review for alcoholism treatment in the United States.

Alcohol-dependent patients with a concurrent psychiatric disorder are at an increased risk of substance-abuse treatment non-compliance, relapse, psychosocial and interpersonal problems, greater severity of psychiatric symptoms, and suicide attempt and completion. The psychiatric disorder often requires treatment concurrently with the substance-use disorder and may not improve simply as a result of reduced alcohol and drug use (for example, serotonergic medications may be effective in reducing drinking in alcohol-dependent patients with concurrent major depression, possibly secondary to improvements in mood and overall psychosocial functioning). A newer non-benzodiazepine anxiolytic, buspirone, has also been found to increase substance-abuse treatment participation and duration **,** and improve outcomes on measures of anxiety, depression, and global psychopathology compared to placebo treatment.

Psychosocial treatments

Most substance-abuse patients are treated in outpatient rather than inpatient facilities (that is, detoxification, residential rehabilitation, therapeutic communities). Outpatient programmes typically offer assessment and diagnosis, individual and group therapy, and referral for other needed services. Recently, outpatient services have increasingly introduced focused, empirically validated treatment interventions, such as cognitive–behavioural skills training programmes, relapse-prevention groups, and marital and family therapy. Family involvement in treatment and patient participation in community-based, self-help programmes such as Alcoholics Anonymous (**AA**) can improve long-term, post-treatment outcomes.

Alcohol-related pregnancy complications

Although many women reduce unhealthy behaviours, including alcohol and drug use and cigarette smoking during pregnancy, approximately one in five women in the United States reports drinking alcohol while pregnant. Among pregnant drinkers, 8 per cent drink on 6 or more days during the month, and 30 per cent consume three or more drinks per drinking day, hence alcohol use remains high during pregnancy despite well-documented and publicized maternal and fetal risks. Because no safe alcohol limits have been established during pregnancy, women are targeted for early intervention at lower alcohol-use levels during pregnancy.

At its most extreme, alcohol consumption during pregnancy can result in the fetal alcohol syndrome, characterized by facial dysmorphology, growth retardation, and CNS disorders, which is the most common preventable cause of mental retardation. Other more common fetal effects have been labelled 'alcohol-related birth defects', and include: reductions in weight, height, and head circumference; decreased cognitive abilities and school achievement; and, possibly, an increased risk of behavioural problems such as attention deficits and impulsiveness. The current global estimated incidence of fetal alcohol syndrome is approximately 1 in 1000 live births in the general obstetric population and 4.3 per 100 births among heavy drinkers.

Pathology, treatment, and pregnancy complications of stimulant drugs

Stimulant-related pathology

Stimulants including amphetamines and cocaine work primarily on three CNS neurotransmitters, norepinephrine (noradrenaline), serotonin, and dopamine. They acutely increase norepinephrine neuronal activity by increasing presynaptic synthesis and blocking reuptake from the synaptic cleft. Effects of which include

hypertension, tachycardia, dilated pupils, diaphoresis, vasoconstriction, and tremor. Norepinephrine levels in brain decrease in the longer term, leading to depression, confusion, restlessness, suicidal ideation, and irritability. Stimulants also acutely diminish CNS serotonin activity, contributing to insomnia. Effects on dopamine transmission, particularly in ventral tegmental/corticomesolimbic regions, are thought to mediate the high potential of stimulants for abuse. Acutely, dopamine transmission is increased, but chronic cocaine use depletes central dopamine levels, such that short-term euphoria, increased energy, and alertness is followed by depression and subsequent drug administration.

Drug-related pathology often results from the method of administration or lifestyle issues (for example, prostitution) rather than direct drug toxicity. Chronic intranasal administration increases rhinitis, maxillary sinusitis and necrosis, and perforation of the nasal septum. Smoked cocaine increases pulmonary complications including pneumonitis, obliterative bronchiolitis, asthma, and pulmonary haemorrhage. Finally, intravenous administration increases the risk of infectious diseases, including human immunodeficiency virus (**HIV**) infection, endocarditis, hepatitis, and sepsis, as well as abscesses and cellulitis at the injection site.

Cocaine use is associated with a number of other serious medical problems, particularly cardiovascular complications, including cardiac arrhythmias, myocardial infarction, myocarditis, cardiomyopathy, endocarditis, and aortic dissection. Myocarditis was present in approximately 20 per cent of regular cocaine users in one autopsy study.

A serious neurological complication of cocaine use and a leading cause of cocaine-associated deaths is seizures. The seizure threshold decreases with repeated cocaine use and associated kindling. Additionally, acute cocaine use increases the risk of stroke secondary to focal artery vasospasm, thrombosis, and elevated blood pressure. Chronic use can result in significant hypoperfusion in the frontal, periventricular, and temporoparietal areas, changes that have been linked to deficits in attention, concentration, learning, visual and verbal memory, and visuomotor integration.

Stimulant use can lead to significant psychiatric symptoms, both acutely and chronically. Acute symptoms include grandiosity, impulsiveness, and aggression. Common complications of chronic use include panic attacks, paranoia, depression, delirium, and hypersomnia.

Medical problems are more frequent among female than male drug abusers. Common complaints include infections, anaemia, sexually transmitted diseases (particularly gonorrhoea, trichomonas, and chlamydia), hepatitis, urinary tract infections, and gynaecological problems. Substance-abusing women are at an increased risk of developing a variety of reproductive dysfunctions compared with other women, including amenorrhoea, anovulation, luteal-phase dysfunction, ovarian atrophy, spontaneous abortion, and early menopause.

Treatment of stimulant-use disorders

Withdrawal management

Stimulant withdrawal is characterized by primarily psychological rather than physical symptoms. The acute 'crash' following discontinuation of intense cocaine use is notable for depression, agitation, cocaine craving, and hypersomnia. Prolonged withdrawal symptoms include anhedonia, anergia, and cocaine craving.

Pharmacotherapy

There has been little progress in identifying effective pharmacological treatments for stimulant dependence and, as a result, psychosocial treatments remain the mainstay of care. Because chronic cocaine use depletes brain dopamine levels, pharmacotherapeutic research has focused predominantly on dopamine agonists. Antidepressants have also been explored for the treatment of dysphoric symptoms accompanying cocaine cessation.

Psychosocial treatments

Retention for longer rather than shorter periods in outpatient treatment is associated with improved long-term, postdischarge outcomes across alcohol, cocaine, and opiate treatments. For cocaine-dependent patients receiving outpatient psychosocial treatments, retention in care for 90 days or longer is associated with a reduced risk of cocaine relapse. Abstinence-focused treatments appear most effective for promoting long-term recovery.

Stimulant-related pregnancy complications

Approximately 2 per cent of pregnant women in the United States report illicit drug use. Across a variety of drug classes, drug-abusing women experience a clinically significant increase in obstetric complications compared with non-drug-using women. Maternal cocaine abuse is associated with intrauterine growth retardation, decreased birth weight, length and head circumference, anaemia, increased risk of intrauterine or perinatal infections (hepatitis, sexually transmitted diseases (**STDs**) and HIV), and cardiac abnormalities. Maternal complications specifically associated with cocaine use include reduced maternal weight gain, precipitous delivery, placental abruption, preterm labour and delivery, and spontaneous abortion. Drug-using women generally participate in fewer prenatal services than non-drug-using women, compromising the delivery of adequate prenatal care for these more complicated pregnancies. Maternal drug use also adversely affects infant health, the most obvious neonatal complication associated with maternal stimulant abuse being drug withdrawal, including tremors, irritability, high-pitched and excessive crying, poor feeding, and abnormal sleep patterns. The overall morbidity for drug-exposed neonates is over twice that of non-drug-exposed neonates.

Pathology, treatment, and pregnancy complications of opioid drugs

Opioid-related pathology

As described above for stimulants, the pathology associated with regular heroin use often results from the method of drug administration or lifestyle issues. Approximately one-quarter of heroin-dependent individuals die from homicide, suicide, accidents, and infectious disease within 10 to 20 years of initiating regular use.

Infections including abscesses, cellulitis, endocarditis, and septicaemia are common among opioid users: many stem from intravenous drug administration, the use of unsterile injection equipment, and contaminated drugs.

Infection with the hepatitis C virus, associated with an increased mortality rate, is a growing concern among intravenous drug users. In the United States, as many as two-thirds of patients seeking drug treatment are positive for hepatitis C; hepatitis B is also fairly common. Both contribute to the liver dysfunction frequently observed in these patients.

More than 30 per cent of adult and 50 per cent of paediatric **AIDS** (acquired immunodeficiency syndrome) cases in the United States are directly or indirectly associated with intravenous drug use, and in both the United States and Europe over one-third of drug-treatment patients are infected with HIV. As a result, more-aggressive, harm-reduction strategies are recommended by some to reduce the spread of HIV, and needle-exchange programmes in which drug-dependent persons can exchange used for new injection equipment are increasing. Other sexually transmitted diseases including syphilis, gonorrhoea, trichomonas, and chlamydia also are common, especially among female drug users.

Tuberculosis (**TB**) emerged in the 1990s as a significant concern among intravenous drug users, with its rising prevalence attributed to increased susceptibility to TB infection among HIV-positive, immunocompromised drug users, and the emergence of antibiotic-resistant strains of the tubercle bacillus.

Treatment of opioid-use disorders

Withdrawal management

Opioids produce a very characteristic withdrawal syndrome, although the speed of onset and duration vary as a function of the half-life of the particular drug. Heroin or morphine withdrawal begins 8 to 12 h following the last dose and subsides over 5 to 7 days. Methadone withdrawal begins 12 to 16 h after the last dose, peaks in approximately 3 days, and can persist for 3 weeks or longer. Typical symptoms include: gastrointestinal distress such as cramping, diarrhoea, nausea, vomiting; arthralgias or myalgias; increased respiratory rate; lacrimation; yawning; rhinorrhoea; piloerection; anxiety, restlessness and irritability; tachycardia and hypertension.

Clonidine, marketed for the treatment of hypertension, is widely used for opioid-withdrawal management and is mainly effective for alleviating milder withdrawal symptoms and anxiety-related complaints. However, because of the high morbidity and mortality associated with heroin use, opioid-substitution therapy is the treatment of choice in the United States and Europe, and generally recommended for opioid-dependent people who have failed in prior drug-free treatments. Opioid-substitution therapy replaces the use of illicit, short-acting, injected, impure drugs with longer and orally active medications of known potency and purity. Outcomes include withdrawal symptom suppression, reduced drug craving, blockade of the euphoric effects of heroin or other opioid administration, and patient engagement in rehabilitative services. Individual and group counselling and urine testing for illicit drugs are part of routine care in most programmes. HIV/AIDS has heightened the importance of treatment approaches focused on reducing or eliminating injection drug use as opposed to achieving drug-free status. Methadone is commonly used for short- and long-term management of heroin and other opioid withdrawal. Buprenorphine, a mixed agonist and antagonist drug, may offer particular advantages for opioid-withdrawal management, although it does not have current United States approval. The details of pharmacotherapeutic management are discussed in Chapter 26.7.3.

Because of the breadth of psychosocial problems associated with chronic opioid use, individual and group counselling sessions are standard treatment components. Patients evidence their greatest improvements in comprehensive care programmes that integrate medical, psychiatric, family, legal, and social services.

Opioid-related pregnancy complications

Complications associated with regular heroin use include spontaneous abortion, amnionitis, chorioamnionitis, intrauterine growth retardation, placental insufficiency, postpartum haemorrhage, pre-eclampsia, premature labour, premature rupture of membranes, eclampsia, toxaemia, and placental abruption. Symptoms of neonatal drug withdrawal are very similar to those of adults, and include CNS hyperirritability, loose stools and other gastrointestinal dysfunction, nasal stuffiness, yawning, sneezing, increased lacrimation, and fever. As described above for stimulants, there is a high frequency of other fetal/neonatal complications, including suboptimal APGAR scores, low birth weight, prematurity, and an increased risk of intrauterine or perinatal infections.

Maternal and infant morbidity and mortality are significantly improved among women receiving opioid-replacement treatment, a major benefit for the fetus being the prevention of repeated, medically unsupervised withdrawal episodes. Maintenance has also been shown to improve the frequency of prenatal care, decrease illicit drug use, improve nutritional status, and decrease risky lifestyles. Infants of methadone-maintained mothers need to be closely monitored and, in most cases, treated for opiate withdrawal, typically using paregoric. Symptom onset is often delayed and duration may be unusually prolonged because of reduced metabolic clearance.

Prevention and early intervention

Given the high prevalence of alcohol and drug disorders, all physicians treat patients with these problems. It is estimated that as many as 20 per cent of primary care patients and 25 to 40 per cent of inpatients are alcohol-dependent or problem drinkers. Physicians should routinely enquire about drinking and other drug use (prescribed and illicit), and facilitate the referral and management of patients with these problems. Most alcohol-related health consequences are experienced not by those who are alcohol-dependent, but by the much larger group of hazardous drinkers whose problems are at an early or relatively mild stage. Brief advice on setting safe drinking limits can have a significant and sustained impact on drinking levels in this at-risk population. These interventions begin with a focused assessment of alcohol and drug use and related problems, followed by a brief, highly directive interaction in which the health professional provides personalized feedback based on the assessment findings (for instance, elevated liver function test results or other medical problems, absenteeism or lateness at work, marital distress). Finally, the provider offers specific drinking-reduction strategies, such as goal-setting for 'sensible' drinking and assigning relevant reading materials. Brief interventions reduce overall alcohol use, binge-drinking episodes, and hospital admissions and are easily conducted in various healthcare settings, including that of primary care. (For further discussion see Chapter 26.7.2.)

Areas of uncertainty/controversy

Controlled alcohol use versus abstinence

Controlled drinking as a therapeutic goal for alcoholism treatment remains controversial, particularly in the United States. Less than one-quarter of surveyed treatment programmes in the United States found controlled drinking acceptable, compared with approximately three-quarters of surveyed United Kingdom programmes. Even the United States and United Kingdom programmes that endorsed controlled drinking recommended it as a therapeutic goal for fewer than 25 per cent of patients based on their dependence severity, drinking history duration, psychological dependence, family history of alcoholism, prior treatment outcomes, and current health damage. Although controlled drinking may offer a harm-reduction option in a subset of treatment-resistant patients, abstinence generally produces the most positive long-term outcomes for patients in treatment.

Pharmacotherapy versus drug-free treatment

Pharmacotherapy for abstinence maintenance continues to be controversial. In part, this may stem from treatment providers' concerns about cross-addiction, but it also reflects the current paucity of medication options for alcoholism treatment. It is very likely that in the next decade new and more effective pharmacotherapies will be identified, and physicians will need to encourage the appropriate use of these medications by their patients since it is unlikely that the momentum for change will come from within specialty alcoholism-treatment facilities.

Smoking cessation as a concurrent treatment goal

While smoking rates have declined in the general population, estimates of smoking prevalence among alcohol- and drug-dependent persons have generally been stable and in the range of 75 per cent to 90 per cent. Indeed, smoking can now be considered as a risk marker of heavy alcohol and drug use, particularly among pregnant women. Historically, treatment professionals have discouraged a concurrent cessation of nicotine and other substance use. However, patients in treatment for alcoholism who decrease or eliminate cigarette use have comparable or slightly improved rates of alcohol abstinence compared with patients who continue smoking. Thus, smoking cessation concurrent with or in close proximity to substance-abuse treatment may decrease the risk of post-treatment relapse. This is a critical area for future research and intervention, given the excessive morbidity and mortality associated with nicotine dependence among alcohol and other drug abusers.

26.7.2 Brief interventions against excessive alcohol consumption

Nick Heather and Eileen Kaner

Introduction

Harm caused by excessive drinking extends far beyond 'alcoholism' or severe alcohol dependence. Alcohol-related problems can be of many different kinds—medical, interpersonal, social, psychological, financial, vocational, legal—and can be associated with various patterns of drinking. For example, problems related to acute alcohol intoxication, such as accidents, violence, and public disorder offences, need not involve high levels of regular consumption or dependence. Even in the area of medical harm, research has shown that patients who develop chronic liver disease are usually only mildly dependent on alcohol, probably because those who escape florid symptoms of dependence are able to sustain a consistent pattern of heavy drinking over many years. When those at risk of harm are added to those who have already incurred it, the number of individuals whose lives may be adversely affected by their drinking becomes very large.

Among specialists in the treatment and prevention of alcohol problems, there is now a consensus that a prior focus on the alcoholism concept had distracted attention from the full range of alcohol problems that occur. This is not to imply, of course, that patients suffering from severe alcohol dependence should be ignored, only that the scope of treatment and preventive efforts should be broadened in an attempt to reduce the aggregate of alcohol-related harm in our society. Brief interventions in medical practice have a crucial role to play in this strategy.

Definitions

Excessive alcohol consumption

'Excessive alcohol consumption' is a term that includes both 'hazardous' and 'harmful' drinking. In the *International classification of diseases* (10th revision), the hazardous use of a psychoactive substance is defined as: 'An occasional, repeated or persistent pattern of use...which carries with it a high risk of causing future damage to the medical or mental health of the user but which has not yet resulted in significant medical or psychological ill effects'. Harmful use is defined as: 'A pattern of use which is already causing damage to health. The damage may be physical or mental'.

Hazardous and harmful alcohol consumption can also be defined by drinking limits recommended by medical authorities in various countries. In the United Kingdom, a joint working group of the Royal Colleges of Physicians, Psychiatrists, and General Practitioners in 1995 defined low risk (or 'sensible') consumption as up to 21 units/week for men and 14 units/week for women, increasing risk (here hazardous) as 22 to 50 units/week for men and 15 to 35 units/week for women, and high risk (here harmful) consumption as above 50 units/week for men and above 35 units/week for women (one unit = 8 g ethyl alcohol). Subsequently, a United Kingdom government report on sensible drinking effectively increased the drinking limits, by advising the public that men could drink up to 4 units/day and women up to 3 units/day. These revised recommendations have been severely criticized and medical practitioners are best advised to continue using the previous limits.

Brief interventions

As delivered by non-alcohol specialists, brief interventions refer to a collection of methods incorporated into routine practice aimed at helping patients who drink excessively to reduce their consumption to low-risk levels. These interventions are often called 'opportunistic' because they typically take advantage of opportunities that arise when people present to a medical facility for reasons unconnected with a possible alcohol problem. Brief interventions are normally restricted to individuals with only low levels of alcohol dependence or alcohol-related problems, those more seriously impaired usually being referred to specialist services. However, this is not always the case, and some doctors feel able to offer intensive treatment to more serious cases, often with advice or help from specialists in the form of shared-care arrangements. Although normally directed at a reduced drinking goal, there is no reason why brief interventions should not be targeted at total abstinence in appropriate circumstances or if the patient prefers it. However, for patients with relatively low levels of dependence and problems, insistence on abstinence is almost always a disincentive to a change in behaviour.

Prevalence

The latest United Kingdom General Household Survey in 1996 showed that 27.5 per cent of adult (over 16 years of age) males and 13 per cent of adult females reported drinking over the limits recommended by the Royal Colleges. Among young (16–24 years of age) men and women, the figures rose to 35 per cent and 21 per cent, respectively. There are reasons for believing that even these figures may be underestimates, but they nevertheless reveal the enormous extent of excessive drinking in the general population of the United Kingdom.

Patients with alcohol problems consult their general practitioners nearly twice as often as the average, their most common problems being gastrointestinal, psychiatric, and accidents. Some 40 harmful drinkers and a further 100 hazardous drinkers would be expected in every 2000 patients in primary care, but it is likely that the primary care physician will be unaware of the problem in more than half of these. In surgical and general medical wards, estimates range up to 30 per cent of all male admissions and 15 per cent of female admissions. Again, few of these patients will be identified as excessive drinkers. It is also well established that excessive drinkers are over-represented among patients of accident and emergency services.

Aims and targets of brief interventions

Opportunistic identification and brief intervention for excessive drinking are often justified as a means of early intercession and secondary prevention of alcohol problems. The attempt is made to help the patient reduce consumption or abstain before seriously adverse consequences arise, and before alcohol dependence and problems have reached levels that make intensive treatment difficult. However, as noted above, brief interventions can also be seen as making an important contribution to the public health approach in reducing alcohol-related harm at the population level. As public health measures, there is no incompatibility between the widespread implementation of brief interventions in medical practice and the adoption of fiscal, legislative, and other alcohol-control policies. These two strategies can be seen as mutually reinforcing and as acting synergistically to reduce and prevent alcohol-related harm.

Brief interventions in the sense defined here should be clearly distinguished from briefer forms of treatment given by specialist alcohol or addiction agencies. Among a number of differences, brief treatment by specialists typically takes longer to deliver than the kind of interventions we are considering here. Various types of brief intervention will be described below, but here it may be noted that they range in length from a few minutes of structured advice, up to perhaps five sessions of counselling spread over 6 months. Doctors, nurses, and other healthcare professionals (for example, specially employed counsellors) can be involved in the delivery of brief interventions.

Effectiveness of brief interventions

There is now abundant evidence that brief interventions delivered in medical settings are effective in leading to reduced alcohol consumption. Randomized controlled trials in general practice demonstrating the effectiveness of such interventions have been carried out in the United Kingdom, the United States, Canada, and Australia, and other trials are currently underway in several non-English-speaking countries. These studies indicate that intervention reduces drinking by an average of about 25 per cent. The best estimate of the proportion of patients who show a good outcome is 15 per cent among men and somewhat less among women, although it is possible than many women will respond simply by having their attention drawn to their drinking in an assessment (that is to say, without a specific intervention). Studies conducted in the 'real-world' conditions of general practice show somewhat less benefit than in those carried out under optimal research conditions, but nevertheless they support the effectiveness of brief interventions. Research in general hospital wards has been less extensive, and evidence for their effectiveness is less impressive, although still positive. Studies of the effectiveness of interventions in accident and emergency departments are just beginning.

It may be that some doctors will find the success rates described above unacceptably low. They may recall many patients who have been advised to cut down, but who have ignored this advice. However, given that up to 80 per cent of the population consult a healthcare professional at least once a year, brief interventions—if widely implemented—would undoubtedly represent a powerful means of reducing excessive drinking in the population at large. From the clinical perspective, patients who do not respond at first may do so on subsequent occasions, and even if advice seems to be ignored, it may well influence an evolving process of behaviour change. The disjunction in aims between the public health approach, which regards even very low success rates as beneficial, and the clinical perspective of most medical practitioners, in which the welfare of the individual patient is paramount, must be recognized, but the widespread and consistent implementation of brief interventions can serve both causes.

Practical approach to brief interventions

Identifying excessive drinkers

Screening is the process of identifying patients whose alcohol consumption places them at increased risk of psychological or physical complications and who might benefit from early detection and brief intervention. There are a number of laboratory indicators of excessive alcohol consumption, such as mean corpuscular volume (**MCV**), g-glutamyl transferase (**GGT**), and blood alcohol concentration (**BAC**). However, in medical practice, standardized questionnaires have been found to have a greater sensitivity and specificity than laboratory indicators; they are also far less intrusive and more acceptable to patients.

Although there are a number of standardized questionnaires, most were developed to detect a severe level of alcohol dependence (in other words, 'alcoholism'). The Alcohol Use Disorders Identification Test (**AUDIT**) is the only standardized instrument designed specifically to detect hazardous and harmful drinking in both primary and secondary healthcare settings. AUDIT is a 10-item questionnaire that includes items on drinking frequency and intensity (binge drinking), together with experience of alcohol-related problems and dependence (see Fig. 1). At a score of 8 out of a possible 40, the ability of AUDIT to detect genuine excessive drinkers (sensitivity) and to exclude false cases (specificity) is 92 per cent and 93 per cent, respectively.

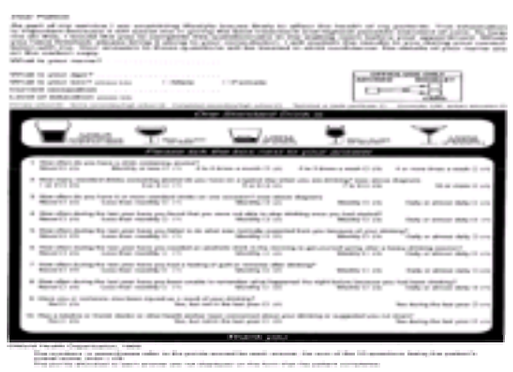

Fig. 1 The audit questionnaire.

Management of excessive drinkers

Patients who are drinking at hazardous levels (AUDIT 8–12 for men and 7–12 for women) should be offered brief intervention. Excessive drinkers who show prima facie evidence of significant alcohol dependence (AUDIT 13+ for women and 15+ for men) should normally receive a fuller assessment of their dependence and alcohol-related problems, including the impact of their drinking on their social functioning. Unless skills and resources exist to assess and treat these patients at the generalist level, they should be offered referral to a specialist alcohol or addiction treatment agency.

Types of brief intervention

The most basic form of brief intervention is simple advice to cut down, delivered in a persuasive but non-judgemental fashion and with clear guidance on consumption targets. This advice should, as far as possible, be personalized by taking into account the particular circumstances of the individual patient, their level of consumption in relation to population norms for their sex, and an appeal to any specific alcohol-related difficulties they may recognize as applying to them, including social and psychological as well as medical problems.

Advice can be supported by the offer of self-help material, and a follow-up appointment to check on their progress in cutting down will also be helpful. Successive feedback of GGT readings or other laboratory markers of alcohol consumption can be a powerful motivator. All this can be accomplished in a 5 to 10 min consultation, and specially developed brief intervention packages are available to assist this task. One such package is the Drink-Less Programme, which was developed for a WHO Collaborative Project on brief interventions in primary healthcare. It has been adapted for use in the United Kingdom, with separate versions for doctors and nurses, and is available at a small cost to cover production expenses from the Department of Primary Health Care, University of Newcastle upon Tyne.

Some doctors may prefer to spend more than 5 to 10 min on intervention, or may have the assistance of nursing or other colleagues with the time and expertise to devote to intervention. In either case, the opportunity arises to engage the patient more thoroughly in the change process. One possibility here is to use a condensed form of a type of treatment that is frequently offered in specialist alcohol treatment centres, known as cognitive–behavioural therapy. In this approach, the attempt is made to identify the types of stress and 'high-risk situations' that lead to excessive drinking in the individual case, and then train the patient in ways of coping with these stressors or situations without heavy drinking. Attention is also paid to modifying cognitive factors (for example, unhelpful beliefs about alcohol, subconscious positive expectations about its effects, lack of confidence in the ability to alter drinking behaviour) that may impede the patient's attempts to change. This form of intervention could be implemented in one session of, say, 40 min, but would probably be more effective if delivered over a series of three to five meetings over several months.

Condensed cognitive–behavioural therapy is most suitable for patients who clearly recognize that damage to their lives is being caused by alcohol and who are ready to try to change their drinking. With patients who refuse to recognize the possibility of harm and who are firmly set against change, probably nothing much can be done except to offer educational material and ask them to return if they change their minds. Between these two extremes, however, there is a large group of patients who will be fluctuating in their concern about their drinking, will be experiencing conflict about the advantages and disadvantages of heavy drinking, and will be ambivalent about attempting to cut down or abstain. For these patients, the approach that should be used is known as 'brief motivational interviewing'. This is based on the fact that ambivalence about changing behaviour is a common feature in healthcare consultations. Although some patients will respond immediately to the delivery of health advice, others will be less ready to change their drinking behaviour and direct persuasion may cause such patients to become defensive. The most effective way of helping ambivalent patients to change is to explore their conflict and encourage them to express their own reasons for concern and arguments for change. It must be emphasized that both condensed cognitive–behavioural therapy and brief motivational interviewing should not be attempted without proper training.

Implementing brief interventions

In a survey of general practitioners (**GPs**; primary care physicians) carried out in the English Midlands during 1995 to 1996, it was found that the levels of detection and intervention for excessive drinking were low. As in studies of junior hospital doctors, it appeared that the GPs did not routinely enquire about alcohol, and that any enquiries were mainly restricted to new patient registrations or those with obvious physical symptoms. Compared with earlier surveys, there was an increase in numbers of GPs who felt that working with alcohol issues was a legitimate part of medical practice, but fewer doctors saw themselves as being effective in this work. The main barriers to implementing brief interventions were stated as insufficient time and training and lack of help from government policy; the main incentives related to the availability of appropriate support services and the proven effectiveness of brief interventions.

As this chapter has shown, there is very good evidence for the effectiveness of brief interventions and it is clearly necessary to disseminate this information more widely. With regard to other barriers and incentives, strenuous efforts are now being made to persuade policy-makers and decision-makers at national, regional, and district levels to create the conditions that are needed to support the widespread implementation in routine medical practice of brief interventions against excessive alcohol consumption.

26.7.3 Problems of alcohol and drug users in the hospital

Carol Ann Huff

Introduction

Alcohol and drug use are two of the most common problems facing physicians and nurses caring for patients in a general medical or surgical unit. It is estimated that up to 25 per cent of adult inpatients have a problem with alcohol or drug use. The implications of this are significant, and many studies have shown that those who abuse alcohol and/or drugs have higher rates of healthcare utilization, more complications, and longer hospital stays. Unfortunately, many of these problems go undetected or are not detected until the patient is in active withdrawal, which complicates their care. When an alcohol or drug use problem is not identified, both physicians and patients miss an important opportunity for counselling and effective early interventions.

There are many reasons why a diagnosis of alcohol or drug abuse may be missed. These include failure on the part of physicians to obtain a complete history of alcohol and drug use, including the quantity and pattern of use of both illicit and prescription medications as well as any personal or family history of substance abuse. Patients contribute to missed diagnoses through denial and minimization of their use of alcohol and drugs, in many cases because they fear social, occupational, legal, and insurance repercussions that may result from the identification of a drug or alcohol problem. These concerns are not unfounded and cannot be fully overcome, but they can be minimized by asking open-ended questions in a non-judgemental and supportive manner.

Central to the success of efforts to deal with those who abuse alcohol or drugs are educational programmes on the nature of addiction and its successful treatment. This in turn leads to the development of a supportive environment, which affords excellent patient care, minimizes ward disruptions, and encourages patients to seek assistance for alcohol or drug-related problems in conjunction with their other medical needs.

Epidemiology

Alcohol and drug use are common problems affecting people of all religions, socioeconomic classes, and geographical areas. Epidemiological studies estimate the lifetime prevalence of alcohol abuse at approximately 13 per cent and problem drug use at 6 per cent. Men are twice as likely as women to develop a drug or alcohol problem. Around 30 per cent of patients with mental illness have a concomitant substance abuse disorder, ranging from approximately 25 per cent in those with anxiety disorders to 50 per cent in those with schizophrenia. Similarly, half of the patients who abuse alcohol or drugs also have a mental illness. Polysubstance use is common and is seen in more than 75 per cent of patients seeking treatment for substance abuse.

It is estimated that more than 50 per cent of accidents and traumas are related to alcohol and or drug use. Many medical illnesses are directly or indirectly related to such use. These include gastrointestinal disorders (for example, bleeding, cirrhosis, and pancreatitis), infectious diseases (for example, pneumonia, human immunodeficiency virus (**HIV**) infection, and hepatitis) and cardiac problems (for example, ischaemia, infarction, and arrhythmias). Patients presenting with these and other medical problems are often the ones in whom a diagnosis of alcohol or drug dependence is not suspected and thus missed entirely, or only made when the patient is in withdrawal.

Clinical features and treatment of intoxications

Alcohol

The clinical picture of alcohol intoxication depends on the rate of ingestion, metabolism, and tolerance of an individual to alcohol's effects. Although legal intoxication is a blood alcohol level of 100 mg/dl, behavioural, psychomotor, and cognitive changes can be seen at levels as low as 20 to 30 mg/dl in those without tolerance. Euphoria occurs at 25 to 50 mg/dl, incoordination at 50 to 100 mg/dl, ataxia at 100 to 200 mg/dl, stupor at 200 to 400 mg/dl, and coma at 400 to 500 mg/dl. Some people become somnolent after modest alcohol ingestion, do not experience euphoria, and therefore rarely abuse alcohol.

The neurological signs of intoxication include slurred speech, impaired coordination, nystagmus, and gait disturbance. Signs of increased sympathetic activity including tachycardia, hypertension, mydriasis, and skin flushing often accompany these changes. Whilst patients may present with what appears to be mere alcohol intoxication, physicians must also be aware of the potential for superimposed problems requiring acute care including hypoglycaemia, subdural haematoma, systemic infections (including aspiration pneumonia), and other ingestions (including methanol, antifreeze, and sedatives).

Alcoholic coma is a medical emergency with a mortality rate approaching 5 per cent. Management requires prompt recognition, careful clinical examination, and an expeditious history, usually from a friend, of the amount and rate of alcohol ingested, as well as any other drugs or medications. If the patient is stuporous or has excessive secretions, he or she should be intubated immediately to provide airway protection and ventilatory support. Once the patient's cardiopulmonary status is stabilized, full investigation—including arterial blood gases, serum chemistries, toxicology screens, and imaging studies—can be undertaken to look for complicating factors when clinically appropriate. Patients may require close monitoring in an intensive care unit with respiratory, cardiovascular, and haemodynamic support and, in some cases, haemodialysis.

Opiates

An opiate overdose can be a life-threatening emergency and requires prompt recognition and institution of therapy. The characteristic signs include varying degrees of clouded consciousness (ranging from somnolence to obtundation), pinpoint pupils, and marked respiratory depression. Aside from protection of the airway, administration of oxygen, and provision of respiratory support as required, treatment involves the administration of an opiate antagonist, usually naloxone. If intravenous access is not available, then this should be administered intramuscularly. The starting dose is 0.2 to 0.4 mg and the onset of action is rapid, typically seen within 2 to 3 min of intravenous administration or 15 min after intramuscular administration. If no response is seen, the dose may be increased. Patients typically respond to doses of less than 2 mg of naloxone, and if the maximum dose of 10 mg is given and the patient has not responded it is unlikely that an opiate overdose is the cause of the problem. The half-life of naloxone is about 90 min, hence re-dosing may be needed, particularly if the overdose is due to a long-acting agent, such as methadone. Pulmonary oedema is often associated with the severe respiratory distress and may improve with restoration of the respiratory drive, but may also require positive-pressure ventilation to fully alleviate it.

Withdrawal syndromes

The clinical features and treatment of withdrawal syndromes are summarized in Table 1.

Alcohol

Clinical features of alcohol withdrawal

Chronic exposure to alcohol leads to upregulation of neural mechanisms within the central nervous system to counteract the depressant effects of alcohol. When the amount of alcohol ingested is diminished or abruptly stopped, these adaptive mechanisms are left unopposed and a hyperexcitable state ensues. This hyperexcitable state can lead to a range of symptoms, from tremulousness and disordered perceptions to seizures and frank delirium, also known as delirium tremens. This spectrum of findings is known collectively as the alcohol withdrawal syndrome.

The first signs of withdrawal begin 6 to 8 h after the alcohol-dependent person's last drink. Tremor is the earliest, most common, and most easily recognized sign. It is coarse, generalized, rapid, and intensified by motor activity and stress. It may be severe enough to interfere with basic motor activities. At this stage, patients are often irritable and complain of nausea and vomiting. In the absence of resumed alcohol consumption or treatment, many go on to develop signs of sympathetic overactivity including diaphoresis, tachycardia, mild hypertension, facial flushing, and increased body temperature. These symptoms peak in intensity between 48 and 72 h and gradually subside by day 4 to 5 unless alcohol consumption is resumed. Anxiety, insomnia, and mild autonomic dysfunction may persist for up to 6 months after alcohol cessation and can predispose some patients to early relapse.

Some 25 per cent of patients with tremor and autonomic instability develop perceptual disturbances. These include hyperacusis, vivid nightmares, and, in some cases, auditory hallucinations which peak in intensity 24 to 36 h after alcohol intake is stopped. The auditory hallucinations can last for several weeks and are termed 'alcoholic hallucinosis'. This condition can be distinguished from schizophrenia by its temporal association to alcohol cessation and its lack of recurrence unless drinking is resumed.

Generalized tonic–clonic seizures occur in up to one-third of patients with chronic alcohol dependence when their alcohol ingestion is stopped. The seizures are usually isolated and begin within the first 12 to 24 h of stopping, occasionally they occur in groups of three or four within a 6-hour period. Alcohol withdrawal accounts for 15 per cent of all seizures, and alcoholics who have seizures during one episode of withdrawal are likely to have them during subsequent episodes of withdrawal. The seizures are self-limited and do not require treatment beyond that given to the patient for alcohol withdrawal, unless another cause is found. Only rarely do alcohol withdrawal seizures progress to status epilepticus.

Delirium tremens is the most severe form of alcohol withdrawal and is seen in about 5 per cent of alcoholics. It is characterized by a state of agitated arousal, global confusion, and disorientation. Patients are delusional, have vivid hallucinations, and insomnia. They exhibit signs of sympathetic hyperactivity: fever, tachycardia, mydriasis, and diaphoresis. The onset is 2 to 4 days after alcohol cessation and may be the first sign of withdrawal in a previously unrecognized alcoholic. Patients are terrified, combative, and often destructive. An episode of delirium tremens may last from 24 to 72 h and often ends as abruptly as it starts. Relapses occur and may continue for days to weeks, often with intervening periods of lucidity. Aggressive treatment with benzodiazepines is essential to calm the patient, control his or her behaviour, and ensure that they do not harm themselves or others.

Treatment of alcohol withdrawal

There are three main aspects to the treatment of alcohol withdrawal. First, one must perform a thorough, yet expeditious, evaluation to look for coexisting medical illnesses. This can usually be accomplished through a careful history, physical examination, and selected laboratory studies. Second, one must ensure adequate nutrition. Patients who abuse alcohol often consume most of their daily calories in the form of alcoholic beverages, which contain carbohydrates but are devoid of minerals, protein, and vitamins. As such, most alcoholics are deficient in folic acid, thiamine, pyridoxine, and nicotinic acid and need to have these vitamins replaced. The most important is thiamine and the patient should be given 100 mg a day for 5 to 7 days. The first dose should be given intravenously or intramuscularly to ensure absorption, and later be changed to an oral preparation. In addition to thiamine, patients should be given a multivitamin and folic acid preparation daily for at least 1 week. Thiamine should be given prior to or concurrent with the administration of dextrose-containing fluids, as glucose increases the need for thiamine and may precipitate or worsen a Wernicke's encephalopathy if given to patients who are thiamine-deficient.

The third aspect of treatment is to replace the central nervous system depressant effect of alcohol with a pharmacological agent that can be tapered over 3 to 5 days. There are several drugs that can be used, but benzodiazepines have the highest margin of safety and are therefore preferred. Diazepam and chlordiazepoxide are the most commonly used, in part because of their longer half-lives. Lorazepam or oxazepam are preferred in patients with hepatic dysfunction, as they do not require hepatic metabolism.

Patients with only a slight tremor or minimal autonomic hyperactivity do not require pharmacotherapy. If additional symptoms are present or patients are in moderate to severe distress, a benzodiazepine should be given. The goal of treatment is to keep the patient sleepy, but easily rousable. Each patient's requirements will therefore differ depending on their tolerance, sex, age, and concomitant medical problems. As a general rule, the average male can be managed with diazepam 10 mg four times a day for the first 1 to 2 days, followed by 10 mg twice daily for 2 days, and 10 mg once a day for 2 days. If chlordiazepoxide is used, the average dose is 25 to 50 mg four times a day for 2 days, followed by 20 mg a day for 2 days, then 5 mg a day for 2 days. An individual patient's requirements may differ and can best be determined by frequently monitoring vital signs, symptoms, and mental status. In women, the starting doses are usually reduced by 20 per cent. The goal of early recognition and treatment is to prevent the development of delirium tremens.

Delirium tremens is a medical emergency and should raise suspicion as to the presence of an intercurrent illness, such as pancreatitis, pneumonia, hepatic failure, or a subdural haematoma. It requires an expeditious assessment, followed by the rapid administration of intravenous benzodiazepines. Between 5 and 10 mg of diazepam may be given every 5 to 15 min until the patient is calm. Maintenance therapy is needed every 1 to 4 h after this, and may exceed 200 mg a day for a period of 3 to 5 days. The goal of treatment is to calm the patient without oversedation until the symptoms have passed. Although this syndrome is being increasingly recognized and treated, it still has a reported mortality rate of 1 to 5 per cent, which is usually due to an intercurrent illness.

Carbamazepine is effective in treating mild to moderate alcohol withdrawal, but data are limited on its efficacy in preventing seizures and delirium tremens, and its use is limited by side-effects in up to 10 per cent of patients. Although commonly used in emergency settings, there is a paucity of data to support the use of phenytoin in treating alcohol or drug-withdrawal seizures and thus, if started, it should not be continued beyond 5 to 7 days unless an underlying seizure disorder is identified. Antipsychotic drugs have no role in the treatment of mild withdrawal. They are sometimes used as adjuncts in the treatment of delirium tremens, although caution must be exercised as they can lower the seizure threshold.

Opiates

Clinical features of opiate withdrawal

The onset and duration of withdrawal depends on which opiate the patient is dependent upon. Opiates with short half-lives have a more rapid onset and shorter duration of symptoms than opiates with longer half-lives. Withdrawal from morphine or heroin usually begins 6 to 8 h after the last dose in a tolerant person and lasts 5 to 7 days. Methadone has a half-life of 22 to 24 h and withdrawal begins more slowly and lasts much longer. **LAAM** (L-a-acetylmethadol) has the longest half-life and thus, the longest withdrawal syndrome in the absence of opiate replacement.

Although uncomfortable, opiate withdrawal is not life-threatening. The symptoms are the opposite of the acute effects of the drugs. They include fatigue, anxiety, irritability, and insomnia. Patients complain of abdominal cramping, nausea, vomiting, and diarrhoea. They frequently yawn, experience rhinorrhoea, excess lacrimation, and increased bronchial secretions. Sweating is common, may be profuse, and is often associated with piloerection. Patients complain of bone pain and myalgias and say that they feel as though they have influenza. These symptoms are accompanied by intense craving for opiates. The physical signs of opiate withdrawal include mydriasis and mild elevations in blood pressure, body temperature, and respiratory rate.

Treatment of opiate withdrawal

Many patients with opiate dependence will have attempted self-detoxification without significant success. As such, when these patients are admitted to the hospital, it is best to treat their withdrawal symptoms pharmacologically. This not only alleviates their discomfort, but also improves the ability of the entire healthcare team to treat their presenting problems and to assess their willingness to seek treatment for their substance abuse. Several approaches can be used, including the use of

opiate replacement therapy or through the use of non-opiate medications to treat the symptoms of withdrawal.

Opiate withdrawal is most effectively treated by the administration of opiates. This can be accomplished by giving a long-acting opiate such as methadone, or by using an opiate with agonist and antagonist properties, such as buprenorphine. When methadone is used, the principle is to give enough methadone on the first day to alleviate the patient's symptoms and then to decrease the dose by 10 to 20 per cent per day over the next 5 to 10 days. Estimating the amount of methadone that an individual patient needs is difficult, and it is generally best to give a test dose of 10 to 20 mg and monitor the patient's response over the next 1 to 2 h. This ensures that the patient is not overmedicated and also that the symptoms are improving. If not, an additional dose or doses may be given then or 12 h later if symptoms recur. Although there are no special licensing requirements for the use of methadone in hospital patients in the United States, its use in the outpatient treatment of opiate dependence is restricted to licensed facilities. As such, when therapy needs to be continued beyond the length of hospital stay, either for detoxification or maintenance, the patient must be referred to a licensed treatment facility. This makes its use in treating medically ill inpatients challenging, particularly as the length of hospital stays continues to decline.

An alternative approach is to use buprenorphine, an opioid with partial μ-agonist/antagonist properties. As such, it treats the symptoms of opiate withdrawal, and blocks the effects of additional opioid stimulation in a dose-dependent manner. It has poor bioavailability and therefore must be given sublingually or parenterally. Its advantages include less physical dependence, a lower risk of overdose, and a less intense withdrawal syndrome. Its half-life is approximately 3 h. The initial dose is usually 0.3 to 0.6 mg intramuscularly or 2 to 4 mg sublingually, repeated at 6 to 8 h intervals and tapered over 4 to 5 days.

The symptoms of opiate withdrawal can also be managed with non-opiate medications. The a2-agonists, such as clonidine, decrease the sympathetic nervous system overactivity in patients with opiate withdrawal. They decrease the patient's nausea, vomiting, abdominal cramping, and diarrhoea, but do little to alleviate myalgias, back pain, and craving for opiates. Most patients respond to oral doses of clonidine 0.1 to 0.3 mg given every 6 to 8 h for the first 24 to 48 h, followed by a taper over the next 3 to 5 days. Dose-limiting side-effects are orthostatic hypotension and somnolence. Clonidine neither shortens the duration of withdrawal nor prevents relapse.

Symptomatic treatment of abdominal cramps and diarrhoea can be achieved with Lomotil® (diphenoxylate and atropine) or loperamide and dicyclomine. Both diphenoxylate and loperamide are opioids with low addictive potential as they are poorly absorbed from the gastrointestinal tract. Myalgias and bone pain may be treated with non-steroidal anti-inflammatory drugs (**NSAIDs**) such as ibuprofen or naproxen, and rhinorrhoea can be managed with nasal decongestants such as pseudoephedrine. Insomnia should be managed expectantly: the routine use of sedatives is discouraged as they have no specific effect on opiate withdrawal and can also be misused.

Cocaine

Withdrawal from cocaine leads to intense neuropsychological symptoms, including dysphoria and intense cravings for more cocaine. Despite these symptoms, which are often severe, cocaine withdrawal is not life-threatening and has no associated physiological instability. Patients with a long history of cocaine use or recent bingeing may also complain of depression, anxiety, anhedonia, and profound fatigue. Nevertheless, patients can usually be managed with reassurance and supportive care, but may require psychiatric assistance if they are suicidal. On rare occasions, a brief course of benzodiazepine therapy (less than 24 h) may be needed if cravings and anxiety are of an intensity to jeopardize the team's ability to care for the patient.

Sedative/hypnotics

Clinical features of sedative/hypnotic withdrawal

The development of a sedative withdrawal syndrome varies in onset and severity based on the half-life of the drug involved, the degree of dependence, and the duration of daily use. Benzodiazepines are the most commonly prescribed sedatives, and although safer than barbiturate and non-barbiturate hypnotics, they still have the potential for abuse and the development of dependence. Benzodiazepine dependence can occur in as little as a month if higher than usual doses are taken on a daily basis, or after several months when standard doses are used. Withdrawal can therefore be seen in a wide range of patients when these drugs are stopped, including those who are unaware of their physical dependence.

The signs and symptoms of sedative withdrawal are variable and do not always follow a specific sequence in their development. Mild irritability, tremor, diaphoresis, and sleep disturbances are common. Physical findings can include orthostatic hypotension, tachycardia, fever, seizures, and delirium. With long-acting preparations, such as diazepam, the onset of symptoms may be delayed for 24 to 48 h after the drug is discontinued and does not peak in intensity until 5 to 7 days later. Symptoms may appear sooner when a shorter acting agent such as alprazolam is involved. A previously unappreciated sedative dependence may first be recognized 2 to 3 days into a patient's hospital stay, when some or all of the above symptoms and signs appear. Thus, it is important to consider benzodiazepine dependence in patients who are symptomatic, even if a history of benzodiazepine use has not been previously elicited.

Treatment of sedative/hypnotic withdrawal

Treatment of sedative/hypnotic withdrawal requires close medical attention, with monitoring for seizures. Detoxification is best accomplished with sedative substitution and gradual tapering in a controlled setting. As with opiate dependence, it is usually best to substitute an agent with a longer half-life, such as diazepam, clonazepam, or phenobarbital for the sedative of abuse. Each patient's level of dependence needs to be determined by giving a test dose and monitoring the patient's response, rather than relying on the patient's historical reports. Tolerance to the subjective effects of sedatives develops quickly; while tolerance to sedation remains low, unexpected central nervous system depression may occur if too large a dose is given. In the absence of sedation or intoxication, it is likely that the patient's tolerance is higher and indicates that a larger dose will be needed. Once the patient's requirements are determined, the dose is divided and can be gradually reduced over 14 to 21 days. This time course may require extension in patients with severe symptoms or a history of withdrawal seizures.

Pain management in patients with substance abuse disorders

Adequate pain management is an integral component of the successful care of all patients who require admission to hospital. This is particularly true for patients with a concomitant alcohol or drug use problem as they are more likely to sustain traumatic injuries and have a higher rate of medical and surgical illnesses. As pain is primarily subjective, physicians and nurses must rely on the patient's assessment of the adequacy of analgesia. Physical signs such as tachycardia, diaphoresis, and hypertension that are associated with acute pain are neither sensitive nor specific, and thus cannot be relied upon in assessing the adequacy of treatment. This is further complicated in patients with problems of dependence, as these findings may also be signs of withdrawal. The complex behavioural and psychological phenomena associated with addiction can alter the patient's perception of pain, and some studies suggest that patients with alcohol or drug-dependence may have a lower tolerance for pain.

Managing pain in this population can therefore be difficult even for experienced clinicians. Yet, by using a systematic approach, one can make a good assessment of the problem and provide the best chance for a successful outcome, diminishing the chances of developing an adversarial relationship between the patient and the medical staff.

The six steps to consider are listed in Table 2.

1. The first and most important step is to identify the source of the patient's pain and direct primary therapy towards it. Examples of this include antibiotics and debridement for an abscess and realignment of a broken bone.
2. The next step is to determine whether the patient has a history of active or remote substance abuse. This helps in determining the dose and frequency of analgesia, as those with a history of active opiate use or who are in methadone maintenance programmes are likely to be tolerant to opiates. Physicians should pay close attention to symptoms of anxiety and depression which can not only influence one's perception of pain, but may require concomitant intervention.
3. The third step involves selecting the appropriate opioid analgesic based on a clear understanding of the pharmacology of the agent selected and the person in whom it is to be used. Patients with tolerance will need higher doses at more frequent intervals to achieve the same analgesic effect as those who are not tolerant. Using opiates with both agonist and antagonist properties is generally not a good way to manage acute pain in dependent patients, as these drugs have lower analgesic potential due to difficulty in overcoming their antagonist activity. While patient-controlled analgesia is very useful in the non-addicted patient, its use in those with drug dependence is usually discouraged because of concerns about the 'high' that patients can receive from intravenous bolusing of opiates.

4. The fourth step involves the addition of non-opioid analgesics, including NSAIDs such as ibuprofen, or ketorolac if parenteral administration is needed. These medications can be effective, usually as adjuncts to opiates, in the treatment of acute pain. They are most helpful in cases where dose-limiting toxicities of opiates have been reached without optimal analgesia. Regional nerve blocks should also be considered in the appropriate clinical setting.
5. The fifth step is the recognition and prevention of aberrant behaviour. Patients with an active drug or alcohol problem can frequently have difficulty with limit-setting and, despite optimal medical care and pain management, may continue to seek drugs, either in the form of prescribed medications or through illicit use during their hospital stay. Patients may tamper with intravenous catheters and infusion devices, may attempt to crush oral medications for intravenous administration, or may surreptitiously use illicit drugs or alcohol. These behaviours are unacceptable and clear limits must be set. This is often best accomplished by discussing with the patient what is acceptable behaviour and which behaviours will not be tolerated. Utilization of behaviour contracts, limitation of visitors, and supervised medication administration have all been employed with some success in individual situations.
6. The last step includes early consultation with substance abuse and psychiatric services to assess the patient's readiness for treatment, to encourage change, and to allow for appropriate referrals to aftercare treatment. In using a multidisciplinary approach to the patient's care, the medical and substance use issues can be addressed simultaneously. This is beneficial both to patients and healthcare providers, and is essential when behavioural management becomes an issue.

Summary

Alcohol and drug dependence are common among patients admitted to a general medical or surgical unit. These problems are frequently missed or may not be detected until a patient exhibits physical or psychological signs of withdrawal. As awareness of the problem increases and physicians become more comfortable recognizing and treating them, these problems will differ little from other medical conditions that are commonly encountered in the hospital and clinic settings.

27 Forensic medicine and the practising doctor

Anthony Busuttil

Introduction

The interface and borders between the law and the medical profession are becoming increasingly wider and more far-reaching, and a doctor has to keep in mind his or her legal responsibilities and duties from the very first day of their practice. Sound ethical principles should form the backbone of professional clinical practice, ensuring competence and integrity of the medical practitioner. The doctor–patient relationship is a partnership based on mutual trust, respect, and confidence with the fundamental rights of every patient being adhered to always and respected fully. These patient rights are succinctly enshrined in the *Declaration of Lisbon* agreed to in September 1981 by the 34th Assembly of the World Medical Association (Box 1).

Box 1 Declaration of Lisbon

- Recognising that there may be practical, ethical and legal difficulties, a physician should always act according to his/her conscience and always in the best interest of the patient. The following Declaration represents some of the principal rights that the medical profession seeks to provide to patients. Whenever legislation or governmental action denies these rights of the patient, physicians should seek by appropriate means to assure and restore them

a. The patient has the right to choose his physician freely.
b. The patient has the right to be cared for by a physician who is free to make clinical and ethical judgements without outside interference.
c. The patient has the right to accept or refuse treatment after receiving adequate information.
d. The patient has the right to expect that his physician will respect the confidential nature of his medical and personal details.
e. The patient has the right to die with dignity.
f. The patient has the right to receive or decline spiritual and moral comfort, including the help of a minister of an appropriate religion.

In addition to dealing with natural illnesses, the services of the medical practitioner, whether in primary care or in hospital practice, are often called upon when injuries and other forms of abuse have taken place, also when death has occurred, particularly if death was sudden and unexpected. As a direct consequence of this, the doctor may acquire information that suggests a suspicious and potentially criminal event. In such instances the doctor's duty of care and bond of confidentiality to the patient must be carefully balanced against his duties as a citizen of a country in which homicide cannot go undetected and crime cannot be condoned.

The courts

It is to be recalled at all times that the system in the courts in Britain, in contrast to other parts of Europe, is very firmly based on the so-called adversarial system, with the sole exception of the HM Coroners' Courts at which an inquisitorial system is in place. In the adversarial system within the criminal courts, the object of the forensic exercise is for those acting for the prosecution on behalf of the State (Her Majesty in England, Wales, and Northern Ireland and the Lord Advocate—or Procurator Fiscal—in Scotland) to prove that the charges laid against the person in the dock (the 'plaintiff' in England and the 'accused' in Scotland) can be proved 'beyond reasonable doubt'. The charges are drafted in terms of alleged contraventions of the Statutes of Criminal Law or of 'common law'. This is a universal system of unwritten law, applied commonly and universally throughout the land, which employs a set of principles, tenets, and maxims that can provide answers to legal problems and can be applied by the judiciary in deciding on cases. Over the years common law has been interpreted and re-moulded by the decisions of one generation of judges after another; these are written down and can be alluded to and quoted in decisions and judgments made by other judges. As a hierarchy of courts developed, thereby enabling an appeal against a decision reached in a lower court to a more senior court, decisions taken by higher courts became binding on lower courts—the concept of 'precedent'. The courts do this by adducing evidence taken under oath or affirmation from witnesses in open court. This enables in minor (summary) cases, the judge, or in serious cases (indictable or solemn cases), the members of the jury (15 in Scotland, 12 in the rest of the United Kingdom) to come to decision. If the verdict is one of 'guilty', the judge will sentence the accused according to tariffs—fines, custodial sentences, community work, etc.—laid down in Statute. The object of the defence is to attempt to cast doubt and demolish the evidence that is being given: they do so through their own witnesses, of which the accused may be one, and by cross-examination of the prosecution witnesses.

The medical practitioner in active employment is usually exempt from jury service but may have to give evidence to fact either as an 'ordinary' witness, like any other citizen, or as a 'professional' witness, by divulging to the court information which he or she has gathered in their professional capacity, for example about injuries, physical or mental illness of the persons in the dock, or other witnesses who have suffered injury. In matters of a scientific and medical nature, when the courts wish to be informed and have explained to them matters which do not fall within the ambit of common knowledge and common sense, persons of a sufficient experience and expertise in the particular subject who can suitably assist may be called as witnesses. By giving information about these matters to the court in this capacity the witness is referred to as an 'expert' (*ex*: from; *peritia*: specialized skill). They are not there to come to a decision on behalf of the court, but solely to assist to the best of their capacity with information, and if required, also to give opinions based on their professional experience and expertise. Details of their qualifications and specialization would be brought to the attention of the courts at the commencement of the expert evidence.

In HM Coroners' courts, whose sole limit is the investigation of death, the questions are asked of all the witnesses by the Coroner, who has to come to a decision at the end of the public 'inquest' as to the identity of the person who has died, when and where they died, and how they came about their death. There is no such office in Scotland, where death investigations are carried out in private by the Procurator Fiscal. There are no public inquests except for deaths in custody and in the course of work as a consequence of the employment; in all other cases the Lord Advocate decides whether 'in the public interest' a 'Fatal Accident Inquiry' is required.

In civil cases one party—persons, or company, or corporate body—sues another party, and the arbiter in almost all such cases is a judge or judges. Both sides can call witnesses, including expert witnesses, to give evidence, and all witnesses can be cross-examined. The only remedy in the civil courts is a pecuniary one, namely

the award of monetary damages. The case requires to be proven 'on the balance of probabilities'.

Duties at a death

Death can be said to have occurred in the body of a person when there is either:

- an irreversible cessation of all function of the brain; or
- an irreversible cessation of the circulation of blood.

In this country there is no statutory definition of death as exists elsewhere, for example in the United States or in New South Wales, Australia. There is also no statutory requirement that the diagnosis of the fact of death is invariably made by a doctor; it is however customary that all diagnoses of death are confirmed by a medical practitioner.

When a doctor is called to a person thought to be have died, six principal responsibilities have to be considered (Fig. 1):

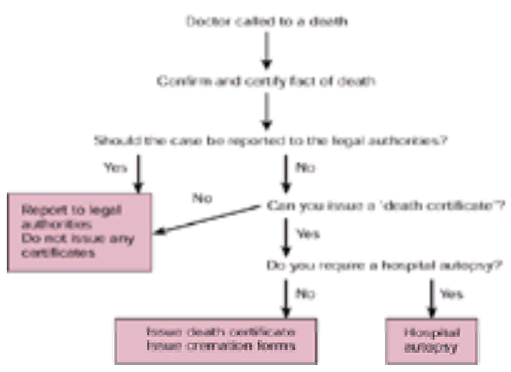

Fig. 1 Doctor called to a death.

1. To confirm the **fact of death** and **document** this at the time.
2. To exclude on medical grounds, where possible, any **suspicions of foul play or negligence** in relation to the death.
3. To identify whether there is a **requirement to report the death** to the appropriate authorities who have a statutory (Her Majesty's Coroners in England, Wales, and Northern Ireland) and/or 'common law' (Procurators Fiscal in Scotland) duty to investigate deaths.
4. To issue a **medical certificate of the causes of death** (commonly referred to as the **Death certificate**) when in a position to do so.
5. If **unable to issue** a Death certificate, to **refer the death to the legal authorities**.
6. If appropriate, and if the medical practitioner is suitably qualified, to issue **other certification** which may be required in relation to the death and the disposal of the decedent.

Confirming and documenting death

In the recently deceased it is essential that a formal clinical examination is carried out to ensure that the pumping action of the heart and breathing have both ceased. This should be done by auscultation over the chest for a timed period of about 2 min. It is also useful to feel the tension in the eyes, which decreases quite promptly after death (due to a lack of blood pressure) and to look into the pupils, which assume a mid-position: the corneal and light reflexes disappear. If the cornea is still transparent and moist (usually until about 10 min after death if the eyelids were closed) and if in any doubt, it may be useful to examine the eye with an ophthalmoscope: the blood in the retinal veins breaks up into segments within 10 s of clinical death in the majority of instances, a phenomenon variously referred to a 'railroading' or 'cattle-trucking'. In all deaths, there is also blanching of all retinal vessels if the eyeball is pressed with a finger.

In the presence of severe mutilation and burning, or if the body is showing obvious features of decomposition, these tests are obviously superfluous and to carry them out would not be sensible.

Great care must be taken in situations in which vital functions and general metabolism may have been decreased to such an extreme as to simulate death. For a doctor to be caught out in such situations is not only a major embarrassment but may lead to civil action for damages and disciplinary procedures for erroneous certification. Such 'apparent death' or 'suspended animation' can take place in instances where there has been:

- an overdose of CNS depressant drugs
- hypothermia from exposure or medical complaints
- (electrocution)
- (drowning)
- (psychiatric catatonic states).

When in any doubt, particularly when such conditions are present in combination, and particularly in the young, it is always wise to attempt full resuscitation (or 're-animation' as it is referred to in Europe) (see Chapter 16.3).

In all situations when death has been medically confirmed, this must be fully documented on the case notes with the entry timed, dated, and signed. This should be done at the time or as soon afterwards as is reasonable, and the entry should list the clinical tests carried out.

Brain death

The diagnosis of brain death (or 'brainstem death') in patients in an apnoeic coma should be done accurately and positively, even in the presence of a beating heart and machine-maintained respiration, by an appropriately qualified and suitably experienced—at least 5 years' registration—medical practitioner. Tests have to be carried by two doctors and on two occasions several hours apart. Details are discussed in Chapter 16.6.3. In brief:

- Any potentially reversible condition that has led to cerebral depression must be positively excluded. The coma must not be due to CNS depressant drugs, neuromuscular blocking agents (muscle relaxants), hypothermia, or metabolic abnormalities, particularly hypoglycaemia, renal or hepatic failure.

Once all these conditions have been excluded, the simple tests used to confirm that brain death has occurred are that:

- both pupils should be fixed, though not necessarily equal and rounded, and do not react to light;
- no response occurs to corneal stimulation with cotton wool;
- no response is found to the presence of the endotracheal tube or any cough response to suction applied to the tracheal lumen;
- no eye movements occur when 20 ml of ice-cold water are injected into the external auditory meati, having previously established clear access to the ear drums;
- no motor cranial nerve responses are elicited to painful stimuli, e.g. ear-lobe pinching, supraorbital pressure;
- there is no spontaneous breathing with the onset of hypercapnia by disconnecting the respiratory for a sufficiently lengthy period to allow the $PaCO_2$ to build up.

If brain death is thus diagnosed, the time when this has been definitively established can be taken as the 'time of death', and not the time that the respiratory support is withdrawn. Any subsequent harvesting of organs will therefore be carried out on a cadaver in whom artificial respiratory and other support has been retained.

The time of death

The actual time of death will always precede the time that 'life is pronounced extinct', and the duration of this period—often referred to as the 'postmortem interval'—is frequently unknown and unknowable. Forensic pathologists are often involved in making estimates of this period by utilizing such phenomena as cooling of the body after death, the onset and distribution of rigor mortis, etc. This is an area fraught with problems and inaccuracies, and one that the non-forensically qualified medical practitioner should best refrain from venturing into and giving any professional opinions on. In those instances where the estimation of the postmortem interval is of specific importance, this matter should be referred to those who are forensically qualified.

Excluding foul play

Doctors, similarly with all other professional persons, have an overriding duty to the 'society' in which they practise, that allows breaches of medical confidentiality when it comes to ensuring that crime is prevented, fully investigated, and detected. Thus, if a medical practitioner suspects or has good reason to believe that a particular death was due to a criminal or negligent act, it is his or her unalienable public duty to ensure that this incident is reported to the police, and that no certification is completed, no matter how obvious the cause of death may be. If the doctor has acted in 'good faith' in such instances, even if their suspicions are eventually found to be unfounded on due investigation, they do not lay themselves open to civil litigation by informing about the death.

No matter the age of the decedent, but particularly so in the elderly and in children, other considerations should not obscure or side-track the doctor from accepting the possibility that death was due to a criminal or negligent act. In this respect, it may be of some importance, as part of the diagnosis of the fact of death, to look carefully for petechial facial haemorrhages in all decedents, particularly around the eyes, behind the ears, on the labial mucosa, and specifically in the conjunctivae. In the absence of known coagulation problems, their presence on the face should always be taken seriously, especially in babies, and if found should always raise the possibility of death being due to a mechanical form of asphyxia, suggesting the possibility of another party's involvement in the death.

Reporting deaths to the legal authorities

Certain categories of deaths are always reportable to the legal authorities. These include all violent deaths, deaths from all types of accidents, including medical mishaps—no matter how long before the death this accident took place, deaths from suicide and suspected suicide, deaths in legal custody and in secure mental institutions, deaths in fires and explosions, from suspected poisoning, from industrial diseases, and from other diseases which by law are notifiable—these include tuberculosis and hepatitis (but not HIV-related deaths). Deaths in which a medical, surgical, or therapeutic mishap may have contributed to or caused the death of the patient always have to be reported.

If the cause of death is not known and yet there is no other reason why the death should be reported, that death is an uncertified death and thus has to be reported. In such instances this notification should precede any attempts to secure an autopsy.

Death certification

This is a privilege accorded to doctors as a consequence of fulfilling the criteria for their registration with the General Medical Council, and thus any misuse or abuse of this principle would render the doctor liable to a disciplinary procedure. The death certificate is an important statutory document and also a very important public health record: it should be filled in carefully and with all due consideration.

The certifier of the Causes of Death does so to 'the best of my knowledge and belief' and records both the immediate causes of death (Part I), these to be placed in a sequence with the initial line (a) being the condition which chronologically resulted from the condition in the second line (b) and so on. Other conditions that have contributed to the death or accelerated it should be listed in Part II of the certificate.

The mode of dying, for example cardiac arrest, cardiac failure, coma, are inappropriate terms to use in this context, except if they are qualified by the underlying causative pathological condition, such as ischaemic heart disease. Terms such as 'senility' and 'old age' should strictly refer to decedents above the age of 80 years, and then only when there was no further recent superimposed pathology. 'Natural causes' is not acceptable. However, it is accepted that in certain instances the determination of the cause of death would have to await laboratory studies, for example overdose deaths, and in such instances a death certificate indicating this may be acceptable.

Reporting to the legal authorities

The bereaved are understandably often in a very distressed state, and great care and sensitivity should be exercised in ensuring that their grief is not made more acute. Any delays in certification would compound such grief, yet the doctor should not feel pressurized, and every effort should be made to follow the rules and regulations strictly. Religious observances and rites, and other social considerations and conventions may also be brought to bear on the doctor. Although the family of the deceased should be heard out with deference and respect, the certifying doctor should not compromise his or her position in any way. If the doctor cannot certify the death or is bound to report it for any other reason, then the case should be referred further.

Consent to a hospital autopsy and to the retention of organs or tissues therefrom can only be sought if the cause of death is known and all other legal requirements have been abided by. This consent should be given in writing by the next-of-kin on the forms designated for this purpose.

Other certification

In the United Kingdom the disposal of the deceased's body by cremation is covered by Statute and Statutory Regulations. For human remains to be disposed of by cremation a series of forms have to be endorsed by medical practitioners. Form B can be signed by any registered doctor and gives details of the death and its causes; form C, a confirmatory certificate, can only be signed by a doctor who has been fully registered for 5 years. Both doctors need to have inspected the body after death, have conferred, and the second doctor needs to have spoken to some other person who had treated, nursed, or been otherwise directly involved in the patient's last illness. The duty of the 'Medical Referee to the Crematorium' is to scrutinize these certificates and the application for cremation (Form A), and if fully satisfied authorize the cremation to proceed. In cases reported to the legal authorities the Coroner or Procurator Fiscal signs the forms that should otherwise have been signed by the two medical practitioners. In all instances, permanent pacemakers and radioactive implants have to be removed prior to cremation.

If the body has to be transported abroad or to other parts of Great Britain, there may be a requirement of further certificates to enable this to take place. These include certificates from the legal authorities enabling the movement of the body outwith their jurisdiction and confirming they require no further access to it, a 'freedom from infection' certificate and often an 'embalming certificate'.

Particular causes of death

Deaths resulting from and in the course of medical care

No matter how vigilant and caring medical and surgical treatment may be, occasional deaths will occur in the course of treatment as a direct consequence of the treatment. This may due to an allergic or idiosyncratic response to medication, and much more rarely through error, such as giving an excessive dose of a drug, or from accidents (for example, intra-arterial versus intravenous injection) and mishaps (for example, internal bleeding after a liver biopsy). For this reason, deaths that occur during operation or in the early postoperative period, deaths during investigative procedures, in the course of the administration of a general or local anaesthetic, or in the progress of clinical trials, invariably become the subject of a legal investigation.

Such deaths in the course of medical care raise the spectre of litigation and claims of medical negligence. There should be absolute transparency in divulging all the facts about such deaths, which should always be investigated by a pathologist who is completely independent of the hospital or other establishment in which the death has occurred, and who has some previous experience in such investigations. The investigating pathologist requires access to all the medical notes of the deceased patient, full statements from the doctors and nursing staff involved, detailing their involvement (disconcertingly, often acquired by the police), a thorough examination of any equipment used, access to batches of drugs used and blood samples collected **premortem**. Such investigations will invariably require the

assistance and participation of a number of 'experts' in other fields.

Sudden infant deaths

The careful investigation of death in infancy and childhood has led to major successful prophylactic campaigns; perhaps if unexpected adult deaths were to be looked at as carefully, similar preventive measures could be implemented. These deaths have also led to the production of universally acceptable protocols for postmortem examination that involve photography, radiology, microbiology, virology, immunology, genetics, etc. If this approach were to be emulated in other death investigations, the end-product therefrom would be much enhanced.

As infectious diseases no longer take a major toll in infancy in most developed countries, and as serious congenital conditions are no longer as prevalent, the most important cause of the sudden death of infants after the first month of life and within the first year is the 'sudden infant death syndrome' (**SIDS**, sometimes referred to as 'cot death' or 'crib death'). The original definition, still applicable, is of 'sudden death of any young child that is unexpected by the history, and in which a thorough post mortem examination fails to demonstrate an adequate cause of death'. Most pathologists would also wish to have a thorough inspection of the scene of the death to exclude potentially noxious environmental agents, for instance carbon monoxide exposure.

The diagnosis of SIDS is therefore only made by carefully and meticulously excluding any other causes, and is a morbid anatomical diagnosis rather than a clinical one; an autopsy is therefore a *sine qua non* to reach this diagnosis. It is especially important to exclude congenital metabolic abnormalities such as medium-chain acyl coenzyme A dehydrogenase (**MCAD**) deficiencies by appropriate testing (plasma/blood spot acylcarnitine profiles in MCAD deficiencies) and thus alert the family to possible further recurrences. Trauma and poisoning by alcohol, or with other sedative or anxiolytic preparations, also have to be excluded specifically on appropriate autopsy samples; the 'Münchhausen syndrome by proxy', first described by Meadow in 1977, is another condition to be aware of.

The incidence of SIDS has decreased dramatically in many industrialized countries as a result of major public health educational campaigns advising parents about the risk factors and means of prevention. Overheating of the child is one such risk factor. Parents are instructed to prevent this by removing the child's headgear when indoors, and by ensuring that the sleeping child does not wear excessive clothing or has too many bedclothes, by preventing the ambient bedroom temperature from being too high, and by seeking medical advice when the child appears feverish. The dangers of cigarette smoking close to the baby have also been emphasized as an important risk factor for this and other childhood complaints. The 'back-to-sleep' campaign, that is ensuring that the child is placed in the prone sleeping position, is based on another epidemiologically established important risk factor. Paradoxically, immunization of the child for common childhood illnesses, once thought related to SIDS, has been shown to be protective and is thus further encouraged in this connection.

The actual pathogenetic cause of SIDS is still uncertain in the majority of instances: hypoxia, cardiac arrhythmias, hypoglycaemia, loss of vascular tone, reflex apnoea, and heat shock have all been proposed, as well as the 'superantigen' effects of bacterial toxins. Other important aspects of the epidemiology of this condition is the seasonal incidence, the familial recurrence, the increased incidence in boys, and the increased association with certain ethnic groups, such as Native Americans and Australian Aborigines, and its absence in others, for example immigrant families from the Indian Subcontinent. The pathognomonic feature of SIDS, which is yet to be explained, is the finding of diffuse, internal petechial haemorrhages overlying the thymus and beneath the pleura and the pericardium.

Sudden unexpected nocturnal deaths in adults

The syndrome of sudden unexpected nocturnal deaths (**SUND**) occurs in young adults and adolescents, mainly in immigrant workers from SE Asia employed in Singapore and Saudi Arabia, and in refugees from the Far East. These decedents are usually employed in manual jobs in the building or the gardening trades, and have been residing in their adoptive country for several months. They are almost exclusively males who smoke or who are passively exposed to smoke in their environment, and who have a recent history of a mild upper respiratory tract infection; petechiae may also be found internally. These deaths mostly occur during sleep and at night.

Various theories have been put forward, including vitamin B and other nutritional deficiencies, familial cardiac arrhythmias, brainstem epilepsy, *Pfeifferinella mallei* infection, stress and homesickness, bacterial toxin production from nasopharyngeal colonization by *Staphylococcus aureus,* but no specific and recurring cause has been identified.

It is also the case that a full autopsy, with comprehensive toxicological and histological investigations, in the occasional sporadic death of an adolescent native of this country fails to yield a cause of death. Such deaths have been labelled as 'deaths from SUND' in Great Britain. However, it must be kept strictly in mind that this diagnosis is also one of exclusion, and should be used sparingly and appositely.

Survivors of violence

Sexual assaults

Over the last few decades the police have appropriately received positive and favourable publicity regarding the manner in which they deal with the survivors of alleged sexual abuse, and investigate their formal complaints. This has enabled more of those who have been abused in this manner to come forward and report the abuse suffered. In spite of this, however, it is not infrequent that the first disclosure of such abuse, particularly abuse which had occurred some time previously—on occasions, several years earlier—is initially made to a doctor in the course of a confidential consultation, perhaps on a totally unrelated matter. The medical practitioner is thus placed in a situation in which they are party to highly confidential and sensitive information relating to a potentially very serious crime, whose investigation requires careful and specialized investigation. This requires the careful interviewing of the survivor of this crime, the description of general and genital injuries, the meticulous collection of trace evidence, and of course the presentation of all this expertly in the criminal courts.

In this situation—as in many other similarly problematic circumstances—the doctor has to determine for himself whether or not, in the eyes of the law, the person disclosing abuse has full competence to take decisions. In Scotland and the rest of the United Kingdom, the legal age above which legally valid consent to medical treatment can be given is 16 years. If the patient is competent in terms of age and of mental and physical faculties, then in all such instances the doctor must firmly put to them the option of immediately involving the police. The police are much more knowledgeable about the process of investigation of allegations of sexual abuse and better equipped for the purpose than any medical practitioner is likely to be. If after due consideration the patient does not wish to inform the police for any or no reason, then patient confidentiality must be maintained.

All efforts should be made to ensure that any problems related to possible sexual abuse are adequately dealt with, including any worries that the patient may have about the possibilities of an unwanted pregnancy, sexually transmitted diseases including HIV infection, and the physical and mental trauma sustained. If the police are brought into the picture, the patient may still require some further support.

In Scotland, below the age of 16 years, the consent by a minor is only competent if in the view of the particular medical practitioner that patient fully understands the implications of the treatment being offered, and this consent can be extended to consent to medical procedures. Elsewhere, medical decisions of all types are also governed by the child's understanding of the proposed line of action or procedure—referred to as ' *Gillick*-competence' in the United Kingdom. If the consent to involve the police is not forthcoming from a minor, then the doctor has to decide whether in the interest of the particular young patient, this decision should be overruled, and perhaps whether those with parental responsibility for the child are to become involved at this stage. This decision-taking tightrope has to be negotiated very carefully, with the best interests of the patient always paramount and with the medical practitioner acting 'in good faith'. Advice from more senior colleagues, from forensic medical practitioners, and from the medical defence unions is often invaluable in such instances.

In the case of young children who are 'not-legally competent', appropriate multidisciplinary guidelines have been put together by every health authority and health board. In these a close co-operation between the health services, the police, the education department, and the social work department forms the basis of the investigation and further management of these cases. These guidelines should be adhered to strictly.

If the police are not involved it may be very difficult to collect evidence that would stand up in a court of law. If the doctor is inexperienced in such examinations then their competence and expertise will be called into serious question by the courts in any eventual adversarial criminal court case; a gynaecological or surgical colleague may have to be involved. For instance, the taking of swabs for seminal fluid analysis may fall short in terms of the unbroken continuity of the chain of evidence and the exclusion of cross-contamination that the courts would always require. These difficulties should be brought specifically to the attention of any patient

who is reluctant to involve the police.

Another way to ensure that any physical evidence of injury to the genital area is recorded permanently at the time of the medical examination is to utilize videocolposcopy, as is now almost invariably performed in examinations of this type in prepubertal children to avoid problems with second examinations and nuances of varying interpretations.

It is a fact of life that a very significant number of prosecutions initiated in sexual assaults fail to produce a conviction. By the very nature of this crime, these incidents are usually perpetrated in private with no eye-witnesses to the event. It often boils down to the oral evidence given in court by the two parties, and to which of the two, tested by cross-examination, the members of the jury are prepared to accept.

The medical notes

On the principle that contemporaneous recording will always provide good evidence in court, and in many cases that will be the best evidence, it is essential that all members of staff keep regularly annotated and thorough medical notes that are adequate, comprehensive, and comprehensible. Conciseness is not an issue at all in these instances: the notes made may be telegrammatic, provided that they convey all that has transpired on that occasion in terms of how the patient was dealt with and managed.

It is important to record dates and timings, to ensure that each page bears the name of the patient (or a 'sticker' bearing their details).

In those patients who allege assault, or have been otherwise injured, the manner and method of presentation, as well as the triage procedures all have to be documented in full. It may be said that some of these issues are normally attended to by other clerical staff; however, it does no harm when urgency and the vagaries of practice has put the system out of kilter, and indeed sometimes saves the day, for the doctor to record such important details, or at least ensure that they have been properly recorded.

The narrative given of the presenting complaint should be carefully recorded at the time, and what is even more important, it is essential to document who gave the initial information that has found its way on to the notes. If it is the ambulance crew or the accompanying relative or police officer from which you obtained this information, indicate so, as this renders it second-hand or 'hearsay information' in a forensic context. If the patient has given you specific details about how their injuries were acquired, transcribe these into text. In cases that may end up in court it is important not to attempt to précis, filter, or alter the information as originally given, perhaps in an attempt to make it sound more plausible and coherent: it should be documented as it was imparted to the doctor at the time.

Always indicate the findings on clinical examination. State what you did and when, and the investigations that were carried out by you (for example, blood pressure, peritoneal lavage), or asked for, either at the accident and emergency department itself (such as breath testing for alcohol, urinalysis for blood), and/or elsewhere (such as blood gases, serum electrolytes). It is also important to ensure that when the reports of such tests are available that these are also quoted in the notes, even if this information has been given to you over the telephone.

If radiographs have been ordered, make sure that in addition to your own viewing thereof and a recording of the diagnosis made by you on your personal 'reading' of them at the time, that the films are also subsequently reported on by the radiology department. These reports will serve as confirmation of your diagnosis and should always find their way into the patient's notes. For instance, it is of little assistance if you believe that there was a fracture of the maxilla or of the nasal bones, both clinically and on radiography, but this has not been confirmed anywhere in the notes in an 'official' radiological report.

If there has been a referral to other units (for example, neurosurgery, maxillofacial surgery, or burns units), this must also be recorded, preferably with a copy of the letter of referral. Consultations with other colleagues, for instance the physicians on call, the otorhinolaryngological specialist registrar, should be fully documented for any future reference.

Describing wounds

It is absolutely essential that wounds in injured persons are carefully described in the medical notes. This holds true whether the presentation is in hospital or in primary care. Domestic violence is on the increase, and the setting up of primary care-manned units in the community is becoming more frequent. It is not a valid excuse to claim that because the doctor to whom the patient presented initially was not an accident and emergency doctor, there was no obligation on them to record appropriate details. (See Box 2.)

Box 2 Wounds

- **In a systematic way:**
- *For each wound:*
- Define the wound.
- Locate the wound in relation to fixed anatomical points.
- Measure the wound (with its edges in apposition).
- Describe its edges, its immediate surroundings, and its floor.
- Describe the wound in terms of its orientation or pattern.
- State whether recent or old.
- Discuss its severity, either individually or collectively.
- Record the baseline general physiological parameters of the patient, e.g. pulse rate, blood pressure, respiratory rate, Glasgow Coma Scale.
- Consider sketching the wound freehand or on a line diagram.
- Consider photographing the wound.

A wound in the medicolegal sense is any traumatically induced abnormality, and this ranges from erythema to abrasion to cuts through the skin or mucous membranes to any internal injury.

For each external 'wound', describe its shape (vertical, transverse, lozenge-shaped), and its exact location—the latter by reference to standard fixed anatomical sites (for example, suprasternal notch, the prominence of the seventh cervical vertebra), and not variable ones such as the nipple or the umbilicus.

The wound should be measured with some degree of accuracy, and if the wound happens to be oriented in any particular manner, this should also be recorded; similarly document any collar of abrasion and bruising around it, and any pattern in the wound itself.

In forensic practice, trivial wounds that may not require any active treatment may be as important as those that are more serious. Abrasions in the form of fingernail scratches may be as important as any full-thickness lacerations that may be coexistent on the same patient. Therefore try to refer to all wounds in your description.

Be careful to define each wound appropriately. By definition, a laceration indicates a wound with very irregular (and perhaps bruised) edges, and the presence of bridging of incompletely damaged tissue in its base. Furthermore, a laceration, again by definition, is also a wound caused by a blunt-force injury—that is to say a force that has stretched the skin excessively, and more usually over a bony point or surface, causing the elasticity of the epidermis and dermis or of a mucosal surface (such as the lip, the vagina, or anus) to be so exceeded that, as a consequence, there is splitting and tearing apart of the skin or mucosa at the site of application of the force.

A sharp and pointed object will produce an incision or an incised wound with clean-cut straight undamaged edges. However, it is often impossible to indicate what specific weapon did cause the injury; for example, a sharp shard of glass, a kitchen knife, and the sharp edge of a tin can all produce incised wounds which look identical, even to someone with plenty of experience in wound interpretation. In the case of lacerations and bruises the difficulty may be even more pronounced. All that one would be able to say with any degree of accuracy is that among other objects that could have produced the wound, its appearances are consistent with having been produced by the particular weapon that is being suggested.

If there is a penetrating stab wound, it is essential to record the length of the wound track after it has been probed or explored, also to what depth the wound has extended, and, if this has been identified, which direction the track leads away from the skin. If the wound has penetrated beyond the skin, it would be important to denote which layers have been breached.

Although it may prove impossible to record individually all the wounds sustained, the use of simple line-drawings with the inclusion thereon of brief comments may be very effective.

Also recall that fractures, dislocations, and internal injuries fall under the category of wounds in this context. Any foreign bodies which have been retrieved from wounds, no matter how banal they may look (for example, grit, glass), may have very important evidential value and should never be discarded.

Wounding in the legal context

The legal practitioner, when looking through descriptions of wounds, often has different priorities and different questions from medics in their mind. Occasionally, these may not be immediately apparent or deemed relevant by the medic, but these queries may be expressed in writing or in court. Samples of such questions include: 'How much force was required to produce the wound under review?'; 'Could the particular wound have been inflicted accidentally, or as part of a self-defence type of response by the patient to an assault on him?'; 'Was the wound inflicted by a right-handed or left-handed assailant?'; 'Were all the wounds inflicted in the course of one assault?'

It is the counsel of perfection only to answer such questions if one feels experienced and fully competent to so do. An off-the-cuff remark on such matters that cannot be substantiated on robust cross-examination may cost dearly in lost face, and perhaps even in reputation, in the witness box.

It is important to be very circumspect about the ageing of wounds; interindividual variation is such that one can only provide general answers to questions on this matter. If a wound is showing healing as demonstrated by scabbing, then it will be about 2 days old, and one which is scarred almost a week old, but statements must be as general as that. Ageing of bruises is particularly fraught, in that the colour change that can be seen as the haemoglobin that has extravasated into tissues is changed to bilirubin and biliverdin, depends on a number of variable local and systemic factors.

Of specific importance to the criminal justice system are also such matters as the severity of the wound in question, and whether a particular wound could be considered as being life-threatening. On the basis of the 'soil and seed' concept, severity should be assessed by the damage produced by the trauma, the amount of blood lost, the degree of surgical shock present; also on the amount of days lost from work, the age of the patient, associated medical conditions that decrease the rate of healing, the ease with which it could be dealt with medically, etc. Indeed, any answers to questions about severity should always be predicated by a series of reasons indicating why the opinion given is being proffered. In doing so it may be useful to distinguish between whether or not the particular wound is 'serious' and 'life-threatening', or whether wounds in that specific anatomical location (for example, neck, anterior chest wall) in general terms are serious and life-threatening. For example, a penetrating stab wound of the chest may not have actually produced a pneumothorax, but had it been slightly deeper or its track slightly more medial or more lateral it could have: thus within these caveats, the wound can be considered as serious and potentially life-threatening. The fact that a particular injury can be salvaged with relative ease in a hospital does not necessarily detract from its degree of severity. Any inevitable or avoidable delay in seeking or obtaining medical help, any intervening wound infection, etc., should also be listed to enable a more balanced assessment of wound severity.

The after-effects of the wounding are also of importance. Any scarring left behind by the wounding, which may be considered as cosmetically disfiguring, even if surgical in origin, can increase the 'legal' severity of the wound, and similarly any residual pain and stiffness of an injured joint.

Photographs of injury

Photographs of wounds may be extremely useful if in due course the case comes to a court hearing: pictures taken prior to stapling or suturing may clearly convey to a jury more poignantly the degree and variety of injury sustained. This may require close co-operation with the police, and above all the 'informed' consent of the patient, if at the time they are in a state in which they are legally capable (*capax*) to give this. If the patient is unconscious and the case is very likely to have been the result of criminal violence, there should be close co-operation with the police. If the management of the patient will not suffer adversely, any reasonable requests for photography made by the police should be considered—even if only a Polaroid—and if at all possible acquiesced to. In all such instances there must always be a careful and considered balance between one's professional obligation as a medical practitioner to provide optimal care and confidentiality for the patient, and one's duty as a citizen of a country in which violence cannot be condoned and for which its perpetrators are brought to justice in the course of a fair trial.

Photographs of wounds after they have been debrided and sutured may not be as useful as photographic documentation prior to such treatment, but they are better than nothing. Patterned injuries which may have to be matched to other weapons (for example, footwear imprints, imprints from blows) may need to be photographed in black and white, in colour, and under different light sources (such as ultraviolet light). If photography cannot be used for any reason, then consider sketching the wound freehand or use anatomical outline drawings to indicate the location and appearances: this will also economize on text.

Human bites

On occasions, human bites may be the presenting injuries. In these instances photography may be essential, and furthermore, valuable information can be gained from appropriately thorough and specialized examination. There may be enough material on the skin to secure a DNA profile of the perpetrator, and an odontological opinion may be able to produce a dental chart of the offending jaws for matching purposes. This cannot be done without the involvement of the police at an early stage, and, as always, the patient's own informed consent would be required.

Intoxication

Alcohol tends to feature prominently in persons who have been assaulted or accidentally injured, and it may be useful for the purposes of the courts to document the degree of intoxication observed in the victims or in the perpetrators. Although 'alcohol' can often be smelled on the breath, it must be remembered that it is not ethanol that is being picked up, but congeners such as esters and other organic compounds that have been consumed together with the alcohol. As with alcohol, these are excreted for a lengthy period after drinking has stopped.

Alcohol is absorbed from the upper gastrointestinal tract, mostly the duodenum, and disseminated uniformly and in an unimpeded fashion throughout all body compartments that contain water. Hence, the amount of water in the body, which relates to body weight and to gender, will influence the eventual concentration and therefore the effects of the alcohol consumed. Typically, the consumption of 1 pint (568 ml) of ordinary beer or a double public-house measure (about 55 ml) of spirits (40 per cent (v/v)—alcohol concentration) will result in a blood alcohol (ethanol) concentration of 30 mg of alcohol per 100 ml of blood, or 13 µg of alcohol per 100 ml of breath. The corresponding legally prescribed limits for driving in Britain are 80 mg for blood and 35 µg for breath.

One should only carry out a formal blood alcohol estimation if this has potential therapeutic indication, and then only with the knowledge and consent of the patient. Alcohol is a CNS depressant and the effects of alcohol intoxication can be elicited by tests of neuromuscular coordination and of higher central functions, including the Glasgow Coma Scale. The eyes will also show evidence of sustained lateral nystagmus and the pupils will be dilated.

In those who may be under the influence of 'controlled substances', with or without additional alcohol intoxication, a full neurological examination should be carried out and recorded. However, it is often unhelpful and profligate to carry out urinary or blood tests for the presence of drugs.

Access to information

The same rules of medical confidentiality apply wherever the patient is seen. Relay of information to others has to be carefully controlled. The police frequently seek information, either acutely and/or after the patient has been discharged. It is therefore important that some basic rules are laid down, enabling the police to know what information will and what will not be divulged to them, without the patient first having been approached and their formal consent obtained.

In terms of statute in the United Kingdom, the police have every right to ask for full details of those persons whom they believe have been driving a 'mechanically

propelled vehicle' which has been involved in a collision, and who have been admitted to hospital. Similarly, in relation to acts of terrorism, the police have a right to obtain information. In other instances it is a question of whether, in terms of their inquiries, information should be divulged to police officers who are seeking it. The admission of a person who is likely to die (or as they would put it, 'a condition that is likely to prove fatal'), whether this is the result of an accident or a criminal assault, is cause enough to bring information to the attention of the police.

If the patient or their legal representative requests a copy of the medical notes, this legitimate request cannot be refused unless it can be shown—if need be to the scrutiny of a Crown Court judge (or a Sheriff, in Scotland)—that disclosure of the notes may disclose the identify of a third party or be detrimental to the physical and/or mental heath of that particular patient. Barring this, such records should be handed over: staff in local hospital edical records' departments are trained to deal with such requests appropriately.

The forensic use of molecular biological techniques—DNA profiling evidence

DNA-based evidence has revolutionized forensic practice over the last few years. Based on the principles that all cells of an organism are derived from one fertilized ovum, and that mitotic division of cells is uniform and precise, all cells inside an organism that contain a nucleus retain an identical DNA content. Thus, DNA from hair, buccal cells, semen, and white blood cells derived from the same individual is identical, and it is possible to determine the exact origin of a particular cell or group of cells if their DNA can be matched to that of some other cells of the same origin. Furthermore, as half of a cell's DNA has originated from each of the parents, it is also possible to derive the genetic origin of a particular cell by comparison of its DNA content with that of its parents.

Variable number of tandem-repeat loci

Groups of DNA loci that are used extensively in forensic analysis are those counting variable numbers of tandem repeats (**VNTR**). These are not genes, since they do produce any known product, and those used in forensic analysis have no known biological role. They are thus less likely to be influenced by natural selection, which can lead to different frequencies in different populations. A typical VNTR region contains 500 to 10 000 base pairs, containing many tandemly repeated units, each 15 to 35 base pairs in length. The exact number of repeats, and hence the length of the VNTR, varies from one allele to another, and different alleles may be identified by their relative lengths. VNTRs have a very high mutation rate, leading to changes in their length, with an individual mutation usually resulting in a change in length by only one or a few repeating units. This leads to a very large number of alleles, often 100 or more, no one of which is common, although only 15 to 25 can be distinguished practically. This means that the number of possible pairs of alleles forming the genotype at a locus is considerable, and given that testing of several different such loci can be combined, the total number of genotypes becomes enormous. For example, for n alleles there are n homozygous genotypes and $n(n-1)/2$ heterozygous ones, in other words: if $n = 20$, there are a total of 210 genotypes, and if four loci are examined with 20 alleles each, then 210^4 or about 2 billion genotypes are possible (assuming that all four alleles are inherited independently).

The main uses of the DNA profiling method in forensic cases are:

1. The identification of crime suspects from trace evidence left behind at the scene, e.g. a specimen of blood from the deceased is found to match stains on the clothing, etc. of the accused person.
2. The elimination of crime suspects in crimes where there has been deposition of body fluids, e.g. the DNA profile of the seminal sample taken from the vagina of the victim does not match that obtained from the white cells of the peripheral blood of the alleged perpetrator of the rape.
3. Paternity testing, when it is necessary to establish which one of two or more males is the actual biological father of a particular child, e.g. in incest or rape cases. Fetal tissue is also suitable for such testing (and is often used).
4. Identification of an unknown person or of unknown mutilated human remains, by comparing material taken at postmortem examination with material, such as hair or blood, which is authenticated as belonging to a particular person during life. This has been extended to buried remains, e.g. the Romanovs, Mengele.
5. Mass disasters—this technique assists with the identification of individuals provided a premortem sample is available for comparison, and has the ability to match together different and separated parts of the same body.
6. Mass screening ('a genetic man-hunt') of a well-circumscribed population from which the murderer or rapist is known to have originated. This was the first use of DNA profiling in a criminal context in the United Kingdom.
7. DNA databases—allowing crimes committed by the same perpetrator in which body fluids have been deposited at the site of the crime to be associated, i.e. serial crimes and previous offenders to be linked with a specific 'new' crime, or resolution of historical unsolved cases.
8. Disputed maternity, e.g. in cases of infanticide and child destruction, when it requires to be proven that a particular child is indeed the offspring of a particular woman.
9. Settlement of immigration problems in relation to the admission into a country of blood relatives rather than 'friends'.

In the civil courts, DNA profiling has also been proving useful in such cases as:

1. divorce (associated with alleged adultery);
2. disputed paternity (and more rarely maternity): in settling estates after death;
3. in immigration disputes (when a country only allows entry of certain closely related relatives, born outside that country, of newly established residents);
4. in disputed pedigrees of animals and origins of biological material.

The forensic applications of DNA profiling are not universally available, and therefore these tests are yet to completely replace and supplant conventional blood grouping methods involving the ABO and isoenzyme (for example, **PGM** (phosphoglucomutase)), systems. In some countries such as the United Kingdom and Switzerland this has already taken place.

The important limitation of DNA profiling is the amount of DNA-containing material available for carrying out the appropriate testing. This is particularly the case when dealing with peripheral blood: only the leucocytes within it that can be of assistance, meaning that a substantial quantity of these cells must be available.

Polymerase chain reaction techniques

In 1987 the polymerase chain reaction (**PCR**) technique was introduced, enabling the rapid and specific, *in vitro*, enzymatic amplification of DNA fragments. This laboratory synthesis utilizes a heat-stable enzyme, DNA polymerase (formerly obtained from a thermophilic bacterium found in hot natural springs and called '*Thermus aquaticus*'—thus '*Taq* polymerase'). The other essential reagents are primers, which are small complementary fragments of single-stranded DNA, also produced artificially. With the correct reaction conditions, a pair of primers can be made to attach themselves to single complementary strands of DNA, and in the presence of an excess of bases in the solution, marshal the formation of replicas of the original DNA fragments. Repeated reaction cycles can be conducted until sufficient quantities of the product are formed to enable standard DNA profiling techniques to be carried out.

The PCR technique is so sensitive that even a very small amount of tissue, such as a single hair root, a single buccal cell, or a single spermatozoon, may be sufficient to produce a DNA profile that is adequate for matching purposes. It can also amplify denatured DNA, and even material from paraffin-embedded histology blocks and formaldehyde-fixed tissue is suitable for replication.

Very strict control of laboratory technique is required in conducting PCR procedures as any minute amount of DNA present in the sample will be replicated. Controls are of the essence in demonstrating the absence of contamination. Protective clothing is necessary when evidence is being collected at scenes of crime, as is careful attention to detail in terms of the collection of material for DNA analytical procedures.

HLA-DQa

A further development is related to one of the genes that controls transplant rejection, *DQA*, coding for a protein HLA-DQa that shows substantial variation in its base sequence from one individual to another. The most variable fragment of this gene may be readily amplified by PCR to distinguish eight different alleles, of which six are used in forensic practice, and thus 21 different combinations of two alleles—6 homozygous and 15 heterozygous. In practice, a reverse blot is used, with the nylon membrane containing preattached probes specific for the individual alleles, making a quick, reliable, and very useful preliminary test if one is required. On average the DQa profile of a person is identical with that of about 7 per cent of the population.

Mitochondrial DNA

Mitochondrial DNA contains a segment called the control region, which is highly variable and has the following additional properties:

1. This DNA can survive in extensively decomposed tissues.
2. It can be successfully amplified, even from the most unpromising tissues such as bones.
3. It is strictly maternally inherited.

Analysis of mitochondrial DNA has been used most frequently in looking at historical cases, and in instances where nuclear DNA is in short supply or where it has been denatured by, for example, contact with soil and the bacteria therein.

Other advances

Microsatellites or short tandem-repeat loci (STRL)

Microsatellites are much shorter than the minisatellites (VNTRs) and comprise 2- to 4-base pair repeats only. They are very common, are distributed widely throughout the genome, and can be amplified singly or together by PCR. Individual specificity can be achieved by typing several loci sequentially. The method can be used with severely decomposed and burnt bodies, using the DNA from a portion of spared voluntary muscle or red bone marrow.

Amplitype polymarker (PM) DNA

This method analyses several loci simultaneously: **LDLR** (low-density lipoprotein receptor), **GYPA** (glycophorin A, the MN blood groups), **HBGG** (haemoglobin gammaglobulin), D7S8 (an anonymous genetic marker on chromosome 7), and **GC** (group-specific component). Each has two to three alleles per locus.

Minisatellite repeat mapping or digital typing

This analyses for length variation and detects sequence differences within the base sequences repeated in VNRTs.

DNA identikit

In the future it may be possible to describe physical (for example, blue eyes, red hair) or other characteristics of a subject from their DNA sequence, thereby obtaining hints as to their actual identity.

Estimation of the population frequency of a DNA pattern

DNA 'exclusions' are easy to interpret: if technical artefacts can be excluded, a non-match is definitive proof that two samples have come from two different sources. However, 'DNA inclusions' cannot be interpreted without knowledge of how often a match might be expected to occur in the general population at random. In simple terms, if two DNA profiles match then there are two logical possibilities: first, that the DNA profile at the scene, on clothing, etc. is actually that of the suspect; and second, that it comes from someone else who has the same profile as the suspect. The commoner the particular DNA profile, the greater is the likelihood that it could come from someone other than the suspect; by contrast, if the suspect's profile happens to be a rare one, then the chances of this are much less likely. Thus the frequency of a particular profile in a particular population must be known to enable this comparison.

The statistical analysis of profiling data has caused problems to the courts: judiciary, jurors, and lawyers alike. Population frequencies of various profiles have been established, a standard method being to count occurrences in a random sample of the appropriate population and then to use classical statistical formulas to place upper and lower confidence limits on the estimate. Because estimates used in forensic science should avoid placing undue weight on incriminating evidence, an upper confidence limit of the frequency should be used in court, which is appropriate in the forensic context because any loss of power can be offset by studying additional loci.

The product rule should be used to estimate the frequency of a particular DNA profile frequency. If the race of the particular individual is known, the database for that particular race should be used; if not, calculations for all prevalent racial groups should be used. The probability that two randomly chosen individuals have a particular phenotype is the square of its frequency in the population. The probability that two randomly chosen persons have the same unspecified genotype is the sum of the squares of the frequencies of all the genotypes. If there are *n* loci, and the sum of the squares of the genotype frequencies at locus 1 is *p*1, then the exclusion power is (1 minus (*p*1, *p*2.....*pn*)).

Population frequencies that are quoted for DNA purposes are not based on actual counting but on theoretical models based on principles of population genetics. Each matching allele is assumed to provide statistically independent evidence, and the frequencies of the individual alleles are multiplied together to calculate a frequency of the complete DNA pattern. Although a databank might contain only 500 persons or less, multiplying the frequencies of enough separate events might result in an estimation frequency of their all occurring in the same person of $1{:}10^{9}$. However, the scientific validity of this multiplication rule depends on whether the events are actually statistically independent. In organizing databanks it is essential that ethnic groups are considered separately, and in the United Kingdom databanks for Caucasian, Afro–Caribbeans, Indians, Pakistanis, Chinese, etc. have yet to be established.

28Sports and exercise medicine

R. Wolman

Introduction

Traditionally, sports medicine has concentrated on injuries that occur during exercise, and therefore has come under the umbrella of orthopaedic surgery. However, with the pursuit of sporting excellence a range of different exercise-related medical disorders are now recognized. These are associated with intense levels of training and may have a detrimental effect on long-term health, as may drugs (and nutrients) that are frequently taken to enhance training and performance. Physicians are therefore increasingly being confronted with medical problems related to sport. This section will cover some of the medical disorders that occur with sport and physical training. It will also address the use of drugs and some of the common overuse injuries that occur with sport.

Developments in exercise physiology over the last 30 years have led to improved training regimes for athletes. A spin-off from this has been the recognition of the benefits of exercise in health promotion and disease management. Exercise prescription now forms an important part of some treatment programmes, with evidence for its use in the management of a range of disorders, including heart disease, diabetes, obesity, hypertension, osteoporosis, arthritis, back pain, chronic fatigue syndrome, and depression. These will be covered in other sections.

Female athlete triad

History

Amenorrhoea in athletes was first recognized in the late 1970s. Prior to this it was unusual for women to train sufficiently hard to develop this syndrome. Since 1980 there has been a growth in the popularity of aerobic sports and in the number of endurance competitions for women, whose first Olympic marathon was in 1984 and first 10 000 metres was in 1988. The other important factor has been the fashion for thinness, which really began in the 1970s. These two changes in female behaviour are the main factors responsible for the development of this syndrome.

In the early 1980s it was thought that training intensity was the main underlying aetiological factor, but studies in the late 1980s indicate that a high proportion of these athletes also have disordered eating habits. It was also thought that the bone density of amenorrhoeic athletes would be normal, as the high levels of exercise would compensate for the low levels of oestrogen. However, studies from 1984 onwards have shown that amenorrhoeic athletes have low bone density. This female athlete triad therefore consists of disordered eating, amenorrhoea, and osteoporosis.

Incidence and aetiology

The female athlete triad is associated with endurance sports. The incidence of amenorrhoea varies in different sports and is a reflection of the requirements for that particular activity, in terms of training intensity, calorie restriction, and age group (Fig. 1).

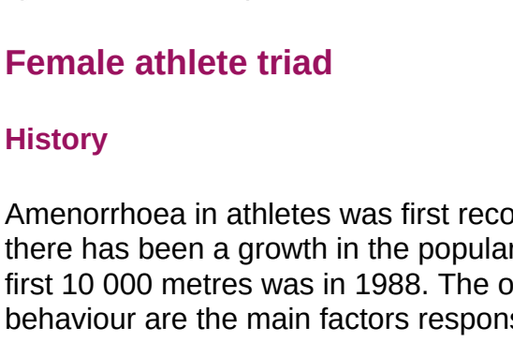

Fig. 1 The incidence of amenorrhoea amongst élite athletes in different sports. (Data taken from Wolman RL, Harries MG (1989). *Clinical Sports Medicine* **1**, 95–100, with permission.)

Training intensity can be difficult to quantify in certain sports, but in runners it is relatively easy as the number of miles run per week provides an accurate estimate. Some work has shown that the incidence of amenorrhoea increases as weekly training mileage increases, with an incidence of about 50 per cent in those running more than 80 miles per week.

Disordered eating is commonly seen in female athletes and may occur in over 60 per cent of competitors in sports such as gymnastics. In many cases this is the result of constant pressure from coaches, and sometimes parents, to maintain a prescribed body weight and appearance. In some of these cases the eventual outcome may

be an overt eating disorder and anorexia nervosa. The two most relevant nutritional deficiencies are of calories and calcium.

The importance of calorie restriction is seen in rowers, where the incidence of amenorrhoea is significantly higher amongst lightweights (who have to be below 59 kg in order to compete) than their heavyweight counterparts. Both groups have similar training regimes, but the lightweights frequently consume restricted diets in order to 'make the weight' for competition. Furthermore, nutritional studies on runners show that those with amenorrhoea have a lower daily calorie intake than their eumenorrhoeic counterparts.

Age is also important, with athletes in their late teens being more vulnerable to menstrual irregularity than those in their twenties. In activities such as gymnastics and ballet, where there are many teenage performers, there is a high incidence of amenorrhoea, both primary and secondary.

Pathophysiology

Endurance training is associated with menstrual dysfunction. At relatively low levels of training a shortened luteal phase may occur, which can be associated with reduced progesterone levels and anovulatory cycles. These abnormalities become more frequent as training intensity increases and eventually cycles may become irregular (oligomenorrhoea) or absent (amenorrhoea). In those sports where training starts before puberty there is often a delay in the menarche. Typically this is seen in gymnasts and ballerinas where, on average, the menarche is delayed by 1 year. However, primary amenorrhoea may result, and in some cases the athlete may be in their twenties before menstruation begins.

There are many similarities between the female athlete triad and anorexia nervosa, and many believe that these are part of the same spectrum of ill health. The psychological profiling of patients with both disorders is very similar. Furthermore, in both there is disordered eating, energy imbalance, and low body weight. The aetiology of the amenorrhoea is also similar, with slowing of the gonadotrophin-releasing hormone (**GnRH**) pulse generator in terms of both amplitude and frequency, leading to a reversible hypogonadotrophic hypogonadism with severe impairment of oestrogen production, which seems to be a reversion to the prepubertal pattern of gonadotrophin release.

Over the last 15 years or so, attention has been directed towards exploring the factors responsible for the suppression of the GnRH pulse generator. There are several hypotheses, including endorphin release, central 'stress', and energy deprivation, in each of which hormones are released that may influence hypothalamic function, including cortisol, insulin-like growth-factor binding protein-1 (**IGFBP-1**) and leptin (aside from endorphin). The inhibitory action of opioids on the GnRH pulse generator is now well established. However, although endorphin levels increase with acute aerobic training (which may account for the so-called 'runners high'), there is much less evidence that they remain elevated with regular exercise, hence endorphin release alone is unlikely to account for the gonadal suppression seen in athletes.

Serum cortisol levels are elevated in amenorrhoeic athletes compared to their eumenorrhoeic counterparts. This represents central 'stress' and occurs as a result of the central activation of corticotrophin-releasing hormone (**CRH**). CRH increases GnRH sensitivity to opioid inhibition, and therefore in combination with endorphin release provides a possible mechanism for amenorrhoea. The raised cortisol level may also adversely affect bone density (see below).

An alternative hypothesis is that amenorrhoea occurs as a result of energy deprivation (Fig. 2). Several independent studies have demonstrated that the energy (calorie) intake of amenorrhoeic athletes is significantly lower than their eumenorrhoeic counterparts, even when matched for exercise intensity. This produces a relative energy imbalance, that is to say a low-energy intake in the diet compared to a high-energy output in the form of exercise, which results in weight loss. Amenorrhoeic athletes, like those with anorexia nervosa, have a low body mass index (usually below 18) and low body fat (usually below 17 per cent). Furthermore, they have a lower resting metabolic rate and reduced levels of insulin, insulin-like growth factor-1 (**IGF-1**), and tri-iodothyronine. These changes are seen in situations of energy deprivation, but it is uncertain whether any of these three hormones act as a metabolic signal influencing the release of GnRH.

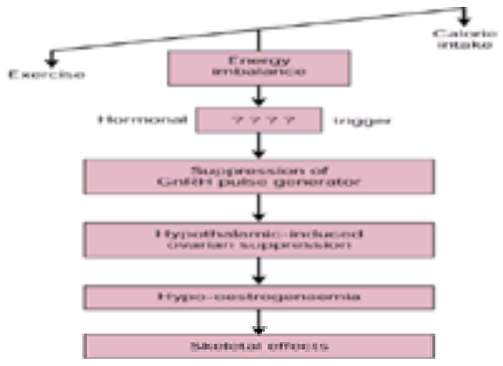

Fig. 2 Energy deprivation hypothesis for the female athlete triad.

Two other possible candidates are IGFBP-1 and leptin. The level of IGFBP-1 is directly suppressed by insulin, and in amenorrhoeic athletes this is elevated. Serum leptin levels are related to body fat and are reduced in anorexia nervosa and probably in the female athlete triad. Further work is needed to determine whether either of these hormones have a direct effect on the GnRH pulse generator.

Skeletal effects

Bone density

The bone density of amenorrhoeic athletes is reduced. This is seen most obviously in the spine where there is a high proportion of trabecular bone, but other sites such as the proximal femur and wrist may also be affected. The fall in bone density is predominantly due to low oestrogen levels, but other factors may be important since bone density does not always improve when oestrogen replacement is given (see below). Levels of IGF-1, which has important anabolic effects on the skeleton, are reduced, whilst those of cortisol, which has a catabolic action, are elevated in the female athlete triad: either of these hormonal changes could enhance the fall in bone density.

The type of exercise undertaken modifies the fall in bone density. For example, amenorrhoeic rowers have a higher spinal bone density than amenorrhoeic runners, presumably due to intense exercise involving the trunk. Amenorrhoeic gymnasts have higher spinal and femoral neck bone density than amenorrhoeic runners, probably due to weight training and jumping activity involved in gymnastic training.

With short episodes of amenorrhoea (6 to 12 months) the fall in bone density is reversible once normal menstruation is restored. With longer episodes, however, the changes may become irreversible and bone density remains persistently low. Occasionally the bone loss is severe, leading to bone densities similar to those seen in postmenopausal women, and in this subgroup there is a significant risk of osteoporotic fracture. More commonly, bone density reduction is less extreme and the risk is of premature osteoporosis (10 to 15 years early).

Other skeletal effects

Stress fractures occur more frequently in amenorrhoeic athletes, which may be related to low bone density. Stress injuries to bone commonly occur in athletes: these are usually repaired, preventing the development of a full stress fracture. The repair mechanism may be less effective in those with amenorrhoea who have low levels of oestrogen and IGF-1, both of which are important in maintaining skeletal integrity.

Athletes with delayed menarche and primary amenorrhoea may have delayed skeletal maturation, including delayed epiphyseal closure that may increase the risk of

epiphyseal injury.

Investigation and management

It is important to exclude other causes of amenorrhoea. This will include taking an accurate history to establish a relationship between training and menstrual abnormalities. Investigations should aim to exclude other causes of amenorrhoea (see Chapter 12.2 and Chapter 12.8.1) and the serum tri-iodothyronine level should be measured, which is likely to be low in the female athlete triad. A nutritional screen is helpful to assess calorie and calcium intake, and bone density should be measured (Table 1).

Once the diagnosis is established the most effective treatment is to re-establish natural menstruation (Table 2). This can be achieved with a combination of reducing training intensity (with the help of the coach) and increasing calorie intake (with the aid of a dietitian). It is very important to educate the athlete about both the short- and long-term risks of remaining amenorrhoeic, otherwise many athletes will not accept this type of intervention. Psychological intervention may be necessary in those athletes where an eating disorder is apparent (see Chapter 26.5.5).

In those athletes who remain amenorrhoeic despite attempts at adjusting their training and diet, oestrogen replacement (either the oral contraceptive or hormone-replacement therapy) should be given. Unfortunately some athletes may have difficulty tolerating this. Furthermore, anecdotal experience suggests that this is not always effective, probably for the reasons given above. Calcium supplements should be considered, especially in those with low intakes, and vitamin D supplements may also be helpful. Experience with bisphosphonates and raloxifene in this age group is too limited to offer clear advice.

Progress should be monitored with bone densitometry. In those who remain amenorrhoeic either the progressive fall in bone density or recurrent injuries will eventually force them to make lifestyle adjustments in terms of training and nutrition. By then it may be too late, hence emphasis needs to be placed on education and counselling at an early stage.

Overtraining syndrome

Introduction

This condition and its associated symptoms are well recognized in the athletic population, but the pathophysiology is poorly understood. It tends to occur in athletes doing high-intensity endurance training and is rarely seen in those who partake in strength and power sports. The most common presentation is with underperformance, for example a worsening of the times for the athletes' favoured events. Often the initial response is to assume that the training is inadequate and therefore to increase the intensity even more. This will perpetuate the problem, eventually forcing the athlete to seek medical advice.

Aetiology

Athletes must train hard to improve their performance. This can lead to transient fatigue and underperformance, hence intensive training should be followed by a period of relative rest to allow regeneration and recovery. This cyclical method of training is called 'periodization' and produces adaptation, allowing progressive increases in training intensity and performance. During the period of intense training, known as 'overreaching', it is common for the athlete to complain of muscle soreness, fatigue, and stress-related symptoms. As part of the stress response serum cortisol may rise, whilst testosterone may decrease, and creatine phosphokinase may be elevated as a reflection of transient muscle damage. These clinical and biochemical features should recover during the rest period. Overreaching is a necessary part of training if the athlete's performance is going to improve.

In some situations the athlete may not allow sufficient time for rest in between periods of heavy training. This leads to under-recovery and prevents full adaptation to increased training loads. This may occur when there is a rapid increase in training intensity, with very prolonged training, and at times of stressful competition. It may also occur when the athlete is exposed to other stresses, including intercurrent infection, travel across several time zones, or other unrelated psychoemotional stresses. In the adolescent athlete it may be seen during a rapid growth spurt. This combination of stresses may lead to underperformance, which will usually respond to a rest period of 2 weeks, but if the athlete fails to recognize the early signs the symptoms become more severe and may require a more prolonged rest period to achieve full recovery.

Pathophysiology

Over the last 15 years or so there have been many studies investigating the pathophysiology of the overtraining syndrome, and these have generated several hypotheses. Unfortunately studies are not always directly comparable because they use different definitions for the syndrome and may perform their evaluations at different stages in its evolution.

Neuroendocrinological features

There are effects on the hypothalamic–pituitary–adrenal axis. In some overtrained athletes there is a rise in salivary cortisol levels and a low testosterone:cortisol ratio. This reflects a rise in free-cortisol levels, which correlates with the depressed mood state seen in some athletes. There is a decreased pituitary ACTH response to insulin-induced hypoglycaemia, and reduced adrenal responsiveness to ACTH. The latter effect leads to a compensatory elevation of ACTH in the early stages of the overtraining syndrome, but in an advanced stage both ACTH release and the cortisol response may be reduced. There is also evidence of sympathetic involvement, with increased resting noradrenaline (norepinephrine) levels associated with decreased nocturnal excretion.

Central fatigue and the branched-chain amino acids

Prolonged endurance exercise leads to a depletion of glycogen stores in muscles and the liver, at which point muscle requires alternative sources of energy. Mobilization of fatty acids provide this, producing increased levels in plasma, where they are bound to albumin. The branched-chain amino acids (valine, leucine, and isoleucine) are another alternative fuel for muscle, with an increased rate of oxidation during exercise. In plasma, fatty acids compete with tryptophan for binding to albumin, hence an increase of bound fatty acids leads to an increase in plasma levels of free tryptophan. Tryptophan and the branched-chain amino acids pass the blood–brain barrier in competition for the same amino acid carrier, an increase in free plasma tryptophan and a decrease in branched-chain amino acids favouring the entry of free tryptophan into the brain. Tryptophan is converted to the neurotransmitter 5-hydroxytryptamine (5-HT, serotonin) in the brain, which plays a role in the induction of sleep and fatigue and has an inhibitory effect on the hypothalamus. This hypothesis might therefore explain some of the effects that are seen in the overtraining syndrome, but human overtraining studies, including interventions with glycogen and with branched-chain amino acids, have so far been inconclusive.

Glutamine and the immune system

The relationship between exercise and the immune system remains controversial. The leucocytosis of exercise is well recognized, and there is also evidence of impaired neutrophil function following intensive exercise, which may explain why upper respiratory tract infections are probably more common following a marathon. They also seem to be more frequent in the overtraining syndrome, although it is uncertain whether this is cause or effect.

Glutamine metabolism provides one possible explanation for the relationship between immune function and exercise. Glutamine is a free amino acid that is utilized at high rates by rapidly dividing cells such as leucocytes, and therefore considered important for normal immune function. Plasma levels fall with intensive exercise, possibly due to the increased glutamine requirement for gluconeogenesis and increased uptake by the liver, gut, and kidney. There is evidence that glutamine supplements may reduce the risk of infection in endurance athletes and also that plasma glutamine levels can act as a marker of the overtraining syndrome, but more research is needed in this area.

Clinical features

The overtraining syndrome is characterized by performance deterioration refractory to normal regeneration strategies. Variable combinations of symptoms are seen in association with this (Table 3). The athlete will commonly complain of fatigue and heaviness in the muscles, which they tend to ignore in the early stages. Sleep disturbance is common with difficulty getting off to sleep, early waking, and feeling unrefreshed on waking. They may complain of depression, anxiety, and irritability,

with loss of appetite and of libido. There may also be a history of upper respiratory tract infections.

The resting heart rate may be elevated, but this gradually returns to normal (usually very low in an élite endurance athlete) as recovery occurs. Physiological testing may show an increased heart rate response to exercise, a reduced maximum oxygen consumption ($\dot{V}O_2$**max**), and an impaired heart rate recovery following exercise. Maximum power output may also be reduced.

Blood tests show non-specific changes consistent with heavy training such as dilutional anaemia and raised muscle enzymes (in some cases the creatine phosphokinase level may be increased several thousand times). There may be evidence of a recent viral illness such as a positive Paul Bunnell test. It is also important to recognize that underperformance may be secondary to an underlying medical disorder such as anaemia, diabetes, or thyroid disease: these secondary causes are rare, but should always be considered.

Management

Prevention

As our understanding of this syndrome improves it may be possible to prevent it from occurring. This is not possible at present, because although it is related to prolonged intensive exercise, the ability to withstand the stress of training varies significantly between different athletes. Furthermore, there is currently no screening test that can reliably predict the onset of the syndrome. Resting heart rate can provide a guide: this is consistently low (within a couple of beats) in the healthy endurance athlete, but with overreaching and overtraining this may increase significantly (by 5–10 beats/min) and only returns to the previous low level when recovery occurs. Psychological assessment can also provide a guide, with the **POMS** (Profile of Mood State) questionnaire proving to be useful in this respect.

It is important to incorporate rest days into any training regime. Racehorses can develop a syndrome similar in many respects to the human overtraining syndrome, and in one study where they were given an alternate-day regime of hard training day/easy training day the frequency of the equine equivalent of the overtraining syndrome decreased and performance improved. There have now been several human studies where rest days have been incorporated into the training regime (for example, four heavy training days, two light training days, and one rest day per week): these seem to be associated with a reduction in the frequency of the syndrome.

It is also important to ensure that dietary intake is sufficient at times of intensive training, especially in terms of carbohydrate and hydration. It is surprising how many athletes are unaware of the nutritional components of diet and have an intake that is inadequate for the intensity of their training.

Treatment of the established syndrome

As many of the symptoms of this syndrome are non-specific, it is important to exclude other causes of underperformance and fatigue, including infection, thyroid disease, diabetes, and anaemia. In most cases tests for these disorders will be negative.

The treatment of the established syndrome requires rest to allow regeneration and recovery. Most athletes will only accept absolute rest for a few days, hence it is important to follow this up with a period of relative rest, that is allowing very low intensity training. The exercise can then be slowly progressed, but it may take up to 12 weeks to achieve full recovery. Many athletes are pleasantly surprised about how well they have maintained their performance despite 12 weeks of light training.

In addition to relative rest, it is important to adopt a holistic approach to treatment. This includes assessing other coexistent stresses and making use of relaxation techniques. Nutrition is important and further advice on this should be offered as appropriate. Athletes should monitor their progress by measuring their resting heart rate, which will decrease as recovery occurs.

Medical complications in sport

Although injuries are the dominant feature of sports medicine, there are several well-recognized medical disorders that occur as a result of sport and physical activity. Some are associated with acute bouts of exercise and others with more prolonged periods of training. The female athlete triad is discussed above, and sudden cardiac death and exercise-induced asthma are dealt with elsewhere.

Delayed-onset muscle soreness, rhabdomyolysis, and heat stroke

Strenuous exercise can produce transient damage to the muscle. Delayed-onset muscle soreness can occur several hours after a bout of unaccustomed, intensive eccentric exercise, reaching a peak between 1 and 3 days. It is associated with objective muscle weakness, which can last for up to 10 days. There are increased serum levels of creatine kinase and myoglobin, with muscle oedema and structural change revealed on magnetic resonance imaging (**MRI**) (*T*2-weighted sequences) and muscle biopsy, respectively. These findings are most obvious after 2 to 3 days. The structural damage fully repairs and the symptoms and laboratory abnormalities resolve by 10 days. This phenomenon is commonly seen following marathon running, when creatine kinase levels may rise to over 2000 IU/l (Fig. 3).

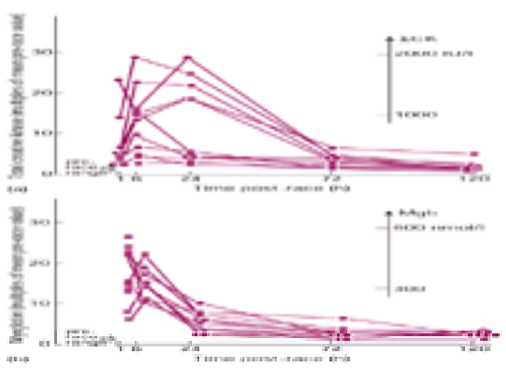

Fig. 3 Changes in (a) serum total creatine kinase (CK) and (b) plasma myoglobin in young men who had completed a marathon (running times: mean, 194 min; range, 163–280 min). (Taken from Young, *et al*. (1984). *European Journal of Clinical Investigation* **14**, 2, 58, with permission.)

There is less muscle damage when a bout of similar intensive eccentric exercise is repeated. This is known as the 'repeated bout effect' and is probably due to a series of adaptations taking place at neural, connective tissue, and cellular levels. These changes make the muscle more resistant to damage with further bouts of intensive exercise.

It is rare for large amounts of myoglobin to be released from muscle during exercise ('exertional rhabdomyolysis'), but when it does occur it can be life-threatening by causing acute renal failure, often with severe hyperkalaemia (see Chapter 20.4). This is associated with intensive eccentric exercise, dehydration, and hyperthermia and forms part of the syndrome of heat stroke.

There is high heat production with exercise: 75 per cent of the energy expended is converted to heat during running. Heat dissipation therefore becomes extremely important, with evaporation through sweating being the most important mechanism, and anything that impairs sweat evaporation will put the athlete at risk of hyperthermia and heat stroke. This can occur in extreme environmental conditions such as high temperature and high humidity, and is more likely when the athlete is dehydrated. A poorly prepared athlete lacking fitness, who is inadequately acclimatized to the heat, has had a recent illness (for example, a cold or gastroenteritis), or wears excessive clothing is more at risk. Nowadays heat stroke is more commonly seen in fun runs than in marathons, when there are often a large number of poorly prepared participants. Furthermore, it can occur when the environmental conditions are not particularly extreme, suggesting that heat production during exercise is the most important factor.

The pathophysiology, clinical features, and management of heat stroke is dealt with elsewhere (Chapter 8.5.1). As patients with heat stroke require immediate treatment, on-site resuscitation facilities should be available at competitions and fun runs. Management includes the use of intravenous therapy and increasing heat loss through evaporation (the patient should be put in the shade and then wetted with lukewarm water and fanned). It is possible to minimize the risk of developing exertional heat stroke by paying attention to certain recommendations (Table 4).

Exercise-induced gastrointestinal symptoms

Up to 50 per cent of long-distance runners will complain of gastrointestinal (**GI**) symptoms. These include reflux/heartburn, intestinal cramps, the urge to defecate, and diarrhoea, which may be bloody. The lower GI symptoms are probably due to reduced blood flow (splanchnic blood flow decreases by up to 80 per cent with intensive endurance activity) and possibly mechanical (jarring) stress on the gut (as symptoms are more common in runners than cyclists). The relative gut ischaemia may lead to the release of several GI hormones, including secretin, glucagon, and vasoactive intestinal polypeptide: the latter can remain elevated for up to 2 h after the termination of exercise. These hormones will increase secretion into the gut while also reducing absorption, effects that are enhanced by dehydration.

Exercise-induced GI symptoms can usually be controlled with appropriate advice and tend to decrease with adequate training. Adaptive changes occur with gradual increases in training volume and intensity, such that there may be an improvement in blood flow through the splanchnic circulation. It is also important for athletes to be adequately hydrated both before and during exercise: they should therefore take account of the ambient temperature and humidity and adapt their fluid intake accordingly. Hypertonic drinks should be avoided as they will tend to increase the risk of dehydration.

Exercise-related anaemia

Haemoglobin concentrations in highly trained endurance athletes are often at the lower end of the normal range or even just below it. In most cases this reflects a dilutional state where, although red cell mass increases with exercise, there is a proportionally greater increase in plasma volume. A true runners' anaemia may be caused by faecal blood loss (see above), also from intravascular haemolysis caused by high foot-impact forces ('march haemoglobinuria'). A similar traumatic haemoglobinuria also occurs in conga-drum players due to high impact on the hands.

Fitness to exercise

Sudden death in sport

Although it often attracts headlines in the press, sudden death in sport is very rare. The frequency of sudden death varies from about 0.5 per 100 000 to 6 per 100 000 per year, depending on the age group being assessed, the level of underlying fitness, and the intensity of activity. Fatal arrhythmia seems to be the most common mechanism of death (Table 5). Atherosclerotic coronary artery disease is the most common cause in those over 40 years of age: in younger athletes underlying causes include cardiomyopathy, valvular heart disease, and Marfan's syndrome.

Myocarditis (see Chapter 15.8.1) is another possible cause of sudden death in sport. This is usually viral in origin, in particular cocksackie B virus, but a series of sudden death cases amongst Swedish orienteers was found to be associated with *Chlamydia pneumoniae* myocarditis. Cardiac concussion is a rare cause of sudden death, thought to be due to a dysrhythmia resulting from a non-penetrating precordial blow from a projectile, such as a cricket ball or an ice hockey puck.

Screening

Although it is accepted that people with certain cardiac risk factors, such as those with hypertrophic cardiomyopathy or aortic stenosis, should avoid competitive sports, there is limited value in cardiac screening of athletes. This is because of the rarity of these abnormalities, the rarity of sudden death, and the cost of screening. It is estimated that 200 000 athletes would have to be screened to find one at-risk case. There is also limited predictive accuracy of some of the cardiac investigations. This is the case with electrocardiography (**ECG**), where it may be difficult to distinguish the physiological changes of the athletes' heart with the pathological changes seen with hypertrophic cardiomyopathy. Further cardiac investigation should probably be restricted to those with a history of cardiac and/or exercise-related symptoms, a relevant family history, or abnormalities found on cardiac auscultation.

Prevention of sudden death in sport

Athletes with confirmed myocarditis should be withdrawn from competitive sports for at least 6 months, while those with more general viral illness should abstain from sport until they have recovered.

Sudden death is most likely to occur in high-intensity competitive sports (for instance, squash), and in this situation the athlete should be offered a basic medical assessment (personal and family history and physical examination) prior to competition. The need for a medical assessment is less important in those participating in recreational sports. Although acute bouts of exercise increase the risk of cardiac death, this transient increase in risk is outweighed by the cardiac benefits of habitual exercise. The importance of graded increases in exercise intensity, allowing cardiac and musculoskeletal adaptations to occur, should be stressed.

Overuse injuries

Overuse injuries are the most common type of injury seen in a sports medicine clinic. It is usually relatively straightforward to make the diagnosis from the history and examination. However, it is equally important to determine the aetiological factors responsible for the injury to prevent a recurrence. These can be divided into training methods, equipment, and biomechanical factors (see Table 6).

Injuries can occur when the training is increased too quickly, when there is an inadequate warm-up or cool-down period, and when there is inadequate flexibility training to complement the overall programme. Injuries can also occur when the athlete suddenly changes from one surface or gradient to another. Equipment factors are also important, which is especially the case for footwear in weight-bearing sport, where it is vital that the shoes provide adequate support for the sport being undertaken and are not overly worn out. In racket sports the size, weight, and string tension of the racket are important factors that may influence the risk of injury.

It is important to consider biomechanical factors in athletes as the repetitive nature of their activities (for example, running action, tennis serve, or cricket bowling) may magnify any minor malalignment. It is therefore necessary to assess for various factors, including leg-length difference, wide pelvis, pelvic tilt, femoral neck anteversion, and tibia varum. The shape of the foot on standing should also be considered, as both overpronated and rigid, high-arched feet can cause problems. Variations in anatomy of the bones may also increase the risk of injury, such as the hooked acromium and rotator cuff impingement in throwers and the os trigonum and posterior ankle impingement in dancers and footballers.

The type of injury will depend on the age of the athlete as this determines the weakest point in the musculoskeletal chain. In the growing adolescent the point of attachment of the tendon to bone is vulnerable, and injuries such as Osgood–Schlatter's disease at the tibial tubercle and Severs disease at the calcaneus are commonly seen. In the young adult tendinitis and injuries at the musculotendinous junction are particularly common, while in the elderly athlete degenerative injuries of the tendon and joint are seen.

Stress (or fatigue) fractures occur as a result of bone overload. They occur when training is increased too quickly, as in rapid preparation for a marathon, or when there are biomechanical factors that increase the stress load on bone, for example rigid, high-arched feet. They also occur more commonly in amenorrhoeic athletes than in their eumenorrhoeic counterparts. Clinically the athlete usually has point tenderness. A bone scan or MRI will allow an accurate diagnosis to be made, although the plain radiograph may be negative.

Drugs and ergogenic aids in sport

Introduction

The use of drugs and nutritional supplements in competitive sports is widespread. The main reason for this is to enhance performance, but supplements are also

taken to improve general health and to increase resistance to infection. In theory, this would reduce the risk of developing coincidental medical problems and hence minimize interruptions to training. The scientific evidence for many of these substances is flimsy, but athletes are often prepared to try them on the basis of the anecdotal experience of fellow athletes, advice from their coach, or even from suppliers at the local gym. Furthermore, surveys suggest that athletes are willing to take substances for short-term performance enhancement, even if it puts their long-term health at risk. The banning of some substances has had an effect on some athletes, but others continue to take them and are prepared go to extremes to avoid detection.

With most performance-enhancing drugs there is a large interindividual response, but the cause for this is not fully understood. Studies on most drugs and nutritional supplements have therefore been unable to demonstrate consistent efficacy. There is a large potential placebo effect, which may obscure any pharmacological action. Large randomized controlled trials would be helpful, but these are virtually impossible to do because most athletes would be unwilling to accept a placebo. Furthermore, if there is any possibility of the drug enhancing performance it is likely already to have been banned by the sports governing body. Studies on the non-athletic population, who exercise at much lower levels, may not be representative of the effects seen in athletes. Moreover, athletes often take a variety of substances in extremely large doses, which makes it difficult to compare the results with the lower doses given in the general population in terms of efficacy and (especially) safety.

Anabolic agents

Anabolic–androgenic steroids

Testosterone, first synthesized in the 1930s, has both anabolic and androgenic effects. Since then several synthetic derivatives have been produced in an attempt to provide a steroid with predominant anabolic actions. The first recorded use of anabolic–androgenic steroids (**AAS**) was during the Second World War when they were given to German troops to increase their aggressiveness. In 1952 the Russian weightlifting team was suspected of taking them when they won three gold medals at the Helsinki Olympic Games. This increased the interest in these drugs, and by 1958 a United States pharmaceutical company had developed AAS. The dangers gradually became apparent, but it was not until 1975 that the International Olympic Committee banned their use.

AAS enhance muscle strength and power but have no effect on aerobic performance. They are also thought to have psychological effects and can promote aggressiveness, which in its most extreme form may lead to 'roid rage'. Athletes may also experience euphoria and reduced fatigue while taking AAS, a combination of effects that may allow them to train harder and for longer.

Although AAS will increase muscle strength in non-exercising people, the greatest increases in strength occur when AAS are taken in conjunction with resistance exercise (Fig. 4). The reason for this may be that physiological stress occurs with intense resistance exercise and leads to increased levels of glucocorticoids, thereby producing a catabolic state with a negative nitrogen balance that anabolic steroids can reverse.

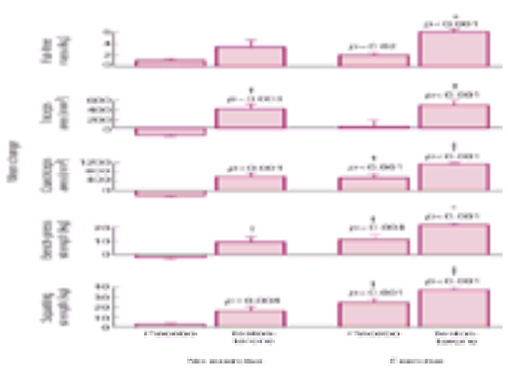

Fig. 4 A randomized trial of exercise and supraphysiological doses of testosterone in men over a 10-week period. Changes from baseline in mean (± SE) fat-free mass, triceps, and quadriceps cross-sectional areas, and muscle strength in the bench-press and squatting exercises. Note the greatest effect is obtained with a combination of exercise and testosterone.

Human growth hormone

The physiological effects of human growth hormone (**HGH**) include nitrogen retention, increased protein synthesis and tissue growth, and an increase in fat-free mass. Recombinant HGH was first produced in 1984 and (although expensive) its use by athletes has since increased.

The anabolic effects of HGH make it potentially valuable as an ergogenic aid for athletes participating in power sports. Furthermore, as it is not detected by most drug-test screenings performed by sports governing bodies, it is an attractive option when compared to anabolic steroids. However, so far there has been only limited research to determine its effectiveness in increasing muscle strength and power.

b_2-Agonists

This group of drugs was initially banned by the sporting bodies because of their stimulant action. However, in the last few years they have gained interest as muscle strengthening agents when taken orally. During the 1992 Barcelona Olympics, two American power athletes were found to have taken clenbuterol.

Animal studies show that clenbuterol can produce muscle hypertrophy. Studies of b_2-agonists in healthy men, in patients following lower limb surgery, and those with spinal cord injury, all showed gains in muscle strength following an exercise programme when compared to a placebo group. However, there is very little data on their effect in highly trained athletes. Although they act as bronchodilators, there is no evidence that they can improve aerobic fitness in non-asthmatics.

Creatine

Creatine was first recognized as an ergogenic aid in the early 1990s and was used by athletes in the 1992 Barcelona Olympics. It is an amino acid present in meat, normal daily intake being less than 1 g. The highest concentration of creatine is in skeletal muscle, in particular in type-II muscle fibres, where most is in the form of creatine phosphate, providing a source of energy and assisting in the restoration of ATP following exercise. Creatine phosphate may also assist in buffering when the pH falls due to lactic acid accumulation during exercise.

Supplements are usually taken in high dosage for a limited period (for example, 25 g for 6 days), following which muscle concentrations of free creatine and creatine phosphate remain elevated for several weeks. It is generally pointless to take high-dose supplementation beyond this period as the majority of muscle creatine uptake occurs during the first few days, but some athletes take a maintenance dose of 2 g/day.

Following this regime many athletes report that they are able to increase their training loads, and studies suggest that supplementation does improve high-intensity performance, especially when repeated exercise bouts are carried out (for example, repetitive sprinting and cycling). The ergogenic effects also extend to strength and power events such as weightlifting. No effect is seen in predominantly aerobic events.

Overall, there is only limited information on the effects of creatine supplementation, but these are consistent with the role of creatine phosphate in enhancing the restoration of ATP. The increase in muscle strength possibly occurs by allowing greater training intensity, leading to an enhanced training response. Within a few days of taking creatine there is a weight gain of between 2 and 5 kg: a large proportion of which can be accounted for by an increase in intracellular fluid volume (it is well known that urine volume decreases during the period of supplementation), but there may also be an increase in fat-free mass.

There are theoretical concerns regarding the side-effects of using large doses of creatine for prolonged periods. These include adverse effects on the kidney,

although, so far, there have been no confirmed reports of this. There are also anecdotal reports of increases in muscle cramps and concerns regarding the impact of weight gain, especially in athletes competing in weight-category sports (for example, boxing and wrestling). In these sports the athlete often has to lose weight rapidly to 'make the weight' for competition, and if they have gained extra weight with the use of creatine they may have to severely dehydrate to achieve such weight reduction.

As supplementation with creatine seems capable of enhancing performance there are ethical issues regarding its use. Some feel it should be banned, others argue against this on the basis that it is a component of a normal meat diet and is therefore no different to taking carbohydrate supplements.

Stimulants

Amphetamines, ephedrine, and cocaine

These stimulate the central and sympathetic nervous systems. As sympathomimetic agents they increase heart rate, blood pressure, metabolic rate, and plasma levels of free fatty acids. These actions could theoretically enhance aerobic performance, but not without risk. There were at least two amphetamine-related deaths in cyclists in the early years of their use (one in the Rome Olympic Games in 1960 and the other in the 1968 Tour de France) and there have also been several deaths in athletes associated with the use of both ephedrine and cocaine.

Research on the use of amphetamines suggests that they have little direct physiological effect during exercise but that they can mask pain and fatigue during activity. This may allow athletes to exercise closer to their limit, which may produce a positive effect, especially on endurance performance. However, this could also have a detrimental effect on health by inhibiting the athlete's awareness of early warning signs (for example, injury or dehydration). The same may apply to ephedrine and cocaine. Ephedrine is also used by athletes to reduce fat and increase fat-free mass, but there is little evidence for this effect. Cocaine can produce euphoria and also lead to addiction, which has caused great concern regarding its use amongst athletes.

Caffeine

Caffeine, which is chemically related to the theophyllines, is metabolized in the liver to produce dimethylxanthine. When used prior to prolonged exercise (in a dose of 3–6 mg/kg body weight, 1 h before exercise) it can delay fatigue and enhance endurance performance, although there is significant individual variation. Although caffeine is known to have effects on the central nervous system, adipose tissue, and skeletal muscle, the mechanism by which it reduces fatiguability is unclear. It has several unwanted effects, including insomnia, headache, and gastrointestinal irritation, but its diuretic effect is of particular concern, especially in athletes competing in hot climates.

The International Olympic Committee considers caffeine to be a performance-enhancing drug. However, it would be impossible to have an outright ban on a substance that is present in so many foods and drinks, hence an athlete found to have a urine concentration of more than 12 mg/l is deemed to be guilty of a doping offence. This has its limitations as some athletes can obtain a performance-enhancing effect at urine concentrations well below this level.

Other agents

b-Blockers

By reducing heart rate this group of drugs reduces aerobic capacity and therefore decreases endurance. However, they are effective in skill sports, with studies confirming that shooters improve their performance when taking b-blockers. These drugs probably exert their effect by reducing hand tremor and heart rate: top-class shooters tend to shoot between one heartbeat and the next, and therefore a reduction in heart rate is helpful. They have also been shown to be effective in treating stage fright in musicians.

Diuretics

Athletes use diuretics when they need to lose weight rapidly. This occurs in sports such as boxing, judo, and light-weight rowing when the individual needs to make a particular weight classification for competition. Diuretics are very effective in producing short-term weight loss, in the order of 4 per cent over 24 h. However, this can lead to dehydration and electrolyte disturbance, both of which can affect performance. Frequently the athlete will have up to 20 h between the weigh-in and competition: this gives sufficient time to replace the fluid loss, but is insufficient to re-establish normal electrolyte balance, which can lead to medical complications during competition, including renal failure, severe hyperkalaemia, and rhabdomyolysis.

Erythropoietin and blood doping

A modest increase in red cell mass of up to 5 per cent occurs with adaptation to endurance training. This can take several months. However, some athletes artificially increase their red cell mass either by infusing previously stored red cells or by the use of erythropoietin. Infusing red cells has probably been used since the early 1970s in sports such as distance running, cycling, and cross-country skiing. In 1984 the United States men's cycling team confessed to using it during the Olympics, and won gold medals. Erythropoietin has probably been used by athletes since the late 1980s and may well have been responsible for a number of deaths seen in cyclists in the last 12 years.

Although homologous transfusions are used by athletes, autologous transfusion is probably more common. During this process several units of blood are removed from the athlete and then stored for several weeks, while the blood count is naturally restored to normal. The red cells are then reinfused, thereby increasing the red cell count, which will be sustained for a few weeks. The alternative method of increasing red cell mass is to administer erythropoietin, when the red cell count rises gradually over several weeks and remains elevated as long as the treatment continues.

Physiological studies confirm improved exercise performance with the use of these techniques to increase the blood count. Maximal aerobic power, submaximal endurance, and race performance have all been shown to improve. Blood doping may also provide a thermoregulatory advantage for those exercising in the heat, and some benefit for those exercising at altitude.

Medical risks include those associated with transfusions. Even autologous infusions can cause problems through clerical errors and mishandling of the stored blood product. Risks also occur in association with the high haematocrit, with blood viscosity rising exponentially as the haematocrit increases above 30 per cent thus leading to an increased risk of thromboembolic events. There have now been numerous deaths related to the use of blood doping by athletes.

Although blood doping is banned by all the main sports governing bodies there is no reliable test for detecting either autologous red cell infusion or erythropoietin administration. It is therefore difficult to prove that an athlete has used this technique and to provide a consistent deterrent.

Bicarbonate

A metabolic acidosis occurs with anaerobic exercise and is thought to be responsible for the progressive fatigue that occurs. By inducing a metabolic alkalosis prior to exercise, it may be possible to delay the onset of fatigue and improve exercise performance. Several studies have been undertaken to assess the effect of pre-exercise bicarbonate ingestion on performance. There are conflicting results from these studies, some showing a benefit, others not. The reason for these differences is probably due to variations in the duration and intensity of exercise, the dosage of bicarbonate, and the length of time between taking bicarbonate and the onset of exercise. Bicarbonate is most likely to have an effect with exercise of only a few minutes duration, when given 2 to 3 h before exercise, and at a dose of about 0.3 g of sodium bicarbonate per kg body weight. Side-effects of this ingestion include vomiting and diarrhoea, which may limit the potential benefits. Bicarbonate is not banned by the sports governing bodies.

29 Adolescent medicine

R. Viner

Introduction

Young people between 10 and 20 years of age comprise 12 to 15 per cent of the population in most developed countries, and are increasingly recognized as a distinct patient group requiring a special approach. Few diseases are unique to adolescence, but adolescents have a distinct epidemiology of disease and present a constellation of symptoms and problems not found in children or adults. Special communication skills are needed to take an accurate history and elicit clinical signs in young people. The effective treatment of illness in adolescence requires adept management of compliance, consent, and confidentiality, and relationships between the young person and their family.

The most serious health problems affecting young people are primary care issues, including teenage pregnancy, drug misuse, mental health problems, and violence. However, young people with acute or chronic medical conditions present management challenges to physicians—challenges that are mounting with the increasing incidence of chronic illness in adolescence.

What is adolescence?

Strictly speaking, adolescence is the period between childhood and adulthood. Theoretical definitions abound; Freud saw adolescence as the period of recapitulation of the childhood Oedipal complex, while Erickson claimed that the struggle between Identity and Role Confusion typified adolescence. The World Health Organization defines adolescence as between 10 and 20 years of age. However, chronological definitions take little account of the timing of the developmental changes at the heart of the concept of adolescence.

Some have suggested that adolescence is merely a socially constructed rite of passage. These claims ignore the biological changes of puberty and psychological developments driven by increasing maturation of the central nervous system. The most useful definition is that adolescence is a period of biopsychosocial maturation leading to functionally independent adult life.

Adolescent development

All clinical interactions with adolescents must be seen against a developmental background. The timing and tempo of the events of biological, psychological, and social development each proceed independently, although they are deeply intertwined (Table 1).

Biological changes

The biological changes of adolescence are puberty, the pubertal growth spurt, and accompanying maturational changes in other organ systems. These include maturation of enzyme systems (such as cytochrome P-450), accretion of peak bone mass, and the development of sexually dimorphic adult patterns in blood lipids, haemoglobin, and red cell indices. It is important for physicians to be able to identify the pubertal stage in adolescents, particularly in chronic illness. The defining event of puberty in girls is the menarche. The biological changes of adolescence are universal to all races, as are psychological changes driven by increasing brain myelination. However, most psychological and social development is culture-specific, varying with the social and cultural norms of childhood and adult roles in society.

Psychological development

Before adolescence, children think concretely, understanding only the immediate and short-term consequences of actions or events. Ideas and concepts can be manipulated only by using concrete representations. From the age of 12 years onwards, thought patterns begin to become formal operational or abstract, with the ability to manipulate ideas rather than things, imagine the future, and conceive multiple outcomes of actions. These capacities are important for the development of a settled personal and sexual identity.

Social development

The essential social tasks of adolescence are developing a sense of personal identity, moving from dependence to relative independence, and developing mature relationships with peers. Rather than achieving 'independence' from the family; adolescence involves renegotiating family relationships from a position of increasing adult equality. These challenges will exist across all cultures; however, the point at which successful completion is expected varies greatly.

Why is medicine different when dealing with adolescents?

Clinical medicine with adolescents is different because adolescents have special patterns of disease and special needs in the management of illness. Few diseases, aside from disorders of puberty, are specific to adolescence. However, the causes of mortality and morbidity in adolescents are distinct from both children and adults. Environmental and social causes of mortality (for example, accidents and suicide) account for a larger proportion of total adolescent mortality than at any other age (Fig. 1). Young people are one of the only groups in which overall mortality rates have fallen little during the past 40 years.

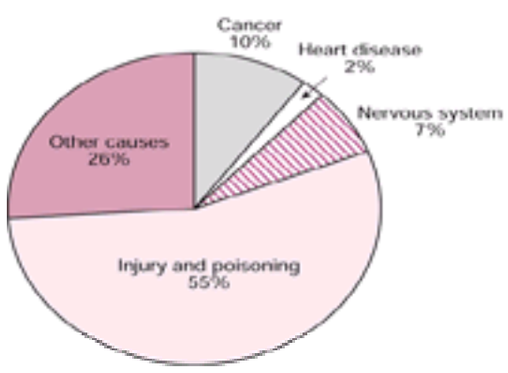

Fig. 1 Causes of death for 15- to 19-year-olds in the United Kingdom, 1997 (*Mortality statistics*, The Stationery Office. DH2, No. 23).

Common paediatric or adult diseases present with different patterns during adolescence. Type I diabetes has its peak age of incidence around 12 to 14 years. Puberty accelerates the progression of diabetic complications and the metabolic control of diabetes is poorer during adolescence than at any other age, due both to the growth-hormone excess of puberty and the psychosocial challenges of chronic illness management. Cancer during adolescence is remarkable for its combination of 'late' presentations of paediatric cancers, 'age-specific' cancers of adolescence (for example, bone tumours), and early-onset 'adult-type' carcinomas.

Medical challenges of adolescent development

The real challenges of medicine in adolescents come from the reciprocal impacts of adolescent development on disease management and quality of life. This is especially true in chronic conditions (Table 2) that may retard adolescent development, producing pubertal and growth delay, delayed social independence, poor body and sexual self-image, and educational and vocational failure. Physicians and paediatricians must monitor growth and pubertal development in chronic illness, until well into the early twenties.

Being chronically ill, having a visible disability, or being required to adhere to difficult treatment regimens is specially difficult during adolescence. Alienation from the peer group and absence from school cause social isolation, failure of socialization, and educational underachievement. The importance of helping young people with chronic illness or disability to develop independent adult living and vocational skills has been shown in longitudinal follow-up studies.

Conversely, developmental issues affect the management of illness. Poor adherence (compliance) and poor disease management are almost 'the rule' in adolescence. Immature abilities to imagine future consequences make the prevention of long-term complications of illness a poor motivator for compliance. Medical advice may be rejected as part of growing independence from parents, particularly in chronic paediatric illnesses where medical staff have become medical 'parents'. Adherence and disease control are also put at risk by the developmental need to explore possible modes of future behaviour, no matter how dangerous (derogatively referred to as 'adolescent risk-taking'). Risky behaviour such as smoking, alcohol, and recreational drug use are as common in adolescents with chronic illness or disability as in the general population.

The management of ill-health in adolescence

Most doctors have adolescent patients, but few are experienced or skilled in dealing with such patients. American studies suggest that only around one-third of physicians and paediatricians enjoy working with adolescents, and that another third have very little interest in caring for them. The effective clinical management of any disease in an adolescent requires a non-judgemental communication style, a knowledge of adolescent development, an awareness of consent and confidentiality issues, and an ethnographic approach that aims at understanding the health beliefs and situations in which the young person manages their disease.

Communication with young people

Neither the standard paediatric consultation (doctor communicates with parents) nor the standard adult consultation (doctor communications solely with patient) is appropriate for adolescents. It is best to see young people together with their parents, and also by themselves. While time consuming, this is essential for obtaining an accurate history, understanding their motivations and goals, and for getting accurate information about risky behaviour.

Frameworks have been developed for best practice with young people, the best known being **HEADSS** which reminds clinicians to cover the important domains of: home life; education; activities (friendships, social relationships, exercise); drugs; sexuality (intimate relationships, risky behaviour); and suicide (depression and self-harming). But having a framework is not enough; the key skills required for effective communication with young people are an understanding of adolescent development, empathy, respect and a non-judgemental attitude, understanding the link between physical and emotional well being, and provision of a physically and emotionally safe environment in which a clinical interaction can take place.

Table 3 summarizes these points.

Confidentiality and consent issues

Adolescents require from clinicians confidentiality, respect, and clinical excellence. Services that are not considered to be confidential are less likely to be used by young people. Confidentiality (including keeping confidentiality from parents) should be assured to young people, unless they are found to be at risk from suicide, sexual abuse, or they reveal plans to harm others.

Adolescents can fall into a no-man's land between parental rights over minors and adult rights. In most countries, including the United Kingdom, adolescents are now deemed to have adult rights to consent to treatment if they are legally competent, regardless of their parents' wishes. The legal criteria for competence differ between countries, but usually require the ability to give informed consent and understand the benefits and risks of treatment or non-treatment. In the United Kingdom, competence is presumed over the age of 18 years, while adolescents between 16 and 18 years can consent to treatment but cannot refuse life-saving treatment. Under 16 years of age, adolescents are presumed incompetent unless they demonstrate otherwise.

Adherence issues

There is little evidence that young people with chronic diseases are any less compliant to medical regimens than adults. Many struggle with the responsibility of organizing difficult regimens; others manipulate their regimen as part of their conflict with parents; and many adhere to a regimen of their own choosing—but one that may have little relationship to that prescribed. Practical measures to improve adherence to medical regimens are outlined in Table 4. The most important aspect is to 'decriminalize' non-adherence by recognizing that some non-adherence is universal, and to work with the adolescent to tailor the regimen to meet their health goals.

Transition

Adolescents with continuing health problems will require transfer from paediatric to adult services. Much more than just a clinic transfer, transition requires a change from the family-centred developmentally focused paediatric approach (which infantilizes the adolescent) to an adult medical culture that acknowledges patient autonomy and reproduction and employment issues but neglects growth, development, and family concerns.

Traditional methods of transfer of care by referral letter can lead to adolescents settling poorly into the new service or even dropping out of medical supervision altogether. This period is particularly dangerous for those diseases where adult services or skills are poorly developed, such as in 'paediatric' metabolic diseases or congenital heart disease. All paediatric specialist clinics should have transition policies and guidelines, especially where many adolescents are transferring. Preparation for transition should begin in early adolescence, and young people should only move to adult care when they have the necessary experience to survive independently in the adult service.

Drug, alcohol, sex, and health promotion

By 15 years of age, around 24 per cent of adolescents in Britain are regular smokers, 38 per cent will be regular alcohol consumers, and around 25 per cent are sexually active. Young people with chronic illness have similar rates of risk, although few physicians (especially paediatricians) address smoking, alcohol, or sex issues with young people with chronic conditions. Healthy behaviour begun in adolescence continues into adult life, and health promotion during early adolescence can discourage smoking, drug use, and unsafe sexual behaviour. Over 70 per cent of adolescents visit a doctor every year; each clinical interaction should provide an opportunity for health promotion.

Psychological issues of illness in adolescence

Epidemiological studies show that up to 20 per cent of adolescents may suffer mental health problems, most not being serious and frequently presenting with physical symptoms. Conversely, many young people with chronic medical conditions suffer adverse psychological sequelae, particularly depression and anxiety and adjustment disorders. During the developmental changes of adolescence, the psyche and soma are inextricably interrelated. Assessment and management of the reciprocal psychosocial impacts of adolescence and chronic illness (see Table 2) are a central part of medicine for adolescents. Severe or chronic illness in adolescence should be managed by multidisciplinary teams, including mental health, social, and youth workers and teachers as well as doctors and nurses.

Conclusions

Adolescent medicine demands that special attention be paid to communication, compliance, and risk behaviour, as the person develops. Greater skill in dealing with young people is required in all areas of the medical profession. These skills can be learned; evidence from randomized trials suggests that training in techniques for communicating with young people is effective and is valued by doctors and young people alike.

30.1 Medicine in old age

John Grimley Evans

Few, if any, diseases occur only in old age. The speciality of geriatric medicine is defined less in terms of the diseases it treats than in the range of responsibility it accepts. This responsibility embraces preventative care, health promotion, and diagnosis and treatment of acute illness followed by rehabilitation and resettlement of patients in the community. Some diseases are so much more common in later life that geriatricians will necessarily have more experience in managing them than will some other physicians. However, the great majority of what is to be found in a textbook of medicine will apply to older as well as to younger adults. Indeed it is an ethical duty of doctors to assume, in the absence of evidence to the contrary, that treatments that are effective for younger adults are at least as effective for those who are older.

Some aspects of medical practice need to take account of common age-associated changes in physiology. This chapter will briefly review some of these areas, but it begins with an outline of the background to medicine in later life provided by the universal processes of human ageing.

Ageing

Table 1 summarizes the sources of differences between young and old people. True ageing comprises those processes whereby differences arise because older people change from what they were when younger. However, not all differences between young and old people are due to ageing:

1. Selective survival leads to very old people showing genetic, sociobehavioural, and psychological differences from younger members of the same ethnic groups. Not surprisingly, differences include a lower prevalence of genes, social factors, and lifestyles associated with the risk of fatal diseases. Psychological variables with survival value include higher intelligence, better education, and a will for self-determination.
2. Cohort effects are prominent as causes of differences between young and old in changing societies. Apart from the effects of poverty and poor nutrition in early life, people born 70 years ago were raised and educated in a society very different from that of young people today. In longitudinal studies, where people are tested against their own former selves, declines in mental abilities appear less dramatic and later than in cross-sectional comparisons with younger individuals. Unfortunately most popular notions of the effects of ageing are based on uncritical acceptance of the findings of cross-sectional studies. Differences between young and old in psychological function partly reflect changes in educational emphasis, for example on computer skills rather than irregular Latin verbs. Also relevant, however, are changes in the cultural valuation of matters such as verbal abilities and good manners over the decades. Older people in England speak more slowly than the young not because they are slower witted but because 70 years ago it would have been considered ill-bred to talk as fast as is the custom nowadays. Another problem with cross-sectional studies is that they distort the pattern of ageing by blurring differences between individuals. Many individuals show preservation of mental function until the last year of life when abilities decline rapidly in what is sometimes termed the 'terminal drop'. With age the proportion of individuals who are in this phase will increase, so lowering the average performance of age groups. The true ageing pattern of a relatively constant level of performance followed by abrupt decline is therefore obscured by an appearance of continuous progressive decay.
3. Differential challenge. Since ageing is characterized by loss of adaptability it can only be accurately assessed by presenting individuals of different ages with similar challenges. In practice, society is organized so that older people may be faced with more severe challenges than are the young, and their poorer outcomes may then be attributed to ageing rather than inequity. This is particularly important in assessing the benefits potentially available to older people from medical interventions. There is abundant evidence from the United Kingdom and the United States that older people are on average provided with poorer quality health care than are younger adults. In the United States this is well documented for cancer treatment and in the United Kingdom for treatment of heart disease. In both countries the problem seems to arise from ageist prejudice among health workers at a local level in that its effects vary from district to district and hospital to hospital. Although less readily documented, there can be little doubt that ageism is as rife in primary as in secondary care. American studies have shown that primary care physicians spend less time with older patients than with younger ones even though the problems of the former are the more numerous, serious, and complex.

True ageing

Ageing, in the sense of senescence, is a progressive loss of adaptability of an individual organism as time passes. As we grow older the homoeostatic mechanisms on which survival depends become on average less sensitive, slower, less accurate, and less well sustained. Sooner or later we encounter a challenge from the internal or external environment to which we can no longer mount an effective response and we die. An increase in the risk of death with age is therefore the biological hallmark of senescence. In the human species death rates, which are high in the early years of life, fall to a nadir around the age of 12 to 13 at which point ageing first becomes manifest as rates turn upwards and continue through late adolescent perturbations due to violent and accidental deaths, to mount continuously and broadly exponentially throughout adult life (Fig. 1). The lowest point on the age-specific mortality curve which marks the onset of manifest senescence has been constant in England and Wales for over 100 years. It presumably therefore represents the point of maximum biological fitness. This is, in fact, to be expected since evolutionary pressure will lead to maximum fitness at the time of onset of reproductive capacity.

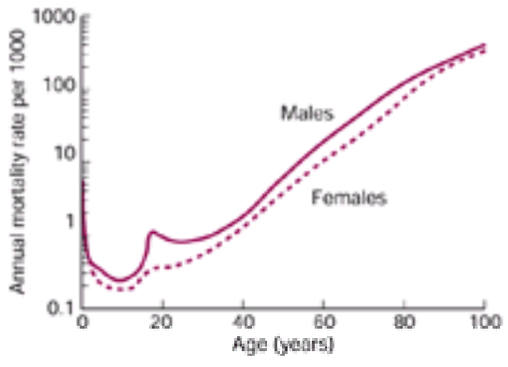

Fig. 1 Sex- and age-specific total mortality rates. England and Wales 1988.

As individuals, we age at different rates and with different patterns. Although average performance on measures of physical and psychological function may decline with age, interindividual variance increases and there will be many people in their eighties or beyond performing within a range normal for young adults. It is important to assess older people as individuals when making judgements about their function and capacity to benefit from medical interventions and not to assume that they are all average members of their age group.

Primary ageing

Primary ageing is the product of interactions between intrinsic, genetically determined, factors and extrinsic factors in lifestyle and environment. Some interactions are specific. A high dietary sodium intake will cause hypertension in genetically predisposed individuals, and excess dietary calories will lead to obesity and type 2 diabetes with its associated problems in people carrying the so-called 'thrifty genes' that allowed our intermittently starving ancestors to survive periods of famine by laying down body fat during the good times. Other interactions have more general effects: for example lack of exercise hastens the ageing of bone, muscle, and the cardiovascular system. Cigarette smoking impairs lung function, has anti-oestrogenic effects, brings forward the age of the menopause, and reduces bone density in addition to causing a variety of cancers.

Extrinsic factors in ageing are identified by epidemiological studies of people ageing under different conditions and by interventional studies of the effects of lifestyle or environmental modification. Epidemiological studies can be difficult to interpret because of clustering of lifestyle factors. Thus women who are health conscious enough to take hormone replacement therapy are more likely to be non-smokers, take regular exercise, have regular health checkups, and watch their weight and blood pressure. Statistical methods aimed, for example, at detecting a specific effect of hormone therapy on cardiovascular disease by 'adjusting' for the other factors are unreliable for ineluctable statistical reasons. Only a randomized placebo-controlled trial could settle this particular issue, but randomized trials of lifestyle modifications are rarely practicable.

The strongest evidence that extrinsic factors must be important comes from changes over time in the pattern of ageing. There have been dramatic improvements in the incidence of coronary heart disease and in some cancers over recent years. Conversely, there has in several countries been an increase in the age-specific incidence of fractures of the proximal femur. Overall, however, over the last 20 years older people in the United States have been living longer and also enjoying a falling prevalence of chronic disability. The presumption is that this is because of the adoption of healthier lifestyles including the use of preventative measures such as control of blood pressure, together with the rational and timely deployment of health interventions which reduce disability, such as hip replacement and coronary surgery. We have no idea whether similar changes are occurring in the United Kingdom or elsewhere, but the American evidence tells us that it could be made to happen.

Intrinsic ageing is due to cumulative damage to cells and their components which comes about because the body's systems of damage control are less than 100 per cent efficient. Damage control comprises processes of prevention, detection, repair, and replacement. Damage occurs from a variety of sources including heat, radiation, glycation (non-enzymatic crosslinking by sugar molecules of proteins, nuclear and mitochondrial DNA, and other biological polymers), and from free oxygen radicals generated in particular by mitochondrial metabolism.

Damage control is expensive in terms of energy. Although it might be biologically feasible to attain 100 per cent accuracy in damage control, organisms which achieved potential immortality in this way would still die from accident, predation, disease, famine, or warfare. They would therefore be at an evolutionary disadvantage in competition with organisms that devoted somewhat less of their resources to retarding ageing but were thereby able to maintain a higher average reproduction rate. Evolutionary pressure towards a longer lifespan will arise as environments become safer, when a slower reproduction rate can be more than compensated for by ensuring greater survival of offspring by strategies such as choice of breeding season or parental care. None the less, for any species in a specific ecological niche, investment of resources in damage control to retard ageing and prolong lifespan will always be at a level less than is necessary to abolish ageing. Thus, although maximum lifespan has increased enormously over the history of our species, we have not completely eliminated the accumulation of damage that manifests as ageing.

The fact that our lifespan has increased so rapidly, however, suggests that a fairly small number of genes may have an important effect. For the reasoning outlined above these genes are likely to be relevant to processes of damage control. Systematic comparisons of the genomes of centenarians with younger people are under way in the hope of identifying 'longevity assurance genes' whose mechanisms of action might be manipulable. Meanwhile, experimental attempts to slow intrinsic ageing are aimed at reducing the sources of damage, particularly from free oxygen radicals. Interventions under investigation include increasing the levels of free radical scavengers in cells, and reducing the production of radicals by limiting food intake and inessential mitochondrial metabolism.

Secondary ageing

Secondary ageing refers to adaptations to primary ageing changes. At the species level the female menopause is thought to be an adaptation to the age-associated increase in risk of maternal and infant death with age. In terms of getting genes into succeeding generations a woman in middle age will do better to give up increasingly dangerous and ineffective efforts to produce children containing 50 per cent of her genes and instead to devote her energies to the survival of her grandchildren each containing 25 per cent of her genes. At the individual level secondary ageing is most obvious in psychological adaptations to age-associated changes in memory and physical capabilities. Adaptations to changes in memory may range from minor obsessive traits to an old person's refusal to go shopping for fear they might get lost. The first is not obsessive–compulsive disorder and the second is not agoraphobia. Doctors need to be aware in a general way of the possibility of secondary ageing in order to resist unthinking attempts to 'normalize' some physiological parameter or aspect of behaviour where the deviation from the normal is in fact adaptive.

Sex differences in ageing

As Fig. 1 shows, death rates in females are lower than in males at all ages. In Westernized societies women outlive men by 5 to 6 years on average. Epidemiological evidence suggests that in the United Kingdom nearly four of these extra years are due to intrinsic differences between the sexes while the remining difference has developed during the twentieth century due to extrinsic effects. There is a paradox in that although women outlive men they are much more likely to become disabled and dependent in old age. As discussed below, the physical basis for this probably lies largely with sex differences in muscle bulk rather than particular disease entities. However, the impact of disability on an elderly woman is increased by the likelihood that she married a man older than herself and so has outlived her husband (and all too often his occupational pension) by more than the average sex difference in lifespan. It has also to be admitted that a woman is more likely to be capable of looking after a disabled husband than man is of caring for disabled wife. The sum of these biological, environmental, and social factors emerges in dependency rates in later life. Although one man in seven who reaches the age of 65 in the United States can expect to spend a year or more in a nursing home before death, the proportion for women is one in three.

Age-associated changes of medical significance

Anatomical and physiological changes associated with ageing are described in almost every body system. Most start to become apparent in early or middle adult life

but their magnitude and practical significance vary considerably.

The cardiovascular system

Interpretation of changes in cardiovascular function in old age is made difficult by the age-associated increase in prevalence of ischaemic heart disease. The principal anatomical alterations in the cardiovascular system include an increase in the amount of fibrous tissue in the skeleton of the heart and in the myocardium and valves and an accumulation of lipofuscin in the myocardial fibres. This last change has no evident functional significance. There is also an increase in amyloid material in the aged heart, but again this does not usually appear to have clinical significance. There is a decrease in the elasticity of the aorta and its main branches, accompanied by an increase in the diameter and length.

There is a minor decline in resting heart rate and maximum heart rate on exercise. These changes probably relate to a decrease in the number of pacemaker cells in the sinoatrial node and to alterations in their reactivity to sympathetic and parasympathetic stimuli. Cardiac output at rest does not fall with age, but maximum exercise-induced cardiac output falls to a variable extent. Mean arterial venous oxygen differences are unaltered. Since the older heart in exercise shows a smaller increase in cardiac rate than is seen in younger patients, the increased cardiac output is achieved by a relatively greater increase in stroke volume than in younger adults. The older heart is essentially more dependent than the young on the Frank–Starling mechanism for increasing output.

Owing to diminished compliance due to heart wall hypertrophy and crosslinking of proteins, the older heart takes longer to fill during diastole then does the young heart. The older patient is therefore relatively intolerant of tachycardia since at very fast rates stroke volume and cardiac output will decline. In addition, the low compliance of the ventricular wall leads to an increase in the relative importance of atrial output to diastolic filling.

Management of heart disease in older people

For various, though less than cogent, reasons older people tend to be omitted from randomized controlled trials, but it has to be assumed for ethical reasons that treatments shown to be effective for younger patients will be at least as effective for the old. In some instances benefits will be greater in later life because of the increase in background risk of morbidity or mortality. This is documented in the use of thrombolytic treatment for acute myocardial infarction and for the benefits of b-blockers after infarction. A recent study (The Heart Outcomes Prevention Evaluation Study) of the benefit of the angiotensin-converting enzyme inhibitor ramipril in secondary prevention of cardiovascular events in high-risk patients showed benefits at least as great in patients aged over 65 as in those younger.

While lack of evidence relating specifically to relevant age groups should not prevent older people from receiving treatment, care is needed with treatments for which an age-associated increase in the risk of undesirable side-effects may be expected. For example, anticoagulation in atrial fibrillation may need more careful and frequent supervision for an older person than for a younger one. The benefit of b-blockade in improving survival in chronic heart failure has so far only been demonstrated for patients aged up to 80, and since the likelihood of ill-effects of b-blockade increases with age, treatment of older patients should be introduced with low doses and increased slowly ('start low, go slow').

Blood pressure

Ordinary vascular pressures are unchanged (except for a slight rise on exercise) as is pulmonary blood volume. Mean systemic arterial pressure rises in most, but not all, populations, and presumably represents a response of susceptible individuals to environmental factors such as excessive salt intake and perhaps sociocultural stress. In populations in which blood pressure rises, systolic arterial pressure increases more than diastolic, probably as an expression of reduced elasticity of the large arteries. As ageing progresses, diastolic pressure rises to a peak and then falls. The combination of these processes leads to the increasing prevalence in old age of isolated systolic hypertension. This is a risk factor for cardiovascular disease and especially for stroke. Trials show that up to at least the age of 85 reduction of systolic pressure reduces the risk of stroke. Indeed this is another area in which, in terms of numbers needed to treat, reduction of blood pressure in older patients is more effective than at younger ages.

Trials of the treatment of high blood pressure in older people have used conventional drugs, and the assumption has been that it is the fall in blood pressure that matters and the drug used is less important. In terms of average effectiveness b-blockers tend to become less effective as hypotensive agents with age while calcium channel blockers become more effective. Concerns expressed over the long-term safety of calcium channel blockers are not convincing. Conventional treatment is of stepped-care type in which drugs are added in sequence if the response is inadequate. Recent studies in younger patients have emphasized individual variability in responsiveness to different classes of antihypertensive drug such as angiotensin-converting enzyme inhibitors, diuretics, b-blockers, and calcium channel blockers. The varying efficacy probably reflects differences in the underlying mechanisms of the hypertension in individual patients. Instead of launching immediately into stepped care, therefore, a formal trial of different classes of drugs should first be undertaken in the hope of finding a suitable monotherapy. These findings need to be verified in older people, but the idea is intuitively attractive.

An important consideration in managing hypertension at older ages is impairment of the responses of blood pressure to postural change. Baroreceptor responses are often blunted in later life, possibly as a result of sclerotic changes in the carotid sinus, and there may in addition be failure of central and perhaps peripheral vasoconstrictor responses to falling blood pressure. Older people are more susceptible to the risk of hypovolaemia. Postprandial hypotension is also common in older populations and may be a constraint on management of hypertension. When assessing older people taking medication that may affect blood pressure, lying and standing pressures should be used routinely. The role of ambulatory blood pressure monitoring in the management of treatment remains to be defined, but can be helpful in identifying episodes of unexpectedly low pressure that are missed in the clinic.

Atrial fibrillation

As noted earlier, loss of cardiac wall compliance with age increases the importance of the atrial phase of diastolic ventricular filling. Not surprisingly, therefore, the onset of atrial fibrillation, particularly if it is associated with a high ventricular rate, often has serious consequences for an older patient. Intermittent atrial fibrillation is also one of the recognized causes of recurrent syncope at later ages. Rate control is often a matter of clinical urgency for an older patient following the onset of atrial fibrillation, and electrical conversion may be required. Unless some definable precipitant such as myocardial infarction or thyrotoxicosis is present the likelihood of subsequent recurrence and permanence of atrial fibrillation rises with age. Longer-term management needs to take this into account.

Large trials have now established that in the absence of contraindications, patients aged 60 and over with atrial fibrillation should receive long-term anticoagulant therapy in order to reduce their three- to fivefold increased risk of stroke. Patients with associated valvular disease or a dilated left atrium are at even higher risk of stroke. Even in the absence of overt stroke, computed tomography scanning has shown that older patients in atrial fibrillation have a higher prevalence of 'silent' cerebral infarcts; anticoagulant therapy may therefore reduce the subsequent incidence of multi-infarct dementia.

Oral anticoagulants have more powerful pharmacodynamic effects in later life and the higher risk of complications calls for more intensive medical supervision of an old person taking anticoagulation than of a younger one. The target international normalized ratio of 2 to 2.5 is appropriate and it is prudent to reduce pre-existing high blood pressure. Where anticoagulants are thought to carry unacceptable risks, owing for example to poor compliance, intermittent high alcohol intake, or frequent falls, antiplatelet therapy should be considered. Published trials relate mostly to aspirin, and newer drugs such as clopidogrel require further evaluation in older patients.

In young patients, paroxysmal atrial fibrillation does not seem to be associated with an enhanced risk of stroke. The situation is less clear for patients aged over 60, some of whom will develop intermittent atrial fibrillation as they progress towards chronic established atrial fibrillation. There is epidemiological evidence that the risk of stroke may be greatest during this phase. Geriatricians will therefore normally anticoagulate an elderly person with intermittent fibrillation.

Respiratory system

The interpretation of changes in respiratory function with age is complicated by a high prevalence of cigarette smoking in many populations. Total lung volume does not alter but vital capacity falls and residual volume increases with age so that over the age of about 60 the critical closing volume exceeds the functional residual volume. Ventilatory capacity falls with age at a slower rate in non-smokers than in smokers. Ventilation-perfusion inequality increases slightly, probably mainly as a result of increasing inequality of ventilation. These changes in lung function reflect a decrease in elasticity of the lungs and of respiratory muscular strength but the overall consequences are minimal in terms of their effect on the blood gases. Closure of small airways during resting breathing can produce crepitations at the lung basis posteriorly in older patients. As an isolated finding these should not be overinterpreted as a sign of left ventricular failure. These same changes can also lead to

areas of atelectasis in ill older patients or following surgery. Physiotherapy for older patients after surgery should therefore concentrate on expanding the lung bases rather than clearing sputum.

The principles of management of respiratory disease do not vary with the age of the patient. Diagnostic probabilities may need to be adjusted for age and for cohort effects. Cough due to left ventricular failure or to oesophageal reflux disease may become more common, and older people are more likely to have experienced past industrial exposures, for example to asbestos and coal dust.

Renal function and fluid and electrolyte balance

Old people are particularly susceptible to disorders of fluid and electrolyte balance. This is due in part to age-associated changes in physiology and partly to a higher incidence of challenges to homoeostasis from disease and drugs.

Renal function

Age-related changes in renal function are well documented. The glomerular filtration rate falls as do tubular reabsorptive and secretory capacities. Typically, these changes exceed the decline in lean body mass so that serum urea and creatinine concentrations rise slightly. Several formulae have been devised to try to estimate the glomerular filtration rate from serum creatinine taking age, weight, and sex into account. Various forms of the Cockroft–Gault equation are available as a means of estimating creatinine clearance from serum creatinine and body weight. This formula is only approximate and can mislead in extreme old age and in the presence of obesity where calculation based on ideal body weight or lean mass body weight may be more accurate. Where accuracy is important, such formulae are no substitute for formal creatinine clearance based on a 24-h urine collection.

The response to an acid load is impaired and the maximum rate of secretion of hydrogen ions falls. Changes in blood pH in response to an acid load are therefore greater in magnitude and longer in duration than in younger people. Response to antidiuretic hormone is reduced and water conservation less efficient.

Thirst

A delayed response to fluid deprivation due to impaired thirst mechanisms in old age may compound the effect of delayed renal responses to changes in fluid status. The sensation of thirst is decreased in later life. In an experimental study of 24 h of fluid deprivation younger volunteers felt thirsty while older volunteers did not. When given access to water the older volunteers drank less than the young. Similar differences between young and old were found following infusions of hypertonic saline in which the younger volunteers were able to adjust serum osmolality by water ingestion more accurately than the old. It is not clear, however, to what extent the changed physiology is due to insensitivity of the osmoreceptors and baroreceptors rather than to a deficit in the opioid-mediated drinking drive.

The decline in thirst sensitivity with age is one reason why older people are at enhanced risk of dehydration. This effect may be exaggerated if an old person voluntarily restricts fluid intake in the hope of controlling urinary urgency or incontinence, or to avoid having to call for nursing assistance when in hospital.

Conversely some elderly people, often hypertensive women, show an enhanced thirst response to diuretics (particularly amiloride) with increased water intake and hyponatraemia.

Other age-associated changes

Average renin and aldosterone levels diminish with age with consequent impairment of sodium conservation. Renal concentrating ability is also reduced, which is partly due to a decrease in medullary hypertonicity and partly to impaired renal responsiveness to vasopressin which may result in excessive water losses. The ability of older patients to cope with volume expansion is also impaired and older individuals take longer to excrete a sodium load. There is also a possibility that vasopressin secretion may be impaired.

Secretion of atrial natriuretic peptide in response to hypervolaemia may be reduced in older people and the responsiveness of the kidney to atrial natriuretic peptide may also be reduced.

Implications for clinical care

Assessment of fluid status is an essential component of the evaluation of an elderly patient who is unwell. Sometimes a degree of fluid deprivation will have preceded the illness because some older patients deliberately minimize their fluid intake with the hope of reducing problems of urinary urgency and incontinence. During an illness the most sensitive assessment of fluid balance is by daily weighings, but every attempt should be made to maintain accurate fluid balance charts as well. Infections, commonly pneumonia or urinary tract infections, are frequent causes of dehydration. This is in part due to loss due to fever, which may be overlooked if body temperature is not measured with especial care and after a patient has recovered from travelling in a cold ambulance to hospital. Older people are also more susceptible than the young to the effects of high environmental temperature.

Many old people are on long-term diuretic treatment which can exacerbate the effects of illness as well as causing problems in their own right. In addition to hypovolaemia and postural hypotension, hyponatraemia and disorders of potassium balance can be caused by diuretic therapy. Diuretics may precipitate hyperuricaemia and gout in older patients and destabilize diabetes. The significance of the lipid-raising effect of diuretics on lipid levels in old age is less clear. As noted above, some older people, especially women with hypertension, seem particularly susceptible to diuretics and overcompensate for diuresis with excess water intake so leading to hyponatraemia.

As far as possible dehydration should be corrected by oral intake. Intravenous therapy provides for more rapid and accurate correction but care must be taken over the rapidity of correction of hypo- or hypernatraemia. Subcutaneous fluid replacement is now established as an option where intravenous access is difficult or fluid correction is less than urgent. The infusion needle can be placed subcutaneously in the abdominal wall, the axilla, or the subclavicular area, but for a confused patient between the shoulder blades can be a less troublesome site. Hyaluronidase, 1500 iu, can be given as a bolus through the cannula if the infusion runs too slowly but is expensive, does not improve comfort, and is not usually necessary with an older patient. The infusion site should be changed every 24 or 48 h. Normal saline is well-tolerated by this route, and 5 per cent dextrose can also be given safely at doses up to 1 ml/min (1.5 litres per day). If necessary, potassium chloride up to 40 mmol can be added to each litre of solution, but this may increase complication rates due to local inflammation and secondary infection of the infusion site. Colloid and hyperosmolar solutions should not be given subcutaneously.

Urinary incontinence

This socially disabling condition affects approximately 2 per cent of middle-aged men and 12 per cent of middle-aged women and increases with age to a prevalence of around 8 per cent in men and 16 per cent in women over the age of 75 years. A number of classifications of urinary incontinence have been proposed and Table 2 presents a common version. The patient with acutely developing incontinence due to illness or injury should be reassured and every effort should be made to ensure that it does not continue into a chronic form. As with all problems of older people, possible iatrogenic causes must be reviewed, including rapidly acting diuretics and sedative drugs. Excessive urine output due to hyperglycaemia or hypercalcaemia may present with urinary incontinence, but nocturnal urinary frequency and incontinence due to unrecognized heart failure is much more common. Faecal impaction is another common remediable cause of urinary incontinence in hospitalized older people.

Many patients with dementia become incontinent, but incontinence should never be attributed solely to dementia unless the latter is severe and until all treatable causes have been excluded. Functional incontinence due to the inability of an old person to reach a toilet in time is unnecessarily prevalent, particularly in hospitals where old people with mobility problems may have their beds too far from the toilet or where nurses cannot or do not answer bells promptly.

Overflow incontinence when the bladder is only able to overcome an outlet obstruction at high volumes is common in men with prostate difficulties. It is diagnosable by postvoiding ultrasound examination and often requires surgical intervention. Where that is not feasible, or if a patient declines surgery, medical approaches including a-adrenergic blockers (given with care on account of the risk of hypotension) may be helpful. Where there is prostate enlargement there is some evidence for benefit from finasteride which inhibits 5a-reductase, which metabolizes testosterone to the more potent dihydrotestosterone. This can lead over a period of some

months to a reduction in prostatic size and improvement in urinary flow rates and obstructive symptoms. There are some antiandrogenic side-effects including impotence and decreased libido, and the drug has to be handled with care by women of child-bearing potential, a fact which may be relevant to carers or nurses involved in dispensing the drug.

Urge incontinence is usually due to instability of the detrusor muscle of the bladder and may also arise through irritation of the bladder by infected urine when it responds to appropriate antibiotic therapy. After identifying the sensitivities of the infecting organism, antibiotic treatment is given and urine culture repeated. If the incontinence is not improved despite eradication of the infection antibiotics should not be continued. Studies have shown no benefit from treatment of asymptomatic urinary infections in older patients. The contractions of an unstable bladder may be inhibited by anticholinergic drugs but these must be used with care as they may induce glaucoma and constipation. Lipid-soluble anticholinergic drugs may also cross the blood–brain barrier and cause delirium. The drugs most commonly in use on account of claims of some degree of specificity for bladder receptors are oxybutynin and tolterodine.

The certain diagnosis of unstable bladder and associated urethral dysfunction requires invasive investigation including cystometry. In practice most cases of urinary incontinence in older patients can be dealt with empirically, and invasive investigations should be reserved for the more intractable cases. It is useful for medical and nursing teams providing care for older people in the community and residential settings or hospitals to agree on a general plan for approaching problems of incontinence. Figure 2 outlines an example of such an approach. In many instances urinary incontinence may be a problem only at night. A single dose of imipramine in the evening may be of benefit, partly through its anticholinergic effects. Setting an alarm to wake the patient to empty his or her bladder prophylactically may also be of benefit. For some patients a small dose of a rapidly acting diuretic in the afternoon followed by restriction of fluids until bedtime will enable the cardiovascular system to reabsorb fluid pooled during the day in the lower limbs without an inconvenient increase in urinary output. The use of dDAVP or other analogues of vasopressin at bedtime in order to produce an antidiuresis during the night has been reported but it carries a high risk of fluid overload and hyponatraemia in older patients.

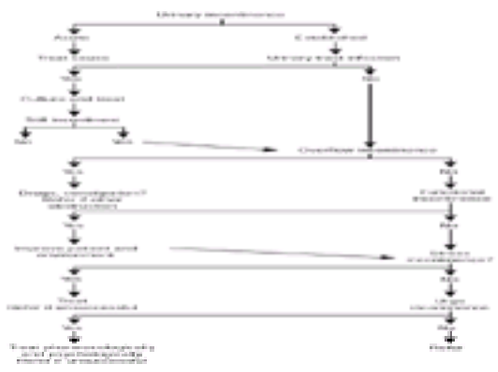

Fig. 2 Illustrative algorithm for management of urinary incontinence in elderly patients 'Refer' indicates referral to specialist urologist or gynaecologist.

Long-term catheterization may need to be considered in intractable situations. This is an invasive procedure with a risk of complications and should be undertaken only after the agreement of the patient. Some older patients will choose catheterization in preference to incontinence pads. Catheters should be inserted and changed under strict asepsis and with consideration of antibiotic cover for patients with cardiac valvular disease or joint prostheses. The urine of an older patient with an indwelling catheter will almost inevitably become infected. Although treatment of symptomatic infection must be considered, and the risk of ascending pyelonephritis and haemosepsis kept in mind, repeated courses of antibiotics can lead to colonization with highly resistant organisms. This is particularly undesirable in institutional care. Although a somewhat old-fashioned approach, manipulation of urinary pH by potassium citrate can help and urinary antiseptics such as hexamine hippurate can also be effective. The last should not be given with alkalinizing agents, and although theoretically less effective where an indwelling catheter prevents bladder filling it can be helpful. It should be avoided in renal failure.

Where possible, leg bags should replace the undignified bag-on-a-stand with which so many hospitals unnecessarily advertise their older patients' disability. Problems of backflow when the patient's bladder is lower than the bag when sitting usually indicate a need for a more suitable chair than for putting the bag on the floor.

For older men who are incontinent only at night a condom-type appliance with drainage bag may be helpful, although leakage and discomfort are common complications. No reliable analogous device has yet been produced for women.

A wide range of incontinence pads and holders is available. Specialist incontinence nurses are available in many hospitals and primary care districts who can advise on the most suitable treatment for individual patients. Charities concerned with disabled people are also a valuable source of expert advice.

The gastrointestinal system

Gastric atrophy becomes increasingly common as age advances but many older people retain full capacity for hydrogen ion secretion. Minor atrophic changes in the mucosa of the small bowel are described but there is no significant change in the absorption of nutrients that are absorbed by passive diffusion. Bacterial overgrowth syndrome may occur in an older patient with an anatomically normal bowel, and needs to be included in the differential diagnosis of diarrhoea, partially intermittent diarrhoea, and malabsorption. The increased risk with age is thought to reflect gastric hypoacidity and reduced motility of the small bowel. Reduced motility of the large bowel is also common and may be associated with diverticular disease or overuse of purgatives.

There is an age-associated reduction in hepatic mass and blood flow, with some consequent changes in first-pass metabolism of drugs and gastrointestinal hormones, but no significant changes in hepatic function as measured by conventional tests.

Gastrointestinal disease

Older people are liable to the full range of gastrointestinal disorders. Even coeliac disease may present for the first time in old age. Gastrointestinal haemorrhage is common and frequently associated with the ingestion of non-steroidal anti-inflammatory drugs. Management of an older patient is along conventional lines but age-associated loss of adaptability should be compensated for by an increased readiness to institute invasive monitoring and to intervene endoscopically or operate sooner rather than later in deteriorating situations. Uncertainty among junior hospital medical staff can be reduced by locally agreed guidelines for management of what is a common but dangerous emergency. Guidelines will only be effective if adhered to by surgeons as well as physicians.

Constipation is a common complaint among older people, but before initiating treatment it may be helpful to ensure that a patient's expectations of bowel function are reasonable. The implications of a recent change of bowel habit must also not be missed. Where chronic constipation is a problem, a daily intake of 10 to 20 g of dietary fibre should be aimed at, with if necessary a stool softening agent such as lactulose. Doses of stimulant laxatives such as senna may be necessary but should be avoided as much as possible.

Faecal incontinence

Recurrent faecal incontinence, with our without associated urinary incontinence, affects about 1 per cent of people aged over 65. Faecal and double incontinence are associated with a range of anorectal and neurological disorders including dementia. In later life, however, the commonest cause is rectal or sigmoid overloading due to constipation (faecal impaction). In middle-aged women a pelvic neuropathy, sometimes possibly a consequence of childbirth, is encountered as a risk of faecal incontinence and may be improved by surgical intervention. Any form of acute or chronic diarrhoea will also lead to incontinence in a proportion of cases. Faecal impaction most commonly occurs in the rectum and can be readily diagnosed by rectal examination. 'High' impaction can occur at the rectosigmoid junction and above and may need to be diagnosed by a plain abdominal radiograph. High impaction must always raise the possibility of obstruction by a carcinoma or inflammatory stricture due to diverticulitis. Treatment of impaction requires enemas and suppositories, rarely manual evacuation, and then a regular regime of a stool softening

medication such as lactulose.

In some cases where faecal incontinence is an intractable problem it can be ameliorated by giving constipating medicine such as loperamide with bowel lavage once a week. This is not an easy regime to establish but can be of help for an old person who wishes to remain in his or her home or to ease nursing problems in residential care.

The locomotor system

Muscle mass, strength, and power

Significant and progressive alterations in average body composition appear in the fifth decade of life. There is a decline in lean body mass with a corresponding fall in oxygen consumption largely attributable to a decline in muscle mass. This is also associated with a decline in muscle strength and power. (As in physics, strength is conceptualized as maximum force and power as the maximum rate of doing work.) The consequences of this trend are more prominent in women who, on average, start adult life with less muscle tissue than men. The age-associated decline is such that by the age of 80 the great majority of women in economically advanced societies are unable to rise from a chair without using their arms to help. This is probably the chief reason why disability levels are so much higher in old women than old men. Improvement in muscular power can be achieved even in the very old by appropriate exercise regimes, which should be considered as part of the rehabilitation programme of an older person who has had to be off his or her feet for more than a day or two.

Bone and joints

Fractures: osteoporosis

The major changes with age in the bony skeleton, which include a steep increase in the prevalence of osteoporosis after middle age, are discussed in Section 19. Loss of bone tissue with age occurs in all humans but appears to vary in severity with place, time, and race. The most important manifestation of the decline in bone mass is a reduction in the mechanical strength of bone and an increase in the tendency to fracture. Although many fractures increase in risk with age and the rising prevalence of osteoporosis, the three 'classical' osteoporotic fractures are those of the vertebrae, the distal forearm, and the proximal femur. Vertebral fractures start to appear at the time of menopause in women and increase in prevalence thereafter. The great majority of limb bone fractures in old age are caused by simple falls. The epidemiological pattern of fractures is partly determined by the causes of falls, the speed of protective responses, and the presence or absence of 'passive' protective factors such as floor coverings, clothing, muscle, or subcutaneous fat. Women are more likely than men to fall and there is an exponential increase in the risk of falling from about the age of 60. It is therefore not surprising that there is a similarly exponential increase in the risk of proximal femoral fracture with a much higher risk in women over the same age range. However, distal forearm fractures which show a steep increase around the age of menopause do not continue to increase in incidence through old age. This probably indicates that the older the person is the less likely he or she is in a fall to throw out an arm in time as a protective response.

Fractures: osteomalacia

Osteomalacia is now rare as a cause of falls and fractures in old age, but it may need to be considered in an older person who has been housebound, has a low dietary vitamin D intake, and takes drugs such as antiepileptics that induce hepatic enzymes that destroy vitamin D derivatives. Age-associated changes in the ability to synthesize vitamin D in the skin and to absorb calcium from the gut are coupled with a reduction in the renal 1a-hydroxylase activity that metabolizes vitamin D into its highly active 1,25-dihydroxy vitamin form. Relative vitamin D deficiency may play a part in the genesis of osteoporosis. There is a growing literature suggesting that minor degrees of vitamin D deficiency during the winter in temperate latitudes may lead to compensatory increases in parathyroid hormone secretion and negative bone balance. This can be prevented by a daily intake of 400 to 600 iu of vitamin D from October to April.

Arthritis

The reasons for the virtual universal occurrence of osteoarthritic changes in many joints in later life are uncertain but may include the mechanical effects of time-related wear and tear, age-associated changes in the metabolism of joint cartilage, and subchondral bone, or a disease process unrelated to age. The epidemiology of knee osteoarthritis suggests that wear and tear from occupation injury and obesity is important. Obesity seems both to predispose to arthritis of the knee and to be a factor in making the arthritis painful. Weight loss is therefore an important therapeutic approach. In contrast, osteoarthritis of the hip seems often to be a long-term consequence of minor (or major) forms of congenital dysplasia of the hip and the effects of occupation and obesity are much less clear. There is evidence of a genetic predisposition to the syndrome of generalized osteoarthritis.

Falls

Falls and the fear of falls are important causes of morbidity among older people. Community surveys indicate that a quarter of people aged 65 to 69 fall at least once in the course of a year and this annual prevalence doubles by the age of 80. Women are more liable to falls than men. This may partly reflect greater activity but is also related to lower muscular strength. Falls are a cause of direct and potentially fatal injuries such as fractures and head injury. Old people who are unable to get themselves up again may suffer the additional problems arising from a 'long lie'. These include hypothermia, pressure sores, and rhabdomyolysis. The last can in severe cases lead to acute renal failure and serum muscle enzymes should be checked in old people presenting to medical care after a fall with long lie. Significant haemorrhage following falls is an increasing problem as more older people are being prescribed anticoagulants for atrial fibrillation. A history of falls is a relevant issue in deciding whether an older person should be established on anticoagulants.

Falling, especially if associated with inability to rise again, is an extremely unpleasant experience for most older people and fear of further falls can lead to a form of 'postfall syndrome' in which the patient becomes morbidly afraid of falls, progressively more immobile (which may increase the risk falls as much as decreasing it), and socially isolated. Old people with this condition may seek premature institutional care or may be pressurized into care by worried family or neighbours. Falls by old people that come to medical attention need therefore to be taken seriously and possible preventive interventions sought. There have also been some studies of primary prevention at a community level but the cost-effectiveness of these approaches has not yet been established.

Causes of falls

Some general age-associated changes contribute to the rise in risk of falls. The syndrome of non-rotatory dizziness, which is common in later life and epidemiologically associated with an enhanced risk of falls, probably represents a temporary failure of the brain to achieve a coherent integration of positional data from eyes, inner ear, and proprioceptors. Proprioceptive information is reduced by increased variance in neural conduction time from peripheral tissues, and by damage to receptors in joint capsules by arthritis in the neck and elsewhere. The older patient therefore becomes increasingly dependent on vision for spatial orientation. Poor lighting levels or a visually confusing environment, as experienced on a moving escalator for example, can be particularly hazardous.

A large number of more specific risk factors for falls have been identified. These are typically classified as intrinsic to the patient and extrinsic in the environment, but as with all such dichotomies interactions are important. Interpretation in terms of causality can be uncertain because of confounding factors. In observational studies sedative and antidepressant drugs emerge as commonly associated with an increased risk of falls. Long-acting benzodiazepines and antidepressants are probably directly associated with an increased risk, but a link between diuretic therapy and falls found in some studies is probably more often mediated by the cardiovascular disease for which the drugs have been prescribed.

Some falls are no more than a misfortune that afflicts all of us by chance. An older person who falls only once or twice in a year will commonly be found to have no specific remediable cause. Old people who fall more than twice in a 12-month period should be investigated further. Extrinsic causes in the home should be identified, and the help of a skilled occupational therapist may be needed. Inadequate lighting, slippery floors, inadequate handholds, sloppy footwear, and loose rugs are common hazards. Where falls are not readily explicable in terms of an identifiable environmental hazard medical appraisal is needed. Table 3 lists some of the commoner medical causes of falls. Patients who find themselves on the floor with no memory of falling may have been unconscious at least momentarily and this suggests cardiac dysrhythmia, syncope, or epilepsy. Such a history may not be obtained consistently from patients subsequently shown to suffer from syncope, however, and this possibility has to be borne in mind for any older patient suffering repeated falls. Full investigation requires tilt-table and carotid sinus massage testing. The mechanism of syncope may be predominantly cardioinhibitory in which case a demand pacemaker can be of benefit. Syncope that is mediated by

systemic hypotension is less amenable to treatment.

Ambulatory electrocardiographic monitoring is a commonly requested investigation for older patients suffering falls or intermittent lapses of consciousness. Findings can be difficult to interpret in the absence of symptomatic events during recording because the prevalence of intermittent cardiographic abnormalities is high in later life. None the less, intermittent arrhythmias or significant pauses may be identified that justify a trial of therapy if compatible with the clinical history.

Where no remediable causes of falls can be established thought needs to be given to tertiary prevention of the consequences of further falls. A physiotherapist should train the older person in getting up after a fall or in moving across the floor to an alarm or telephone to summon help. An alarm system may need to be installed in the patient's home provided he or she can be trained to use it. Otherwise, some system of regular surveillance by statutory services, volunteers, or good neighbours may be more useful. The risks of further falls need to be discussed fully with the patient and with concerned relatives. The right of an old person to continue to live in his or her own home, even where that carries some risk, may need to be defined for relatives pressing for institutionalization to relieve their anxieties rather than the patient's.

The endocrine system

Historically, there have been many attempts to explain ageing as a consequence of sequential endocrine failure, in the hope that suitable replacement therapy might halt or reverse the process. Apart from the obvious changes in ovarian function with the menopause, there are minor declines in circulating thyroid hormone levels, a reduction in the rate of secretion of insulin in response to raised blood sugar levels, and a decline in tissue sensitivity to insulin. The release of antidiuretic hormone in response to osmotic loads increases, perhaps in association with reduced renal responsiveness and changes in the sensitivity of blood volume receptors. There is little evidence of any abnormality of parathyroid, adrenal, or pituitary function as a universal feature of old age. The response of the adrenals and of adrenocorticotrophin secretion to stress is essentially unaltered. Indeed, following injury ACTH secretion is more prolonged in older patients than younger but the significance of this is unclear.

There is a gradual age-associated decline in average testosterone levels in ageing men. There is no abrupt change corresponding to the female menopause, nor, on evolutionary grounds, would one expect there to be. Testosterone implants are available in the private medical sector in some countries but there is at present no scientific justification for the claimed benefits of 'normalizing' testosterone at young adult levels. Some older men have been found to have very low levels of growth hormone and in uncontrolled experiments show increases in muscle bulk and strength when replacement therapy is provided. Functional benefits have yet to be demonstrated, and side-effects from growth hormone can be severe.

Blood levels of dehydroepiandrosterone, a weak androgen, are high in fetal life, decline after birth, and then rise again from puberty into early adult life. There follows a steep decline with age and there have been reports of improvements in function and wellbeing in later life from supplements. Again, larger and better trials are needed.

Diabetes mellitus

The clinical presentation of diabetes in old age may differ from that of younger patients. Many patients are diagnosed as a result of routine testing during a medical or surgical illness and some because of the development of disorders associated with diabetes such as peripheral vascular disease or cataract. Relatively few present because of classical symptoms such as weight loss and polyuria but a small proportion present with life-threatening metabolic decompensation in a hyperosmolar state.

There is now sufficient evidence to justify trying to control hyperglycaemia. Dietary treatment and oral hypoglycaemic agents are firstline treatment but insulin should not be withheld if it is necessary for control of hyperglycaemia. Shorter-acting oral hyperglycaemic drugs such as gliclazide are preferred and longer-acting drugs such as chlorpropramide and glibenclamide should not be used for older patients.

Diabetes mellitus interacts with other risk factors for cardiovascular disease. Diabetic patients of any age should be persuaded to give up smoking. Control of blood pressure is very important, with evidence to support the use of angiotensin-converting enzyme inhibitors in preference to other classes of drugs. Hypercholesterolaemia should be reduced.

The specific complications of diabetes occur more frequently in older than in younger patients. The majority of patients blind from diabetes are aged over 60 and the prognosis of diabetic retinopathy in old age is less favourable than at younger ages. Photocoagulation remains effective, and the results of cataract extraction are excellent except when retinopathy is contributing to the visual impairment.

Foot care is an important aspect of the management of diabetes and it is important to bear in mind that peripheral neuropathy and vascular disease may render the elderly diabetic patient particularly prone to pressure sores of the heels if confined to bed for any length of time.

Hypothyroidism

Most cases of hypothyroidism in old age are of autoimmune origin, although previous thyroid surgery and radio-iodine therapy account for a proportion. Classical clinical signs such as cold intolerance, hair loss, and coarsening of the skin are less common as presentations in old age than an insidious decline in health and mobility with psychiatric manifestations, particularly depression. Hypothyroid coma, sometimes associated with severe headache and fits, and hypothermia are less common but important presentations. The most physical signs are a change in voice and delayed relaxation in tendon reflexes, often most easily recognized in the arm reflexes of an older patient.

The principle of 'start low, go slow' in prescribing for older people is important when starting thyroid replacement therapy, particularly if myocardial ischaemia is known to be present. A problem in management may be failure to comply with treatment and the responsible doctor must ensure that lifelong treatment is in fact lifelong. It may be necessary to enlist the aid of a relative, neighbour, or visiting nurse in ensuring compliance.

Hyperthyroidism

Hyperthyroidism is less common in old age than hypothyroidism but is even more likely to present in an 'atypical' manner. Weight loss, anorexia, gastrointestinal, and cardiovascular symptoms predominate. Cardiac failure, often associated with atrial fibrillation resistant to digitalis, is a common cardiac presentation. Eye signs and goitre are less common in elderly patients, and apathy or depression, rather than tremor and agitation, may be prominent.

Treatment is begun with carbimazole followed when thyroid function is returned to normal by radio-iodine. Thyroid replacement therapy is often required later either because of an ablative dose of radio-iodine or because of subsequent decline in thyroid function. Careful follow-up is therefore necessary.

The nervous system

Age changes in the nervous system are among the most important because of their significance in the psychology and psychiatry of ageing and in the production of disorders of movement. Numbers of neurones in some parts of the nervous system, for example the motor neurones of the spinal cord, the Purkinje cells of the cerebellum, the cells of the substantia nigra, and parts of the neocortex, fall with age. There are no changes in other parts, for example in several brainstem nuclei. Anatomical abnormalities of the neurones that remain are also described including the accumulation of lipofuscin and the loss of dendrites and dendritic spines in cortical neurones. The anatomical basis of alterations in cortical function may thus be due both to a reduction in the number of neurones and in the connections between them. There is a reduction in peripheral nerve conduction velocities, both motor and sensory, differing in different nerves and reflecting a fallout of fibres of all sizes. There is also an increase in the variance of nerve conduction velocities which probably contributes to the inaccurate transmission of information and may impair the cognitive function of the brain as a parallel computer. The increase in nerve conduction variance may explain the frequent bilateral loss of ankle tendon reflexes above the age of 60. Loss of vibration sense in the feet and ankles may be another manifestation of the same process. Although commonly of no clinical significance, such findings need to be interpreted with care as it is important not to overlook a peripheral neuropathy, due for example to vitamin B_{12} deficiency.

Temperature control

Central autonomic nuclei, for example the intermediolateral cells in the spinal cord and first- and second-order autonomic neurones outside the central nervous system, show a fall in cell numbers with age. Associated changes in autonomic function include alterations in the control of heart rate (see above) and abnormalities of temperature regulation. Older people are more susceptible to hypothermia and to heat stroke. The threshold for appreciation of skin temperature changes may increase by as much as tenfold over the age range. This contributes to older people's inability to recognize temperature change and to respond appropriately. There is reduced cutaneous vasoconstriction in response to cold and impaired vasodilatation and sweating in response to increase in body temperature. Reduction in sweating is due in part to a reduction in the number of sweat glands. Failure of shivering is common and makes hypothermia more likely, while coexisting undernutrition, even of brief duration, reduces hepatic thermogenesis.

Hypothermia

In many countries, especially the United Kingdom, there is an excess of deaths during winter. This is mostly due to influenza and to cardiovascular disease and the contribution from hypothermia is very small. None the less the diagnosis is important as it can easily be missed in its early stages and carries a high fatality. Most elderly patients with hypothermia present after a period of 2 or 3 days of cold weather, but it is entirely possible for hypothermia to develop in hospital in midsummer at United Kingdom latitudes especially if disease or drugs play a part. The fall in central temperature occurs over 24 to 48 h and its principal manifestations are progressive ataxia and slowing of cerebration continuing to stupor and finally coma. On clinical examination, the skin on unexposed surfaces such as the axilla, chest, and abdomen feels cold to the touch. There may be oedema of the face and eyelids resembling that of myxoedema but due to redistribution of fluid between the intra- and extracellular compartments and resolving with correction of hypothermia. The pulse is slow unless severe physical illness has raised it towards normal, and the blood pressure is difficult to record or is low. Tendon reflexes are normal unless there is associated hypothyroidism. The diagnosis is made by recording the rectal or other form of core temperature, and this should be done without delay on all occasions when an oral temperature is recorded at 35 °C or less. The electrocardiogram may show characteristic bradycardia and J waves (Fig. 3), but in severe hypothermia there is often atrial fibrillation with a slow ventricular response.

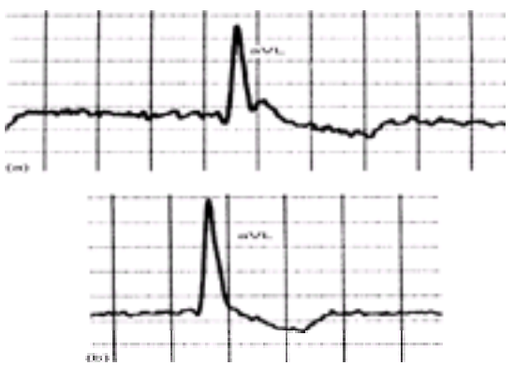

Fig. 3 An Osborne (J) wave seen in the electrocardiogram of a patient during hypothermia (a) and after recovery (b). The characteristic deflection lies between the QRS complex and the beginning of the ST segment. The pathophysiology of the J wave is uncertain.

Hypothermia in elderly patients carries a high fatality. Although patients with hypothermia due to drugs commonly recover, those with severe physical illness as a cause usually die. Management is rendered difficult by the absence of comparative trials. There is no rational basis for the use of steroids, and intravenous fluids are dangerous because they may produce pulmonary oedema. Intravenous glucose is not metabolized and insulin is ineffective in the hypothermic state. In some younger patients, particularly those suffering acute accidental hypothermia, there may be benefits from rapid warming, but in older patients slow rewarming is the usual practice. A rise in body temperature, optimally 0.5 °C/h, is obtained by exposing the patient to a relatively high ambient temperature of 30 °C. Improvement is shown by an increase in rectal temperature and pulse rate, maintained blood pressure, and improvement in level of consciousness.

An elderly patient who has recovered from hypothermia should be regarded as at risk for further episodes, and relatives and social agencies should be alerted. The long-term prognosis is better in patients who have survived an episode of hypothermia due to identifiable causes.

Hyperthermia

An increase in mortality on continuing care wards and among elderly people living at home has been recognized during heat waves. It is not known how many of the extra deaths are due specifically to hyperthermia, in the sense of rise in body temperature, rather than to dehydration or general stress. As with hypothermia part of the problem seems to be the failure of the older person to recognize that a problem is developing and for many a cool environment is not easily available. Adequate fluid intake should be recommended and tepid bathing may be the only available way of preventing a rise in body temperature.

Vision

Age-associated changes in the eye and ear are well documented. Decrease in elasticity of the lens begins early in life but only becomes symptomatic in the fifth decade when presbyopic hypermetropia results from failure of accommodation due to changes in the lens itself and in its capsule and suspensory ligaments. Cataracts increase in prevalence with age but vary in frequency between racial groups and with factors such as diabetes and family history. The media of the eye become less translucent with age and there is more scattering of light. Older people therefore have lower contrast sensitivity than the young and need more light and sharper contrast in reading material and in important environmental cues such as marker strips along the edges of steps. At a practical level, use of the inverse square law in placing lights nearer to what they are required to illuminate may be preferable to simply increasing their wattage. The eye media also become yellow with age so that the older eye is less sensitive to blue, a problem that can on occasion lead to mistakes in medication as the older patient fails to register which tablet is 'the blue one'. The public environment, including buildings such as hospitals, is often unnecessarily difficult for older people to use because of failure by architects to understand the visual problems of an ageing population.

Driving

Vision is an important determinant of fitness to drive a car. The loss of the right to drive can interfere seriously with an older person's quality of life as well as having a profound symbolic impact as a sign of disability and social marginalization. The common notion that older drivers are dangerous is exaggerated. In terms of preventing fatal road accidents the most effective intervention would be to refuse licences to males aged under the age of 25. Accident rates are very high for drivers, especially men, in early adult life where high-speed accidents with high injury and fatality rates are characteristic. Rates then fall into middle age but begin to rise again after the age of 70. At later ages, however, accidents tend to occur at low speeds with correspondingly low death and injury rates, and typically involve side collisions at road intersections. One reason for this may be a diminution in the size of the functional visual field with age. There is laboratory evidence that the functional visual field can be enlarged by training but the practical impact is not yet convincing. As with so many other aspects of modern life, road design could be improved to make travel safer and pleasanter for the increasing numbers of older drivers in society.

In addition to vision, a range of attributes including cognitive function and physical ability in manipulating controls, contribute to a person's ability to drive safely. In the absence of gross abnormalities, an older person's driving ability can only be assessed in a road test. Clinical examination and computer simulation are not adequate substitutes.

Specialized testing may also lead to useful advice about modifications to an old person's car that will enhance safety.

Hearing

A degree of high-tone deafness (presbyacusis) is probably universal in humans. It reflects several mechanisms and although it is partly an intrinsic true age change,

there is little doubt of the importance of prolonged exposure to industrial and other environmental noise. Loss of high-tone hearing with the associated difficulty in following one voice against a background of others is socially and occupationally disabling. Minor degrees of deafness also have a more subtle effect on cognitive performance. Normal language has a high degree of informational redundancy, so that in conversation the hearer has often already understood and is preparing an answer before the speaker has concluded. Hearers who have to concentrate on listening to complete sentences in order to be sure they have understood are at a disadvantage in terms of processing and reacting to what is being said. This is all too often interpreted as cognitive impairment, and in confrontational situations, such as legal proceedings, can be exploited by unscrupulous interlocutors.

Psychiatric disorders in later life

Physicians should be aware that there is always a psychological element to physical disease. At one extreme physical symptoms and even signs can be a manifestation of a somatization syndrome. At the other extreme there will inevitably be a psychological reaction to physical illness. This may include a panic reaction, but more commonly fear and anxiety manifest in different ways ranging from denial of symptoms to morbid preoccupation with them. It is part of a physician's duty to recognize the psychological dimension to a patient's illness and to respond to it appropriately. All this is true at any age but requires particular thought with older patients for whom the possibility of death is a constant presence and disability a constant dread. These problems may be compounded with a degree of cognitive impairment, background depression, and an increased susceptibility to delirium. For practical reasons the physician will need to deal directly with a broad range of such problems but should be ready to invoke the aid of psychogeriatrician colleagues in situations that are less than straightforward.

Delirium

Delirium, one form of acute confusional state, can affect an acutely ill patient of any age but becomes more common in later life. Any toxic febrile condition can precipitate delirium as can primary insult to the brain such as stroke, meningitis, encephalitis, or subarachnoid haemorrhage. The mechanisms of delirium remain obscure but there is suggestive evidence that in toxic states it may involve the leakage across the blood–brain barrier of neuroactive compounds, normally not present in the bloodstream or normally excluded from passage into the brain. In some instances the patient may be quiet, drowsy, and withdrawn, perhaps quietly muttering, but more commonly a delirious older patient is agitated, restless, noisy, paranoid, and sometimes aggressive. The diagnosis must be suspected in old person who shows an abrupt deterioration in cognitive function or an abrupt change in personality. In toxic conditions such as urinary infection, haemosepsis, or pneumonia the delirium may appear before any other signs of infection such as fever or leucocytosis.

The central element of management is to diagnose and treat the underlying cause and in some instances this may call for the 'blind' institution of antibiotic therapy while cultures of blood and urine are awaited. Although an agitated depression can be made more manageable by sedative drugs such as haloperidol these bring with them a risk of secondary complications and as far as possible doses should be kept to a minimum and the patient's disturbed behaviour handled by skilled nursing. This will be facilitated by an attempt to understand what the patient is experiencing as the cause for his or her behaviour. In a delirious state consciousness is clouded and experience may have a dreamlike quality with all that means in a sense of ill-understood dread and powerlessness to escape or defend oneself. Memory is impaired so that although careful explanation to the patient of who people are and what is happening is an important part of care it may need to be repeated at frequent intervals. Attention is disrupted so that the patient may not be listening when spoken to or may focus on some unimportant feature of the environment which may take on particular and often menacing significance. This is often coupled with misinterpretation of what is seen or heard so that a smoke alarm in the ceiling becomes a Martian death ray machine, or a pop song on a distant television set becomes the howling of a fellow prisoner in a torture chamber. In some instances, characteristically where alcohol or certain drugs have played a part in the delirium, visual hallucinations may occur which are often of a frightening or threatening kind.

Where possible a delirious patient should be nursed in a quiet room with good lighting and preferably in the company of a well-known friend or family member. Extraneous noise should be avoided as far as possible and constant reassurance and explanation provided. It is reassuring to delirious old people if doctors are dressed and behave like doctors, and nurses like nurses of more gracious times. Being addressed in old age by some overfamiliar ambiguous stranger using one's forename can be alarming. All forms of physical restraint are terrifying and should not be used.

Patients with pre-existing brain disease such as dementia are more prone than average to delirium but one of the differential diagnoses of delirium is of the acute panic and alarm of a demented person removed from their familiar environment. It is important to recognize this syndrome of 'decompensated dementia' in an older patient since if they are not returned as quickly as possible to their familiar environment their cognitive hold on reality may become permanently disrupted. The accident and emergency unit of a busy general hospital is a common setting for this problem.

Dementia

Dementia is distressingly common in later life with a prevalence of approximately 5 per cent over the age of 65. In its fully developed form it is conceptualized as an acquired global impairment of cognitive function. At earlier stages it is diagnosed on the basis of progressive impairment in two or more areas of cognition (memory, language, visuospatial and perceptual ability, thinking and problem-solving, personality) sufficient to interfere with work, social function, or relationships, in the absence of delirium or major 'non-organic' psychiatric disorders such as depression (section XXX). In the earlier stages, diagnosis may require formal neuropsychological testing. At present the diagnosis is essentially clinical, although functional neuroimaging is showing promise as a diagnostic aid.

The commonest cause of dementia in old age is Alzheimer's disease with cardiovascular causes second. Normal pressure hydrocephalus, classically associated with the triad of urinary incontinence, apraxia of gait, and mild cognitive impairment, is always sought for even though operative ventricular shunting often confers no benefit. Dementia with cortical Lewy bodies is being increasingly recognized. Although commonly described as a subacute disorder it is likely that more chronic forms will become increasingly recognized. Mood disorders, particularly depression, are common in the early stages and visual hallucinations are an early and persistent feature. Parkinsonian symptoms and signs are commonly present but are rarely severe. The importance of recognizing the disease lies in the particular sensitivity of sufferers to the ill-effects of phenothiazine drugs, which should be avoided.

Unfortunately there is little in the way of specific treatment for dementia. Patients with vascular dementia are commonly prescribed aspirin, although there is little evidence at present to support this practice. Patients in atrial fibrillation with stepwise progressive dementia suggestive of cerebral emboli will normally be offered anticoagulation, although careful supervision of dosage and monitoring of the international normalized ratio may be required. The memory defect of Alzheimer's disease is associated with a deficiency of acetylcholine in the brain and drugs which inhibit cholinesterase in the brain are now becoming available. The first of these, tacrine, had too severe a side-effect profile to be clinically useful but its successors, donepezil, galantamine, and rivastigmine, are proving more acceptable. Both drugs bring about a small improvement in cognitive function but, as to be expected, do not retard the continuous decline in function associated with the underlying dementing process. There is evidence that some patients with clinically diagnosed Alzheimer's disease do not respond to these drugs and it is important that if they are tried some formal measurement of cognitive function be applied at baseline and then a decision taken at a 6-week review as to whether the drug should be continued. If cognitive function has declined further the drug is not worthwhile. If there is been improvement or maintenance of function further review should take place at 12 weeks. Side-effects of these drugs are to be expected due to their cholinergic properties and include nausea, stomach cramps, and diarrhoea.

Depression

Depression is probably no more common in old age than at any other time of life but its effects can be more prominent and disabling. The present generation of older people are often unwilling to acknowledge that they may have a mental illness so that the clinical presentation and treatment may be complicated by denial and somatization. The classical features of depression may be present but more subtle manifestations such as a change of personality or behaviour, self-neglect, and asocial behaviour may be the presenting feature. Late-onset alcoholism or other forms of drug abuse, usually of sleeping tablets or pain killers, may also be symptoms. It is also important to recognize depression complicating physical disease; for example, rehabilitation of a stroke patient is often interrupted by the understandable onset of a depressive illness. As a physical sign avoidance of eye contact by an older patient can be very significant even if other aspects of demeanour are not typical of depression. Treatment is along conventional lines and old people respond as well as young to antidepressants. Doses should start low and be increased with care, particularly with drugs such as the tricyclics which because of their anticholinergic properties may induce delirium. The risk of suicide increases steeply with age and is particularly high in older men. Where a suicide is thought to be a high risk urgent psychogeriatric help should be sought and in such circumstances, or in the case of an old person whose health is compromised by withdrawal and refusal to eat, electroconvulsive therapy may be life saving.

Paraphrenia

Although for a long time thought to be a form of late-onset schizophrenia, this syndrome is now suspected more often to have its basis in organic brain damage. It is usually readily recognized as a primary psychiatric illness but may occasionally present to the physician, sometimes in a patient brought up to an accident and

emergency unit because of abnormal behaviour. Chronic undernutrition due to delusional ideas about food being poisoned or unsafe is one of the causes for the geriatric syndrome of 'failure to thrive'. In contrast with earlier-onset schizophrenia, personality is usually well preserved and although the patient may have alarming delusions they rarely become dangerously aggressive. The typical patient is an elderly solitary female, somewhat deaf with prominent semistructured auditory hallucinations. Ideas of being subjected to influence from outside, extraterrestrial aliens, or merely the television set are common and auditory noises attributed to the neighbours may lead to friction. The physician should not necessarily leap to the conclusion that a patient's description of strange noises is necessarily delusional. The old lady diagnosed as paraphrenic before the family of illegal immigrants living in her roof space was discovered is a possibly apocryphal but cautionary tale. Patients with paraphrenia require skilled psychogeriatric care, but can often be supported in their own homes if visiting psychiatric nurses or social workers can establish adequate rapport.

Unusual personalities

Old people display the same range of personalities as seen at any other age, from the delightfully eccentric to the perfectly odious. A syndrome of self-neglect, commonly, though unhelpfully, called the Diogenes syndrome, is well recognized. Characteristically this affects an old person living alone with a good work record and rather rigid personality, who for obscure reasons accumulates enormous piles of rubbish through a pathological inability to throw anything away. Such a patient may come to medical attention through the consequences of self-neglect, but sometimes as a victim of burglary and violence as a consequence of their being assumed by local villains to be the archetypal rich old miser. Complaints from neighbours about rat infestations, fire risks, or odours may also precipitate medical attention.

Other forms of personality disorder may resurface in old age, perhaps when protective spouses die or families and other carers reach the limit of their tolerance. Placement problems can arise since aggressive, abusive, or even merely 'difficult' behaviour can be hard to accommodate where some form of collective living is required.

Clinical pharmacology and the older patient

In epidemiological studies, the incidence of adverse effects of drugs increases with age. It has been suggested that at least 10 per cent of hospital admissions of older people in the United Kingdom are due in whole or part to adverse reactions to drugs. Higher incidences have been reported from general practice. Conventionally, adverse drug reactions are categorized into the idiosyncratic, usually due to host factors such as allergy or genetic susceptibility, and the dose-related, which are undesirably intense effects of the drug's pharmacological actions. In some instances adverse drug reactions are related to both dose and duration of exposure; the adverse effects of long-term high-dose steroids in older people being an example. Most adverse drug reactions affecting older people are dose-related or dose and duration-related. The chief reason for this is that more older people than younger take medications and are also more likely to be taking multiple medications with the risk of interactions. Although patients suffering from cognitive or visual impairment are at risk of making mistakes with their medications, there is no evidence that older people are any worse than younger ones at following treatment advice. Unnecessarily complex drug regimens may cause problems in compliance, and care in prescribing is an important aspect of good-quality medical care for older people. There are some age-associated changes in pharmacokinetics and, probably, pharmacodynamics that increase the risk of adverse drug reactions.

Bioavailability

In general there is no significant change with age in intestinal absorption of drugs that are absorbed, as most are, by passive diffusion. Absorption of substances such as iron, thiamine, calcium, and vitamin B_{12} which undergo active transport across the intestinal mucosa may be lower in older people. Loss of gastric acidity and bacterial overgrowth in the small intestine increase in prevalence with age and may affect drug absorption. The absorption of levodopa increases with age, probably because of reduced dopa decarboxylase activity in the gastric mucosa.

Hepatic metabolism

First-pass metabolism in the liver has an important effect on the bioavailability of drugs. The size of the liver declines with age, as does the density of its blood supply. For drugs such as propanolol and morphine that undergo significant first-pass metabolism, a higher proportion of drug absorbed from the intestine will reach the systemic circulation. Hepatic drug metabolism has been classified into phase 1 (oxidation–reduction) reactions mediated by the mixed-function oxidase system and phase 2 (conjugation) reactions. The clearance of some drugs (chlordiazepoxide and diazepam) metabolized by phase 1 reactions is retarded with age, but conjugation reactions seem unimpaired. Phase 2 reactions are, however, a potential site for important interactions between drugs that share common pathways of elimination. As with all age-associated phenomena, these are generalizations based on averages derived from groups of people of different ages. They reflect in part the increasing prevalence with age of 'frail' people with multiple disease and acquired impairments, and may not apply to individuals who are fit and healthy.

Body composition

Average body composition changes with age. Even though total body weight may not alter, muscle mass and total body water fall, while fat increases. These changes affect volumes of distribution of drugs and also have consequences for drug binding and retention. Water-soluble drugs such as digoxin, gentamicin, theophylline, and cimetidine have reduced volumes of distribution in older patients. Although, in acute single-dose studies, these drugs may produce higher serum levels in older than in younger patients, higher levels will lead to more rapid excretion. There is therefore no consistent effect in steady state conditions. Lipid-soluble drugs such as hypnotics and anaesthetics, diazepam and thiopental for example, have increased volumes of distribution contributing to prolonged serum half-lives in older people.

Renal function

Particular care is required in prescribing drugs that undergo renal elimination. As noted earlier, most individuals show an age-associated decline in glomerular filtration, which may be intensified by illness or medications, and which can retard the elimination of drugs, such as digoxin, that are largely excreted renally. Drugs eliminated by renal tubular secretion, such as penicillins and aminoglycosides, are also affected by the age-associated decline in renal mass and loss of nephrons.

Blood–brain barrier

The blood–brain barrier comprises the mechanical barrier provided by the endothelial cells of the cerebral vasculature with their characteristic tight (non-porous) junctions, and the metabolic barriers provided by the glial cells. It is not clear whether there is any general age-associated change in the efficiency of the blood–brain barrier. An increased susceptibility of older people to the adverse effects of benzodiazepines is well documented, but it is not known whether this is a pharmacodynamic effect at receptor level or where such drugs enter the brain in higher concentration in later life. Clinically, patients with cerebrovascular disease often seem more susceptible than average to drugs acting on the central nervous system, and this should be borne in mind when prescribing, but again it is not known whether this represents increased permeability of the blood–brain barrier or a pharmacodynamic effect.

Protein binding

There is a very small reduction in serum albumin concentration in healthy elderly people which has no clinical significance. The much greater reduction in albumin levels in many elderly people in hospital is due to the effects of disease and subnutrition and is a predictor of poor prognosis. Low serum albumin levels might in theory increase the proportion of unbound and metabolically active drugs that are normally highly protein bound. Interactions due to one drug displacing another from protein binding sites is also an enhanced theoretical possibility. Bound drugs that might be affected are particularly warfarin, tolbutamide, and phenytoin, and common displacing drugs are aspirin and sulphonamides. Other things being equal, any effect should be transient as the unbound drug is also more rapidly eliminated, but with older patients it is wise to be alert to any avoidable possibility of harm.

Pharmacodynamic effects

Age-associated increases in the effects (including adverse effects) of some drugs are not readily explicable in terms of gross pharmacokinetic changes, and pharmacodynamic effects at receptor level have been proposed. Such effects may contribute to the increased susceptibility of older people to benzodiazepines and warfarin, and to the age-associated reduction in sensitivity of b_1 receptors to adrenergic b-blockers. The susceptibility of older people to gastric complications of non-steroidal anti-inflammatory drugs may also have a pharmacodynamic element.

Preventing adverse drug effects

The possibility of an adverse drug reaction needs to be included in every differential diagnosis considered for an older patient. It is important to seek information about over-the-counter and self-prescribed preparations (perhaps 'borrowed' from a spouse or neighbour) as well as prescribed drugs. The use of over-the-counter drugs by older people varies between countries and social classes but is generally increasing. Table 4 lists some of the commoner adverse drug reactions seen in clinical practice. In addition to the effects listed in Table 4, older people often feel non-specifically unwell when taking drugs, especially antibiotics. Another frequent problem arises from oesophageal dysmotility, which is common in later life and can cause temporary delay in the clearance of tablets or capsules from the lower oesophagus into the stomach. This can cause local oesophagitis, which may be misinterpreted as ischaemic heart disease or an indicator of gastro-oesophageal reflux. Although well recognized as an adverse effect of alendronate, virtually any drug can cause the problem, and antibiotic capsules are among the most common. The remedy is for the patient to take tablets or capsules while standing and to wash them down well with a glass of water. Some older patients find that following tablets or capsules with a small piece of bread will stimulate enough oesophageal peristalsis to clear the drugs into the stomach.

Of the drugs causing adverse effects listed in Table 4, diuretics are probably the commonest offenders because they tend to be over-prescribed in general practice, usually for minor stasis oedema in older women. In terms of severity and permanence of damage, steroid-induced osteoporosis is one of the most serious complications of drug therapy for older people. If there is a possibility of steroid therapy becoming prolonged, as when prescribed for polymyalgia rheumatica or giant-cell arteritis, treatment to prevent osteoporosis should be initiated from the time of first prescription. For older patients this will normally consist of oral supplements of vitamin D and calcium with a bisphosphonate.

Table 5 outlines the principles of safer prescribing for older patients. Most of these are self-evident. In choosing a drug for an older patient a common problem, already alluded to, is that all too often there is no evidence on effectiveness specific to older people. Other things being equal, one is wise to choose a class of drug for which there is relevant evidence rather than extrapolate from data on younger patients. In general, with drugs with powerful and potentially dangerous effects, shorter-acting forms are preferable to longer, even though this may complicate dosage regimens. Thus, with oral hypoglycaemic drugs, tolbutamide or gliclazide should be prescribed in preference to chlorpropamide or glibenclamide. Benzodiazepines are best avoided entirely for older patients, but if essential for sleep disturbance only shorter-acting forms should be used and only for short periods. In a range of studies, longer-acting benzodiazepines have been consistently associated with falls. Although allegedly short acting, temazepam has longer effects on psychological function than its plasma half-life would suggest and is best regarded as a longer-acting drug.

Various prescribing practices are aimed at helping patients to avoid mistakes in medication. If possible drugs should be chosen to minimize the number of different times a day that they have to be taken. Combinations of four and three times a day regimes can be particularly troublesome if followed religiously. Patients should be helped by knowing what each of the medications they are taking is intended to do. Although there is little direct evidence in support, it is common geriatric practice to try to offer older patients drugs with distinctive shapes and colours rather than a collection of anonymous white tablets. Such a policy has to be consistent across repeat prescriptions and may call for specific rather than generic prescribing with attendant increases in costs. Patients discharged from specialist geriatric or psychogeriatric departments are often given cards with specimens of each prescribed tablet attached with transparent tape against a description of its purpose and dosage schedule. This can be helpful provided that general practitioners and pharmacists continue to provide the same brands of drug. A more reliable approach is to make use of one of the various forms of box or packet in which tablets can be sorted, by pharmacist or carer, into separate compartments labelled by day and time. These can be helpful to patients and also to carers who need to check whether drugs have been taken or not.

Arrangements should be made for regular and frequent review of medications given to older people, not least because dosage adjustments are often required with longer-term therapy. Even more important, no drug should be prescribed without thought to when it should be stopped, and unintended continuation of treatments is one source of unnecessary morbidity in old people. Pill counts are helpful in detecting inadvertent non-compliance with therapy. Surveillance of drug therapy for older patients is also important if adverse effects are to be detected promptly. It may be constructive to involve carers in the surveillance process. While it is clearly wise practice to warn patients and carers about possible adverse effects, comprehensive warnings of the type included in packet inserts can frighten people into not taking the drug at all.

General approaches to medical care for older people

Conditions such as stroke, cancer, heart disease, and dementia increase in incidence and prevalence with age, but old people do not suffer from any diseases that never afflict younger adults. It is in the treatment of the patient rather than of the disease that medical care for older people has to provide particular emphasis and sensitivity. Central is the loss of adaptability characteristic of age. Older patients may have little physiological reserve to cope with even minor shortcomings in care. Loss of adaptability may need to be compensated for in the design of medical services. More frequent checking of the international normalized ratio of older patients taking anticoagulants, and readier deployment of invasive monitoring for older patients after trauma or at risk of cardiovascular instability are examples.

Table 6 sets out some of the characteristics of illness in later life of which health workers must be aware and to which health services should be ready to respond. All of these characteristics are directly or indirectly aspects of the loss of adaptability that is the fundamental property of ageing. The first four underlie a need for rapid access to high-quality diagnostic and treatment facilities when an older person falls ill. Because of the frequent conjunction of multiple diseases with non-specific presentation, older people often need more investigations than do younger patients to establish an accurate diagnosis. An elderly patient with pneumonia may present with delirium or falls before any localizing signs appear in the chest. In infections, fever may appear late and may be missed if core temperature is not accurately measured or the patient is not given time to recover from a cold ambulance drive. Visceral pain from the peritoneum in acute appendicitis or intestinal perforation, or from the heart in myocardial infarction, may be reduced or absent in older patients. The slowness of the aged body in mounting its defences can lead to rapid deterioration unless an accurate diagnosis is made and correct treatment instituted urgently.

Reduced adaptability in old age also leads to a high incidence of secondary complications both of disease and treatment with consequent need for careful surveillance by medical and nursing staff. Good-quality medical and nursing care depends on scrupulous attention to detail, since even the smallest error of judgement or lack of observation may have serious consequences for the patient. A typical example lies with the development of pressure sores. A young person can usually lie immobile for 4 h without suffering serious pressure sores. An older person can develop sores in half that time. Pressure sores are most likely to develop if a patient is lying on a hard surface; particular hazards include time spent lying on a hospital trolley in a casualty department or on an operating table while junior orthopaedic surgeons spend an age doing their first hip replacement. High-quality care for an older population puts demands on the managers as well as the practitioners in health services.

Specialist geriatric care

The last two items in Table 6 underlie the need for specialist geriatric rehabilitation teams to be closely linked to the working of acute medical and surgical services. Most older patients, approximately 70 per cent of those referred to British hospitals as medical emergencies, have fairly straightforward illnesses such as pneumonia, myocardial infarction, or deep venous thrombosis. Treatment can be along normal lines, and patients discharged directly back home. The average length of stay will need to be longer than for younger patients because older people need longer to recover full function after a debilitating illness, and they are more likely to be living alone with no one to support them during convalescence. A proportion of older people admitted to medical wards, typically 10 to 15 per cent, have complex illnesses and functional problems that call for the multiprofessional approach of a specialist geriatric service if best outcomes are to be attained. Such patients need to be identified early on in their illness, and the ideal way of ensuring this is for physicians with special responsibility for older people to be part of the clinical team on acute medical wards. This approach ensures that the majority of older people, whose chief need is unimpeded access to the skills of other specialties, are not disadvantaged as they may be if admitted initially to a purely geriatrics service.

The approach to an elderly patient

Table 7 outlines the four stages that should structure the approach to elderly patients, especially those with complex problems.

Assessment

Assessment may require contributions from all members of the core geriatric team—doctor, nurse, occupational therapist, physiotherapist, and social worker. In addition to dealing with technical matters, this stage should also be seen by the team as an opportunity for 'getting to know' the patient as an individual and for building mutual trust and friendship. Functional assessment is best documented in terms of performance as measured using standard scales agreed both among the

geriatric team and with the relevant social services of community teams who will care for the patient after discharge. A wide range of scales is available, but one of the commonest in use for activities of daily living is the Barthel scale (Fig. 4). This is robust and reliable if the rules of administration are agreed and followed. It is useful as an indicator of needs for help but is primarily applicable to patients with moderate to severe disabilities. At higher levels of performance, scales for assessment of instrumental activities of daily living such as ability to use the telephone or travel on public transport may be more relevant.

Fig. 4 The Barthel activities of daily living scale with instructions for administration. (Formatted by courtesy of Dr S. J. Winner.)

Assessment of mental function usually calls for a global performance scale and may also require assessment of mood. The abbreviated mental test score (Table 8) is widely used in British hospitals and is easily applied but was developed for use in geriatric and psychogeriatric inpatient units; a patient scoring at the significantly low score of 7 out of 10 is quite severely impaired. Milder degrees of impairment are better detected by the Folstein mini-mental status examination. Neither the mental test score nor the mini-mental status examination is a diagnostic instrument, and reduced scores may reflect any cause of impaired cognitive function including dementia, depression, or delirium. If depression is suspected, a screening questionnaire such as the geriatric depression scale may be helpful but should not be regarded as an adequate substitute for a skilled and sensitive clinical assessment.

Understanding a patient's cultural and educational background is an important stage in ensuring good communication and information needs. Protection of patients' autonomy is imperative but forcing patients to make worrying decisions they do not understand is to mistake the form for the substance. The most important resource available to an older patient is often his or her family who must be appropriately involved in planning care. 'Appropriately' implies taking their needs and priorities into account but not letting them over-ride those of the patient.

Setting the objectives of care

The second stage of setting objectives of care is essentially a dialogue and negotiation between the doctor who knows what could effectively be done, and the patient who decides what should be done. This should be an essential stage of care for any patient but is often omitted with younger patients for whom it is usually assumed, not always appropriately, that prolongation of life is the only objective to be considered. Older people may have other priorities; they may value dignity and independence more than life. If alone in the world they may have the privilege of being able to please themselves without having to worry about the effects their decision may have on others. It is at this stage of care that issues of quality of life are most important. Standard questionnaires are of limited worth because they assume that everyone shares the same system of values. In identifying what a person enjoys in life, and the effects that different treatment options may have on a particular patient's quality of life, more individualized methods are required. Psychometrically based questionnaires responsive to the value systems of individual patients are under development, and interactive computer programs can help with specific issues such as choice of treatment of prostatic hypertrophy, but for older patients with complex problems it has yet to be shown that anything is more reliable than compassionate human interchange. Once objectives have been agreed they need to be specified clearly in the notes and, subject to the patient's agreement, explained to relevant family members and future carers.

The management plan

Formulating a management plan calls for appropriate and timely treatment for any relevant acute diseases together with rehabilitation of the patient for resettlement in the future abode of choice, usually his or her own home. In order to achieve this the management plan must provide for bridging any 'ecological gap' between what patients can do and what their homes are going to demand. The gap is closed by improving the patient through therapeutic interventions and reducing the demands of the environment by prosthetic interventions. Therapeutic interventions often involve the whole geriatrics team. A hemiplegic stroke patient, for example, might be helped by the doctor improving exercise tolerance through tighter management of heart failure, the physiotherapist improving walking, the occupational therapist teaching him or her how to dress, the nurse devising the best programme for the diuretic therapy and ensuring proper nutrition, and the social worker steadying morale and sense of security about future support in the community. At the same time that the therapeutic programme is under way plans should be going forward for any prosthetic changes to the patient's home that are likely to be needed. These may include aids and adaptations such as extra banisters on stairs, grab rails in the bathroom, a raised toilet seat, fitting an alarm, as well as providing for personal help for shopping, bathing, supervision of medication, or other needs. In difficult situations rehousing, or, in the worst case, the ultimate prosthetic environment of institutional care might have to be arranged. It is important that the therapeutic and prosthetic programmes are managed in step since it can be extremely demoralizing for a patient who is physically and psychologically ready to go home to have to wait because aids and services are not yet in place.

Home visits with the patient prior to discharge can be very helpful both in identifying what prosthetic input is necessary and also in reassuring an apprehensive patient and possibly anxious relatives that a return home is feasible. The team must pay careful attention to the needs of relatives and others involved in the patient's care. Those who will make a personal contribution may need to spend time in the rehabilitation ward under the tutelage of nurses or therapists learning any necessary skills in helping the patient both physically and psychologically. An important element in this may be to prevent carers from being too helpful, as that can lead later to the patient becoming unnecessarily dependent. A less welcome aspect of the rehabilitation team's dealing with relatives is in relation to objections, often from those who will be contributing least to a patient's later care, that attempts at return into the community are impractical and 'she would be much better off in a nursing home'. This situation is often more complex than it seems in that it may reflect family tensions arising from half a century of unspoken animosities. The problem may also arise because relatives think that responsibility for the success or failure of the discharge will fall upon them, or feel guilty that they will not be able to contribute, or fear criticism for not doing so. The first step in negotiations is therefore always to try to find out what social and psychological crosscurrents are running—an activity in which all members of the team need to acquire skill, although the social worker is the most specifically trained. Discussion with a primary care physician who has known the patient and family for years can often prove illuminating. Tact and avoidance of confrontation are called for, followed sometimes by delicate diplomacy in negotiating between differing factions in a patient's family. It may surprise some to learn that this aspect of the work of specialist geriatrics departments, far from being seen as an impediment to rational medicine, is actually a source of great professional satisfaction when done well.

A follow-up visit 10 days or so after discharge is also helpful, both to make sure that all is well and for the rehabilitation team to savour the satisfaction of seeing their patient happily back in his or her natural habitat or to learn from any insufficiencies.

Regular review of a patient's progress is usually formalized in a weekly multiprofessional meeting. The meeting is chaired by the clinically responsible doctor, but decisions are collective and must be formally recorded in the patient's notes. In addition to a general review of progress towards treatment goals, an important task for the meeting is to recognize when progress is not as had been expected. This may mean that the original plan was inappropriate, either in setting unrealistic goals or in specifying a less than optimum treatment programme. More often the problem arises because some new factor has intervened to interrupt the patient's progress. This may range from medical problems such as a depressive illness (a particularly common sequela in stroke), a drug side-effect, or urinary tract infection, to psychosocial factors such as discouragement from something a visitor has said, or some adverse change in the ward environment. The new factor should be dealt with or the management plan or treatment goals modified as appropriate. Relevant family members and carers, as well as the patient, should be informed if significant changes to aims and means of rehabilitation are made.

The future

Populations are ageing throughout the world and for more than a decade the majority of the world's population of people aged over 65 have been living in developing

rather than developed countries. The older patient is now the norm, and the practice of medicine and the design of services must continue to adapt. The demand for medical care will rise as the numbers of older people increase and new medical technologies become increasingly appropriate for frailer patients. These changes must be planned for, but in so far as they represent the fact that more people are living longer and more actively, they should be welcomed as one aspect of the progress of civilization. Emphasis in health care needs to shift from the prolongation of life at all costs to the prevention and cure of disability. This needs to apply at all ages. Age-based rationing of health care is not compatible with the democratic ideal, nor would it make economic sense as it would merely substitute the long-term costs of disablement for the short-term price of treatment. But in association with the development of rational heath care systems there needs to be a public health strategy for the lifelong primary prevention of disability. Because of the age-associated loss of adaptability, the later in life a potentially disabling disease strikes the more likely the patient is to die from it rather than linger on in disability. Postponement of disease is prevention of disability. Our collective aim is to spend a long time living and a short time dying.

30.2 Mental disorders of old age

Robin Jacoby

Mental disorders of old age are of the greatest importance because:

- demographic trends in **all** countries are leading to a marked increase in the number of elderly persons, especially the very old;
- this age group is particularly prone to debilitating mental illness;
- presentations of mental illness in the elderly may differ from those at younger ages and go unrecognized;
- the pattern of morbidity differs; the elderly suffering more from organic disorder—delirium and dementia;
- mental and physical illness often occur together, the one sometimes masking the other.

Elderly inpatients on non-psychiatric wards show high rates of mental disorder of various sorts. Community rates are also high. For instance, the prevalence of dementia is about 7 per cent over 65 years of age, but approaches 20 per cent in those over 80. For major depressive illness defined by ICD-10 or DSM-IV the prevalence is no more than 3 per cent, but for pervasive depressive symptoms, which most psychiatrists would consider in need of treatment, it is around 12 per cent. There are no valid data for the prevalence of very-late-onset schizophrenia-like psychosis. The closure of large mental institutions in most developed countries has resulted in a greatly increased number of elderly patients in the community suffering from chronic schizophrenia that began much earlier in their lives.

Assessment

Factors to be considered are:

- the setting in which the patient is examined;
- the patient's ability to provide information.

Assessment in the patient's own home gives invaluable clues about premorbid adjustment, activities of daily living, and even causes of an abnormal mental state—for example, a waste bin full of empty whisky bottles. Patients in general hospital wards should be assessed in a side-room if possible. Many elderly patients are unable to give a history. It is therefore essential to find reliable informants, even if this means disturbing neighbours or making long-distance telephone calls. Doctors visiting patients outside hospital should carry equipment for physical examination. A low-reading thermometer, sphygmomanometer, and sugar-detection urine sticks may also prove invaluable at home in detecting the cause of mental disturbance.

Examination of the mental state of an elderly person is essentially the same as for any adult, but with differences of emphasis. More attention is paid to the level of consciousness, particularly subtle fluctuations throughout 24 h. For patients with suspected dementia a full cognitive examination is undertaken, frequently in several brief sessions because patients become easily fatigued and unable to co-operate. Tired or inattentive patients may fail a test that they might otherwise have been able to perform satisfactorily. Systematic evaluation of all higher cerebral functions, such as memory, praxis, and language, is essential. On general hospital wards or home visits the routine administration of standardized questionnaires is of value as an alerting mechanism, but not a substitute for full evaluation. The Mini-Mental State Examination (**MMSE**) is the preferred questionnaire because it assesses a range of higher cerebral functions, not just memory and orientation.

Because the capacity to live independently is frequently compromised in elderly people and becomes the crucial determinant of social outcome, it is essential to assess the patient's ability to perform activities of daily living (**ADL**)—dressing, feeding, toilet care, and so on. Impairment in ADL may reveal dyspraxia or agnosia undisclosed by formal clinical tests. The informant's account is important, as patients' assessments of their own abilities may be misleading.

Delirium

The clinical features of delirium are described elsewhere. The elderly are particularly susceptible because:

- They more commonly suffer from the physical disorders that cause delirium: hypoxia, infections, toxicity (especially from drugs), and metabolic and CNS disorders.
- Many have a decreased cerebral reserve because of incipient or overt dementia.

An underlying physical cause for delirium must therefore be sought assiduously, as it is generally more important to treat this than the mental symptoms. Physical illnesses causing delirium can be relatively minor: for example, a urinary tract infection, especially in patients with dementia. Because the elderly generally suffer high physical morbidity they tend to receive more prescribed medication. Single or multiple drugs, as well as drug withdrawal effects, are potent causes of delirium. Management is essentially that of the underlying cause and psychotropic drugs should be avoided whenever possible. However, short-term treatment of mental symptoms and behavioural disturbance with a small dose of a neuroleptic drug is sometimes unavoidable to allow medical treatment to proceed unhindered.

Dementia

The importance of dementia lies not only in the suffering it causes to patients but also in the demands it makes upon family caregivers and the medical and social services. The clinical features of the dementia syndrome are described in Chapter 24.13.8. Global impairment is required for diagnosis, and memory loss alone, of which elderly people invariably complain, is **not** a sufficient criterion. Accurate diagnosis is required because:

- treatable or arrestable causes may be discovered;
- management can be planned and implemented;
- caregivers are helped by a clearer understanding of the process affecting the patient and its likely course;
- knowledge of the underlying conditions is accrued and advanced.
- treatment with a central cholinesterase inhibitor may be indicated.

Rational management requires an appreciation of the practical implications of cognitive impairment: for example, ensuring nutrition in a patient with dyspraxic inability to feed herself. However, the non-cognitive, behavioural, and psychiatric disturbances in dementia are the manifestations which cause most problems to caregivers and often require management by specialist services. Patients should be maintained at home for as long as possible, both for humane reasons and because they will have lost the capacity to adapt easily to a new environment. This is best achieved through a continuing partnership between clinicians, family caregivers, and local statutory and voluntary social services. Such interagency co-operation and discussion facilitates access to community services, which include those brought to the patient—meals, nursing, bathing, house cleaning—and day care away from home. Intercurrent illness should be treated along with other medical problems, such as incontinence, which is due more commonly to urinary tract infections and faecal impaction, respectively, than to the underlying disease processes of dementia. Attention must be given to principal caregivers (most frequently spouses or adult daughters, but sometimes unrelated neighbours), who show high levels of psychiatric morbidity themselves due to their burden of care.

Affective illness

Depression

Depressive illness in the elderly differs only in emphasis from that in earlier life, varying from mild dysthymia to major psychosis with high risk of suicide. Psychosocial factors are as important, but genetic loading is usually lower in patients with late-onset depression. Cerebral organic change is more common in late-onset cases.

Psychomotor retardation is frequent, as in younger patients, but anxiety and agitation are also characteristic. Delusions of guilt and unworthiness are typical, but hypochondriacal or nihilistic beliefs also often occur. Histrionic or other bizarre behaviour, which is out of premorbid character, is also seen. Some patients with severe depression perform badly on cognitive tests, so called 'depressive pseudodementia', which may lead to a wrong diagnosis of organic dementia,. Hypochondriacal delusions together with anorexic weight loss can be mistaken for physical illness, such as cancer. Some patients may even deny low mood ('masked depression'), but the presence of other typical affective manifestations and a favourable response to antidepressant treatment reveal the correct diagnosis. The clinician should not avoid treating depression in patients, such as those with severe physical illnesses, simply because they appear to have a valid reason to be unhappy.

The elderly are vulnerable to the unwanted effects of psychotropic drugs but respond well to standard antidepressants. Selective serotonin-reuptake inhibitors (**SSRIs**) are usually preferred as first-choice drugs because of their safety and fewer side-effects. However, tricyclics, such as amitriptyline and imipramine, are highly effective, especially in major depression, if care is taken to observe the general principle of small initial doses increasing slowly to lower therapeutic doses than are given to younger patients. The elderly also respond well to electroconvulsive therapy (**ECT**), regarded by many as the treatment of choice for deluded and/or suicidal patients. Extreme age, dementia, and physical infirmity are **not** contraindications to electroconvulsive therapy. After recovery from an episode of major depression, antidepressant treatment should be continued for at least 2 years, and probably indefinitely.

Mania/hypomania

Manic illness, which accounts for about 5 per cent of psychogeriatric admissions, is usually less florid than in younger patients. Mixed manic and depressive pictures have been described as typical, but are probably not more common in old age than before. Cerebral organic disease is found in a high proportion of cases. Diagnosis is sometimes difficult to make because patients may present with a rather non-specific psychosis, or one mimicking delirium. The clinician should therefore enquire about a previous history of affective illness. Secondary mania, defined as a first onset in close temporal relationship with a physical illness or drug treatment in patients with no previous history of affective disorder, is also seen. Patients respond well to treatment with neuroleptics and lithium carbonate in the acute phase. Lithium is also widely used to prevent relapse. Here, frequent monitoring of renal and thyroid function is essential, and the serum lithium level should be maintained at the lower end of the therapeutic range, that is to say around 0.6 mmol/l.

Paranoid disorders

Paranoid ideas, usually but not invariably of persecution, are common in dementia and affective disorder. In dementia they tend to be transient, variable, and unsystematized. In affective disorder they are usually mood-congruent, for example persecution deserved because of guilt. Persecutory ideas are also seen in paranoid personalities and acute paranoid reactions, but very-late-onset schizophrenia-like psychosis * is the main paranoid syndrome of old age, equivalent to, but distinct from, paranoid schizophrenia of earlier adult life. The following aetiological factors have been consistently reported:

- a high female to male ratio (up to 7:l);
- a family history of schizophrenia intermediate between the general population and younger schizophrenic patients;
- social isolation and poor premorbid interpersonal relationships;
- low marriage and fecundity rates compared with age-matched peers;
- long-standing deafness.

The clinical picture is sometimes indistinguishable from early-onset paranoid schizophrenia, but the patient usually presents with a few simple delusions and associated auditory hallucinations. For example, she may complain of hearing the neighbours plotting against her, or impugning her sexual virtue. Medication with atypical antipsychotic drugs, such as risperidone or olanzapine, to minimize the risk of extrapyramidal side-effects, is the treatment of choice. However, neuroleptics rarely extinguish delusional beliefs that become 'encapsulated', meaning set aside or compartmentalized and not permitted to intrude into so many aspects of mental and daily life, as happens during the acute phase of illness. Adherence to treatment is often poor but can be improved with the help of a community psychiatric nurse.

Neurotic, personality, and other disorders

These are too complex to discuss briefly and the reader is referred to specialist texts. However, some general principles can be stated. It is essential to differentiate lifelong neurosis from neurotic symptoms of first onset in old age because the latter, predominantly anxiety and phobia, are most likely to indicate an underlying depressive illness. Elderly patients with lifelong neurosis have frequently adapted to their disability in spite of continued suffering. Mild and moderate lifelong personality deviations are common, but severe disorders are occasionally encountered, such as the senile squalor (Diogenes) syndrome, which can require compulsory removal from home under mental or public health legislation. Illicit drug taking is rare among the present generation of elderly, but the abuse of prescribed drugs, notably benzodiazepines, is common. Alcohol abuse is increasingly recognized as a cause of mental and social disability in elderly people.

---

*Recent international agreement states that cases with onset between 40 and 59 years of age should be termed 'late-onset schizophrenia'; whereas cases from 60 years onwards should be called 'very-late-onset schizophrenia-like psychosis'.

31 Palliative care

Robert Twycross and Mary Miller

In Western countries, about 25 per cent of the population die of cancer. Even more die of progressive non-malignant disease. In this chapter the focus is on symptom management in patients with far-advanced cancer.

Palliative care is far more than symptom relief. It addresses physical, psychological, social, and spiritual aspects of suffering, thereby helping patients to come to terms with their impending death as constructively as they can while living as actively and creatively as possible. Palliative care also provides a parallel support system to help families cope during the patient's illness and in bereavement; it is best provided by a multiprofessional team.

General principles of symptom management ('EEMMA')

The principles underlying management are:

- *evaluation*: diagnosis of each symptom before treatment;
- *explanation*: explanation to the patient before treatment;
- *management*: individualized treatment;
- *monitoring*: continuing review of the impact of treatment;
- *attention to detail*: no unwarranted assumptions.

Evaluation is based on probability and pattern recognition. For example, hiccup in advanced cancer is mostly associated with gastric stasis or distension, and the most common cause of pruritus is dry skin. Symptoms are not always caused by the disease itself but by treatment, debility, or a concurrent second disorder. Some symptoms are caused by multiple factors. **Explanation** by the doctor of the cause(s) of a symptom does much to reduce its psychological impact on the sufferer.

Management falls into three categories:

- correct the correctable
- non-drug measures
- drugs.

By adopting a multimodality approach, although the underlying disease cannot be cured, it is generally possible to obtain significant, and sometimes complete, relief.

Drugs for a persistent symptom should be prescribed regularly on a prophylactic basis. The use of drugs 'as needed' instead of regularly is the cause of much needless distress. Although many symptoms respond to a combination of non-drug and drug measures, often the main part of the management of symptoms such as anorexia, weakness, and fatigue is helping the patient (and family) accept the irreversible physical limitations of terminal disease.

Patients vary, and it is not always possible to predict the optimum dose of opioids, laxatives, and psychotropic drugs. Adverse effects may also jeopardize patient compliance. **Monitoring** is crucial, with adjustments made as necessary.

Attention to detail is important at every stage of symptom management. It is equally important in relation to the non-physical aspects of care—all symptoms are exacerbated by anxiety and fear.

Pain

At diagnosis, between 20 and 50 per cent of patients with cancer have pain. Prevalence varies according to the primary site of the cancer and metastatic spread. In advanced cancer, 75 per cent of patients have pain and two-thirds of these have multiple pains.

Evaluation

Each pain described by the patient should be recorded on a body chart with a comment about the probable cause (Fig. 1). In addition, pain may be classified as:

- nociceptive, i.e. pain caused by physical and/or chemical stimulation of free nerve endings;
- neuropathic, i.e. pain caused by compression or injury to the peripheral or central nervous systems.

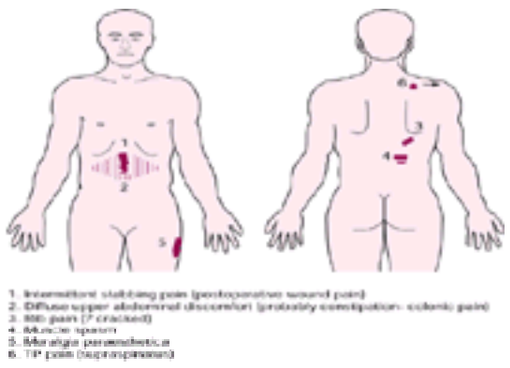

Fig. 1 Pain chart of a 63-year-old woman with cancer of the pancreas, 10 days postoperatively. TP, myofascial trigger point.

Nerve compression pain, like nociceptive pain, is aching in character. On the other hand, nerve injury pain tends to be superficial and burning, and associated with allodynia (light touch caused pain). There may also be spontaneous stabbing pain with or without an underlying aching component. Peripheral neuropathic pain is neurodermatomal in distribution, not local to the lesion, and there may be associated numbness.

A history of analgesic use is part of the evaluation. Not all pains respond equally to analgesics, and information about the benefits of specific medication (or lack of it) may help to identify the underlying mechanism. A detailed pain history coupled with physical examination is generally sufficient to guide management. Further radiological investigations are necessary in only a minority of patients.

Management

- Although analgesics are the mainstay of management, it is important not to overlook correctable causes of pain or ignore other treatment modalities (Box 1). Analgesics can be divided into three classes: non-opioid (antipyretic), opioid, and adjuvant. Their use is governed by the following maxims:
- *By the mouth*—the oral route is the preferred route, including for morphine and other strong opioids.
- *By the clock*—analgesics should be given regularly and prophylactically for persistent pain; 'as needed' medication is irrational and inhumane.
- *By the ladder*—use the 3-step analgesic ladder (Fig. 2).
- *Individualized treatment*—analgesic combinations and doses should be determined individually for each patient.
- *Use adjuvant medication*—meaning adjuvant analgesics, antidotes for adverse effects (e.g. laxatives, antiemetics), and psychotropic medication.

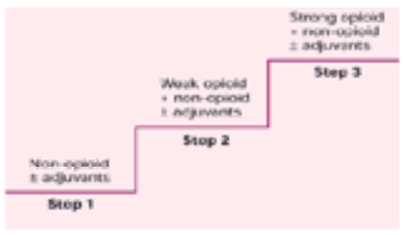

Fig. 2 The World Health Organization analgesic ladder for cancer pain management.

Box 1 Pain management in cancer

Modification of the pathological process	**Psychological**	
Radiation therapy	Relaxation	
Hormone therapy	Cognitive–behavioural therapy	
Chemotherapy	Psychodynamic therapy	
Surgery		
	Interruption of pain pathways	
Analgesics	Local anaesthesia	
Non-opioid (antipyretic)		lidocaine (lignocaine)
Opioid		bupivacaine
Adjuvant	Neurolysis	
	corticosteroids	chemical (e.g. alcohol, phenol)
	antidepressants	cold (cryotherapy)
	antiepileptics	heat (thermocoagulation)
	muscle relaxants	Neurosurgery
	antispasmodics	cervical cordotomy
Non-drug methods	**Modification of way of life and environment**	
Physical	Avoid pain-precipitating activities	
	massage	Immobilization of the painful part
	heat	cervical collar
	transcutaneous electrical nerve	surgical corset
	stimulation (TENS)	slings
		orthopaedic surgery

Walking aid
Wheelchair
Hoist

Non-opioids

The non-opioid (antipyretic) analgesics comprise paracetamol/acetaminophen and the non-steroidal anti-inflammatory drugs (**NSAIDs**). Paracetamol can be taken by two-thirds of patients who are hypersensitive to aspirin. NSAIDs and paracetamol can be used together with an additive effect. The main drawback with paracetamol is the frequency of administration, generally every 4 to 6 h.

NSAIDs inhibit cyclo-oxygenase (**COX**), an important enzyme in the arachidonic acid cascade which results in the production of tissue and inflammatory prostaglandins. COX exists in two forms; COX-1 is present in all normal tissues, whereas COX-2 is more limited in its distribution but massively induced by inflammation (Fig. 3). Recently introduced COX-1 sparing NSAIDs and specific COX-2 inhibitors cause less gastric toxicity than most dual COX inhibitors.

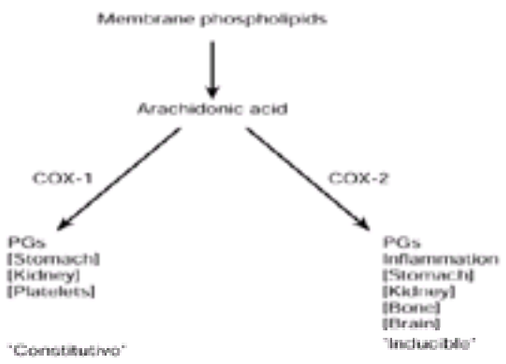

Fig. 3 The different effects of COX-1 and COX-2.

NSAIDs are of particular benefit for pains associated with inflammation, for example soft tissue infiltration and bone metastases. NSAIDs differ in their effect on platelet function. In patients undergoing chemotherapy or with thrombocytopenia from another cause, it is best to use an NSAID which has no effect on platelet function (Table 1).

Weak opioids

There is little to choose between codeine, dextropropoxyphene, and dihydrocodeine in terms of efficacy. Pentazocine is not recommended; it acts for only 2 to 3 h and often causes psychotomimetic effects (hallucinations, feelings of unreality, dysphoria). Generally, a weak opioid should be added to a non-opioid, not substituted for one. If a weak opioid is inadequate when given regularly in an optimal dose, change to morphine (or an alternative strong opioid); do not switch from a weak opioid to a weak opioid.

Tramadol forms a bridge between the classic weak and the classic strong opioids. By injection, it is one-tenth as potent as morphine. By mouth, it is about one-fifth as potent as morphine because of its high oral bioavailability. Tramadol has a dual mechanism of action, partly via opioid receptors and partly by blocking the presynaptic reuptake of 5-hydroxytryptamine (5-HT, serotonin) and noradrenaline (norepinephrine), similar to a tricyclic antidepressant. Tramadol causes less constipation than codeine and morphine.

Strong opioids

The use of strong opioids is dictated by therapeutic need, not by brevity of prognosis.

Morphine is the strong opioid of choice for treating cancer pain (Box 2), and is generally given with an NSAID (and/or paracetamol). Morphine is available as tablets (for example, 10 mg, 20 mg) or in a solution (for example, 2 mg and 20 mg in 1 ml). Modified-release preparations are mostly administered twice a day, some once a day.

Box 2 Starting patients on oral morphine

- Morphine is indicated in patients with pain that does not respond to the optimized combined use of a non-opioids and a weak opioid.
- The starting dose of morphine is calculated to give a greater analgesic effect than the medication already in use:
- If the patient was previously receiving a weak opioid, give 10 mg every 4 h or modified-release 20–30 mg every l2 h.
- If changing from another strong opioid, a much higher dose of morphine may be needed (Table 2).
- If the patient is frail and elderly, a lower dose (e.g. 5 mg every 4 h) helps to reduce initial drowsiness, confusion, and unsteadiness.
- Because of cumulation of an active metabolite, a lower and/or less frequent regular dose may be preferable in renal failure, e.g. 5–10 mg every 6 h.
- If the patient takes two or more 'as needed' doses in 24 h, the regular dose should be increased by 30 to 50 per cent every 2 to 3 days.
- Upward titration of the dose of morphine stops when the pain is relieved or intolerable undesirable effects supervene. In the latter case, it is generally necessary to consider alternative measures. The aim is to have the patient free of pain and mentally alert.
- *Modified-release morphine may not be absorbed satisfactorily in patients troubled by frequent vomiting or those with diarrhoea or an ileostomy. M/r morphine should be used with caution if there is evidence of renal failure.*
- **Scheme 1: ordinary (normal-release) morphine tablets or solution**
- morphine given 4-hourly regularly 'by the clock' with 'as needed' doses of equal amounts up to 1-hourly;
- after 1–2 days, adjust the dose upwards if the patient still has pain or is using two or more 'as needed' doses per day;
- continue with 4-hourly doses regularly with 'as needed' doses of equal amounts up to 1-hourly;
- increase the regular dose by 30 to 50 per cent every 2 to 3 days until there is adequate relief throughout each 4-h period;
- *a double dose at bedtime obviates the need to wake the patient for a 4-hourly dose during the night* .
- **Scheme 2: ordinary (normal-release) morphine and modified-release morphine**
- begin as for Scheme 1;
- when the 4-hourly dose is stable, replace with modified-release morphine every l2 h, or once daily if a 24 h preparation is prescribed
- each l2-hourly dose will be *three times* the previous 4-hourly dose; a once-daily dose will be *six times* the previous 4-hourly dose, rounded to a convenient number of tablets;
- continue to provide ordinary morphine solution or tablets for 'as needed' use. Give the equivalent of a 4-hourly dose, i.e. 1/6 of the total daily dose.
- **Scheme 3: modified-release morphine and ordinary (normal-release) morphine**
- starting dose generally modified-release morphine 20-30 mg 12-hourly or 40–60 mg once daily;
- use ordinary morphine tablets or solution for 'as needed' medication; give about 1/6 of the total daily dose;
- increase the dose of modified-release morphine by 30 to 50 per cent every 2–3 days until there is adequate relief around the clock.
- Supply an antiemetic in case the patient becomes nauseated, e.g. haloperidol 1.5 mg to be taken immediately and then regularly at bedtime.
- Prescribe laxatives, e.g. co-danthrusate or senna ± docusate; adjust the dose as necessary.
- Suppositories and enemas continue to be necessary in about one-third of patients.
- *Constipation may be more difficult to manage than the pain.*
- Warn all patients about the possibility of initial drowsiness.
- If swallowing is difficult or there is persistent vomiting, morphine may be given per rectum by
- suppository; the dose is the same as by mouth. Alternatively give half the oral dose by injection,
- or one-third as diamorphine, preferably by subcutaneous infusion.
- For outpatients, write out the drug regimen in detail with times, names of drugs and amount to
- be taken. Arrange for follow-up.

Morphine rarely causes respiratory depression in patients with pain because pain is a physiological antagonist to the central depressant effects of morphine. However, morphine is potentially dangerous in renal failure. Its main metabolites are morphine-3-glucuronide (**M3G**) and morphine-6-glucuronide (**M6G**). Both cumulate in renal failure but, whereas M3G is inactive, M6G is more potent than morphine. In this circumstance, there is danger of sedation and respiratory depression if the dose is not closely monitored and, if necessary, reduced both in quantity and frequency.

Psychological dependence (addiction) does not occur when morphine is used appropriately as an analgesic. Physical dependence—a phenomenon seen with many psychoactive drugs when taken for prolonged periods (months rather than weeks)—does not prevent a step-by-step reduction in the dose of morphine if the pain ameliorates, for example as a result of radiotherapy or a nerve block. Tolerance to morphine is not a practical problem.

Other modes of administration are necessary at times (Fig. 4). Transdermal fentanyl patches, available in several sizes (25, 50, 75, 100µg/h over 3 days), are an alternative option for patients on a stable dose of morphine, and for those with a tablet phobia or dysphagia. Patients who have not been taking morphine should always start on the lowest dose. Fentanyl is less constipating than morphine. However, acquisition costs are much higher.

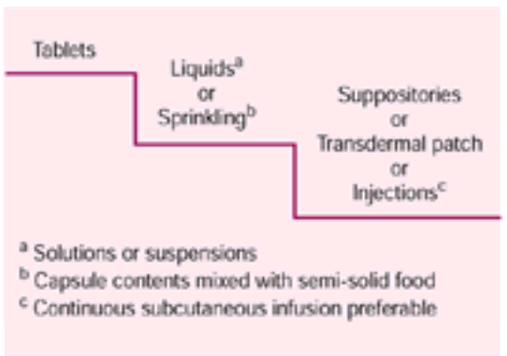

Fig. 4 Alternatives routes of administration.

Injections are indicated when there is:

- persistent nausea and vomiting;
- severe dysphagia (alternatively use transdermal fentanyl);
- extreme weakness;
- a diminished level of consciousness.

In the United Kingdom, diamorphine hydrochloride (diacetylmorphine) is used when injections are necessary. It is more soluble than morphine salts and large amounts can be given in small volumes. By injection, diamorphine is twice as potent as morphine. Because of rapid deacetylation, however, diamorphine by mouth is essentially a prodrug for morphine and is only marginally more potent than morphine.

There are several opioid receptor subtypes (µ, _, †). Opioids differ in their receptor-site affinity, intrinsic activity, and concomitant non-opioid effects. These differences can be capitalized on in patients who are intolerant of morphine (mainly a µ-receptor agonist) by converting, for example, to methadone (µ-receptor agonist with non-opioid properties) or oxycodone (µ-, _-receptor agonist).

When switching from another strong opioid to oral morphine (or vice versa), the initial dose depends on the relative potency of the two drugs (Table 2). The main reason for changing from morphine to another opioid is intolerance of morphine, for example marked dysphoria, sedation, and/or persistent hallucinations. Pethidine is not recommended for cancer pain—it acts for only 2 to 3 h.

Adjuvant analgesics

Adjuvant analgesics are miscellaneous drugs that relieve pain in specific circumstances. The main ones are corticosteroids, antidepressants, antiepileptics, muscle relaxants, and antispasmodics.

Corticosteroids

Corticosteroids are particularly useful for pain associated with nerve root or nerve trunk compression, and with spinal cord compression. Dexamethasone, 4 to 8 mg once a day, is prescribed for the former and 12 to 20 mg (sometimes more) for cord compression together with radiotherapy.

Antidepressants and antiepileptics

Nerve injury pains often do not respond well to non-opioids and opioids because of central (dorsal horn) sensitization. Additional measures are commonly necessary to obtain satisfactory relief. These aim to:

- dampen the hyperexcitability of damaged peripheral nerves;
- inhibit the glutamate excitatory system in the dorsal horn;
- enhance the g-aminobutyric acid (**GABA**) inhibitory system in the dorsal horn (Fig. 5).

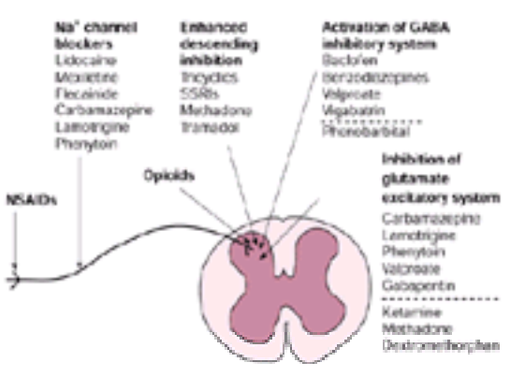

Fig. 5 Impact of analgesics and adjuvant analgesics on peripheral nerves and the dorsal horn of the spinal cord. Drugs below the dotted lines are channel blockers; the rest are receptor ligands.

For example, amitriptyline 25 to 75 mg at night (an antidepressant) and sodium valproate 400–1000 mg at night (an antiepileptic) can be used either singly or together. These should generally be given in addition to morphine and a non-opioid analgesic if the nerve injury pain is associated with an infiltrating cancer, but they may well be effective alone in 'pure' nerve injury pain (for example, chronic postsurgical incision pain, postherpetic neuralgia).

Gabapentin is the only antiepileptic drug that is specifically licensed in the United Kingdom for the relief of neuropathic pain. The effective dose varies between 100 and 1200 mg given three times a day. Like many drugs acting on the central nervous system, gabapentin can cause drowsiness; most patients with cancer cannot tolerate more 600 mg three times a day.

With nerve injury pain which does not respond to such measures, it may be necessary to supplement or replace the antidepressant and antiepileptic with a glutamate (**NMDA**, *N*-methyl-D-aspartate) receptor-channel blocker, for example methadone and ketamine. A few patients (<1 per cent) require spinal analgesia (for example, morphine plus bupivacaine, with or without clonidine) or a neurolytic procedure to obtain adequate relief. Some patients derive benefit from other non-drug measures, for instance transcutaneous electrical nerve stimulation (**TENS**).

Antispasmodics and muscle relaxants

Muscle spasm pain (cramp) secondary to underlying bone pain and/or skeletal deformity is common in cancer patients. Myofascial trigger-point pains also occur. For these the correct approach is not more analgesics but explanation, physical therapy (massage and local heat), diazepam, and relaxation therapy. Trigger points can be injected with a local anaesthetic and a corticosteroid, for example bupivacaine 0.5 per cent and depot methylprednisolone.

Antispasmodics such as hyoscine butylbromide and glycopyrronium (given by subcutaneous infusion) are necessary in some patients with inoperable endstage intestinal obstruction.

Nausea and vomiting

Nausea and vomiting occurs in about half of the patients with advanced cancer. Intestinal obstruction, gastric stasis, drugs, and biochemical abnormalities are responsible in about 80 per cent of cases. It is often the sequence of events (plus an appropriate level of suspicion) that points to the likely cause.

In **acute** bowel obstruction there is typically a single discrete lesion, whereas in **chronic** obstruction (persistent or remittent) there may well be several sites of partial obstruction in both small and large bowels. Retroperitoneal disease may cause visceral neuropathy and functional obstruction. In consequence, the quartet of symptoms and signs that point to a diagnosis of acute intestinal obstruction (abdominal distension, pain, vomiting, and constipation) is often not so obvious in patients with advanced cancer and chronic obstruction. For example, distension may be minimal because of multiple intra-abdominal malignant adhesions. Bowel sounds vary from absent to overactive with borborygmi; tinkling bowel sounds are unusual. Some patients have diarrhoea rather than constipation.

A degree of gastric stasis is present in many patients with advanced cancer. Diagnosis depends on a high level of clinical suspicion and pattern recognition (Box 3). There are several causes of gastric stasis and multiple factors may be responsible:

- dysmotility dyspepsia (often long-standing);
- drugs, e.g. opioids, antimuscarinics;
- cancer of the head of the pancreas (disrupts duodenal transit);
- retroperitoneal disease leading to neural dysfunction;
- spinal cord compression;
- paraneoplastic autonomic neuropathy;
- diabetic autonomic neuropathy.

Box 3 Clinical features of gastric stasis

- Some or all of the following symptoms may occur:

  - early satiety
  - postprandial fullness
  - epigastric bloating
  - epigastric discomfort
  - heartburn
  - belching
  - hiccup
  - nausea
  - retching
  - vomiting

- On examination there may be:

  - epigastric distension
  - a succussion splash

  The absence of these features does not rule out symptomatic gastric stasis.

  If associated with autonomic neuropathy, there is often evidence of other autonomic abnormalities, e.g. orthostatic hypotension without a compensatory tachycardia.

  •bowel sounds are generally normal but may be decreased if the stasis is opioid-induced

  The use of metoclopramide (a prokinetic drug) often leads to improvement and the resolution of the succussion splash.

Management

Correct the correctable

Medication may need to be modified, ascites drained, and hypercalcaemia corrected (unless coincidental in a moribund patient). Surgery for bowel obstruction should be considered if all the following criteria are all fulfilled:

- an easily reversible cause seems likely, e.g. postoperative adhesions or a single discrete neoplastic obstruction;
- the patient's general condition is good, i.e. does not have widely disseminated disease and has been independent and active; and
- the patient is willing to undergo surgery.

Surgical intervention for bowel obstruction is contraindicated in each of the following circumstances:

- previous laparotomy findings preclude the prospect of a successful intervention;
- diffuse intra-abdominal carcinomatosis as evidenced by diffuse palpable intra-abdominal tumours;
- massive ascites that reaccumulates rapidly after paracentesis.

Non-drug measures

Make sure that the patient is not assailed by food smells from the kitchen. Offer only small helpings of food. Possibly try an acupressure band on one or both wrists.

Drugs

The initial choice generally lies between four drugs: metoclopramide, haloperidol, hyoscine butylbromide, and cyclizine (Box 4). Second-line drugs may need to be added or substituted in some patients.

Box 4 Guidelines for the management of nausea and vomiting in palliative care

1. 1.After clinical evaluation, document the most likely cause(s) of the nausea and vomiting in the patient's case notes.
2. Ask the patient to record their symptoms and response to treatment.
3. Treat correctable causes/exacerbating factors, e.g. drugs, constipation, severe pain, infection, cough, hypercalcaemia. *Correction of hypercalcaemia may not be appropriate in a dying patient*.
4. Anxiety exacerbates nausea and vomiting from any cause and may need specific treatment, pharmacological and/or psychological.
5. Prescribe the most appropriate first-line antiemetic for the most likely main cause: immediately, regularly, and 'as needed'. Give subcutaneously if continuous nausea or frequent vomiting, preferably by subcutaneous infusion.
6. **First-line antiemetics:**
7. *Prokinetic antiemetic*
8. For gastritis, gastric stasis, functional bowel obstruction:
9. metoclopramide 10 mg immediately by mouth, and then four times a day; or 10 mg immediately subcutaneously, and 40–100 mg/24 h as a subcutaneous infusion, and 10 mg 'as needed' up to four times daily.
10. *Antiemetic acting principally in chemoreceptor trigger zone (area postrema)*
11. For most chemical causes of vomiting, e.g. morphine, hypercalcaemia, renal failure:
12. haloperidol 1.5–3 mg immediately by mouth, and at bedtime; or 2.5–5 mg immediately subcutaneously, and 2.5–10 mg/24 h by subcutaneous infusion and 2.5–5 mg 'as needed' up to four times daily.
13. Metoclopramide also acts here.
14. *Antispasmodic and antisecretory antiemetic*
15. If bowel colic and/or need to reduce gastrointestinal secretions:
16. hyoscine butylbromide 20 mg immediately subcutaneously, and 80–160 mg/24 h by subcutaneous infusion, and 20 mg 'as needed' up to every lR.
17. *Antiemetic acting principally in the vomiting centre*
18. For organic bowel obstruction, raised intracranial pressure, motion sickness:
19. cyclizine 50 mg immediately by mouth, and two or three times per day; or 50 mg immediately subcutaneously, and 100–150 mg/24 h by subcutaneous infusion, and 50 mg 'as needed' up to four times daily.
20. Review the dose of antiemetic every 24 h, taking note of 'as needed' use and the patient's diary.
21. If there is little or no benefit, despite optimizing the dose, have you got the cause right?
22. •if no, change to an alternative first-line antiemetic and optimize
    - if yes, provided the first-line antiemetic has been optimized *add* or *substitute* the second-line antiemetic
    - for patients with obstructive vomiting, follow the steps in Fig. 6.

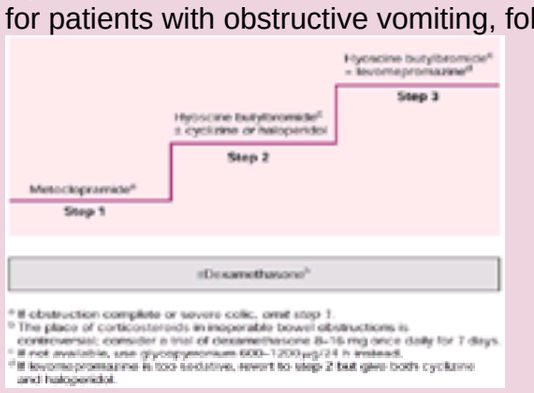

Fig. 6 Antiemetics for endstage bowel obstruction. These are normally given by subcutaneous injection/infusion. (a) If the obstruction complete or there is severe colic, start at step 2. (b) The role of corticosteroids in bowel obstruction is controversial; consider a trial of dexamethasone 8–16 mg once a day for 5 days. (c) If not available, use glycopyrronium 600–1200 µg/24 h instead. (d) If levomepromazine is too sedative, revert to step 2 and add haloperidol.

23. **Second-line drugs for nausea and vomiting**
24. *Broad-spectrum antiemetic*
25. If first-line antiemetics (in appropriate combination, dose, and route) are inadequate:
26. *levomepromazine (methotrimeprazine) 6–12.5 mg by mouth or subcutaneously immediately, at bedtime, and* 'as needed' up to four times daily.
27. *Corticosteroids*
28. Adjuvant antiemetic
29. *dexamethasone 8–16 mg immediately by mouth or subcutaneously, and once daily; consider reducing the dose after 7 days.*
30. *5-HT3-receptor antagonist*
31. Use when there is a massive release of 5-HT (serotonin) from enterochromaffin cells or platelets, e.g. chemotherapy, abdominal radiation, bowel obstruction, renal failure:
32. tropisetron 5 mg *immediately by mouth or subcutaneously, and once daily*.
33. Some patients with nausea and vomiting need more than one antiemetic.
34. *Do not prescribe a prokinetic and an antimuscarinic drug concurrently because the latter blocks the cholinergic final common pathway through which prokinetics act*.
35. Except in organic bowel obstruction consider converting to the oral route after 72 h of good control with injections.
36. Continue antiemetics indefinitely unless the cause is self-limiting.

A systematic approach for inoperable bowel obstruction is shown in Fig. 6. For those with severe colic or who are not passing flatus, prokinetic drugs are contraindicated and step 1 is omitted. Bulk-forming, osmotic, and stimulant laxatives should be stopped, but patients may well benefit from a faecal softener, for example docusate 100 to 200 mg once to twice a day. Octreotide, a somatostatin analogue, has intestinal antisecretory properties and is occasionally indicated. It is much more expensive than hyoscine butylbromide but has no antimuscarinic effects. A venting gastrostomy is rarely necessary for symptom relief in patients with advanced cancer and bowel obstruction.

Patients who are inoperable and are managed by drug therapy should be allowed to drink and eat small amounts of their favourite beverages and food. Some patients find that they can manage food best in the morning. Antimuscarinic drugs and diminished fluid intake often result in a dry mouth. This is generally relieved by conscientious mouth care. A few millitres of fluid every 30 min, possibly given as a small ice cube, is often helpful.

Constipation

Constipation (difficulty in defaecation) is common in advanced cancer. Diminished food and fibre intake, lack of exercise, and drugs are common causal factors.

Evaluation

Many patients who are constipated do not need a rectal examination (by definition, an assault which must be justifiable). On the other hand, a rectal examination is essential in patients with faecal leakage or diarrhoea to confirm or exclude faecal impaction.

In non-obese patients, firm faeces are often palpable in the left iliac fossa and left side of the abdomen. Faeces may also be palpable in the transverse colon, and occasionally in the ascending colon as well, together with caecal distension and tenderness. Bowel sounds are variable. Sometimes it is not clear whether the problem is severe constipation, chronic intestinal obstruction, or both. Although plain radiographs confirm the presence of retained faeces, they cannot reliably differentiate between the two conditions. Pattern recognition and probability may enable a presumptive diagnosis to be made, but sometimes only the passage of time and the response (or lack of response) to treatment confirm whether it is just constipation or obstruction.

Management

Laxatives are the mainstay of treatment for patients with a limited physical capacity and reduced intake of food and fibre. For patients not taking an opioid, start with senna or bisacodyl tablets, adding a faecal softener (for example, docusate) if necessary. Alternatively, a combination preparation (for example, codanthramer, codanthrusate) can be substituted (Box 5). Some patients do better with lactulose but may require 30 ml twice daily or more. Opioids cause constipation by decreasing propulsive activity and increasing non-propulsive activity in both the small and large bowel; peristalsis is impeded and absorption of fluid and electrolytes is facilitated. So-called stimulant laxatives act principally by reducing intestinal ring contractions, thereby facilitating propulsive activity.

Box 5 Management of opioid-induced constipation

- Ask about the patient's past (premorbid) and present bowel habit and use of laxatives; record date of last bowel action.
- Do a rectal examination if faecal impaction is suspected or if the patient reports diarrhoea or faecal incontinence (to exclude impaction with overflow).
- For inpatients, keep a daily record of bowel actions.
- Encourage fluids generally, and fruit juice and fruit specifically.
- When an opioid is first prescribed, prescribe co-danthrusate [a] (one capsule at bedtime) prophylactically; although occasionally appropriate to optimize a patient's existing bowel regimen, rather than change automatically to co-danthrusate.
- If already constipated, prescribe co-danthrusate (two capsules at bedtime).
- Adjust the dose every few days according to results, up to three capsules three times a day.
- If the patient prefers a liquid preparation, use co-danthrusate suspension; 5 ml is equivalent to one capsule.
- If more than 3 days since the last bowel action, 'uncork' with suppositories, e.g. bisacodyl 10 mg and glycerol 4 g.
- If suppositories are ineffective, administer a high phosphate enema; possibly repeat the next day.
- If the maximum dose of co-danthrusate is ineffective, switch to an osmotic laxative, e.g. lactulose 20–30 ml twice daily or macrogol 3350 1 to 3 sachets daily ± a reduced dose of co-danthrusate.
- If co-danthrusate causes abdominal cramps, divide the total daily dose into smaller more frequent doses, e.g. change from co-danthrusate two capsules twice daily to one capsule four times daily or change to lactulose or macrogol 3350.
- An osmotic laxative may be preferable to co-danthrusate in patients with a history of colic with other colonic stimulants.

About one-third of patients receiving morphine continue to need rectal measures (suppositories, enemas, digital evacuation) either regularly or intermittently. Danthron-containing laxatives are inadvisable in patients with faecal leakage or incontinence because danthron can cause a contact skin burn. Because of concern that it may be carcinogenic, danthron-containing laxatives are now only licensed for use in terminally ill patients.

Dyspnoea

Dyspnoea is an unpleasant subjective awareness of difficulty in breathing. Objective signs generally include tachypnoea (an increased rate of respiration) and sometimes hyperpnoea (an increased depth of respiration). Dyspnoea becomes more common as death approaches; overall it is experienced by about 70 per cent of patients with advanced cancer.

Evaluation

In most patients with advanced cancer, dyspnoea is caused by several factors, for example chronic obstructive pulmonary disease, progressive intrathoracic malignant disease, anaemia of chronic disease, weakness (Box 6). The history and examination are often sufficient to determine the main causes.

Box 6 Causes of breathlessness in advanced cancer

Caused by cancer	**Related to cancer and/or debility**
Pleural effusion(s)	Anaemia
Obstruction of main bronchus	Atelectasis
Replacement of lung by cancer	Pulmonary embolism
Lymphangitis carcinomatosa	Pneumonia
Mediastinal obstruction	Empyema
Pericardial effusion	Weakness
Massive ascites	
Abdominal distension	**Concurrent causes**
Cachexia–anorexia syndrome	Chronic obstructive pulmonary disease (COPD)
Caused by treatment	Asthma
Pneumonectomy	Heart failure
Radiation-induced fibrosis	Acidosis
Chemotherapy	
bleomycin	
doxorubicin	

Management

Non-drug measures

The key to successful management at the end of life is at an earlier stage, when dyspnoea on exertion first becomes a symptom. Acknowledgement of and discussion about the terror associated with acute episodes of breathlessness, for instance when climbing stairs, is very important. Referral to a physiotherapist for breathing advice and relaxation techniques is important.

Correct the correctable

Specific treatment should be given for specific causes, for example: bronchodilators for reversible airways obstruction; diuretics for cardiac failure; aspiration and pleuradesis for pleural effusion; and radiotherapy or stenting for superior vena caval obstruction.

Drugs

When the patient is close to death, breathlessness may be present at rest as well as on exertion, or become apparent on minimal activity. Often the patient is bedbound, more because of breathlessness than weakness. In this situation, an opioid (to slow the respiratory rate towards normal), an anxiolytic, and oxygen therapy may all be helpful (Box 7).

Box 7 Relief of breathlessness at rest in a dying patient

- **Bronchodilators**
- The use of bronchodilators should be reviewed and tested clinically for efficacy; it may be necessary to use a spacer to ensure adequate inhalation from an inhaler, or to convert to a nebulizer. Benefit is not always correlated with improvement in peak flow.
- **Opioids**
- Morphine reduces respiratory drive and can be used to ease the sensation of dyspnoea:
- if on morphine for pain, increase the dose by 50 per cent;
- if not on oral morphine, 5–6 mg every 4 h is a good starting dose.
- Nebulized morphine is not recommended; it is no better than saline.
- **Anxiolytics**
- Diazepam by mouth is a good choice:
- 5–10 mg immediately and bedtime;
- 2–5 mg in the very elderly;
- reduce dose after several days if drowsy.
- Use midazolam subcutaneously for patients who find tablets difficult to take:
- 2.5–5 mg immediately and 'as needed';
- 10–20 mg/24 h by subcutaneous infusion.
- **Oxygen**
- Oxygen 4 L/min, preferably via nasal prongs, should be tried to see if benefit gained either continuously or before and during activity (e.g. moving from bed to commode or chair). The benefit of oxygen is not dependent on correction of hypoxaemia; a trial of therapy is the only way to determine benefit, not improvement in blood gases.

Anorexia

Anorexia (diminished or absent appetite) is normal in advanced cancer.

Evaluation

Anorexia may be primary (cachexia–anorexia syndrome) or secondary. Secondary anorexia may be caused by:

- medication which causes dyspepsia or nausea, e.g. NSAIDs, opioids, antibiotics, selective serotonin-reuptake inhibitors (**SSRIs**);
- nausea;
- pain;
- altered taste;
- difficulty feeding because of weakness, dysphagia, or a sore mouth;
- fatigue;
- psychological distress, e.g. fear, anxiety, depression.

Patients are generally more tolerant of anorexia than their families, for whom it is a source of great concern. Many patients state that their carers try too hard to encourage eating, resulting in conflict. Eating is an important social interaction and anorexia may be interpreted by the family as giving in to the cancer. Explanation should be given about the cause(s) of anorexia and the limitations of treatment.

Management

Correct the correctable

Review the current medication for a possible cause; treat pain, nausea, and sore mouth. Obtain dietary advice to minimize the impact of an altered sense of taste.

Non-drug measures

'A little of what you fancy when you fancy' is good advice. Frequent snacks high in calories and low in bulk are preferable to traditional meals.

Drugs

If anorexia appears to be mainly due to early satiety, a prokinetic agent should be tried, for example metoclopramide 10 mg four times daily by mouth.

Prednisolone (15 to 20 mg once a day) or dexamethasone (2 to 4 mg once daily) help about 50 per cent of patients. To avoid cumulative adverse effects, a corticosteroid should be discontinued if there is no benefit after a week or, if effective, reduced to a maintenance dose. Patients and families should be forewarned that the benefit often lasts for only a few weeks.

Medroxyprogesterone acetate (400 mg once daily up to 500 mg twice daily) or megestrol acetate (160 mg once daily up to 800 mg once daily) often lead to weight gain after 3 to 4 weeks, particularly in patients with breast cancer, as a result of an increase in both fat and body water. The effect may last for months. Progestogens are much more expensive than corticosteroids.

Cachexia

Cachexia (marked weight loss and muscle wasting) occurs in up to 80 per cent of patients with advanced cancer. Muscle wasting results in weakness and fatigue. The incidence is highest in cancers of the gastrointestinal tract and lung.

Evaluation

Cachexia is caused by several interrelated metabolic disturbances (Box 8). Concurrent exacerbating factors may be reversible and should be considered.

Box 8 Causes of cachexia in advanced cancer

Paraneoplastic	**Concurrent**
Cytokines produced by host cells and tumour (e.g. TNF, IL-6, IL-3 [a])	Anorexia ® deficient food intake
	Vomiting

Abnormal host metabolism of protein, carbohydrate, and fat	Diarrhoea
	Malabsorption
Increased metabolic rate ® increased energy expenditure	Bowel obstruction
Nitrogen trap by the tumour	Debilitating effect of surgery, radiotherapy, chemotherapy
	Ulceration } excessive loss
	Haemorrhage of body protein

Management

Correct the correctable

As for anorexia (see above).

Non-drug measures

Avoid routine weighing. Explain that 'forced feeding' cannot correct primary cachexia. Some patients benefit psychologically from powdered or liquid nutritional supplements, and a few gain weight. Dietary advice is important if there are changes in taste sensation.

Drugs

As for anorexia. In most patients the effect is small or non-existent. Management is often best focused on acceptance and adaptation.

Dehydration

As the dying patient becomes weaker, intake of both food and fluid becomes less. Decreased fluid intake may be caused by dysphagia, nausea, anorexia, lack of energy and interest, and a reduced level of consciousness, either singly or in combination. There is a big difference between acute and chronic dehydration. Whereas the former is accompanied by intense thirst, this is not the case in dying patients when there is a slow progressive reduction in fluid intake. Conscientious mouth care (cleaning and moistening) is generally all that is called for. As a general rule, intravenous fluids should not be administered if the decreased intake is best interpreted as part of the process of dying. Guidelines from the British Medical Association support this approach.

Confusion

An acute confusional state (delirium) eventually occurs in most dying patients. This typically manifests as disorientation, bewilderment, and drowsiness, often compounded by a spectrum of cognitive disturbances such as poor concentration, impairment of short-term memory, misinterpretation, paranoid ideas, hallucinations, rambling incoherent speech, agitation, and noisy aggressive behaviour.

Evaluation

Multiple factors may contribute to confusion (Box 9). Biochemical investigations are generally contraindicated in patients close to death. It is important not to overlook urinary retention and faecal impaction.

Box 9 Common causes of acute confusion in the dying

Cancer	Drugs
paraneoplastic effect	sedative
cerebral involvement	psychostimulant
Infection	antiparkinsonian
Dehydration	Drug withdrawal
Change of environment	psychotropics
Unfamiliar excessive stimuli	alcohol
too hot	nicotine
too cold	Biochemical derangement
wet bed	hypercalcaemia
crumbs in bed	hyponatraemia
creases in sheets	hypoglycaemia
pain	hyperglycaemia
constipation	Cerebral anoxia
retention of urine	anaemia
pruritus	cardiac failure
Anxiety	Organ failure
Depression	hepatic
Fatigue	renal

Management

Correct the correctable

The patient's drug regimen should be reviewed and a reduction in psychoactive drugs considered, for example amitriptyline 75 mg once a day reduced to 25 mg once a day. Occasionally nicotine or alcohol withdrawal may be the main cause (see below). Pneumonia often precipitates confusion. Treating pneumonia with antibiotics is generally inappropriate in a debilitated, bedbound, dying patient.

Non-drug measures

The presence of a close relative or friend is generally helpful. Visual cues (day, date, soft light, and photographs) and auditory cues (favourite music) may help (Box 10).

Box 10 Treatment of acute confusion

- **Non-drug measures**
- Explanation to patient, family, nurses.
- Stress that patient is not going mad.
- Stress that almost always there are lucid intervals.
- Continue to treat patient as a sane, sensible person.
- Be aware that illusions, hallucinations, and nightmares may reflect unresolved fears and anxiety.
- **Drugs**
- Use drugs only if symptoms are marked, persistent, and cause distress to the patient and/or family. Review sooner rather than later if a sedative drug is prescribed in case it exacerbates symptoms.
- *Specific*
- Dose reduction of present psychotropic medication?
- If hypoxic or cyanosed, give oxygen.
- If cerebral tumour, give dexamethasone 8–16 mg once daily. *Correction of cerebral oedema may not be appropriate in a dying patient.*
- If nicotine withdrawal, give nicotine either as a nasal spray or transdermal patch.
- *General*
- Haloperidol 1.5–5 mg by mouth or subcutaneously, particularly if hallucinations and paranoid ideas.
- Diazepam 5–10 mg by mouth or midazolam 5–10 mg subcutaneously if still restless after two doses of haloperidol (or give concurrently if there is myoclonus):
- initial dose depends on previous medication, weight, age, and severity of symptoms;
- subsequent doses depend on initial response;
- daily- or twice-daily maintenance doses are generally adequate;
- sometimes more frequent administration is necessary.
- In extreme situations, it may be necessary to deeply sedate a dying agitated patient, e.g.:
- levomepromazine 25–50 mg immediately and 50–200 mg/24 h subcutaneously;
- phenobarbital 100–200 mg immediately and 800–1600 mg/24 h subcutaneously.

Drugs

If the patient is agitated, haloperidol should be given, for example 1.5 to 5 mg by mouth or 2.5 to 5 mg subcutaneously. Diazepam or midazolam should be added if the patient remains agitated after 5 to 10 mg of haloperidol (Box 10). If nicotine or alcohol withdrawal is suspected and the patient is unable to smoke or drink, specific treatment should be considered—for instance, transdermal nicotine patches, or a benzodiazepine with or without thiamine for delirium tremens.

Terminal anguish

Terminal anguish is a tormented state of mind that relates to long-standing unresolved emotional problems and/or interpersonal conflicts, or to long-hidden unhappy memories often with a guilty content. These problems have festered in the mind but have never been brought into the open. The possibility of such an outcome highlights the need to make every effort to deal with psychological 'skeletons in the cupboard' before the patient becomes too weak to be able to address them. A few patients, however, resist every attempt to explore what has been suppressed.

Terminal anguish is managed in the same way as an agitated confusional state, for instance by combining an antipsychotic and a benzodiazepine. Large doses may be required and sometimes the more sedative levomepromazine (methotrimeprazine) is preferable to haloperidol. A dose of 50 to 100 mg per 24 h is often very sedative, but this (or more) is what may be necessary to ensure calm. On rare occasions, it may be necessary to use subcutaneous phenobarbital (Box 10).

Death rattle

Evaluation

The inability to clear secretions from the oropharynx and trachea results in noisy (rattling) breathing as the secretions oscillate with respiration. When a death rattle develops the patient is almost always unconscious and untroubled by the secretions. It helps the family to appreciate this, but some families still find it distressing.

Management

Non-drug measures

Placing the unconscious patient in the recovery (semi-prone) position aids the drainage of secretions from the mouth. Suctioning is generally contraindicated; it can distress a patient who is otherwise settled.

Drugs

Because antimuscarinic drugs do not dry up secretions already present, it is important to act at the first sign of rattling. Hyoscine hydrobromide (0.4 to 0.6 mg immediately subcutaneously and 1.2 mg by subcutaneous infusion over 24 h) or hyoscine butylbromide (Buscopan; 20 mg subcutaneous at once and 20 to 40 mg by infusion over 24 h) are both widely used. Glycopyrronium may be used instead, for example, 0.2 mg immediately subcutaneously and 0.6 mg by infusion over 24 h). Such measures are successful in about 50 to 60 per cent of patients. Intravenous diuretics are of benefit if there is concomitant left ventricular failure, which is unusual.

Ethical considerations

The cardinal principles that underpin clinical practice, including palliative care, are:

- respect for patient autonomy (patient choice);
- beneficence (do good);
- non-maleficence (minimize harm);
- justice (fair use of available resources).

These four principles need to be applied against the background of respect for life and an acceptance of the ultimate inevitability of death. Thus, in practice, three dichotomies need to be held in balance:

- the potential benefits of treatment versus the potential risks and burdens;
- striving to preserve life but, when the burdens of life-sustaining treatments outweigh the potential benefits, then withdrawing or withholding such treatments and providing comfort in dying;

- individual needs versus the needs of society.

Principle of double effect

The principle of double effect states that:

> A single act having two possible foreseen effects, one good and one harmful, is not always morally prohibited if the harmful effect is not intended.

This is a universal principle without which the practice of medicine would be impossible. It follows inevitably from the fact that all treatment has an inherent risk. However, discussions of the principle of double effect are often limited to the use of morphine or similar drug to relieve pain in terminally ill patients. This gives the false impression that the use of morphine in this circumstance is a high-risk strategy. When correctly used morphine (and other strong opioids) are very safe drugs, safer than NSAIDs, which are widely prescribed with relative impunity. The use of both classes of analgesic is justified on the basis that the benefits of pain relief far outweigh the risk of serious adverse effects. Indeed, clinical experience suggests that those whose pain is relieved live longer than would have been the case if they had continued to be exhausted and demoralized by severe unremitting pain.

However, the intended aim of treatment must be the relief of suffering and not the patient's death. Although a greater risk is acceptable in more extreme circumstances, it remains axiomatic that effective measures that carry less risk to life should normally be used. Thus, in an extreme situation, although it may occasionally be necessary (and acceptable) to render a patient unconscious, it remains unacceptable (and unnecessary) to cause death deliberately. Deliberate hastening of death by intentionally giving an overdose of one or more drugs (euthanasia) is illegal in almost all countries. Palliative care and euthanasia are essentially mutually exclusive philosophies.

Appropriate treatment

A doctor is not obliged legally or ethically to preserve life 'at all costs'. Priorities change when a patient is clearly dying. There is no obligation to employ treatments if their use can best be described as prolonging the process of dying. A doctor has neither duty nor right to prescribe a lingering death. In palliative care, the primary aim of treatment is not to prolong life but to make the life that remains as comfortable and as meaningful as possible. Part of the art of medicine is to decide when to allow death to occur without further medical impediment.

However, it is not a question of to treat or not to treat but what is the most appropriate treatment given the patient's biological prospects and his personal and social circumstances? Appropriate treatment for an acutely ill patient may be inappropriate in the dying (Fig. 7). Nasogastric tubes, intravenous infusions, antibiotics, cardiac resuscitation, and artificial respiration are all primarily support measures for use in acute or acute-on-chronic illnesses to assist a patient through the initial crisis towards recovery of health. The use of these measures in patients who are irreversibly close to death is generally inappropriate (and therefore bad practice) because the burdens of such treatments exceed their potential benefits.

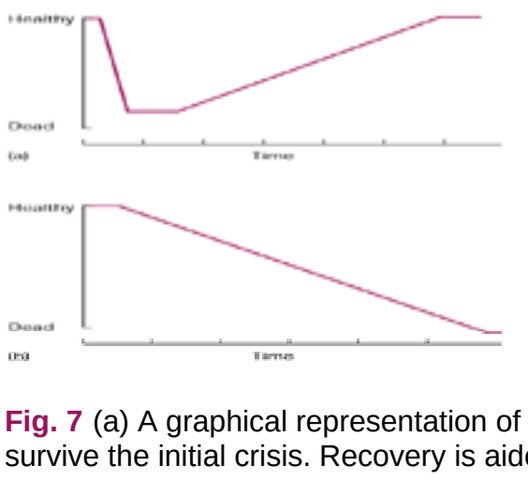

Fig. 7 (a) A graphical representation of acute illness. Biological prospects are generally good. Acute resuscitative measures are important and enable the patient to survive the initial crisis. Recovery is aided by the natural forces of healing; rehabilitation is completed by the patient on his own, without continued medical support. (b) A graphical representation of terminal illness. Biological prospects progressively worsen. Acute and terminal illnesses are therefore distinct pathophysiological entities. Therapeutic interventions that can best be described as prolonging the distress of dying are essentially futile and inappropriate.

Although the possibility of unexpected improvement or recovery should not be totally ignored, there are many occasions when it is appropriate to 'give death a chance'. Interest in hydration and nutrition often becomes minimal as death draws near. The patient's disinterest or positive disinclination is part of the process of letting go.

At the end

Although eventually you may feel powerless in the face of approaching death, patients are generally more realistic. They know you cannot perform a miracle and time is limited. Despite possibly having nothing new to offer, it is important for the doctor to:

- continue to visit;
- quietly indicate that, 'The important thing now is to keep you comfortable';
- simplify medication;
- arrange for medication to be given sublingually, rectally, or by continuous subcutaneous infusion when the patient cannot swallow;
- continue to inform the family of the changing situation;
- control agitation, even if it results in sedation;
- listen to the nurses.

32Reference intervals for biochemical data

P. A. H. Holloway and A. M. Giles

Classification of laboratory results

Intervals are presented in the following format;

- for individual tests see general text:
- Everyday tests and enzymes Table 1
- Blood gases Table 2
- Paediatric reference ranges Table 3
- Hormones Table 4
- Tumour markers Table 5
- Vitamins and related tests Table 6
- Lipids and lipoproteins Table 7
- Proteins and immunoproteins Table 8
- Trace elements and metals Table 9
- Urinary values Table 10
- Faecal values Table 11
- Cerebrospinal fluid Table 12
- Functional tests Table 13
- Therapeutic drugs Table 14
- Common drug toxicology Table 15

Introduction

The precise quantitation of a substance in easily accessible body fluids is an integral part of the clinical assessment of patients. The results are used in screening for disease as well as in diagnosis and for monitoring the response to therapy in established disease. Much diagnostic weight rests on single determinations and patterns of biochemical tests. To this end it is important to consider biological variations between healthy individuals, inherent variations in laboratory methods, and the errors of sampling and hospital practice which can influence every determination. The first (and the last) are the provinces of the physician ordering the test. The second is the concern of the laboratory which provides quality control and the reference intervals for the test.

An important growth area in diagnostic pathology is emerging in the field of 'point-of-care' testing (**POCT**), particularly in the critical care environment. Whilst technology has advanced to enable rapid analytical turnaround times in POCT—usually far less than 10 min from sample withdrawal to result—with consequent hastening to clinical decision-making, the laboratory responsibility for interpretation and overseeing test results is partially devolved to the nurse or doctor at the bedside. In this context there is greater need for an understanding of the appropriate reference intervals as well as of any limitations on the analytical precision when compared to central laboratory methods.

'Normal range' and 'abnormal' results

Clinical diagnostic decisions may depend equally upon finding a 'normal' or 'abnormal' result for any test requested. The physician should be clear as to the meaning of these terms. An important task of the clinical biochemist is therefore to provide relevant sets of reliable reference data. For any individual the ideal reference value for an analyte should be that obtained when that individual is healthy. However, in practice, laboratory test results are interpreted by comparison to traditional, but often inadequately, defined reference intervals (formerly termed 'normal' ranges). The wide belief that biological data assume a gaussian distribution is inappropriate. Most biological data are not symmetrically distributed and require statistical tools that assume other kinds of distribution or are independent of distribution form. Ideally, each laboratory should establish sets of reference intervals derived from a local reference population.

Reference interval

In the past many texts quoted a 'reference range' defined as the mean ± 2 standard deviations from the mean of results obtained from the reference population. This is, however, not now the commonest method applied to clinical biochemistry tests. Many of the 'intervals' quoted in clinical practice are in fact derived from a skew-distribution, which is calculated from the geometric mean to include 95 per cent of values obtained from what is considered to be a 'healthy' population (95 per cent confidence intervals). The merits of a diagnostic test are determined by the relationship between the data for healthy and unhealthy populations, and an example of a relatively poor test is given in Fig. 1. By whatever criteria it is obtained, the reference interval is compounded of both physiological variation and the irreducible error. More elaborate statistical handling of human biochemical data is available for individual tests, but is not generally required in making a diagnosis. By way of warning, however, it will readily be appreciated that if this criterion of health (that is, the biochemical results within 95 per cent limits for the given value), is applied to multiple tests in any individual, then with a battery of say 12 tests only 50 per cent of 'normal' individuals will be found to be 'healthy'. An important example of the limitations of strict referral to the 'reference interval' is highlighted by plasma total cholesterol measurements within certain populations, where established reference intervals may be considered to contain a considerable proportion of individuals with 'undesirable' or 'unhealthy' values. In such situations it may be appropriate to define an 'ideal' or 'optimum' range for that parameter. Other difficulties arise from situations where the reference interval has not been constructed from a population of matched ethnic mix.

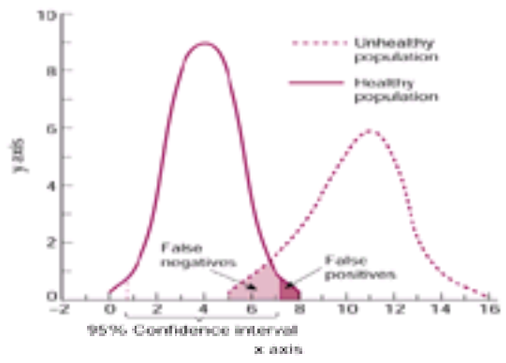

Fig. 1 Theoretical distributions of an analyte in healthy (symmetrical) and unhealthy (negatively skewed) populations.

In conclusion, the use of the following tables of reference intervals for biochemical tests must therefore include an appreciation of the limitations in reference intervals of analytical variation and differences between methods of analysis, as well as sex, age, posture, diet, and other biological variables, as well as sampling, that contribute to such an operation. The physician should constantly bear in mind the need to see individual results of laboratory tests in their clinical context, and not to

hesitate in questioning an unexpected or unlikely result.

The reference intervals given here are predominantly those established for laboratory investigations available at the John Radcliffe Hospital in Oxford, in the United Kingdom. Throughout the tables intervals are given in SI and conventional units, together wherever possible with the factor for converting from SI to conventional. Where appropriate, specific, specimen collection details are given, although it should be recognized that with varied methodologies for most assays it is not possible to make these prescriptive.

33 Emergency medicine

J. D. Firth, C. A. Eynon, D. A. Warrell, and T. M. Cox

1 Heart and circulation

1.1 Cardiac arrest

See Chapter 16.3 in main text

Clinical features	History
	1. Sudden collapse

	Examination 1. Patient unresponsive 2. Airway, breathing—no respiration or agonal breathing 3. Circulation—pulse not palpable
Immediate management	See Fig 1 and Fig 2

Fig. 1 European Resuscitation Council guidelines for adult basic life support.

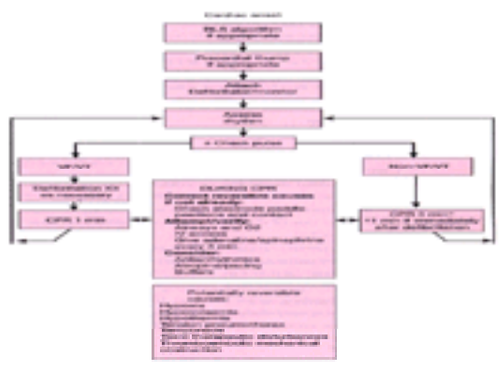

Fig. 2 European Resuscitation Council guidelines for advanced life support.

1.2 Cardiorespiratory collapse: the patient *in extremis*

See Chapter 16.1 in main text

Clinical features	**History**

A patient who is in extremis is unlikely to be able to give a lucid history and may die during (unwise) interrogation, but the following clues may be elicited and be very useful diagnostically:

1. Chest pain—suggests myocardial infarction or other cardiorespiratory catastrophe
2. Chest and back pain—dissection of thoracic aorta must be seriously considered
3. Abdominal pain—suggests ruptured abdominal aortic aneurysm or other intra-abdominal emergency
4. Recent surgery—pulmonary embolism likely
5. High fever/rigors—suggests infective cause
6. Recent travel to relevant area—malaria until proven otherwise

Examination
Airway and breathing 1. Is the airway patent? 2. Is the patient making a respiratory effort, and is the chest expanding with it? 3. Is the chest expanding symmetrically? Could there be a tension pneumothorax? (trachea deviated, mediastinum shifted, absent breath sounds on hyperinflated side of the chest, see Emergency Medicine section 2.3) 4. Widespread crackles in the chest—suggests pulmonary oedema in this context (see Emergency Medicine, section 1.8). 5. Does the patient look as though they could keep this breathing up for the next 10 min?—If not, the patient is very likely to need respiratory support. Call for assistance from the ICU immediately
Circulation 1. Do the peripheries feel cold or warm?—if warm, sepsis is likely 2. Pulse rate and rhythm—if rate <60/min or >120/min, consider whether arrhythmia is primary cause of hypotension 3. Blood pressure • Is there a postural drop if the patient is moved from lying to being propped up? If so, indicates intravascular volume depletion in this context. • Does BP fall substantially on inspiration? If so, indicates large intrathoracic pressure swings with breathing (likely in upper airway obstruction or asthma) or cardiac tamponade 4. What is the JVP? • If low, indicates intravascular volume depletion or dilated circulation • If high, suggests primary cardiorespiratory problem
General 1. Rash—purpura suggests meningococcal or other septicaemia 2. Temperature—high fever suggests infection 3. Loss of left radial pulse, or BP lower in left arm than right arm, indicates aortic dissection 4. Abdominal tenderness/peritonism—suggests ruptured abdominal aortic aneurysm or other intra-abdominal emergency See Table 1 for further information

Immediate management

Airway and breathing

1. Ensure airway is clear: consider oropharyngeal airway
2. Keep oxygen saturation >92 per cent (monitor using pulse oximetery), giving high flow oxygen (10 l/min) by face mask with reservoir bag if needed
3. If tension pneumothorax, decompress immediately (see Emergency Medicine, Section 10.4.3.1).
4. Give intravenous naloxone (0.8–2.0 mg repeated at intervals of 2–3 min to a maximum of 10 mg) if there is any suspicion that patient has received opioids
5. Consider elective intubation and ventilation

Circulation

Obtain IV access using a safe technique (see Emergency Medicine, section 10.1)

Also: begin resuscitation according to volume status as indicated in Table 2

1. Insert urinary catheter and monitor fluid input/output hourly in any patient with cardiorespiratory collapse.
2. Give broad spectrum antimicrobial cover to any patient with unexplained cardiorespiratory collapse, e.g. cefotaxime 1 g intravenously twice daily, as dictated by clinical suspicion of likely pathogen (see Emergency Medicine, section 7.7)

Key investigations See Table 1

Further management Determined by underlying condition.

1.3 Acute myocardial infarction (AMI)

See Chapter 15.4.2.3 and Chapter 15.4.2.4 in main text

Clinical features

History

1. Ischaemic chest pain
2. Cardiorespiratory collapse
3. May be non-specific or silent, especially in the elderly or in diabetics

Examination

May be normal, but look for

1. 'Pump failure'—cool peripheries, hypotension
2. Pulmonary oedema—see Emergency Medicine, section 1.8.
3. Cardiac—gallop rhythm, murmurs

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Otherwise

1. Give high flow oxygen by facemask.
2. Give aspirin 300 mg p.o. immediately, chewed or dispersed in water (if not given before admission to hospital)
3. Give adequate analgaesia, e.g. (i) diamorphine by slow intravenous injection at 1 mg/min, usual maximum initial dose is 5 mg, but may be repeated if necessary, or (ii) morphine by slow intravenous injection at 2 mg/min, usual maximum initial dose is 10 mg, but may be repeated if necessary. Both to be accompanied by appropriate antiemetic, e.g. metoclopramide 10 mg IV over 1–2 min, or cyclizine 50 mg IV over 1–2 min (caution in severe heart failure)
4. If appropriate, give thrombolysis as soon as possible (Table 3 and Table 4)
5. If appropriate, consider percutaneous intervention (Table 5)

Key investigations

To establish the diagnosis

1. ECG—looking for ST segment elevation and/or (presumed or proven) new bundle branch block
2. Cardiac biochemical markers (troponins, CK-MB)

Other important tests

1. Assess risk factors for ischaemic heart disease, e.g. cholesterol
2. As indicated by clinical examination, e.g. chest radiograph to look for pulmonary oedema; echo-cardiography to assess LV function or cause of pansystolic murmur (?mitral valve dysfunction, ?ventricular septal defect)

Further management

Consider

1. b-Blockade
   - Early—if no contraindication (e.g. hypotension, heart failure, heart block) give, e.g. atenolol 5 mg IV over 5 min, repeated after 10–15 min
   - Long term—if no contraindication continue oral b-blockade for at least 2–3 years.
2. Angiotensin converting enzyme inhibition
   - Early—start within 24 h in patients who are nor-motensive and continue for at least 5–6 weeks
   - Long term—recommended for any patient with left ventricular dysfunction
3. Long term aspirin (75–150 mg/day)
4. Long term statin (lipid lowering agent) will benefit most if not all patients after AMI

Note

1. Treat complications, e.g. venodilator or diuretic for pulmonary oedema. Severe heart failure/shock may require ventilation, inotropes +/- intra-aortic balloon pump
2. Diabetic patients will benefit from intensive insulin therapy during admission with AMI and afterwards
3. For all patients: give advice regarding lifestyle issues before and after discharge from hospital—smoking, diet, exercise—also regarding resumption of normal activities. Consider referral to cardiac rehabilitation services
4. Consider need for specialist cardiological opinion and/or investigation by cardiac stress test (e.g. treadmill exercise tolerance test) and/or coronary angiography

1.4 Unstable angina or non-ST segment elevation myocardial infarction (non-Q-wave myocardial infarction)

See Chapter 15.4.2.3 and Chapter 15.4.2.4 in main text

Clinical features

History

1. Ischaemic chest pain at rest or on minimal exertion
2. Chest tightness/breathlessness

Examination

Usually no specific signs, but may be

1. 'Pump failure'—cool peripheries, hypotension
2. Pulmonary oedema—breathing difficulty, pulmonary crackles (see Emergency Medicine, section 1.8)
3. Cardiac—gallop rhythm, murmurs

Immediate management

1. Give high flow oxygen by facemask.
2. Give aspirin 300 mg orally immediately, chewed or dispersed in water (if not given before admission to hospital)
3. Give thienopyridine, e.g. clopidogrel 300 mg orally (then 75 mg daily)
4. Give nitrate, e.g. (1) sublingual glyceryl trinitrate (GTN), 0.3–1 mg repeated as required; (2) buccal GTN, up to 5 mg, with tablet placed between upper lip and gum and left to dissolve; (3) intravenous infusion of isosorbide dinitrate at initial dose of 2 mg/h (increasing as necessary to maximum of 20 mg/h to relieve pain and as limited by hypotension)
5. If pain not relieved by nitrate give adequate analgaesia, e.g. (1) diamorphine by slow intravenous injection at 1 mg/min (usual maximum initial dose is 5 mg, but may be repeated if necessary), or (2) morphine by slow intravenous injection at 2 mg/min (usual maximum initial dose is 10 mg, but may be repeated if necessary). Both to be accompanied by appropriate antiemetic, e.g. metoclopramide 10 mg IV over 1–2 min, or cyclizine 50 mg IV over 1–2 min (caution in severe heart failure)
6. Give low molecular weight heparin, e.g. enoxaparin 1 mg/kg (100 units/kg) every 12 h, or dalteparin 120 units/kg every 12 h (maximum 10000 units twice daily), unless contraindicated
7. Give intravenous or oral b-blocker (see Emergency Medicine section 1.3) unless contraindicated
8. Consider heart-rate-lowering calcium antagonist (e.g. diltiazem or verapamil) if b-blocker is contra-indicated in patient without left ventricular dysfunction
9. Consider glycoprotein IIb/IIIa inhibitor in high risk groups, e.g. those with ST segment depression and/ or troponin positive, or those receiving urgent percutaneous intervention for unstable angina or non-ST segment elevation AMI. Agents tested in large scale randomized trials include abciximab, epti-fibatide, and tirofiban
10. Consider percutaneous intervention (Table 5)

Key investigations

To establish the diagnosis

1. ECG—looking for transient ST segment shift with pain; T wave changes are less specific and ECG may be normal
2. Cardiac biochemical markers (troponins, CK-MB)

Other important tests

As for acute myocardial infarction (see Emergency Medicine section 1.3)

Further management

1. Angiotensin converting enzyme inhibition— recommended for any patient with left ventricular dysfunction
2. Long-term aspirin (75–150 mg/day).
3. Long-term statin (lipid lowering agent) will benefit most patients with ischaemic heart disease

Consider:

4. Clopidogrel 75 mg/day

Note

1. For all patients: give advice regarding lifestyle issues before and after discharge from hospital—smoking, diet, exercise—also regarding resumption of normal activities. Consider referral to cardiac rehabilitation services
2. Consider need for specialist cardiological opinion and/or investigation by cardiac stress test (e.g. treadmill exercise tolerance test) and/or coronary angiography

1.5 Dissection of the thoracic aorta

See Chapter 15.14.1 in main text

Clinical features

History

1. Chest pain, particularly if of sudden onset, tearing in quality, and radiating to the back
2. Collapse

Examination

1. Patient will usually look very unwell: cool peripherally, hypotensive
2. Look for loss/reduction of one or more peripheral pulses: most likely is compromise of the left sub-clavian artery. Check left radial pulse in comparison with right; measure blood pressure in both arms; any deficit on the left strongly supports the diagnosis of aortic dissection. Examine also for reduction of carotid or femoral pulse(s)
3. Evidence of focal ischaemia, eg. focal neurological deficit ('stroke')
4. Could the patient have Marfan's syndrome? (risk factor)

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. The key to correct management is a high index of clinical suspicion that aortic dissection might be the diagnosis. Most patients with chest pain and circulatory collapse have acute myocardial infarction, the management for which (thrombolysis) could clearly be fatal in the patient with aortic dissection
2. Give high flow oxygen by facemask
3. Give adequate analgaesia, e.g. (i) diamorphine by slow intravenous injection at 1mg/min (usual maximum initial dose is 5mg, but may be repeated if necessary) or (ii) morphine by slow intravenous injection at 2 mg/min (usual maximum initial dose is 10 mg, but may be repeated if necessary). Both to be accompanied by appropriate antiemetic, e.g. metoclopramide 10 mg IV over 1–2 min, or cyclizine 50 mg IV over 1–2 min (caution in severe heart failure)

Key investigations

To establish the diagnosis

1. CT angiography of chest
2. Transoesophageal echocardiography

Other important tests

1. Chest radiograph—look for widened mediastinum
2. ECG—may have features of acute myocardial infarction (usually inferior) if dissection has compromised a coronary artery (usually right coronary artery)
3. Cardiac biochemical markers—to exclude acute myocardial infarction
4. Full blood count, clotting screen, electrolytes, renal and liver function tests—may give a lead to an underlying medical condition and will establish baseline
5. Group and save/crossmatch blood.

Further management

1. Reduce blood pressure using agents that will not cause tachycardia or increase the rate of cardiac ejection, e.g. titrate IV labetolol (initial dose 1 mg/min) or esmolol (50–200 µg/kg/min) to achieve SBP <110 mmHg. If blood pressure remains too high, add intravenous infusion of sodium nitroprus-side (0.5–8 µg/kg/min) after b-blockade established (pulse <60 /min)
2. Obtain opinion from cardiothoracic surgeon: immediate surgical repair will usually be the best management for patients with dissection of the ascending aorta (Stanford Type A) who are in reasonable condition

1.6 Bradycardia

See Chapter 15.2.3 and Chapter 15.6 in main text

Clinical features

History

1. Syncope or presyncope
2. Fatigue/breathing difficulty
3. Drugs (especially b-blockers)

Examination

The most important immediate issue is to decide whether or not the circulation is compromised: is the patient cool peripherally? What are the rate, rhythm, and blood pressure? Is there pulmonary oedema (see Emergency Medicine, section 1.8)?

If seen in the presence of bradycardia, note rate and

1. Abnormal rhythm, e.g. dropped beats in second degree AV block
2. Other cardiovascular abnormality, e.g. cannon waves in JVP in third degree (complete) AV block
3. Temperature (hypothermia—see Emergency Medicine, section 9.4)

Immediate management

Obtain ECG

If the patient is haemodynamically compromised

1. Give atropine, 0.3–1.0 mg IV, repeated as necessary
2. Consider isoprenaline, 0.5–10 µg/min by IV infusion
3. Consider temporary pacing (see Emergency Medicine, section 10.3)
4. Consider glucagon 50–150 µg/kg intravenously in 5 per cent glucose in cases of b-blocker overdose, with precautions to protect the airway in case of vomiting (NB unlicensed indication and dose)

Key investigations

To establish the diagnosis

12-lead ECG

Other important tests

1. Electrolytes (particularly potassium)
2. Cardiac biochemical markers (depending on context)
3. Chest radiograph—look at heart size and for evidence of pulmonary oedema
4. 24 h ECG monitor (if symptoms intermittent and 12-lead ECG not diagnostic)
5. Echocardiography (if clinical suspicion that heart is structurally abnormal)

Further management

Dependent on diagnosis. If not reversible likely to require permanent pacing

1.7 Tachycardia

See Chapter 15.2.3 and Chapter 15.6 in main text

Clinical features

History

1. Syncope or presyncope
2. Palpitations
3. Fatigue/breathing difficulty
4. Chest pain

Examination

The most important immediate issue is to decide whether or not the circulation is compromised: is the patient cool peripherally? What are the rate, rhythm and blood pressure? Is there pulmonary oedema (see Emergency Medicine, section 1.8)?

Physical examination is unlikely to aid diagnosis of the particular type of tachycardia, excepting for the presence of an irregularly irregular rhythm in atrial fibrillation. However, note the following:

1. Jugular venous pulse—absence of 'a' waves in AF; rapid flutter waves in atrial flutter; cannon waves in ventricular tachycardia
2. First heart sound—variable intensity in AF
3. A dilated heart increases the chance that tachycardia is ventricular in origin

Immediate management

Obtain ECG

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

FOR ARRHYTHMIAS THAT ARE POORLY TOLERATED, SYNCHRONISED DC SHOCK (UNDER GENERAL ANAESTHESIA OR DEEP SEDATION) USUALLY PROVIDES RAPID RELIEF.

Management otherwise depends upon clinical context and type of tachycardia

Key investigations

To establish the diagnosis

1. 12-lead ECG (see Table 6)

Other important tests

1. Electrolytes (particularly potassium)
2. Cardiac biochemical markers (depending on context)
3. Chest radiograph—look at heart size and for evidence of pulmonary oedema
4. 24 h ECG monitor (if symptoms intermittent and 12-lead ECG not diagnostic)
5. Echocardiography (if clinical suspicion that heart is structurally abnormal)
6. Thyroid function tests (in atrial fibrillation)

Further management

Uncertain of the diagnosis of a broad complex tachycardia? See Table 7

With severe haemodynamic compromise Atrial fibrillation/flutter

- DC cardioversion, or
- Amiodarone, 5 mg/kg over 20–120 min followed by 1200 mg/24hrs until sinus rhythm restored (into central venous catheter), or
- Sotalol, 1.5 mg/kg intravenously over 30 min.

Atrioventricular nodal re-entry (AVNRT) and atrioventricular reentry tachycardias (AVRT) (supraventricular tachycardias, SVTs)

- Adenosine, 3 mg intravenously given over 2 s, if necessary followed by 6 mg after 1–2 min, and then by 12 mg after a further 1–2 min (note— contraindicated in those with asthma, and patients taking dipyridamole are very sensitive, requiring reduced initial dose of 0.5–1 mg)
- Verapamil, 5–10 mg by slow intravenous injection over 2–3 min is an alternative in patients with asthma, but NOT in those who might have ventricular tachycardia, or in those who are receiving b-blockers

Ventricular tachycardia

- DC cardioversion (see Emergency Medicine, section 1.1)

Without severe haemodynamic compromise Atrial fibrillation/flutter

Duration <48 h or trans-oesophageal echocardiography shows no intracardiac thrombus

- Consider prompt chemical or synchronised DC cardioversion.
- Flecainide (Class 1C) 2 mg/kg intravenously over 30 min if there is no evidence of ischaemic heart disease or left ventricular dysfunction
- Amiodarone or sotalol (Class III) can be used to restore sinus rhythm and maintain it
- Digoxin is useful for rate control only but will not restore sinus rhythm. If digoxin is ineffective in controlling ventricular rate, and cardioversion is unsuccessful or inappropriate, consider adding verapamil or b-blocker

Duration >48 h or thrombus on trans-oesophageal echocardiography

- Anticoagulate for 4–6 weeks before synchronised DC cardioversion

Note

- Atrial fibrillation arising in the context of intercurrent illness is usually best managed by treatment of the underlying medical condition and with digoxin (plus or minus verapamil or b-blocker) to control ventricular rate. The patient is likely to return to sinus rhythm when the underlying condition has resolved

Atrioventricular nodal re-entry (AVNRT) and atrioventricular re-entry (AVRT) tachycardias (supraventricular tachycardias, SVTs)

- Vagal stimulation by respiratory manoeuvres (Valsalva), prompt squatting, or pressure over one carotid sinus (but not the latter in those with recent ischaemia, digitalis toxicity, or in the elderly)
- Adenosine if vagal stimulation fails
- Other options include verapamil, b-blocker, flecainide, sotalol, or amiodarone

Ventricular tachycardia

- Consider synchronized DC cardioversion.
- Lignocaine (lidocaine) 50–100 mg as intravenous bolus over a few min followed immediately by infusion of 4 mg/min for 30 min, 2 mg/min for 2 h and then 1 mg/min up to 24 hr.
- Other antiarrhythmics that can be used includeamiodarone, sotalol, procainamide and disopyramide—but seek expert help.

Torsade de pointes

This form of ventricular tachycardia requires particular treatment

- Give magnesium sulphate, 8 mmol of magnesium over 10–15 min, repeated once if necessary
- If torsade is associated with bradycardia and pauses, consider isoprenaline infusion or overdrive atrial/ventricular pacing to increase heart rate

1.8 Pulmonary oedema

See Chapter 15.15.2.2 in main text

Clinical features

History

1. Breathing difficulty
2. Orthopnoea, paroxysmal nocturnal dyspnoea
3. Palpitations
4. Chest pain
5. Ankle oedema
6. Of any cardiac disorder

Examination

1. How unwell is the patient? If very ill, see Emergency Medicine, section 1.2
2. Respiratory rate, cyanosis, peripheral circulation (cold, clammy), pulse rate and rhythm (?arrhythmia, see sections 1.6 and 1.7), blood pressure, JVP (likely to be elevated), apex beat (displaced in congestive cardiac failure), heart sounds (gallop rhythm, murmurs), crackles and/or wheezes in chest, peripheral oedema (suggests biventricular failure in this context)

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Sit the patient up
2. Give high flow oxygen via reservoir bag to achieve PaO_2 >92%
3. Give frusemide 40–80 mg intravenously If not improving rapidly
4. Give either
   - Diamorphine by slow intravenous injection at 1 mg/min (usual maximum initial dose is 5mg, but may be repeated if necessary), or
   - Morphine by slow intravenous injection at 2 mg/min (usual maximum initial dose is 10 mg, but may be repeated if necessary)
   - Both to be accompanied by appropriate antiemetic, e.g. metoclopramide 10 mg IV over 1–2 min (not cyclizine in severe heart failure)
5. Unload with intravenous nitrate, e.g. isosorbide dinitrate 2–20 mg/h
6. Consider elective ventilation: non-invasive or after endotracheal intubation

Key investigations

To establish the diagnosis

Chest radiograph

Other important tests

1. ECG—look for arrhythmia or acute myocardial infarction
2. Cardiac biochemical markers

Further management

Depending on clinical context

1. Acute myocardial infarction—see Emergency Medicine, section 1.3
2. Arrhythmia—see Emergency Medicine, sections 1.6 and 1.7
3. Acute mechanical cause—e.g. aortic incompetence, mitral regurgitation, ventricular septal defect—may require surgical intervention

1.9 Deep venous thrombosis and pulmonary embolus

See Chapter 15.15.3.1 in main text

Clinical features

History

Deep venous thrombosis

1. Calf/leg pain
2. Calf/leg swelling
3. Features to suggest PE

Pulmonary embolus

1. Shortness of breath, developing over hours, days, or (sometimes) weeks
2. Pleuritic chest pain, haemoptysis (lung infarction, peripheral emboli)
3. Circulatory collapse (massive PE)
4. Features to suggest DVT

Deep venous thrombosis and pulmonary embolus Risk factors—immobilization, recent surgery, previous episodes, malignancy, travel, family history etc.

Examination

Deep venous thrombosis

1. Calf/leg swelling—measure circumference 10 cm below tibial tuberosity: difference between sides of >1cm likely to be significant
2. Calf tenderness; palpable cord; positive Homan's sign
3. Dilated superficial veins; leg feels warmer than the other
4. Check for signs of PE
5. Consider alternative diagnoses—especially Baker's cyst, cellulitis, haematoma in muscle

Pulmonary embolus

1. May be no abnormal signs
2. Tachypnoea (70% of cases), crackles (50%), tachycardia (30%), pleural rub (<10%)
3. Circulatory collapse with cool peripheries, hypotension, and cyanosis. Look particularly for signs of right heart strain: elevated JVP, parasternal heave, S3 over right ventricle, loud P2
4. Check for signs of DVT
5. Consider alternative diagnoses—especially pneumonia, musculoskeletal pain

Note

1. Low grade fever is common in both DVT and PE
2. In cases of DVT or PE—perform rectal/pelvic examination (before discharge from hospital)

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2
If index of clinical suspicion for PE is high, start IV standard (unfractionated) heparin pending the results of investigation

Key investigations **To establish the diagnosis**

Tests commonly used to demonstrate the presence of thrombus/embolus are as follows:

- DVT—venous ultrasonography, contrast venography
- PE—lung ventilation/perfusion (VQ) scan, CT pulmonary angiogram, or pulmonary angiogram

Many patients referred for medical opinion have a low probability of having DVT or PE and not all require imaging to exclude DVT or PE. Follow management algorithms as follows:

- DVT—see Table 8
- PE—see Table 9

Other important tests

Pulmonary embolus

1. ECG—commonest abnormality is sinus tachycardia and/or non-specific ST segment or T wave abnormalities. Look for signs of right heart strain, e.g. T wave inversion in V1/V2, S1Q3T3, axis shift
2. Chest radiograph—look for atelectasis or pulmonary parenchymal abnormality, also pleural effusion. May be normal
3. Arterial blood gases—look for hypoxia; but normoxia does not exclude PE

Deep venous thrombosis and pulmonary embolus

1. Full blood count, electrolytes, renal and liver function tests—may give a lead to an underlying medical condition and will establish baseline
2. At a later stage a thrombophilia screen may be appropriate, also investigations dictated by clinical findings or investigations detailed above

Further management

1. Anticoagulation with standard (unfractionated) heparin (Table 10) *or* low molecular weight heparin (e.g. Tinzaparin 175 units anti-Factor Xa IU/kg subcutaneous o.d.) *until* oral anticoagulation (usually with warfarin, Table 11) is established
2. In cases with circulatory collapse consider thrombolysis, e.g.
   - Streptokinase by intravenous infusion of 250000 units over 30 min, then 100000 units/h for 12–72 h, OR
   - Alteplase 10 mg by intravenous infusion over 1–2 min, followed by 90 mg over 2 h (maximum 1.5 mg/kg in patients of <65kg)

Notes

1. No monitoring of low molecular weight heparin treatment is required
2. Methods of reversing anticoagulation are shown in Table 12

1.10 Cardiac tamponade

See Chapter 15.9 in main text

Clinical features **History**

1. There are no specific features to indicate this condition
2. Can follow acute myocardial infarction, aortic dissection, cardiac trauma (including iatrogenic with cardiac catheterization)
3. There may be evidence of a condition that can cause pericardial effusion, e.g. tuberculosis, cancer, advanced renal failure

Examination

The key to making this rare but very important (because treatable) diagnosis is to consider it in any patient with unexplained cardiorespiratory collapse. Look for:

Signs of tamponade

1. Grossly elevated JVP that rises (if its top can be seen) on inspiration (Kussmaul's sign)
2. Pulsus paradoxus—meaning an exaggerated fall in systolic blood pressure on inspiration (normal <10 mmHg), but a rapid screening test for severe cases is to ask 'does the radial pulse disappear on inspiration'?

Evidence of a (large) pericardial effusion, although these will NOT be present unless there is a pre-existing effusion

3. Increased area of cardiac dullness
4. Quiet heart sounds

Immediate management

If the patient is *in extremis* proceed as in Emergency Medicine, section 1.2
As soon as the diagnosis of cardiac tamponade is established, perform or arrange for immediate/urgent pericardial aspiration (see Emergency Medicine, section 10.2.3)
Give colloid, e.g. gelofusin 500 ml by rapid intravenous infusion, to support blood pressure

Key investigations **To establish the diagnosis**

1. Echocardiography.
   - The most sensitive test for the presence of pericardial fluid.
   - Diastolic collapse of right ventricle or right atrium and a striking increase in the amplitude of septal motion with respiration indicate severe circulatory embarrassment
2. Cytology and culture of pericardial fluid

Other important tests

1. Chest radiograph—look for globular heart (almost invariably with clear lung fields)
2. ECG—look for low voltage QRS complexes and electrical alternans (in large pericardial effusion) and for evidence of acute myocardial infarction

Further management

As determined by underlying condition

1.11 Accelerated ('malignant') hypertension

See Chapter 15.16.3 in main text

Clinical features

History

1. Headache
2. Blurring of vision
3. Drowsiness
4. Epileptic fits

Examination

1. Blood pressure—will usually be grossly elevated with diastolic pressure >130 mmHg, but note that accelerated hypertension can occur at lower pressures than this and the diagnosis is established not by a particular elevation of blood pressure but by signs of fibrinoid necrosis
2. Ocular fundi
   - Grade III retinopathy: flame-shaped superficial haemorrhages, 'dot and blot' haemorrhages, cotton wool spots (retinal microinfarcts), hard exudates
   - Grade IV retinopathy: as Grade III + papilloedema (Note that there is no difference in management or prognosis of patients with Grade III or Grade IV disease)
3. Urine—stix testing shows proteinuria and haematuria, microscopy may show red blood cell casts

Also look for signs of

4. Pulmonary oedema—see Emergency Medicine, section 1.8
5. Aortic dissection—see Emergency Medicine, section 1.5
6. Scleroderma—scleroderma renal crisis

Immediate management

In an uncomplicated case*:*

1. Admit to hospital
2. Bed rest
3. No smoking (causes an acute rise in blood pressure)
4. Aim to lower diastolic pressure into range 100–105 mmHg over 2–3 days using:
   - Atenolol 25–50 mg orally, or
   - Nifedipine 10–20 mg of modified release preparation orally (tablets, not sublingual)
   - Further dosing determined by response
   - Maximum initial fall in blood pressure should not exceed 25% of presenting value

   In a complicated case (aortic dissection, epileptic fitting, acute pulmonary oedema, oral medication not possible) use intravenous infusion of:
   - Labetolol, initial bolus of 20 mg, then at 20 mg/h, increased as necessary every 30 min to maximum of 120 mg/h, or
   - Sodium nitroprusside at initial dose of 0.25–0.5 µg/kg/min, increasing up to 8 µg/kg/min

Key investigations

To establish the diagnosis

Accelerated hypertension is a clinical diagnosis

Other important tests

1. ECG—looking for evidence of left ventricular hypertrophy and acute myocardial ischaemia
2. Chest radiograph—looking for heart size, pulmonary oedema, and (if chest/back pain) for aortic dissection
3. Electrolytes and renal function—if serum creatinine >250 µmol/l renal function is likely to deteriorate further (at least in the short term)
4. 'Autoimmune/vasculitic' serology—ANCA, ANA etc.—for evidence of multisystem disorder that can present with accelerated phase hypertension and which (if present) will require specific treatment
5. CT angiography of chest if aortic dissection suspected

Further management

When acute emergency is controlled, all patients that have suffered from accelerated phase hypertension require thorough investigation for secondary causes of hypertension

1.12 Anaphylactic shock

See Chapter 16.4 in main text

Clinical features

History

1. Facial, tongue or throat swelling
2. Stridor or wheeze
3. Sudden collapse
4. Premonitory aura—apprehension, light-headedness, dizziness, tingling or itching of skin
5. Exposure to preciptant

Examination

1. Cyanosis
2. Hypotension
3. Facial, tongue, or throat swelling
4. Stridor or wheeze
5. Urticaria, angio-oedema, skin erythema, or extreme pallor

Immediate management

1. High flow oxygen (10 l/min) by face mask with reservoir bag to keep PaO_2 >92%.
2. Adrenaline (epinephrine)
   - Give 0.3–0.5 ml of 1:1000 (0.3–0.5 mg) intramuscularly, repeated every 5–10 min as needed
     If this is ineffective, or if the patient is about to die
   - Give 1–4 mg (1–4 ml) of 1:1000 adrenaline nebulized with oxygen, and
   - Make up 1:100000 preparation of adrenaline by drawing up 1ml of 1:1000 adrenaline (total of 1 mg) in 20 ml syringe, adding 9 ml of 0.9% saline to give total volume of 10 ml. Discard all but 2 ml (leaving 200 µg of adrenaline in the syringe), and then draw up further saline to a total volume of 20 ml, giving a final concentration of 10 µg/ml. Give 0.75–1.5 mg/kg of 1:100000 adrenaline IV at 10–20 µg/min (1–2 ml/min) initially, repeated as necessary
3. Colloid—give 10–20 ml/kg as rapid intravenous infusion if patient is hypotensive
   Second line therapy, after cardiorespiratory stability has been achieved:
4. Give H_1-blocker, eg. chlorpheniramine 10–20 mg IV, repeated up to 40 mg in 24 h (change to oral when patient tolerates)
5. Give H_2-blocker, e.g. ranitidine 50 mg IV three times daily (change to oral when patient tolerates)
6. Give hydrocortisone 5 mg/kg IV, then 2.5 mg/kg IV four times daily (change to oral prednisolone 40 mg daily when patient tolerates)
7. Give salbutamol 5 mg (repeated as necessary) via oxygen-driven nebulizer if bronchospasm is a persistent problem

Key investigations

To establish the diagnosis

1. Anaphylaxis is a clinical diagnosis
2. Mast cell tryptase

Other important tests

1. ECG, chest radiograph, electrolytes, renal function, arterial blood gases (depending on context)

Further management

1. Determination of allergen (if any)
2. Advice regarding avoidance
3. Medic Alert bracelet
4. Instruction regarding self-injection of adrenaline and supply of appropriate medication, e.g. EpiPen ™

2 Respiratory

2.1 Acute on chronic respiratory failure

See Chapter 17.6 and Chapter 17.7 in main text

Clinical features

History

1. Chronic respiratory condition—usually chronic obstructive pulmonary disease
2. Recent increase in breathlessness
3. Evidence of infection—fever, sweats, increased sputum production, increased sputum purulence
4. 'Cor pulmonale'—worsening ankle oedema

Examination

1. Cyanosis
2. Respiratory rate
3. Temperature
4. Evidence of carbon dioxide retention—drowsiness, asterixis, metabolic flap
5. Chest signs—of chronic respiratory condition, of infection, and exclude pneumothorax
6. Signs of cor pulmonale—elevated JVP, right ventricular heave, right ventricular gallop, loud P2, congested liver, ascites, peripheral oedema
7. Check PEFR if patient is able to use PEF recorder
8. Check pulse oximetry.

Is the patient getting exhausted? Remember that a 'normal' respiratory rate in the patient who looks very tired may mean that they are close to death.

Immediate management

The patient who is extremely ill

If the patient is *in extremis,* proceed as in Emergency Medicine, section 1.2, with the exception that a high concentration of inspired oxygen should NOT be given to patients who are KNOWN to have acute on chronic respiratory failure. If the patient is known to have chronic respiratory failure:

1. Give controlled oxygen (24–28% or 1–2 l/min by nasal prongs)
2. Initiate other aspects of management listed below
3. Check arterial blood gases, adjusting inspired oxygen concentration if allowed by clinical response, PaO_2, $PaCO_2$, and pH (pH, not hypoxia, is the most important factor related to survival in patients with acute on chronic respiratory failure)
4. Consider need for urgent intubation and ventilation if matters do not improve rapidly

Note

If it is UNCERTAIN whether or not a patient has acute on chronic respiratory failure, then high concentration oxygen should be given to all patients who are extremely ill. All such patients require continued close monitoring of their clinical state and arterial blood gases, allowing (amongst other things) detection of the few who will have acute on chronic respiratory failure and lose their respiratory drive in response to high concentration oxygen

The patient who is moderately unwell

1. Give 24% oxygen, increasing concentration to 28% (or 1 to 2 l/min by nasal prongs) depending on the results of subsequent blood gas analysis
2. Give nebulized b_2-agonist, e.g. salbutamol 2.5–5 mg, terbutaline 5–10 mg, using air as the driving gas, repeated as required
3. Give nebulized anticholinergic, e.g. ipatropium bromide 500 µg (can be combined with b_2-agonist), repeated as required
4. Give diuretic, e.g. frusemide 40–80 mg IV, if evidence of fluid overload
5. Give corticosteroid, e.g. hydrocortisone 100 mg IV twice daily or prednisolone 30 mg orally once daily
6. Give antibiotic that will cover likely respiratory pathogens if two of the following symptoms are present—increased breathlessness, increased sputum volume, or increased sputum purulence, e.g. amoxycillin 250 mg orally three times daily or (if allergic to penicillin) clarithromycin 250–500 mg orally twice daily (intravenously if oral administration not possible)
7. Consider aminophylline, loading dose (in patient not previously treated with theophylline) of 5 mg/kg given intravenously over 20 min, then an infusion of 0.5 mg/kg/h aiming for serum concentration in the range 10–20 mg/l
8. Consider need for non-invasive positive pressure ventilation if patient does not improve.

Note—use intravenous fluids to correct and prevent dehydration

Key investigations

To establish the diagnosis

1. Chest radiograph—looking for focal consolidation and to exclude pneumothorax
2. Sputum culture To determine severity and monitor response to treatment
3. Arterial blood gases
4. Serial measurements of peak flow

Other important tests

1. Full blood count
2. Electrolytes, renal and liver function
3. ECG

Further management

1. Optimization of treatment for chronic pulmonary condition, usually chronic obstructive pulmonary disease
2. Emphasize need to stop smoking

2.2 Tension pneumothorax

See Chapter 16.2 and Chapter 17.12 in main text

Clinical features	**History** 1. Collapse with extreme difficulty in breathing **Examination** 1. Patient looks as though they are about to die 2. Gasping respiratory effort 3. Cyanosis 4. Chest looks asymmetrical, being prominent on side of tension 5. Tracheal deviation, away from side of tension 6. Mediastinal shift, away from side of tension, most reliably detected by percussion of cardiac dullness 7. Chest is silent on side of tension, the only breath sounds being heard in the opposite axilla
Immediate management	Insert needle to decompress chest, see Emergency Medicine, section 10.4.3
Key investigations	**To establish the diagnosis** 1. Tension pneumothorax is a clinical diagnosis to be treated immediately without delay for investigation **Note** 1. The signs of tension pneumothorax are not subtle, but you will not make the diagnosis unless you consider it and seek the presence of the signs listed above 2. If a patient appears to be dying and you think that they might have a tension pneumothorax, then— after calling for help and initiating resuscitation (see Emergency Medicine, section 1.1)—there is nothing to be lost (and potentially much to be gained) from an attempt at chest decompression **Other important tests** Chest radiograph will confirm diagnosis of pneumothorax after decompression
Further management	Insertion of chest drain (see Emergency Medicine, section 10.4.3.3) after tension has been relieved

2.3 Upper airway obstruction

See Chapter 17.8.1 in main text

Clinical features	**History** 1. Extreme difficulty in breathing 2. Coughing /choking 3. Noisy breathing 4. Difficult/unable to speak 5. 'Something stuck' **Examination** 1. Extreme but ineffective respiratory effort 2. Cyanosis 3. Drooling (cannot swallow saliva) 4. Stridor
Immediate management	1. Heimlich manoeuvre if the patient has inhaled a foreign body • Patient sitting or standing—rescuer stands or kneels behind patient, encircling the patient's waist with their arms, placing one fist just above the navel (well below xiphoid process) and using their other hand to press the fist into the patient's abdomen with a quick upward thrust. Repeat as necessary • Patient lying—place patient on their back. Rescuer kneels astride patient and puts the palm of one hand between the navel and xiphisternum, places their other hand on top of this, and pushes upwards and inwards 2. If Heimlich manoeuvre is inappropriate or has failed • If there is time and you have the expertise—spray the pharynx with local anaesthetic (e.g. 5% cocaine and adrenaline) and examine the pharynx and upper airway by indirect laryngoscopy to establish the cause of obstruction and allow (if possible) its removal (with finger sweep under direct vision or long handled forceps) or passage of an endotracheal tube • If there is time and you are not experienced in upper airway management—call immediately for help from anaesthetic or ENT colleagues
Key investigations	**To establish the diagnosis** 1. Upper airway obstruction is a clinical diagnosis **Other important tests** As dictated by cause of obstruction
Further management	As dictated by cause of obstruction See Emergency Medicine, section 10.4.2.3

2.4 Asthma

See Chapter 17.4.4 in main text

Clinical features	**History** 1. Worsening asthma 2. Increasing difficulty breathing 3. Decrease in exercise tolerance 4. Increasing wheeze 5. Chest tightness 6. Cough 7. Difficulty in speaking 8. Fall in self-monitored peak flow 9. Failure to obtain improvement with use of regular b_2-agonist

Precipitating factor

1. Exposure to known precipitant, eg. exercise, cold air, dusty environment
2. Respiratory infection, e.g. upper respiratory tract infection

Examination

Moderate uncontrolled acute asthma

1. Breathlessness
2. Wheeze
3. Chest tightness
4. Peak flow 50–70% of predicted or personal best

Acute severe attack

1. Cannot complete sentences in one breath
2. Increased respiratory rate: >25 breaths/min
3. Use of accessory muscles of respiration
4. Tachycardia: >110/min
5. Peak flow <50% of predicted or personal best

Life-threatening asthma

1. Exhaustion or poor respiratory effort
2. Inability to speak.
3. Altered level of consciousness.
4. Cyanosis
5. Silent chest.
6. Hypotension or bradycardia
7. Peak flow <33% of predicted or personal best (or unrecordable)

Note

1. A 'normal' respiratory rate is consistent with the patient being near to death if they are exhausted
2. Always check carefully for signs of pneumothorax
3. Always check pulse oximetry
4. Asking the patient to count out loud as far as they can on a single breath provides a rapid, quantitative, and repeatable measure of respiratory function

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Moderate uncontrolled acute asthma

1. b_2-Agonist via spacer and mask or nebulizer (see below)
2. Oral prednisolone 30 mg once daily
3. Inhaled steroids—commence or increase dose

Acute severe attack

1. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%
2. Salbutamol 5 mg or terbutaline 10 mg via oxygen-driven nebulizer, repeated up to every 15–30 min as needed, and then 4 hourly
3. Steroids—hydrocortisone 200 mg intravenously four times daily or prednisolone 30–60 mg orally once daily

Life-threatening attack or patient failing to improve

4. Add ipatropium 0.5 mg to nebulized b_2-agonist
5. Give aminophylline, loading dose (in patient not previously treated with theophylline) of 5 mg/kg given intravenously over 20 min, then an infusion of 0.5 mg/kg/h aiming for serum concentration in the range 10–20 mg/l. Omit loading dose if patient already taking oral theophylline

Consider intravenous salbutamol (3–20 µg/min) or terbutaline (1.5–5 µg/min) infusion

Note

1. IF THE PATIENT IS DETERIORATING, CALL FOR HELP FROM THE INTENSIVE CARE UNIT SOONER RATHER THAN LATER—ELECTIVE INTUBATION AND VENTILATION IS BETTER THAN THAT DONE AFTER CARDIORESPIRATORY ARREST (SEE CHAPTER 16.1)
2. Use intravenous fluids to correct and prevent dehydration

Key investigations **To establish the diagnosis**

Acute asthma is a clinical diagnosis

Other important tests

1. Chest radiograph—exclude pneumothorax
2. Arterial blood gases—markers for life-threatening asthma being:
   - Normal or high $PaCO_2$ (>5 kPa)
   - Low pH
   - Severe hypoxia (*P*aO2 <8 kPa) in spite of high flow oxygen treatment
3. Electrolytes, renal and liver function, full blood count

Further management

1. Optimization of long-term asthma management
2. Education regarding how to recognize severe attacks and how to respond when they develop

2.5 Pneumonia

See Chapter 17.5.2.1 in main text

Clinical features

History

1. Breathing difficulty
2. 'flu-like prodrome
3. High fever, sweats, rigors
4. Pleuritic chest pain
5. Sputum production (but note that this is not expected in atypical pneumonia)
6. Travel
7. Pet birds

Examination

1. Fever
2. Respiratory—cyanosis, respiratory rate, focal lung signs (consolidation, pleural rub, pleural effusion)
3. Circulation—peripheral perfusion (hot or cold), pulse, blood pressure
4. Look at the sputum (if any)
5. Always check pulse oximetry

British Thoracic Society definition of severe pneumonia states that one or more of the following must be present in a patient with clinical and/or radiological signs of pneumonia:

1. Respiratory rate >30/min
2. Systolic blood pressure <90 mmHg
3. PaO_2 <8 kPa (breathing room air)
4. Multilobar involvement on chest radiograph
5. Blood urea >7 mmol/l

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%
2. Appropriate antimicrobial agent

British Thoracic Society guidelines for treatment of community-acquired pneumonia

- Mild/moderate pneumonia
- Oral therapy with extended spectrum penicillin (eg. amoxicillin 250–500 mg three times daily) alone or with a macrolide (eg. clarithromycin 250–500 mg twice daily). Omit the penicillin in patients with penicillin allergy
- Severe pneumonia
- Intravenous therapy with a second- or third-generation cephalosporin (e.g. cefotaxime 1g twice daily) plus a macrolide (e.g. erythromycin 500 mg four times daily)
- Suspected legionnaire's disease
- High-dose intravenous erythromycin (1g four times daily) plus consider adding oral rifampicin (0.6–1.2 g daily in two to four divided doses)

In areas/countries where there is serious concern that *S. pneumoniae* may be resistant to penicillin and other agents

- Mild/moderate pneumonia
- Second- or third-generation cephalosporin (e.g. cefotaxime 1g intravenously twice daily) plus macrolide (e.g. erythromycin 500 mg orally or intravenously four times daily), OR fluoroquinolone (e.g. levofloxacin 500 mg orally or intravenously once or twice daily) alone
- Severe pneumonia
- Second/third-generation cephalosporin (e.g. cefotaxime 1 g intravenously twice daily) plus macrolide (e.g. erythromycin 500 mg intravenously four times daily), OR second-/third-generation cepha-losporin (e.g. cefotaxime 1g intravenously twice daily) plus fluoroquinolone (e.g. levofloxacin 500 mg intravenously twice daily)

Note

1. If staphylococcal pneumonia is suspected, add flucloxacillin 1g intravenously four times daily
2. See Chapter 17.5.2.2 and Chapter 17.5.2.3 for discussion of antimicrobial treatment of patients with hospital-acquired pneumonia or pneumonia in the immuno-compromised
3. Intravenous fluids to maintain adequate hydration

Key investigations

To establish the diagnosis

1. Chest radiograph—looking for focal consolidation (lobar pneumonia) or more widespread interstitial shadowing.
2. Blood culture.
3. Sputum culture.
4. Blood sample for serological testing.

To establish severity

Arterial blood gases—if patient is very ill or pulse oximetry shows PaO_2 <92%

Other important tests

Full blood count, electrolytes, renal and liver function

Further management

Follow up chest radiograph to ensure complete resolution

3 Gastrointestinal and hepatological

3.1 Upper gastrointestinal haemorrhage

See Chapter 14.3.2 in main text

Clinical features

History

1. Haematemesis or 'coffee-ground' vomiting
2. Melaena
3. Presyncope
4. Indigestion or reflux or medication for these symptoms
5. Retching before haematemesis (consider Mallory Weiss tear)
6. Previous upper gastrointestinal investigation or surgery
7. To suggest recent development of anaemia
8. Drugs that predispose to upper gastrointestinal haemorrhage—aspirin, non-steroidal anti-inflammatory agents, anticoagulants
9. Risk factors for, or presence of, chronic liver disease (consider varices)
10. Anorexia and weight loss (consider malignancy)

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Mucous membranes—chronic anaemia
3. Evidence of chronic liver disease—jaundice and other manifestations (consider varices)
4. Evidence of portal hypertension—especially splenomegally (consider varices)
5. Lymphadenopathy—especially in left supraclavicular fossa (consider malignancy)
6. Abdomen—for epigastic mass (consider malignancy)
7. Rectal examination—for blood/melaena

Notes

1. The most reliable signs of intravascular volume depletion are postural hypotension (sitting versus lying) and a low jugular venous pressure
2. Clinical assessment of severity, see Table 13

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Establish intravenous access with one or more large-bore peripheral venous cannulae (look in the antecubital fossae in the patient who is shut down). If you cannot do this, then insert femoral venous catheter (see Emergency Medicine, section 10.1.3). DO NOT ATTEMPT TO INSERT AN INTERNAL JUGULAR OR SUBCLAVIAN VENOUS CATHETER INTO A PATIENT WHO OBVIOUSLY HAS SEVERE INTRAVASCULAR VOLUME DEPLETION (see Chapter 16.1 for discussion).
2. If clinical evidence of intravascular volume depletion, give 1000 ml of intravenous fluid (colloid, e.g Gelofusin ™, or 0.9% saline) as fast as possible. Repeat clinical examination. If the patient still has intravascular volume depletion, give further 500 ml of fluid as fast as possible. Repeat cycle until arterial pressure and jugular venous pressure restored towards normal, then slow down rate of infusion. Use blood instead of colloid/saline as soon as it is available
3. Cross-match blood for transfusion
4. Consider need for urgent upper gastrointestinal endoscopy
5. If oesophageal varices—see Table 14

Also

1. Keep oxygen saturation >92% (monitor using pulse oximetery), giving high flow oxygen (10 l/min) by face mask with reservoir bag if needed
2. Insert urinary catheter and monitor fluid input/output hourly in any patient with substantial gastrointestinal haemorrhage—a satisfactory urine output is the best gauge of adequate resuscitation
3. Correct any coagulopathy—see Emergency Medicine, section 1.9, Table 3 (iatrogenic overanticoagulation) and section 9.1 (disseminated coagulation)
4. Nurse to avoid aspiration, and do not insert nasogastric tube, which makes this more likely

Key investigations

To establish the diagnosis (and also potentially therapeutic)

1. Upper gastrointestinal endoscopy
   - Within 24 h of admission in anyone with a substantial gastrointestinal bleed
   - Urgently if oesophageal varices are suspected or the patient is actively bleeding

See Table 13 for assessment of risk of rebleeding and mortality after endoscopy

Other important tests

1. Full blood count—but remember that the initial haemoglobin concentration is a poor estimate of the volume of acute blood loss
2. Electrolytes, renal and liver function tests
3. Coagulation screen
4. To pursue possibility and causes of chronic liver disease (if clinically indicated)

Further management

1. Inform surgical colleagues of all cases of substantial gastrointestinal haemorrhage immediately
2. Dependent on cause of haemorrhage, e.g.
   - Acid suppression for ulcer healing—high dose intravenous proton pump inhibitor, e.g. omeprazole 80 mg bolus followed by 8 mg/h
   - Eradication of *H. pylori*

3.2 Lower gastrointestinal haemorrhage

See Chapter 14.3.2 in main text

Clinical features

History

1. Haemorrhoids
2. Abdominal pain—if long-standing and intermittent may suggest diverticular disease, if severe may indicate mesenteric ischaemia
3. Previous lower gastrointestinal investigation or surgery
4. To suggest recent development of anaemia
5. Anorexia, weight loss, recent alteration in bowel habit (consider malignancy)
6. Drugs that predispose to gastrointestinal haemorrhage—aspirin, non-steroidal anti-inflammatory agents, anticoagulants
7. Risk factors for, or presence of, chronic liver disease (consider rectal varices)
8. Family history—colonic polyps/neoplasia, hereditary haemorrhagic telangiectasia

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Mucous membranes—chronic anaemia
3. Jaundice—suggests malignancy or chronic liver disease
4. Lymphadenopathy—suggests malignancy
5. Abdomen—for localized tendeness, peritonism or palpable mass
6. Rectal examination—for piles and blood
7. Peripheral vasculature—generalized disease increases likelihood of mesenteric ischaemia
8. Telangiectasiae on skin or mucosae

Notes

The most reliable signs of intravascular volume depletion are postural hypotension (sitting versus lying) and a low jugular venous pressure

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Establish intravenous access—as Emergency Medicine, section 3.1
2. If clinical evidence of intravascular volume depletion, resuscitate as described in Emergency Medicine, section 3.1
3. Cross-match blood for transfusion

Also

4. Keep oxygen saturation >92% (monitor using pulse oximetery), giving high flow oxygen (10 l/min) by face mask with reservoir bag if needed
5. Insert urinary catheter and monitor fluid input/output hourly in any patient with substantial gastrointestinal haemorrhage—a satisfactory urine output is the best guage of adequate resuscitation
6. Correct any coagulopathy—see Emergency Medicine, Section 1.9, Table 3 (iatrogenic overanticoagulation) and Section 9.1 (disseminated intravascular coagulation)

Key investigations

To establish the diagnosis

In all patients

1. Proctoscopy and rigid sigmoidoscopy

As required:

2. Colonoscopy
3. Mesenteric angiography

Other important tests

1. Full blood count
2. Electrolytes, renal and liver function tests, coagulation screen, inflammatory markers
3. To pursue possibility and causes of chronic liver disease (if clinically indicated)

Further management

1. Inform surgical colleagues of all cases of substantial gastrointestinal haemorrhage immediately
2. Dependent on cause of haemorrhage

3.3 Acute colitis

See Chapter 14.11 and Chapter 14.17 in main text

Clinical features

History

1. Bowel motions—frequency and type (blood, mucus, pus)
2. Abdominal pain
3. Rapidity of onset
4. Systemic features—fever, malaise, anorexia
5. Previous episodes/known colitic disease
6. Recent diet (contaminated or infected food)
7. Have close contacts also been ill?
8. Recent antibiotic treatment (consider *C. difficile*)
9. Use of non-steroidal anti-inflammatory agents
10. Associated vomiting
11. Travel
12. Risk factors for HIV (in some cases)

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Signs of toxicity—fever
3. Mucous membranes—chronic anaemia, ulceration, Candida
4. Abdomen—for distension, localized tenderness, peritonism or palpable mass, or altered bowel sounds (absent, reduced)
5. Rectal and perineal examination—for fistulae and nature of stool (blood, pus)
6. Peripheral vasculature—generalized disease increases likelihood of ischaemic colitis
7. Peripheral oedema—suggests hypoproteinaemia and chronic disease in this context

Notes

The most reliable signs of intravascular volume depletion are postural hypotension (sitting versus lying) and a low jugular venous pressure

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Fluid and potassium resuscitation as necessary—see Emergency Medicine, section 3.1 and section 5.5.
2. Most cases of acute colitis do not require antimicrobial therapy and settle with rehydration and time, the results of stool culture and rectal biopsy (which should be available in 24–48 h) being used to guide further treatment decisions. However, patients who are very ill with marked systemic symptoms and bloody diarrhoea (indicating probable colitis) should be given antimicrobial therapy pending culture results. Treat empirically with, e.g. ciprofloxacin (500–750 mg orally twice daily, or 200–400 mg intravenously twice daily) and metronidazole (400 mg orally three times daily or 500 mg intravenously three times daily).
3. Also, in cases of known colitis (and to be considered in those with new and undiagnosed presentations of colitis), give steroids to those who are very ill, e.g. hydrocortisone 100 mg intravenously every 6 h or prednisolone 60 mg orally once daily

Note the features of a severe acute attack of ulcerative colitis (Table 15)

Key investigations

To establish the diagnosis

In all patients

1. Abdominal radiograph—to assess extent of inflammation and to exclude toxic megacolon (required before proctoscopy/sigmoidoscopy), and erect chest radiograph—looking for air under diaphragm (perforation)
2. Flexible or rigid sigmoidoscopy and rectal biopsy
3. Stool—microscopy, culture and testing for *C. difficile* toxin
4. Blood cultures

Other important tests

1. Full blood count
2. Group and save or crossmatch blood
3. Electrolytes, renal and liver function tests, inflammatory markers, coagulation screen

Further management

1. Inform surgical colleagues of all cases of acute colitis, urgently if radiography shows perforation or toxic dilatation
2. Nurse in side room (if possible) until infective cause excluded
3. Further management dependent on cause of colitis
4. Note that suspected or proven food poisoning and typhoid are notifiable diseases in the UK

3.4 Acute hepatic failure

See Chapter 14.21.3 in main text

Clinical features

Definitions

1. Acute hepatic failure is hepatocellular jaundice, hypertransaminasaemia, and prolongation of the prothrombin time associated with an acute liver disease
2. Fulminant hepatic failure is acute liver failure with hepatic encephalopathy, most definitions specifying that this must occur within a particular time (variable) from the onset of clinical evidence of liver disease (usually jaundice)

History

1. Jaundice—not always present in fulminant hepatic failure
2. Confusion/drowsiness—note timing of onset of mental changes in relation to jaundice
3. Relevant to cause of acute liver failure, e.g. paracetamol overdose, full drug history (prescribed and non-prescribed), risk factors for viral hepatitis
4. Is there a background of chronic liver disease?—alcohol, risk factors for viral hepatitis
5. Autoimmune conditions (associated with autoimmune chronic active hepatitis)
6. Family history (Wilson's is a rare cause of fulminant hepatic failure)

Examination

1. State of circulation—vital signs are normal in the early stages. Tachycardia and hypotension occur later. Hypertension and bradycardia are very late and sinister signs of cerebral oedema
2. Jaundice
3. Liver—usually tender, but normal size or only slightly enlarged in acute hepatic failure. If hepatomegaly consider hepatic venous obstruction (Budd Chiari), malignant infiltration, chronic liver disease
4. Ascites—if substantial consider Budd Chiari
5. Encephalopathy
   - Grade 1—mild confusion, irritability, decreased attention
   - Grade 2—drowsiness, lethargy, inappropriate behaviour
   - Grade 3—somnolent but rousable, disorientated
   - Grade 4—coma
6. Signs of chronic liver disease

Notes

Focal neurological signs are not expected in acute hepatic failure. If present they suggest a focal cerebral lesion, most likely haemorrhage in this context

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Acute hepatic failure

1. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92% (monitor with pulse oximetry)
2. Treat/prevent hypovolaemia—give 4.5% serum albumin intravenously to keep CVP at +10 cm of water
3. Treat/prevent hypoglycaemia—give 50% glucose intravenously (central line) at 5–10 ml/h (monitor BM stix regularly)
4. *N*-Acetyl cysteine by intravenous infusion
   - Paracetamol overdose 150 mg/kg in 200 ml 5% dextrose over 15 min, then 50 mg/kg in 500 ml 5% dextrose over 4 h, then 100 mg/kg in 1000 ml 5% dextrose over 16 h
   - Other diagnosis 150 mg/kg in 1000 ml 5% dextrose over 24 h
5. Give prophylactic broad spectrum antibiotic, eg. cefotaxime 1 g intravenously twice daily
6. Give prophylaxis against gastrointestinal stress ulceration, e.g. ranitidine (150 mg orally twice daily, 50 mg intravenously three times daily)

Hepatic encephalopathy To prevent or treat

1. Removal or correction of precipitating factors
   - Drugs—stop all if possible, particularly sedatives/hypnotics and diuretics
   - Fluid and electrolyte balance—maintain carefully. Avoid/treat dehydration, hypoglycaemia, hypokalaemia, hypophosphataemia
2. Minimize absorption of nitrogenous substances

   The following treatments may or may not be given

   - Give enemas ($MgSO_4$ or phosphate) to encourage bowel emptying
   - Give disaccharide laxative, e.g. lactulose 30–50 ml three times daily, dosage then adjusted to produce 2–3 soft stools daily
   - Give broad spectrum poorly-absorbed antibiotic, e.g. neomycin 1 g four times daily by mouth
3. If Grade 3 or 4 encephalopathy, also
   - Intubate and ventilate
   - Give parenteral feeding

Notes

1. Hyponatraemia is common and due to water excess rather than sodium deficiency. It should be treated with fluid restriction and not by infusion of saline
2. If there is a history of chronic high alcohol intake or malnourishment, give thiamine intravenously BEFORE giving glucose to avoid risk of precipitating Wernicke's encephalopathy, e.g. Pabrinex ™ intravenous high potency injection, 10 ml (2 ampoules) over 10 min (repeated three times daily)
3. Insert urinary catheter and monitor fluid input/output hourly in any patient with acute hepatic failure
4. Cerebral oedema
   - Avoidance—Avoid overfilling with intravenous fluids
   - Treatment—Nurse in quiet room with trunk and head elevated at 40°; consider transfer to facility where intracranial pressure can be monitored; consider mannitol 1 g/kg as intravenous bolus of 20% solution (if plasma osmolality <315 mosmol/ kg and the patient is not oliguric), repeated 4 hourly (0.5 g/kg) if previous infusion induced a diuresis

Key investigations

To establish the presence of acute liver failure

1. Liver blood tests—bilirubin, transaminases (ALT, AST, gGT)
2. Prothrombin time/coagulation screen

To establish the cause of liver disease

If no history of paracetamol overdose

1. Hepatitis B core IgM, hepatitis A IgM, liver autoantibodies, immunoglobulins
2. Abdominal ultrasound and Doppler of hepatic veins—looking for size/echogenicity of liver, splenomegaly, signs of Budd Chiari
3. If <40 years: serum copper and caeruloplasmin; ophthalmic examination for Kayser-Fleischer rings (Wilson's disease)

Note

1. Tap ascites if present—microscopy, culture, and sensitivity. Culture/swab blood, urine, nasal, high vagina
2. Do not correct coagulopathy unless the patient is bleeding: the prothrombin time is an important prognostic indicator
3. Where the prothrombin time (in s) is greater than the time after a paracetamol overdose (in h), there is a substantial risk of developing acute liver failure

Other important tests

1. Full blood count
2. Glucose, renal function tests, amylase
3. Arterial blood gases

Further management

1. Discuss all cases of acute hepatic failure with a specialist (transplant) centre (see Table 16): urgent orthotopic liver transplantation may be required and appropriate
2. Dependent on cause of hepatic failure

3.5 The acute abdomen

See Chapter 14.3.1 in main text

Clinical features

History

1. Abdominal pain—duration, constant or colicky, where is it worst (point with one finger), radiation
2. Gastrointestinal symptoms—anorexia, nausea, vomiting, diarrhoea, constipation (precisely when were the bowels last open), blood in vomit or stool
3. Urinary symptoms—frequency, pain on micturition, haematuria
4. Gynaecological symptoms—last menstrual period, vaginal discharge
5. To suggest sepsis—sweats, fevers, rigors
6. History of gastrointestinal problems—indigestion, peptic ulceration, gallstones, pancreatitis
7. History of atheromatous vascular disease—ischaemic heart disease, cerebrovascular disease, peripheral vascular disease (increase the likelihood of bowel ischaemia or of abdominal aortic aneurysm, also relevant to surgical risk)

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Signs of toxicity—fever
3. Foetor
4. Abdomen
   - Inspection—distension, movement on respiration
   - Palpation—tenderness, guarding, rigidity, rebound tenderness, palpable mass
   - Auscultation—bowel sounds
   - Check all hernial orifices and abdominal aorta
5. Rectal examination—for tenderness and nature of stool, blood in stool
6. Vaginal examination—tenderness, pelvic mass
7. Test urine for blood

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Establish intravenous access—as Emergency Medicine, section 3.1
2. If clinical evidence of intravascular volume depletion, resuscitate as described in Emergency Medicine, section 3.1
3. Immediate liaison with surgical colleagues
4. Provide effective analgaesia e.g.
   - Non-steroidal anti-inflammatory agent: e.g. diclofenac 75 mg intramuscularly, repeated after 30 min if necessary
   - Opioid: e.g. morphine 5 mg subcutaneously plus 5 mg intramuscularly, repeated if necessary and accompanied by appropriate antiemetic, e.g. metoclopramide 10 mg IV over 1–2 min, or cyclizine 50 mg IV over 1–2 min
5. Nasogastric tube
6. Urinary catheter

Key investigations

To establish the diagnosis

1. Abdominal radiograph—is there intestinal obstruction?
2. Erect chest radiograph—is there gas under the diaphragm indicating intestinal perforation?
3. Serum amylase—a substantial increase suggests pancreatitis
4. Abdominal ultrasound—?free fluid/swollen appendix/ovarian cyst
5. Abdominal CT scan

Note

Patients with generalized peritonitis require an urgent LAPAROTOMY provided that pancreatitis has been excluded. DO NOT DELAY. If the patient requires resuscitation, then make arrangements for theatre whilst initiating resuscitation and continue to resuscitate in the anaesthetic room. Do not wait 'until the patient is a bit better' before involving anaesthetic and surgical colleagues

Other important tests

1. Full blood count
2. Group and save or crossmatch blood
3. Electrolytes, renal and liver function tests
4. Coagulation screen

Further management

Dependent on the cause of the acute abdomen

Note

1. Adhesive small bowel obstruction may resolve with conservative management
2. Remember rare 'medical' causes of abdominal pain, e.g. pneumonia, shingles, drugs (digoxin), diabetes, sickle cell crisis, porphyria, familial mediterranean fever … remember also that these are rare: if in doubt, diagnose a common condition

4 Renal

4.1 Acute renal failure

See Chapter 20.4 in main text

Clinical features

History

1. There are no specific features to suggest acute renal failure: presentation is dominated by the precipitating condition
2. Previous renal or urinary tract disease
3. Drugs, prescribed and non-prescribed
4. Evidence of multisystem disease
5. ALWAYS seek the results of previous tests of renal function

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Evidence of infection—fever, localizing signs
3. Breathing—evidence of pulmonary oedema or acidosis (Kussmaul)
4. Abdominal—is the bladder palpable? (obstruction)
5. Rectal—is there pelvic malignancy? (obstruction)
6. General—signs indicating multisystem disorder: rash, joints, eyes, nose. Are muscles swollen/tender? (rhabdomyolysis)

Note

The most reliable signs of intravascular volume depletion are postural hypotension (sitting versus lying) and a low jugular venous pressure

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Treatment of life-threatening complications

1. Hyperkalaemia—see Emergency Medicine, section 5.4
2. Pulmonary oedema—see Emergency Medicine, section 1.8
3. Severe acidosis, causing circulatory compromise
4. 'Gross uraemia', causing encephalopathy or bleeding Aside from immediate life-saving medical treatments, patients with these features will need urgent renal replacement therapy (preferably by haemodialysis or haemofiltration, as dictated by clinical context) unless their renal function can be restored rapidly

Optimization of intravascular volume—many patients presenting with acute renal failure will be volume deplete

1. Establish intravenous access—as Emergency Medicine, section 3.1
2. If clinical evidence of intravascular volume depletion, resuscitate as described in Emergency Medicine, section 3.1

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

Make diagnosis of cause of renal failure

1. Is it acute or chronic?—previous biochemical measurements; renal size on ultrasonography (small kidneys indicate chronic disease)
2. Is it due to urinary obstruction?—history of problems with urinary flow, urinary stones etc.; dilated pelvicalyceal system on ultrasonography (but beware of obstruction without dilatation)
3. Is it due to renal inflammation?—dipstick proteinuria and haematuria; urinary red cell casts
4. Is it due to prerenal failure/acute tubular necrosis?— clinical context; evidence of circulatory compromise/intrvascular volume depletion

Note

1. Stop all drugs that can be haemodynamically deleterious to renal function unless there is a very pressing indication for them, e.g. non-steroidal anti-inflammatory agents, angiotensin converting enzyme inhibitors, angiotensin II receptor blockers; also stop all nephrotoxic agents (e.g. aminoglycosides) and substitute non-toxic alternative
2. Insert urinary catheter and monitor fluid input/output hourly in any patient with acute renal failure— remove after 24 h if the patient is anuric/oliguric

Key investigations

To establish the diagnosis

Renal function tests—acute renal failure is usually diagnosed clinically on the basis of rapid rise in serum creatinine

Other important tests

1. ECG—looking for manifestations of hyperkalaemia
2. Electrolytes—especially potassium
3. Full blood count, coagulation screen, liver function tests
4. Creatine kinase (rhabdomyolysis)
5. Blood and other cultures—if clinically indicated
6. Autoimmune/vasculitic screen (anti-GBM, ANCA, ANA, immunoglobulins, cryoglobulins)—if clinically indicated
7. Ultrasonography of urinary tract—to determine renal size and look for evidence of obstruction
8. Chest radiograph—looking for pulmonary oedema or (less likely) evidence of lung haemorrhage in pulmonary-renal syndrome
9. Arterial blood gases—quantitate acidosis

Further management

Dependent on the cause of acute renal failure

Note

1. When intravascular volume has been restored to normal (JVP clearly visible/CVP in normal range; no postural drop in blood pressure), fluid input should then be given in equal volume to measured output of urine and other fluids, plus an allowance (500–1000 ml/day) for insensible losses. The prescription of fluid should be refined on the basis of (at least) twice daily clinical examination and daily measurement of the patient's weight
2. Precise diagnosis of the cause of acute renal failure due to renal inflammation (glomerulonephritis, tubulointerstitial nephritis, vasculitis) will probably require renal biopsy
3. If imaging suggests urinary obstruction, then this requires urgent relief, e.g. by urethral catheterization, suprapubic catheterization or percutaneous antegrade nephrostomy as appropriate

4.2 Rhabdomyolysis

See Chapter 20.5 in main text

Clinical features

Rhabdomyolysis is the breakdown of muscle fibres, when leakage of potentially toxic cellular contents into the circulation can lead to hypovolaemia, acidosis, hyperkalaemia, acute renal failure, and disseminated intravascular coagulation.

History

Muscular symptoms

1. Pain, tenderness—focal or generalized
2. May be none

Related to cause

1. Focal muscle damage
   - Obvious—e.g. crush injury, high-voltage electrical injury
   - Not so obvious—e.g. ischaemic injury following arterial embolus to limb; pressure damage following prolonged immobilization (commonly coma)
2. Generalized muscle damage
   - Excessive muscular activity

     Severe exercise—e.g. marathon running

     Epileptic fitting—prolonged (see Emergency Medicine, section 6.5)

     Status asthmaticus

     Severe dystonia

     Acute psychosis
   - Infections

     Septicaemia—see Emergency Medicine, section 7.7

     Viral myositis—e.g. influenza
   - Toxins

     Prescribed drugs—e.g. HMG CoA reductase inhibitors

     Substance abuse—e.g. alcohol, barbiturates, opioids, methanol, ethylene glycol (antifreeze), cocaine, amphetamine, ecstacy (MDMA), LSD (lysergic acid diethylamide)

     Other—e.g. snake bite, spider (black widow), bee sting (multiple), carbon monoxide, toluene, hemlock (quail that have eaten hemlock)
   - Heatstroke (see Emergency Medicine, section 9.3)
   - Malignant hyperpyrexia (see Emergency Medicine, section 9.3)
   - Neuroleptic malignant syndrome (see Emergency Medicine, section 9.3)
   - Myopathies

     Consider particularly if rhabdomyolysis occurs without clear precipitant

     Metabolic—ask for history of intermittent muscular fatigue/pain, e.g. McCardle's syndrome Inflammatory—e.g. polymyositis
   - Metabolic /endocrine

     Hypothyroidism

     Electrolyte disturbance—e.g. hypokalaemia Diabetic ketoacidosis

Examination

General

1. Vital signs—temperature, pulse rate, blood pressure, respiratory rate
2. Full physical examination

For cause of rhabdomyolysis

1. Muscles
   - Are any swollen or tender?
   - Is there a compartment syndrome?
2. Ischaemia
   - Are legs and arms all well perfused?
   - Can you feel all peripheral pulses?
3. Pressure damage
   - Look especially at the back of the head, spine, pelvis and heels—pressure sores indicate likelihood of pressure damage to muscles
4. Systemic condition
   - Rash—septicaemia (common), dermatomyositis (very rare)
   - Slow relaxing tendon jerks (hypothyroidism)

Immediate management

As for acute renal failure: see Emergency Medicine, section 4.1

To prevent rhabdomyolysis from leading to renal failure

1. Restore intravascular volume rapidly: see Emergency Medicine, section 3.1
2. Monitor
   - Urine output—urethral catheter
   - Urinary pH—dipstick
3. Fluid

   Encourage brisk diuresis (urine output >150 ml/h) of alkaline urine (myoglobin more soluble at elevated pH)—when intravascular volume has been restored give:

   - 0.9% sodium chloride/5% dextrose (alternating bags), or 0.45% sodium chloride and 2.5% dextrose (same bag), at 200 ml/h—adjust rate to achieve urine output of approx 200 ml/h
   - 1.25% sodium bicarbonate (=150 mmol/l each of sodium and bicarbonate) at 25 ml/h—adjust rate to achieve urinary pH>7
4. Mannitol / diuretic

   If urine output remains low give:

   - Mannitol—1 g/kg as 20% solution intravenously over 30–60 min and/or
   - Diuretic—e.g. frusemide 40 mg (push) –500 mg (over 2 h) intravenously

Note

1. If urine output remains low, then infusion of fluid as described here will inevitably lead to overload— FLUID INFUSION MUST BE REDUCED OR STOPPED BEFORE PULMONARY OEDEMA DEVELOPS. Then proceed as for acute renal failure (see Emergency Medicine, section 4.1)
2. There is no randomized controlled trial proof of the efficacy of a regimen comprising high volume fluid infusion/alkalinization/mannitol such as that described here, but use of this (or similar) treatment produces outcomes far superior to historical controls
3. Do not correct hypocalcaemia with calcium (risk of inducing / worsening metastatic calcification)

Key investigations

To establish the diagnosis

1. Urine
   - Dipstick test positive for blood, but microscopy shows no red blood cells
2. Blood
   - Creatine kinase—grossly elevated in severe cases (>10,000 IU/l)

Other important tests

1. ECG
   - Look for features of hyperkalaemia (see Emergency Medicine, section 5.4)
2. Blood
   - Electrolytes

     Hyperkalaemia—POTENTIALLY LIFE THREATENING. May develop rapidly. See Emergency Medicine, section 5.4

     Hypocalcaemia, hyperphosphataemia, hyperuricaemia
   - Renal function
   - Liver function tests—elevated transaminases from muscle (also LDH)
   - Coagulate on screen—risk of disseminated intravascular coagulation
3. As dictated by clinical suspicion, e.g.
   - Blood cultures
   - Thyroid function tests
   - Muscle biopsy

Further management

1. Dependent on the cause of rhabdomyolysis
2. Compartment syndrome—measure compartment pressure. Consider fasciotomy if elevated

5 Metabolic and endocrine

5.1 Hypoglycaemia

See Section 12.11 in main text

Clinical features

History

1. Coma
2. Epileptic fitting
3. Confusion and/or delirium
4. Focal neurological signs (including hemiplegia, uncommon)

The patient may not be able to give any useful history: obtain as much information as possible from others in attendance (relatives, friends, ambulance crew, bystanders etc.). Ask in particular regarding:

1. Diabetes mellitus
2. Patient self-medication, and access to insulin/oral hypoglycaemic agents
3. Previous episodes
4. Alcohol and food consumption
5. Other medical conditions

Examination

Immediate priorities

1. Airway, breathing, circulation
2. Glasgow Coma Score
3. Bedside stick test for blood glucose
4. Other features
5. Typically very pale and shut down peripherally with a cold sweat
6. Evidence that the patient is diabetic: search for Medic Alert bracelet/necklace, medication (insulin, oral hypoglycaemic agents), documentation (glucose monitoring, outpatient clinics), sites of insulin injection
7. Evidence of chronic liver disease or endocrine disorder

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Give glucose after establishing hypoglycaemia by bedside stick test, as follows:

1. Patient alert and co-operative: give glucose 10–20 g by mouth (2 teaspoons sugar, or 3 sugar lumps, or one 23 g oral ampoule of Hypostop™ gel)
2. If impaired consciousness and not protecting airway: give glucose 50% solution, 50 ml intravenously (note that the solution is viscous and irritant if extravasated, hence give through large bore needle/cannula into large vein)
3. If impaired consciousness, not protecting airway and intravenous access not possible: give glucagon 1 unit (= 1 mg) intramuscularly
4. Repeat blood sugar measurement 10 min later: repeat glucose if still hypoglycaemic

Note

Hypoglycaemic symptoms are unusual if the plasma glucose is >2.5 mmol/l, but the threshold varies from person to person; hence it is appropriate to administer one dose of glucose intravenously (50% solution, 50 ml) to any patient with impaired consciousness whose plasma glucose is <3.0 mmol/l

Key investigations

To establish the diagnosis

Blood glucose—take sample through cannula BEFORE giving intravenous glucose

Other important tests

Hypoglycaemia in a known diabetic is unlikely to require further investigation. However, if the situation is not clear-cut, then a serum sample should be taken BEFORE intravenous glucose (or intramuscular glucagon) is given for serum insulin and C-peptide levels—to determine whether hypoglycaemia is due to endogenous or exogenous insulin

The following investigations may also be appropriate

Electrolytes, renal and liver function tests

- Blood and other cultures—if clinical suspicion of sepsis

Tests for endocrine disease—adrenocortical insufficiency, hypothyroidism, hypopituitarism

- Salicylate level—if possibility of overdose
- Chest radiograph—?aspiration in any patient who has been unconscious

Further management

Dependent on the cause of hypoglycaemia

Note

1. Hypoglycaemia may recur—patients who have been given intravenous glucose and recovered from hypoglycaemia should be observed for at least 12 h, longer if they have taken long acting insulin/oral hypoglycaemic agents
2. Education—most cases of hypoglycaemia occur in known diabetics and can be avoided by the patient checking their blood glucose and responding appropriately in the event of warning signals

5.2 Diabetic ketoacidosis

See Section 12.11 in main text

Clinical features

History

1. Polyuria and polydipsia
2. Drowsiness
3. To suggest precipitating condition—often infection, but can be any acute illness
4. Monitoring and treatment of diabetes (in known diabetics)—in particular recent details of blood glucose measurements and medication with insulin or oral hypoglycaemic agents

Examination

1. State of circulation/dehydration—temperature of peripheries, skin turgor, pulse rate, blood pressure, tongue and mucous membranes, eyes, jugular venous pressure
2. Breathing—in particular for indication of acidosis (Kussmaul) and for smell of ketones
3. Glasgow Coma Score.
4. Evidence of infection—fever, localizing signs, including careful examination of the feet and skin for ulceration/sepsis

Note

1. The most reliable signs of intravascular volume depletion are postural hypotension (sitting versus lying) and a low jugular venous pressure
2. Examine carefully for evidence of complications of diabetes, but not in the immediate emergency setting

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Restoration of intravascular volume/hydration— patients will typically have a total body fluid deficit of 3–6 litres
   - Establish intravenous access—as Emergency Medicine, section 3.1
   - Give 1 litre of colloid as fast as possible (if hypotensive and shut down peripherally, if not, then omit this and proceed directly to give saline)
   - 0.9% saline, 1 litre over 30 min, then
   - 0.9% saline, 1 litre over 1 h, with potassium (see below), then
   - 0.9% saline, 1 litre over 2 h, with potassium (see below), then
   - 0.9% saline, 1 litre every 4–6 h until rehydrated, with potassium (see below)
   - When blood glucose <15 mmol/l, switch from saline to 5% dextrose infusion until eating normally (do NOT simply allow the glucose concentration to keep falling into the normal range, reducing the insulin infusion rate to low levels according to the sliding scale. The patient continues to require insulin in dosage sufficient to allow them to metabolize ketones effectively)
2. Correction of electrolyte imbalance—all patients will have a very substantial deficit in body potassium, even though serum potassium concentration will usually be elevated at presentation. Replace potassium as follows, monitoring the serum concentration every few hours:

Serum potassium (mmol/l)	Potassium (mmol) added to each litre of fluid replacement
<3	40
<4	30
<5	20

3. Correction of hyperglycaemia

Give insulin (actrapid 50 units mixed in 50 ml of 0.9 per cent saline) intravenously according to a sliding scale as follows:

Blood glucose, measured hourly (mmol/l; reagent stick	Insulin rate (units/h)
<4	0.5
4–7	1
7.1–11	2
11.1–15	3
15.1–19	4
19.1–24	5
>24	6

4. Correction of acidosis

Acidosis will correct with restoration of circulating volume and administration of insulin; hence most cases do NOT require administration of bicarbonate. However, consider giving sodium bicarbonate (1.26% solution, 500 ml by intravenous infusion over 1 h) in cases where there is profound acidosis (e.g. arterial pH<7.0) that is thought to be causing circulatory compromise

Also

1. Empty the stomach with nasogastic tube—gastroparesis/acute gastric dilatation is a particular risk in diabetic ketoacidosis, with a high risk of vomiting and aspiration, which can be fatal
2. Give prophylaxis against venous thromboembolism (high risk) with low molecular weight heparin, e.g. enoxaparin 40 mg by subcutaneous injection once daily

---

And
Treat any precipitating condition vigorously. Note that surgical attention may be required, in particular when there is foot sepsis

---

Note

1. Hyperosmolar non-ketotic diabetic coma (HONK)
   - Typically occurs in elderly patients with non-insulin dependent diabetes mellitus (NIDDM)
   - Glucose usually >40 mmol/l
   - Not ketoacidotic (by definition)
   - Look for plasma osmolality >350 mosmol/kg, calculated as 2 × (Na+K) + Urea + Glucose (all measured in mmol/l)
   - Give colloid and 0.9% saline as for diabetic ketoacidosis, but switch to 0.45% saline when intravascular volume deficit is replaced (no postural hypotension, JVP clearly visible) if serum sodium remains >150 mmol/l
   - Insulin requirements are typically low: hence use a reduced dose of insulin on the sliding scale to avoid hypoglycaemia

---

Key investigations

To establish the diagnosis

1. Blood glucose
2. Reagent stick test of urine for ketones

Other important tests

1. Serum electrolytes
2. Arterial blood gases
3. Full blood count, renal and liver function tests
4. 'Infection screen'—chest radiograph, urine and blood culture, swab any potentially infected site
5. ECG (may have silent infarct)

Further management

Education—most cases of diabetic ketoacidosis occur in known diabetics and can be avoided. The key issue to emphasize is that illness increases insulin requirements, hence diabetics who are ill:

1. Still need to take insulin, even if they are not eating
2. Should check their blood glucose regularly (up to every 2 h or so)
3. Should give themselves frequent appropriate doses of short-acting insulin if their blood glucose starts to rise
4. Should have access to a phone number that they can call for advice if they run into problems

5.3 Metabolic acidosis

See Section 11.11 in main text

Clinical features

History

In the Emergency Medicine context presents non-specifically with

1. Altered conscious level
2. Circulatory collapse
3. Hyperventilation.
4. Key points to establish
5. In what circumstances was the patient found?
6. History of diabetes mellitus
7. History of chronic renal failure
8. Overdose—most commonly salicylates
9. Consumption of poison—e.g. ethylene glycol, methanol, antifreeze

---

Note

Medical conditions that can cause profound metabolic acidosis (with normal anion gap, see below) include:

1. Severe diarrhoeal illness
2. Renal tubular acidosis

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Breathing—in particular for indication of acidosis (Kussmaul) and for smell of ketones
3. Glasgow Coma Score

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Restoration of intravascular volume

1. Establish intravenous access—as Emergency Medicine, section 3.1
2. If clinical evidence of intravascular volume depletion, resuscitate as described in Emergency Medicine, section 3.1

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

Should bicarbonate be given? This is a contentious issue: if acidosis is severe (pH<7.0) and there is circulatory compromise, give intravenous sodium bicarbonate (e.g. 1.26% solution, 500 ml by intravenous infusion over 1 h; or an equivalent amount of bicarbonate as a more concentrated solution if the patient is fluid overloaded), then assess clinical response and repeat estimation of arterial blood gases.

Note

Correction of metabolic acidosis requires careful attention to serum potassium concentration: profound hypokalaemia can occur if this is neglected

Key investigations

To establish the diagnosis

1. Arterial blood gases—show metabolic acidosis (by definition)
2. Plasma glucose and reagent stick test for urinary ketones—to exclude diabetic ketoacidosis (see Emergency Medicine, section 5.2)
3. Plasma salicylate concentration—to exclude overdose
4. Renal function tests—to exclude uraemic acidosis
5. Plasma potassium—acidosis may be associated with hypokalaemia or hyperkalaemia, but with profound deficit in total body potassium in both situations. Close monitoring required
6. Blood lactate concentration—many types of severe illness are associated with lactic acidosis, especially overwhelming sepsis
7. Plasma bicarbonate concentration
8. Calculate the anion gap: are there unusual anions in the blood? The blood 'anion gap', calculated as $(Na^{+} + K^{+}) – (Cl^{-} + HCO_3^{-})$, usually equals 10–18 mmol/ l. If there is acidosis with a high anion gap, then there must be an unmeasured substance in the blood, in which case discuss measurement of specific toxins with a clinical biochemist

Other important tests

1. Full blood count, electrolytes, liver function tests
2. Blood paracetamol level (rarely causes profound acidosis, but combined overdoses are common)
3. Chest radiograph—consider aspiration in any patient with a depressed conscious level
4. Abdominal radiograph—in cases of unexplained normal anion gap acidosis: renal tubular acidosis may be associated with nephrocalcinosis

Further management

Dependent on the cause of metabolic acidosis

5.4 Hyperkalaemia

See Chapter 20.2.2 and Chapter 20.4 in main text

Clinical features

History

1. Hyperkalaemia does not produce specific symptoms. Patients may sometimes develop 'odd feelings' in their muscles, but these are rarely dramatic
2. Cardiac arrest
3. Context—almost always occurs in the context of acute or chronic renal failure

Examination

1. Hyperkalaemia does not produce specific signs
2. Cardiac arrhythmia

Immediate management

If there are ECG changes that are more severe than tenting of the T waves:

1. Give 10 ml of 10% calcium gluconate by slow intravenous injection, repeated as necessary until ECG shows clear evidence of returning towards normal

   If ECG changes are not severe, or after giving calcium gluconate:
2. Give 10–20 units of soluble insulin in 50 ml of 50% dextrose intravenously over 20 min, and/or
3. Give nebulized b_2-agonist, e.g salbutamol 10 mg

   These treatments will lower serum potassium concentration by 1–2 mmol/l over 20–30 min and buy a few hours of time, but hyperkalaemia will recur unless the cause can be treated rapidly, hence consider:
4. Referral to nephrological services for renal replacement therapy

Note

5. Intravenous infusion of sodium bicarbonate 50–100 mmol (approx. 300–600 ml of 1.26% solution or approx. 50–100 ml of 8.4% solution) can usefully be employed to treat hyperkalaemia in the setting of severe acidosis. In other cases it has no advantage over insulin/dextrose or b_2-agonist and has the disadvantages of not only requiring a substantial sodium/fluid load (a problem in those who are already overloaded), but also that concentrated solutions are chemically irritant and hence must be administered through central venous lines

Key investigations

To establish the diagnosis

1. ECG—the following changes occur progressively as the plasma potassium concentration rises
   - Tenting of T waves
   - PR interval lengthens and P wave diminishes before disappearing
   - QRS complex widens
   - 'Sine wave' pattern
2. Serum potassium concentration >5.5 mmol/l

Other important tests

1. Renal function tests
2. To determine cause of acute renal failure—if clinical context is appropriate

Further management

1. Ion exchange resins, eg. calcium resonium™ 15 g in water three of four times daily by mouth (with concurrent prescription of a laxative), or 30 g in methylcellulose solution given as an enema, retained for 9 h and then removed by irrigation—these can be helpful in patients with persistent (but not life-threatening) hyperkalaemia who would not otherwise require renal replacement therapy. Note, however, that ion exchange resins take at least 4 h to have any effect and are NOT an emergency treatment for hyperkalaemia
2. Stop all drugs that might exacerbate hyperkalaemia unless there is a very pressing need for them and no alternative is available, e.g. potassium supplements, potassium-sparing diuretics, angiotensin converting enzyme inhibitors, angiotensin II receptor antagonists, trimethoprim, heparin
3. Dependent on the cause of hyperkalaemia

5.5 Hypokalaemia

See Chapter 20.2.2 in main text

Clinical features

History

1. In almost all cases of hypokalaemia there are no symptoms (or only non-specific symptoms) attributable to the low plasma potassium concentration
2. Cardiac arrhythmia (rare)
3. Muscular paralysis (very rare)
4. Relevant to cause of hypokalaemia

Examination

1. Hypokalaemia does not produce specific signs
2. Cardiac arrhythmia
3. Muscular paralysis (very rare)

Immediate management

Emergency treatment is rarely required.

If life-threatening cardiac arrhythmia or muscular paralysis

- Give 40 mmol of potassium intravenously via volumetric pump over 1 h, then repeat measurement of serum potassium concentration and adjust rate of potassium infusion as appropriate
- If thyrotoxic periodic paralysis
  - Give propanolol 3 mg/kg orally

Key investigations

To establish the diagnosis

1. Defined by serum potassium concentration <3.5 mmol/l, severe <3.0 mmol/l

Other important tests

1. ECG – looking for flattening of the T wave, depression of the ST segment, and the development of a prominent U wave, also for arrhythmia
2. To determine cause of hypokalaemia

Further management Dependent on the cause of hypokalaemia

5.6 Hyponatraemia

See Chapter 20.2.1 in main text

Clinical features

History

1. Does not produce specific symptoms
2. Altered consciousness, epileptic fitting
3. Relevant to cause of hyponatraemia

Examination

1. Glasgow Coma Score
2. Fluid status
   - Intravascular volume depletion—low JVP, postural hypotension
   - Clinically normal volume status
   - Volume expansion—peripheral oedema

Immediate management

Chronic asymptomatic hyponatraemia

Do NOT aim to correct rapidly:

1. If intravascular volume depletion—give 0.9% saline intravenously until intravascular volume restored, then restrict water intake
2. If euvolaemic or hypervolaemic—restrict fluid intake to 1000 ml/day. Provide swabs to moisten the mouth and give the fluid allowance as ice cubes in aliquots throughout the day

Acute symptomatic hyponatraemia

- Infuse saline intravenously, with the aim of:
  - Effecting initial correction of serum sodium concentration at a rate of 1 mmol/l/h
  - Reducing the rate of correction/stopping infusion of saline as soon as the patient's neurological condition begins to improve, or when serum sodium is elevated into the range 120–125mmol/l. DO NOT ATTEMPT RAPID CORRECTION OF SODIUM CONCENTRATION INTO THE NORMAL RANGE (probably increases risk of inducing central pontine myelinolysis)

Saline concentration	Rate of infusion (ml/h)
0.9%	3.3 × body weight (kg)
1.8%	1.7 × body weight (kg)
3.0%	1 × body weight (kg)

Monitor the serum sodium concentration regularly and adjust infusion as required

Note

If glucocorticoid deficiency is possible, then give steroid replacement immediately, e.g. hydrocortisone 100mg intravenously 6 hourly, until the diagnosis is excluded

Key investigations

To establish the diagnosis

1. Defined by serum sodium concentration <130 mmol/l

Other important tests

1. Plasma and urinary osmolality
2. Urinary sodium concentration

Further management

Dependent on the cause of hyponatraemia

5.7 Hypercalcaemia

See Chapter 12.6 in main text

Clinical features

History

1. Does not produce specific symptoms
2. Acute hypercalcaemia—general malaise, anorexia, thirst, polyuria, constipation. In severe cases vomiting, confusion, coma
3. Chronic hypercalcaemia—urinary stones, abdominal pain, mental disturbance
4. Relevant to cause of hypercalcaemia

Examination

1. Acute hypercalcaemia does not produce specific signs
2. Fluid status
   - Intravascular volume depletion—postural hypotension, low JVP
   - Dehydration—reduced skin turgor, dry mucous membranes
   - Evidence of malignancy

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

1. Restoration of intravascular volume (if necessary)—as described in Emergency Medicine, section 3.1
2. Saline diuresis—give 0.9% saline intravenously at a rate of 1 l/6 h until calcium restored towards normal, assuming adequate urinary output (monitor carefully, and examine the patient regularly for signs of fluid overload). Give loop diuretic, e.g. frusemide 40–80 mg orally or intravenously twice daily, if urine output slow to increase

When diuresis initiated:

3. Bisphosphonate, e.g. disodium pamidronate, 15–60 mg by intravenous infusion at a rate of 1 mg/min, repeated as necessary to give up to a total of 90 mg over 2–4 days

Also:

4. Glucocorticoids, e.g. prednisolone 40–60 mg daily, if hypercalcaemia is due to sarcoidosis, vitamin D toxicity, or haematological malignancy

Note

If glucocorticoid deficiency is possible, then give steroid replacement immediately, e.g. hydrocortisone 100mg intravenously 6 hourly, until the diagnosis is excluded

Key investigations

To establish the diagnosis

1. Defined by serum calcium concentration >2.6 mmol/l, acute symptomatic cases usually >3.0 mmol/l.

Other important tests

1. Full blood count, electrolytes, renal and liver function tests
2. Serum PTH, immunoglobulins. Protein electrophoresis of serum and urine
3. Chest radiograph
4. Directed by clinical suspicion of malignancy

Further management

Dependent on the cause of hypercalcaemia

5.8 Addisonian crisis

See Chapter 12.7.1 in main text

Clinical features

History

1. Cardiovascular collapse
2. Context of non-specific symptoms compatible with glucocorticoid deficiency: tiredness, weakness, dizziness, anorexia, weight loss, gastrointestinal disturbance. May have salt craving
3. Related to cause: personal or family history of autoimmune/endocrine disease, steroid usage (and cessation), tuberculosis, recent flank pain (?adrenal haemorrhage/infarction)
4. May occur in context of septicaemia

Examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, jugular venous pressure
2. Hyperpigmentation—palmar creases, scars and buccal mucosae
3. Loss of axillary and pubic hair in women
4. Vitiligo

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

1. Restoration of intravascular volume—give 0.9% saline intravenously as described in Emergency Medicine, section 3.1
2. Steroid, e.g. hydrocortisone 100 mg intravenously (give immediately, then every 6 h)

Key investigations

To establish the diagnosis

1. Serum cortisol and ACTH—taken at the time of venous cannulation for resuscitation
2. Short synacthen test—performed later

Other important tests

1. Electrolytes, glucose, renal function tests, calcium, full blood count
2. Autoantibodies (adrenal, thyroid, intrinsic factor)
3. Thyroid function
4. Plasma renin activity—to assess mineralocorticoid status (high renin in primary adrenal insufficiency; not high in secondary adrenal insufficiency, where mineralocorticoid reserve is normal)
5. Chest radiograph—small heart, ?evidence of TB.
6. Adrenal CT scanning (where not available, abdominal radiograph—when adrenal calcification suggests TB)

Further management	1. Long-term steroid replacement therapy: usually hydrocortisone (30 mg/day in divided doses), also fludrocortisone (50–150 µg/day) if mineralocorticoid deficient 2. Education—patients need to know that they will require increased steroid dosage at times of intercurrent illness. All patients must carry a steroid card. Medic Alert bracelet

5.9 Thyrotoxic crisis

See Chapter 12.4 in main text

Clinical features	**History** 1. Usually known thyroid disease 2. Compatible with thyrotoxicosis: weight loss, palpitations, heat intolerance, sweating, diarrhoea, tremor, agitation/anxiety/irritability 3. Precipitant of thyrotoxic crisis: infection, trauma, withdrawal of antithyroid drug therapy, radio-iodine treatment, iodinated contrast dyes, thyroid surgery, childbirth 4. Personal or family history of autoimmune/endocrine disease **Examination** 1. Hyperpyrexia 2. Profuse sweating 3. Extreme restlessness, confusion, psychosis, eventually progressing to coma 4. Cardiac arrhythmia—particularly fast atrial fibrillation. Eventually cardiorespiratory collapse 5. Signs of thyroid disorder—goitre, eye signs of Graves' disease
Immediate management	THYROTOXIC CRISIS IS A POTENTIALLY FATAL DISORDER THAT REQUIRES IMMEDIATE TREATMENT ON THE BASIS OF CLINICAL SUSPICION If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2. Restoration of intravascular volume—as described in Emergency Medicine, section 3.1 Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92% Give 1. Antithyroid drug: propylthiouracil is better than carbimazole in thyrotoxic crisis • Propylthiouracil 600 mg orally or via NG tube given immediately, then 250 mg every 6 h (may also be given rectally if severe vomiting prevents oral/NG route), or • Carbimazole 20 mg orally or via NG tube given immediately, then 20 mg every 6 h 2. Iodide, starting 1–4 h after the antithyroid drug • Aqueous iodine oral solution, e.g. Lugol's (iodine 5%, potassium iodide 10% in purified water) 5 drops orally or via NG tube every 6 h 3. Hydrocortisone, 200 mg intravenously, then 100 mg every 8 h 4. Propanolol, 1 mg by intravenous injection over 1 min, repeated if necessary every 2 min to maximum of 5 mg, then 40–80 mg orally every 6 h 5. Active cooling—cooling blankets, antipyretics (use paracetamol, not aspirin, which displaces thyroid hormone from thyroid-binding globulin) Consider 6. Digoxin for atrial fibrillation—may need larger dose than usual 7. Diuretics for pulmonary oedema Also 8. Specific treatment of precipitating event (if possible)
Key investigations	**To establish the diagnosis** Thyroid function tests—these confirm the diagnosis of hyperthyroidism, but note that the diagnosis of thyrotoxic crisis is made on clinical grounds. The severity of disturbance of the thyroid function tests does not correlate with the clinical picture **Other important tests** 1. Full blood count, electrolytes, renal and liver function tests, calcium 2. Autoantibodies (adrenal, thyroid, intrinsic factor) 3. ECG—arrhythmia, especially atrial fibrillation 4. Chest radiograph—pulmonary oedema, infection
Further management	Dependent on the cause of thyrotoxicosis

5.10 Pituitary apoplexy

See Chapter 12.2 in main text

Clinical features	**History** Most commonly 1. Sudden onset retro-orbital headache 2. Visual field defect Sometimes 3. Nausea and vomiting 4. Meningism 5. Altered conscious level 6. Diplopia Also 7. Compatible with hypopituitarism or hyperprolactinaemia: lethargy, reduced libido, oligomenorrhoea/ amenorrhoea, impotence, galactorrhoea **Examination** 1. Glasgow Coma Score 2. Vision—acuity and fields 3. Eye movements—looking for ophthalmoplegia 4. Signs of underlying pituitary disease, e.g. acromegaly, are rarely present

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

On clinical suspicion of diagnosis

1. Take blood for serum cortisol assay to establish baseline retrospectively
2. Take blood for urgent prolactin assay
3. Assume anterior pituitary dysfunction and give
   - Corticosteroid, e.g. hydrocortisone 100 mg intravenously (immediately, then every 6 h)

Key investigations

To establish the diagnosis

MRI (or CT) scan of pituitary fossa—looking for haemorrhage into pituitary adenoma or other tumour

Other important tests

1. Electrolytes, glucose, renal function, calcium, full blood count, coagulation screen
2. Anterior pituitary function—baseline tests: cortisol, thyroid function tests, prolactin, LH, FSH, oestrogen/testosterone

Further management All cases require

1. Full endocrine evaluation
2. Management dependent on hormonal deficiencies and the cause of pituitary apoplexy

Prolactin <1500 mU/l

1. If vision is severly affected—urgent surgical decompression
2. If vision is not severely affected—consider surgical decompression within one week (improves visual and endocrine outcomes)

Prolactin >1500 mU/l (suggests prolactinoma)

1. A conservative (non-surgical) approach may be adopted if there is no progressive visual or neurological deficit and prolactin levels are very high, suggesting a prolactinoma
2. Start immediate treatment with dopamine agonist drug such as bromocriptine or cabergoline

5.11 Acute porphyria

See Chapter 11.5 in main text

Clinical features

History

Intermittent episodes of:

1. Acute abdominal pain, vomiting and constipation
2. Severe proximal limb and/or back pain
3. Seizures, coma
4. Psychiatric disturbance

Notes

5. Family history—nearly all the acute porphyrias are dominantly inherited, but many carriers are latent
6. Rash—in variegate and hereditary coproporphyria (which can cause acute neurovisceral attacks) but NOT in acute intermittent porphyria
7. Precipitant—alcohol, sex steroids, drugs (see Table 17), anaesthetic agents, starvation

Examination

1. Cardiovascular—looking for sinus tachycardia, hypertension
2. Abdominal—may have signs indistinguishable from those of the acute 'surgical' abdomen, but tenderness is usually lacking
3. Neurological—Glasgow Coma Score (if appropriate); look for sensorimotor neuropathy, respiratory muscle weakness

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

If coma, as described in Emergency Medicine, section 6.1 Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

1. Stop all known precipitant drugs, especially any that have recently been prescribed. Consult Table 17 before prescribing ANY agent
2. Give 5% dextrose intravenously, 1 litre every 8 h (except if hyponatraemic, when give reduced volume of more concentrated dextrose solution). Start high carbohydrate diet when patient able to eat
3. Give haem arginate, 3 mg/kg once daily for 4 days (maximum 250 mg daily) by intravenous infusion in 0.9% saline over at least 30 min

Notes

1. Supplies of haem arginate can be obtained from Orphan Europe Ltd., 32 Bell Street, Henley on-Thames, Oxon RG9 2BH. Tel 44(0)1491–414333. e-mail: info.uk@orphan-europe.com. Also from the on-call pharmacist at the University College of Wales, Cardiff ([029] 2074 7747); St James' University Hospital, Leeds ([0113] 243 3144 or [0113] 283 7010); St Thomas' Hospital, London ([020] 7928 9292)
2. Seizures pose difficulties since many anticonvulsants precipitate or worsen porphyric attacks: temazepam, lorazepam, and midazolam are probably safe
3. Distress may be helped by chlorpromazine. Morphine and pethidine (safe) may be required
4. Propanolol is useful for controlling hypertension and extreme tachycardia

Key investigations

To establish the diagnosis

1. Detection of porphyrin precursors in fresh urine (which may rarely become red/purple/brown on standing)

Other important tests

1. Electrolytes—may cause profound hyponatraemia. Monitor serum sodium daily in the acute phase
2. Full blood count, renal and liver function tests, calcium
3. ECG
   Further investigation to exclude serious abdominal or neurological disease will be determined by clinical presentation, especially if excretion of haem precursors is normal, e.g.
4. Amylase/chest and abdominal radiograph/CT abdomen/senior surgical opinion
5. CT brain/lumbar puncture

Note

In a patient with known porphyria, the absence of excess porphobilinogen (PBG) or d-aminolaevulinic acid (ALA) in the urine renders acute porphyria an unlikely cause of the current illness

Further management

1. Seek expert advice to establish diagnosis and investigate family
2. Medic Alert bracelet important as warning to health care personnel in the future

6 Neurological

6.1 Coma

See Chapter 24.13.1 in main text

Clinical features

History

Coma is defined as a Glasgow Coma Score (GCS) <8, hence the patient will not be able to give any useful history. Obtain as much information as possible from others in attendance (relatives, friends, ambulance crew, bystanders etc.). Ask in particular regarding:

1. The circumstances in which the patient was found
2. Alcohol consumption
3. Diabetes mellitus
4. Epilepsy
5. Drugs of abuse, in particular opioids
6. Head injury
7. Regular medications
8. Past medical history

Examination

Initial survey

1. Airway, breathing, circulation
2. Reagent stick test for blood glucose (?hypoglycaemia)
3. Check for small pupils and slow respiratory rate (?opioid overdose)
4. Check temperature (?hypothermia)
5. Look for Medic Alert bracelet or necklace
6. Check Glasgow Coma Score (see Table 18)

Further examination

1. State of circulation—temperature of peripheries, pulse rate, blood pressure, JVP
2. Respiratory—look for evidence of aspiration
3. Neurological
   - Focal/lateralizing signs—a structural lesion is likely if these are present
   - Meningism
   - Movements (can be subtle)—status epilepticus
4. Tongue biting or incontinence of urine—suggest (but do not prove) epilepsy
5. Back of head and neck—for bruising or bleeding to suggest head injury
6. Ears and nose—for bleeding or CSF leak to suggest basal skull fracture
7. Search pockets etc. for clues—e.g. anticonvulsant tablets

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Nurse in recovery position (when injury to neck excluded).

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%. Consider oropharyngeal airway Patients with a GCS <8 are likely to need endotracheal intubation to protect and maintain their airway if they do not respond to glucose or naloxone. This is obligatory if they need to be moved from an area where they can be given intensive nursing care to one where they cannot, e.g. to CT scanner

Establish intravenous access

1. If hypoglycaemic—give 50 ml of 50% glucose (dextrose monohydrate) intravenously. IF IN DOUBT, TREAT
2. If possibility of opioid overdose—give naloxone 0.8–2 mg intravenously, repeated at intervals of 2–3 min to a maximum of 10 mg. IF IN DOUBT, TREAT
3. If hypothermic—start rewarming

Key investigations

To establish the diagnosis

1. Glucose.
2. CT brain—if diagnosis not clinically apparent and patient not improving rapidly. Look for:
   - Extradural, subdural, subarachnoid, or intracerebral haemorrhage
   - Signs of raised intracranial pressure
   - Focal ischaemia (may not be visible on early scan)
3. Blood film for malaria—if relevant travel history

Other important tests

1. Electrolytes, renal and liver function tests, calcium, full blood count
2. ECG—note that 'ischaemic' changes can occur in subarachnoid haemorrhage
3. Chest radiograph—?aspiration pneumonia
4. Arterial blood gases—if diagnosis not clear, or if PaO_2 <92% on air
5. Sepsis screen (selected cases)
6. Lumbar puncture (selected cases)
7. EEG (selected cases, ?non-convulsive status)

Further management

Dependent on the cause of coma.

6.2 Acute confusional state

See Chapter 24.8 and Section 30 in main text

Clinical features

History

Is the patient confused?:

1. Establish that the patient is not dysphasic rather than confused
2. Abbreviated Mental Test (AMT) score—a score of 6 or less is likely to indicate impaired cognition
   - Age
   - Time (to nearest hour)
   - What year is it?
   - Name of institution
   - Recognition of two persons (can the patient identify your job and that of a nurse?)
   - Date of birth (day and month)
   - Year of First World War
   - Name of present monarch
   - Count backwards from 20 to 1
3. The patient who is confused cannot (by definition) give an accurate and reliable account of themselves

Obtain as much information as possible from others in attendance (relatives, friends, ambulance crew bystanders etc). Ask in particular regarding:

1. The situation in which the patient was found
2. Any recent change in health, in particular:
   - Symptoms to suggest infection
   - Medications—especially any recent change
3. Previous cognitive function
4. Alcohol consumption (consider intoxication, withdrawal, Wernicke's encephalopathy)
5. Drugs of abuse (if relevant)
6. Regular medications
7. Past medical history
8. Social circumstances

Examination

1. General appearance—well-presented clothing and cleanliness indicates an acute problem or an assiduous carer.
2. Nutritional state—reflects previous weeks/months
3. Hydration state—reflects previous 48 h
4. Full physical examination—look in particular for:
   - Temperature—pyrexia or hypothermia
   - Pulse rate, blood pressure, JVP—hypotension from any cause can lead to confusion
   - Evidence of sepsis—in particular chest, urine, cellulitis
   - Neurological—focal signs (indicating a focal neurological lesion, most commonly stroke), head injury, Wernicke's encephalopathy
   - Evidence of organ failure—cardiac, respiratory, hepatic, renal
   - Urinary retention or faecal impaction
   - Hip or pelvic fracture.

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

If hypoglycaemic—give 50 ml of 50% glucose (dextrose monohydrate) intravenously. IF IN DOUBT, TREAT

1. Fluids—encourage oral intake, but if intravenous fluids are required, then insert venous cannula into flat site and bandage carefully
2. Treat any obvious precipitating condition—if none apparent then consider initiating antibiotic treatment for, e.g. urinary infection, on a 'best guess' basis (e.g. ciprofloxacin 500 mg orally twice daily, but note local hospital policy)
3. Anticipate and avoid problems:
   - Do not exacerbate confusion—nurse in lit room (darkness makes confusion worse), expose to limited number of staff (many people 'popping in' increase confusion), enlist assistance from relatives/carers/friends (a sensible person that the patient knows can be enormously helpful)
   - Pressure areas—appropriate mattress
   - Urine—try to avoid catheterization if possible (will make any infection harder to clear), but need to strike a difficult balance with concern for skin/pressure areas
   - Bowels—suppositories, laxative, enema as required
   - Venous thromboembolism—low molecular weight heparin, e.g. enoxaparin 20 mg subcutaneously once daily
4. Sedation—try to avoid if possible, but if necessary use risperidone 0.5 mg orally twice daily (increased in steps of 0.5 mg twice daily to 1–2 mg twice daily) or haloperidol 0.5–2 mg orally/intramuscularly two to three times daily. (Dosage of both drugs appropriate for the elderly—higher doses likely to be required for younger patients)

Key investigations

To establish the diagnosis

These will be guided by any clinical leads, but as nonspecific presentation is common, the following are advisable in almost all patients:

1. Reagent stick test for blood glucose.
2. Full blood count, electrolytes, renal and liver function tests, calcium, phosphate, cardiac enzymes, glucose, thyroid function, inflammatory marker (CRP or ESR)
3. Oxygen saturation—check arterial blood gas if PaO_2 <92%. on air
4. Sepsis screen—urine dipstick test, urine and blood culture
5. Chest radiograph
6. ECG

Other important tests

Guided by clinical findings or results of screening investigations, e.g. new focal neurological signs—imaging of brain by CT scan or MRI

Further management

Dependent on the cause of confusion

6.3 Acute stroke

See Chapter 24.13.7 in main text

Clinical features

History

May be difficult to obtain, particularly if the patient has dysphasia. If this is the case, get as much information as possible from others in attendance (relatives, friends, ambulance crew, bystanders etc.)

1. Focal neurological deficit—usually of sudden onset
2. Previous episodes—stroke, transient ischaemic attack, amaurosis fugax
3. Risk factors
4. Other medical conditions
5. Medications
6. Normal level of functioning—do they need help with activities of daily living?
7. Social circumstances

Examination

1. Airway, breathing, circulation
2. Neurological
   - Glasgow Coma Score
   - Nature of focal deficit (see Table 19)
3. Cardiovascular—pulse rate and rhythm (?atrial fibrillation), blood pressure, carotid bruits, cardiac murmurs, absent peripheral pulses

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

1. Nurse in recovery position if impairment of consciousness
2. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%. Consider oropharyngeal airway
3. Establish intravenous access
4. Reagent stick test for blood glucose: if hypoglycaemic—give 50 ml of 50% glucose (dextrose monohydrate) intravenously. IF IN DOUBT, TREAT

Notes

1. Urgent neurosurgical assessment is required for patients with large cerebellar infarcts or haemorrhages or hydrocephalus, and for some cases with cerebral haemorrhage
2. There is no proven benefit for drugs in the limitation of neural damage, including corticosteroids, nimodipine, plasma volume expanders, barbiturates. or glutamate receptor antagonists. Patients treated rapidly (?within 3 h of stroke) may benefit from thrombolysis, but this should only be given in centres that use the treatment routinely, and preferably in the context of controlled trials

Key investigations

To establish the diagnosis

CT or MRI brain—also to distinguish between infarction and haemorrhage

Other important tests

1. Full blood count, electrolytes, renal and liver function tests, calcium, inflammatory markers (CRP or ESR), coagulation screen
2. ECG—look for arrhythmia or signs of recent myocardial infarction
3. Chest radiograph—?aspiration pneumonia
4. Echocardiography; ultrasound/Doppler examination of carotid arteries—in selected cases

Further management

Short term

1. Nursing and physiotherapy—protect pressure areas, attention to bladder and bowels, prevent contractures, aid recovery of function, psychological support
2. Hydration/nutrition—If swallowing impaired, stop oral feeding and start intravenous fluids
3. Blood pressure—this is commonly elevated immediately after a stroke, cerebral autoregulation is impaired, and aggressive attempts to reduce it are likely to cause more harm than good. If BP >220/130 then many physicians would treat, e.g. using modified release nifedipine 10 mg orally, but some would only do so if there was evidence that the hypertension were causing acute organ damage
4. Venous thromboembolism—high risk: use compression stockings
5. Antiplatelet therapy—usually aspirin 300 mg once daily – should be started to prevent recurrence as soon as haemorrhage has been excluded
6. Blood glucose—use intravenous sliding scale of insulin (see Emergency Medicine, section 5.2) to obtain good control in diabetics

Medium/long term

1. Rehabilitation and social support as required
2. Control of vascular risk factors—hypertension, hyperlipidaemia, cessation of cigarette smoking
3. Consider imaging of the carotid arteries in all patients who have made a reasonable recovery from a carotid territory stroke: endarterectomy may be indicated

6.4 Subarachnoid haemorrhage

See Chapter 24.13.7 in main text

Clinical features

History

1. Presentation is very variable: typically severe headache ('worst ever') of sudden onset, but can vary from minor symptoms to collapse/coma or sudden death
2. Previous episodes; recent unusual headache
3. Risk factors—hypertension, cigarette smoking, alcohol (binge drinking), adult polycystic kidney disease, connective tissue disorders (some)

Examination

1. Airway, breathing, circulation
2. Glasgow Coma Score
3. Focal neurological signs—in particular:
   - Third nerve palsy—posterior communicating artery aneurysm
   - Sixth nerve palsy—posterior fossa aneurysm, but usually a false localizing sign
   - Bilateral leg weakness—anterior communicating artery aneurysm
   - Dysphasia/hemiparesis—middle cerebral artery aneurysm
4. Neck rigidity
5. Retinal haemorrhages
6. Cardiovascular—arrhythmia, hypertension

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

1. Nurse in recovery position if impairment of consciousness.
2. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%. Consider oropharyngeal airway
3. Establish intravenous access and resuscitate if volume depleted or dehydrated
4. Bed rest for all patients
5. Nimodipine 60 mg orally every 4 h, started within 4 days of subarachnoid haemorrhage and continued for 21 days, should be given to all patients with subarachnoid haemorrhage who are not hypotensive (systolic BP <110 mmHg). This is to prevent ischaemic neurological deficit
6. Keep arterial pressure <160/100 mmHg (using conventional agents)

Key investigations **To establish the diagnosis**

1. CT brain, without contrast, taking thin cuts through the base
2. Lumbar puncture—perform not earlier than 12 h after the ictus if CT normal: look for xanthochromia after centrifugation of CSF

Other important tests

1. Electrolytes, renal and liver function tests, full blood count, coagulation screen
2. ECG—note that 'ischaemic' changes can occur in subarachnoid haemorrhage
3. Chest radiograph—?aspiration pneumonia

Further management

Depends on the patient's clinical condition: if

- GCS = 12 or more, or
- GCS <12 with space occupying intracranial haemorrhage or hydrocephalus

Then surgery should be considered in patients with proven intracranial aneurysms: hence discuss with neurosurgical colleagues with a view to arranging fourvessel angiography (CT angiograms may be done first, and sometimes instead)

6.5 Status epilepticus

See Chapter 24.13.3 in main text

Clinical features

Definition

Continuous seizures or serial (two or more) discrete seizures between which there is incomplete recovery of consciousness

History

1. Loss of consciousness, usually with obvious fitting The patient will not be able to give any useful history. Obtain as much information as possible from others in attendance (relatives, friends, ambulance crew, bystanders etc.). Ask in particular regarding:
2. The circumstances in which the patient was found
3. Past history of epilepsy
4. Alcohol consumption
5. Any possible drug abuse
6. Diabetes mellitus
7. Regular medications
8. Any other medical history

Examination

Initial survey

1. Airway, breathing, circulation
2. Signs of injury—especially of tongue, which can compromise breathing
3. Respiratory—?aspiration
4. Glasgow Coma Score
5. Medic Alert bracelet/necklace

Further examination

1. Vital signs—temperature, pulse rate, blood pressure
2. Neurological
   - Pupil size and reactions
   - Other brainstem signs
   - Symmetry of tone and reflexes in the limbs
   - Neck stiffness
   - Note that focal signs may indicate focal pathology, but can be seen as a post-ictal phenomenon (i.e. Todd's paresis)
3. Search pockets etc. for clues—e.g. anticonvulsant tablets

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2.

1. Place in recovery position (if possible)
2. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%. Consider oropharyngeal airway, but do not try to insert one against resistance i.e. when the patient is actually fitting
3. Establish intravenous access.
4. Reagent stick test for blood glucose—if hypoglycaemic: give 50 ml of 50% glucose (dextrose monohydrate) intravenously. IF IN DOUBT (GLUCOSE <3 mmol/l), TREAT
5. Anticonvulsant—first line
   - Lorazepam 0.1 mg/kg intravenously at 2 mg/min. THE FIRST LINE TREATMENT OF CHOICE
   - Diazepam 10–20 mg intravenously at a rate of 5 mg/min. This may be repeated after 30–60 min if necessary, and can be followed by infusion (add 10–40 mg of diazepam to 100 ml of 5% dextrose to make a solution containing 0.1 0.4 mg/ml) at a rate of e.g. 5 mg/h, adjusted according to clinical response, but with maximum dose of 3 mg/kg body weight over 24 h
6. Anticonvulsant—second line. If seizure activity still continues, consider
   - Fosphenytoin, 15 mg phenytoin-equivalent (PE)/kg body weight (fosphenytoin 1.5 mg = phenytoin 1 mg) by intravenous infusion at a rate of 100–150 mg PE/min, followed by 4–5 mg PE/kg daily in 1–2 divided doses. Dose adjusted according to clinical response and trough plasma phenytoin levels. THE SECOND LINE TREATMENT OF CHOICE
   - Phenytoin, 15 mg/kg body weight by intravenous infusion at a rate not exceeding 50 mg/min, followed by 100 mg every 6–8 h. Dose adjusted according to clinical response and trough plasmaphenytoin levels
7. Anticonvulsant—Third line treatments. If seizure activity still continues, consider
   - Phenobarbital (phenobarbitone), 20 mg/kg by intravenous infusion at a rate of not more than 50–75 mg/min, maximum dose 1000 mg. Note that this treatment may lead to respiratory depression. THE THIRD LINE TREATMENT OF CHOICE
   - Paraldehyde, 5–10 ml by deep intramuscular injection (not more than 5 ml at any one site), or 10–20 ml administered by enema as a 10% solution in physiological saline or mixed with an equal volume of olive oil. Note that this treatment is only to be used if other treatments listed above are not available
8. Anaesthesia. If seizure activity still continues after first, second and third line treatments (or earlier if required to achieve adequate airway protection/ventilation):
   - Call anaesthetist and arrange ICU admission for anaesthesia with thiopental or propofol. Ventilate with EEG monitoring until clinical and EEG epileptic activity ceases

Key investigations

To establish the diagnosis

Status epilepticus is a clinical diagnosis, although EEG is used to diagnose the very rare condition of non-convulsive status in a patient with unexplained coma

Other important tests

1. A reagent stick test for blood glucose should be performed in all patients.
   The intensity of further investigation depends on the context: the patient that is known to have epilepsy who has frequent prolonged seizures does not require extensive investigation after each and every one. In other cases:
2. Glucose, electrolytes, renal and liver function tests, calcium, creatine kinase, anticonvulsant level (if appropriate)
   And consider:
3. Arterial blood gases.
4. Chest radiograph—?aspiration
5. ECG
6. Sepsis screen
7. Toxicology screen
8. CT or MRI brain
9. Lumbar puncture—only after imaging to exclude raised intracranial pressure or intracerebral mass

Further management

Dependent on the cause of status epilepticus

6.6 Spinal cord compression

See Chapters 24.13.16 and 24.13.17 in main text

Clinical features

History

Cord compression

1. Leg weakness—developing over hours or days
2. Sensory symptoms—in particular, is there a sensory level, which can be suspended?
3. Bladder disturbance

Cause of cord compression

1. Back pain
2. Intervertebral discs—any previous problem?
3. Malignancy—any known previous, or any features to suggest this diagnosis, e.g. anorexia, malaise, weight loss
4. Infection—sweats, fevers, rigors. Tuberculosis. Risk factors for osteomyelitis or abscess, e.g. previous septicaemia (particularly staphylococcal), intravenous drug abuse, haemodialysis

Examination

Cord compression

1. Motor—look for increased tone, weakness, and hyperreflexia below the site of the lesion. Do the plantars go up or down?
2. Sensory—is there a sensory level, which can be suspended? In particular, check for sensory loss in the saddle area, which would suggest a cauda equina lesion
3. Bladder—is this palpable?

Cause of cord compression

1. General examination for signs of malignancy—e.g. cachexia, clubbing, lymphadenopathy, pallor, jaundice, chest/abdominal examination, pelvic mass
2. Suggestion of infective cause—temperature

Immediate management

1. Nurse on pressure-relieving mattress
2. Relieve urinary retention with urethral catheter (if appropriate)
3. EMERGENCY IMAGING AND CONSULTATION WITH NEUROSURGICAL COLLEAGUES
4. Specific treatments depending on precise diagnosis
   - Disc protrusion—surgical decompression
   - Metastasis—high dose steroids (e.g. methylprednisolone) and radiotherapy
   - Abscess—surgical decompression/drainage; antimicrobials. For an immunocompetent patient with a pyogenic abscess give intravenous antimicrobials as follows: third-generation cephalosporin, e.g. cefotaxime 1–2 g 12 hourly PLUS flucloxacillin 1–2 g 6 hourly PLUS metronidazole 500mg 8 hourly. Modify regimen when microbiological results are available.
   - Spinal cord tumours (rare)—neurosurgical intervention may be appropriate

Note

Acute spinal cord injury—give methylprednisolone 30 mg/kg as intravenous bolus over 1 h, followed by 4.0 mg/kg/h for 23 h

Key investigations

To establish the diagnosis

MRI spine, performed as an emergency (if this is not available, discuss best available imaging modality with radiological colleagues, e.g. CT scan, myelography)

Other important tests

1. Full blood count, electrolytes, renal and liver function tests, calcium, inflammatory markers, coagulation screen, immunglobulins, and protein electrophoresis
2. Urinary Bence Jones protein
3. Chest radiograph
4. Other tests as dictated by clinical suspicion, e.g. blood cultures, lymph node biopsy

Further management

Dependent on the cause of spinal cord compression

6.7 Acute inflammatory polyneuritis (Guillain Barré)

See Chapter 24.19 in main text

Clinical features

History

1. Sensory symptoms—begin distally and ascend symmetrically
2. Motor—weakness, usually ascending (but can sometimes be proximal), symmetrical. Muscle pain is common (particularly lower back or interscapular)
3. Legs usually worst affected, but can sometimes be arms
4. Progression usually occurs over days (no longer than 4 weeks, by definition) but can sometimes be more rapid
5. Patients often have upper respiratory tract or diarrhoeal illness (especially *Campylobacter jejuni*) in the few weeks prior to onset

Examination

1. Motor—reduced tone; lower motor neurone weakness, distal > proximal; areflexia. May have facial involvement and ophthalmoplegia (Miller Fisher syndrome)
2. Sensory—glove and stocking sensory disturbance, often mild
3. Respiratory—RESPIRATORY FAILURE DUE TO MUSCLE WEAKNESS IS AN AVOIDABLE CAUSE OF DEATH: check forced vital capacity and monitor frequently
4. Autonomic—look for variable pulse rate, variable arterial pressure, intestinal ileus, urinary retention

Immediate management

1. Respiratory
   - CONSIDER ELECTIVE ASSISTED VENTILATION SOONER RATHER THAN LATER IF THE PATIENT IS TIRING
   - Note that tracheal suction can trigger hypotension or bradycardia in the presence of autonomic dysfunction
2. Cardiac
   - Monitor ECG
   - Arrhythmias can be fatal—treat as appropriate
   - Use antihypertensive drugs with extreme caution (if at all) in the face of autonomic dysfunction
3. Fluids
   - If gag reflex impaired—stop oral feeding and start intravenous fluids
   - Will need to consider PEG feeding as an early option
4. Nursing and physiotherapy
   - Keep chest clear
   - Protect pressure areas
   - Attention to bladder and bowels
   - Prevent contractures: move all joints through their full range of movement daily
   - Aid recovery of function
   - Psychological support: emphasize that most cases recover well
5. Pain—give non-steroidal anti-inflammatory agents as required. Consider amitriptyline, carbamazepine, gabapentin
6. Compression stockings and low molecular weight heparin (e.g. enoxaparin 40 mg subcutaneously once daily)—to reduce the risk of venous thromboembolism
7. Intravenous immunoglobulin, 0.4 g/kg body weight/ day, for 5 days—give to all patients, excepting those with very mild disease

Key investigations **To establish the diagnosis**

Acute inflammatory polyneuritis (Guillain Barré syndrome) is primarily a clinical diagnosis: investigation may confirm it, but initial management is dictated by clinical suspicion

1. Nerve conduction studies—the earliest abnormality is impersistence or absence of F waves. Peripheral demyelination starts proximally in the nerve roots, hence distal conduction velocities and motor latencies are often normal early in the illness, even when there is profound weakness
2. Lumbar puncture—look for elevated protein (but not cells)
3. Anti GQ1b antibodies—present in all cases that are associated with ophthalmoplegia

Other important tests

Relevant to cause

1. Stool culture and serology for *Campylobacter jejuni*
2. Serology for atypical pneumonias
3. CSF analysis for viral infection

   Need to exclude

   Acute intermittent porphyria—see Emergency Medicine, section 5.11

General

1. Full blood count, electrolytes, renal and liver function tests, plasma calcium, magnesium and phosphate concentrations
2. ECG
3. Chest radiograph

Further management

Dependent on the nature of any residual disability. Significant weakness remains in about 10% of cases, especially those with the axonal form

6.8 Myasthenia gravis

See Chapter 24.22.2 in main text

Clinical features

History

Myasthenic crisis

1. Breathing difficulty due to muscular weakness in a patient with known myasthenia.

Presentation of myasthenia

2. Droopy eyelid(s)/double vision
3. Difficulty chewing, swallowing, talking (nasal speech), holding the head up
4. Limb weakness
5. Symptoms less severe in the morning, getting worse as the day goes on
6. Exacerbation by intercurrent illness, pregnancy, menses, and by some drugs

Examination

Myasthenic crisis

1. Exhaustion
2. Ineffective respiratory effort
3. Inability to clear airway secretions
4. Cyanosis
5. Low vital capacity
   Also
6. Check for focal lung signs

Myasthenia

Muscular weakness that becomes worse with repetitive effort (fatiguability)

Immediate management

Respiratory failure caused by muscular weakness in a patient with myasthenia can be due to a myasthenic crisis (attributable to the disease itself) or rarely to an overdose of anticholinesterases (cholinergic crisis). These cannot reliably be distinguished on clinical grounds, hence safe management consists of:

1. Airway, breathing, circulation
2. Intubate and ventilate
3. Stop all anticholinesterases.
   IF there is specialist expertise, AND in conjunction with someone skilled in intubation, then edrophonium chloride, 2 mg by intravenous injection, can be used to discriminate between underdosage and overdosage of cholinergic drugs

Key investigations

To establish the diagnosis

Myasthenic crisis is a clinical diagnosis

Of myasthenia gravis

1. Edrophonium chloride (Tensilon) test: after pretreatment with atropine (0.6 mg intravenously), give edrophonium 2 mg intravenously and look for transient improvement in e.g. ptosis, diplopia, dysarthria. If no improvement after 1–2 min give edrophonium 8 mg intravenously and watch for effect. Note that this test has limited sensitivity and specificity
2. Serum acetylcholine receptor antibodies—highly specific, being present in 85% of patients with generalized myasthenia
3. Electromyography: look for increased jitter, also decremental response to repetitive nerve stimulation— this test has good sensitivity and specificity

Other important tests

In myasthenic crisis

1. Arterial blood gases
2. Chest radiograph
3. Electrolytes, renal and liver function tests, calcium, phosphate, full blood count
4. Sepsis screen (if appropriate)

Further management

In myasthenic crisis consider the following:

1. Plasma exchange—e.g. 50 ml/kg body weight/day for 4 or 5 days
2. Intravenous immunoglobulin—e.g. 0.4 g/kg body weight/day, for 5 days

Long-term treatment of myasthenia. Consider:

1. Immunosuppression—usually prednisolone (starting at a low dose of e.g. 10 mg on alternate days) and azathioprine (2.5 mg/kg body weight/day)
2. Anticholinesterase, e.g. pyridostigmine bromide 30–120 mg at suitable intervals throughout the day (total daily dose 0.3–1.2 g). Together with antimuscarinic agent if needed
3. Thymectomy

6.9 Acute Wernicke's encephalopathy

See Chapter 26.3 and Chapter 26.7.3 in main text

Clinical features

History

1. Alcoholism—usually, but also other states of nutritional deficiency and protracted vomiting
2. Difficulty standing/walking
3. Confusion

The patient will almost certainly not be able to give a reliable history: corroborate as much information as possible from other sources (relatives, friends, general practitioner etc.)

Examination

Related to Wernicke's encephalopathy, the classic triad of:

1. Ophthalmoplegia
   - Horizontal and vertical nystagmus
   - Weakness/paralysis of lateral rectus muscles
   - Weakness/paralysis of conjugate gaze
2. Ataxia—predominantly affecting stance and gait, often without clear-cut intention tremor
3. Confusion, confabulation

Related to clinical context:

1. Cardiovascular—look for evidence of intravascular volume depletion and/or dehydration
2. Consider other complications of alcoholism
   - Acute alcohol withdrawal
   - Acute liver failure
   - Chronic liver disease and its complications
3. Consider other causes of an acute confusional state—see Emergency Medicine, section 6.2
4. Nutritional status

Immediate management

Thiamine—give parenteral thiamine immediately, usually in combination with other vitamins B and C, e.g. Pabrinex ™I/V high potency, 2–3 pairs of ampoules intraven- ously over 10 min every 8 h (each pair of ampoules contains ascorbic acid 500 mg, anhydrous glucose 1 g, nicotinamide 160 mg, pyridoxine hydrochloride 50 mg, riboflavin 4 mg, and thiamine hydrochloride 250 mg in a total of 10 ml). Note—facilities for treating anaphylaxis should be available

Key investigations

To establish the diagnosis

1. Wernicke's encephalopathy is a clinical diagnosis
2. Red cell transketolase—a reduced level confirms thiamine deficiency

To exclude other conditions

CT scan brain—should be done in all cases because of the high incidence of structural lesions, e.g. subdural haematoma, in this group of patients

Other important tests

Depending of clinical context, consider as for acute confusional state—see Emergency Medicine, section 6.2

Further management

1. After 3–5 days, switch from intravenous to oral vitamin replacement, e.g. thiamine 50 mg once daily + vitamin B tablets, Compound, Strong, 1–2 tablets three times daily + vitamin C 100 mg once daily
2. If alcohol withdrawal—see Emergency Medicine, section 8.2
3. Other aspects: as for acute confusional state—see Emergency Medicine, section 6.2—except avoid antipsychotics which lower seizure threshold
4. Long term—measures to help alcoholism

7 Infectious disease

7.1 Malaria

See Chapter 7.13.2 in main text

Clinical features

Clinical features

Falciparum malaria is the life-threatening form and the immediate concern in patients presenting to medical services in malarious areas, or who have travelled to such areas

Transmitted to man by the bite of an infected *Anopheles* mosquito. The interval between bite and first symptom is usually 7–14 days. Most patients with imported falciparum malaria present within 3 months of return from the malarious area, but a few present up to 1 year or more later

History

1. Risk of exposure to malaria—anyone who has travelled to a malarious area and presents to medical attention with a febrile illness has malaria until proved otherwise
2. Symptoms of malaria
3. Early—malaise, headache, backache, myalgia, anorexia, low grade fever.
4. Later—dizziness, nausea, vomiting, abdominal discomfort, diarrhoea, rigors and drenching sweats.

   Symptoms of cerebral malaria
5. Gradual decline in conscious level over several hours
6. Generalised epileptic convulsion without post-ictal recovery of consciousness (present in 50 per cent of adult cases).

Note

'Classical' tertian (48 h) or subtertian (36 h) periodicity of fever spikes is rarely seen in falciparum malaria

Examination

1. Vital signs—temperature, pulse rate, blood pressure, respiratory rate. A high fever (rising to >39°C) is typical, which can be of any periodicity
2. General—anaemia, jaundice
3. Abdominal—ook for moderate tender enlargement of liver and/or spleen
4. Neurological—look for signs of cerebral malaria
   - Glasgow Coma Score—reduced (by definition in cerebral malaria)
   - Focal signs—note presence of dysconjugate gaze, brisk tendon reflexes, ankle clonus, extensor plantar responses and absent abdominal reflexes; and of decorticate or decerebrate posturing in severe cases
   - Fundi—retinal haemorrhages are common (exudates and papilloedema also occur)

Notes

1. The following are NOT found in malaria
   - Lymphadenopathy
   - Rash—excepting herpes simplex 'cold sores' in some cases
   - Focal signs
2. Signs of hypoglycaemia may be misinterpreted as merely being manifestations of cerebral malaria

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

If clinical evidence of intravascular volume depletion, establish intravenous access and resuscitate as described in Emergency Medicine, section 3.1

If hypoglycaemic—give 50 ml of 50% glucose (dextrose monohydrate) intravenously, followed by infusion of 10% glucose at sufficient rate to maintain blood glucose concentration >3 mmol/l. IF IN DOUBT, TREAT

Antimalarial drugs for falciparum malaria (adult dosages)

Assume chloroquine-resistance

Patients who can swallow and retain tablets

Use ONE of the following regimen

1. Mefloquine
   - By mouth: 15–25 mg/kg of mefloquine base (maximum 1500 mg), divided into two doses 6–8 h apart
2. Proguanil with atovaquone ('Malarone')
   - By mouth: 4 tablets (each containing 100 mg proguanil and 250 mg atovaquone) once daily for 3 days
3. Artemether with lumefantrine ('Riamet')
   - By mouth: 4 tablets (each containing 20 mg artemether and 120 mg lumefantrine) twice daily for 3 days
4. Quinine—*the treatment of choice in many countries*
   - By mouth: 600 mg of quinine salt every 8 h for 7 days
   - Afterwards: when the 7 day course is completed, give tetracycline 250 mg four times daily for 7 days or doxycyline 100 mg daily for 7 days
5. Fansidar™ (each tablet containing pyrimethamine 25 mg and sulfadoxine 500 mg)
   - 3 tablets as single dose.

Patients with severe malaria or who cannot swallow and retain tablets

Use ONE of the following regimen:

1. Quinine—*the treatment of choice in many countries*
   - By intravenous infusion: loading dose of 20 mg/kg dihydrochloride salt (maximum 1400 mg) diluted in 10 ml/kg isotonic fluid and given over 4 h, then after 8 h give maintenance dose of 10 mg/kg (maximum 700 mg) over 4 h, repeated following further 8 h gaps until patient can swallow tablets to complete 7 day course
   - By intravenous infusion in the intensive care unit: loading dose of 7 mg/kg dihydrochloride salt by infusion pump over 30 min, followed immediately by 10 mg/kg (maintenance dose) over 4 h, repeated after 8 h gaps as above.
   - By intramuscular injection (if intravenous infusion not possible): loading dose of 20 mg/kg of dihydrochloride salt diluted to 60 mg/ml, by deep intramuscular injection (half dose into each anterior thigh) with strict sterile precautions, then 10 mg/kg every 8–12 h until patient can take oral medication
   - Afterwards: when the 7 day course is completed, give tetracycline 250 mg four times daily for 7 days or doxycycline 100 mg daily for 7 days
2. Quinidine—replaces quinine for parenteral treatment of malaria in the USA
   - By intravenous infusion: loading dose of 15 mg/kg of quinidine base given over 4 h, then 7.5 mg/kg given over 4 h three times daily until the patient can swallow and take quinine. Followed by tetracycline or doxycycline as above
3. Artesunate
   - By intravenous 'push': loading dose of 2.4 mg/kg followed by 1.2 mg/kg at 12 and 24 h, then 1.2 mg/kg daily for 6 days
4. Artemether
   - By intramuscular injection: loading dose of3.2 mg/kg on the first day (in one or two doses), followed by 1.6 mg/kg/day for 6 days

Other measures

1. High fever—control by fanning, tepid sponging, cooling blankets, antipyretics (e.g. paracetamol 15 mg/kg in tablets, or powder washed down an NG tube, or as suppositories)
2. Anaemia—transfuse with whole blood or packed cells if haematocrit falls to <20% or if there is severe bleeding
3. Urine output—insert urinary catheter to monitorclosely
4. Cerebral malaria—appropriate nursing care for the unconscious patient. Control convulsions (see Emergency Medicine, section 6.5). Consider elective intubation and ventilation if airway in danger of compromise
5. Hyperparasitaemia—consider exchange transfusion or haemophoresis in non-immune patients who are severely ill, who have deteriorated on convention altreatment, and who have parasitaemia >10%

Key investigations

To establish the diagnosis

Depends on the detection of parasitaemia (stop antimalarial chemoprophylaxis)

1. Repeated examination of thick and thin blood films (8–12 hourly for 72 h) by an experienced microscopist
2. Antibody detection technique, e.g. dipstick antigen-capture assay

Note
If patient remains unwell and no other diagnosis can be made, then consider therapeutic trial even if early smears are negative

Other important tests

1. Reagent stick test for blood glucose— ?hypoglycaemia
2. Full blood count—anaemia with evidence of haemolysis is usual. Neutrophilia is common, but white cell count can be normal or low
3. Electrolytes, renal and liver function, glucose, coagulation screen—mild hyponatraemia is common
4. Arterial blood gases
5. Blood culture—to exclude secondary bacterial septicaemia in those with an obvious focus of such infection and in patients who are very unwell or have a raised blood white cell count
6. Depending on clinical context (mainly to exclude differential diagnoses)—CT brain, lumbar puncture, chest radiograph

Further management	Emphasize need for avoidance and prophylaxis with any future travel to malarious areas

7.2 Meningitis

See Chapter 7.11.3, Chapter 7.11.5, Chapter 7.11.12, and Chapter 24.14.1 in main text

Clinical features

Clinical features

Acute bacterial meningitis has a mortality of 70–100% if untreated and is the immediate concern in patients pre- senting to medical services

History

General symptoms

1. Early—malaise, headache, fever, vomiting, diarrhoea
2. Later—increasingly severe headache, photophobia, drowsiness
3. Very late—coma, convulsions

Localizing (if meningitis secondary to infection elsewhere)

4. Respiratory—pneumococcal disease (pneumonia)
5. Ear—*H. influenzae* (otitis media)

Also

6. Contact with a case of meningitis
7. Previous history of meningitis
8. History of immunodeficiency
9. Pregnancy—increased risk of Listeria
10. Travel history—particularly meningococcal disease

Examination

1. Vital signs—temperature, pulse rate, blood pressure, respiratory rate
2. General
   - Skin: petechiae/purpura—characteristic of meningococcal disease, but not specific
   - Conjunctivae/palate: petechiae—characteristic of meningococcal disease, but not specific
   - Posture—patients with severe meningism often lie with the back and neck in hyperextension
3. Neurological
   - Meningism—neck stiffness. Kernig's sign (with the leg flexed at the hip, an attempt by the clinician to passively extend the knee is resisted by hamstring spasm)
   - Ocular fundi—papilloedema indicates raised intracranial pressure, but absence of papilloedema does not exclude this
   - Cranial nerve lesions—most commonly VIth (false localizing sign)
4. Other—in secondary meningitis there may be signs of primary focus, e.g. pneumonia, otitis media, CSF shunts/reservoirs

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

If clinical evidence of intravascular volume depletion, establish intravenous access and resuscitate as described in Emergency Medicine, section 3.1

Antimicrobial chemotherapy (empirical treatment, adult dosages)

Spontaneous meningitis

Drug	Dose	Route	Frequency	Duration*
Cefotaxime	2g	IV	4 hourly	2 weeks
				Or
Ceftriaxone	2g	IV	12 hourly	2 weeks
If high prevalence of penicillin-resistent pneumococci, then add				
Vancomycin	1g	IV	12 hourly	2 weeks
If underlying immunosuppression, pregnancy or age >65 years, then add				
Ampicillin	2g	IV	4-6 hourly	3 weeks

Post-traumatic meningitis

Community acquired

Treat as for spontaneous meningitis

Nosocomial

Drug	Dose	Route	Frequency	Duration*
Probability of *Pseudomonas* spp. high				
Ceftazidine	2g	IV	8 hourly	3 weeks
				Or
Meropenem	2g	IV	8 hourly	3 weeks
Probability of *Pseudomonas* spp. low				
Cefotaxime	2g	IV	4 hourly	3 weeks
				Or
Ceftriaxone	2g	IV	12 hourly	3 weeks

Shunt-associated meningitis

Insidious onset

Drug	Dose	Route	Frequency	Duration*
Vancomycin	1g	IV	12 hourly	2 weeks
				PLUS
Vancomycin	5–10g	IT	48–72 hourly	2 weeks

Acute onset

Treat as for nosocomial post-traumatic meningitis

Notes

* Antimicrobial therapy can be refined as soon as organism is isolated, otherwise patients with suspected bacterial meningitis should receive treatment with the regimen indicated.

Doses of antimicrobials to be adjusted in renal failure (especially vancomycin)

IV, intravenous; IT, intrathecal.

Key investigations **To establish the diagnosis**

1. Epidemiological data (any current epidemics)
2. Lumbar puncture to obtain specimen of CSF— looking in bacterial meningitis for:

General appearance

- Cloudy or purulent, but can be clear

Microscopy

- White cell count—usually raised (although can rarely be normal, i.e. <6 lymphocytes/µl) with neutrophils accounting for >80% of cells, but can have a lymphocytic pleocytosis in early bacterial meningitis or with *L monocytogenes*
- Gram stain—shows organisms in 50–80% of cases

Biochemical testing

- Glucose—usually reduced (<40% that of a parallel serum sample)
- Protein—usually elevated (>0.45 g/l)

Microbiological culture

Bacterial antigen detection for common pathogens

PCR for meningococcal disease

Notes

1. Give antibiotics immediately—before referral to hospital, and if in hospital before lumbar puncture— in cases of suspected meningococcal meningitis/septicaemia
2. Lumbar puncture should not be performed if there are
   - Symptoms or signs to suggest raised intracranial pressure, namely
   - Drowsiness/coma
   - Focal neurological signs
   - Loss of retinal vein pulsation/papilloedema
   - Bradycardia/hypertension
   - Local skin sepsis at the sight of puncture
   - Clinical suspicion of spinal cord compression
   - Bleeding diathesis
3. If symptoms or signs suggest raised intracranial pressure—arrange for CT brain to exclude space occupying lesion or cerebral oedema

Other important tests

For specific diagnosis

1. Blood culture
2. Throat swab—for viral and bacteriological culture
3. Skin lesion—disrupt with needle and make contact slide for Gram stain.
4. Blood sample—in EDTA (as full blood count) for bacterial PCR

Other

1. Full blood count
2. Electrolytes, renal and liver function, glucose, clotting screen
3. Arterial blood gases (severe cases)
4. Chest radiography—?pneumonia (pneumococcal disease), ?aspiration (if impaired conscious level)
5. CT/MRI brain—may demonstrate skull fractures or parameningeal septic foci

Further management

1. Meningitis is a notifiable disease
2. If meningococcal meningitis
   - Household and other intimate contacts—give prophylaxis (e.g. rifampicin 600 mg orally twice daily for 2 days, or ciprofloxacin 750 mg orally as single dose) and immunize if serogroup C or A
   - Staff—prophylaxis is not required unless mouth to mouth resuscitation given

7.3 Encephalitis

See Chapter 7.10.2, Chapter 7.10.12, Chapter 7.10.6.1, and Chapter 24.14.2 in main text

Clinical features

Clinical features

Encephalitis is an acute inflammation of the brain and/or spinal cord (encephalomyelitis) presenting as alteration of consciousness, convulsions and/or focal neurological signs. It is usually caused by an acute viral infection of the central nervous system (typically Herpes simplex, Japanese encephalitis, or an arthropod-borne virus), or it complicates a systemic viral infection such as measles (post-infectious encephalomyelitis) or vaccination (post-vaccinal encephalomyelitis). Case fatality is extremely variable but may exceed 40% when there is no antiviral therapy (e.g. Japanese encephalitis), and there is a high incidence of permanent neurological sequelae

History

General symptoms (after incubation period of a few days to 2 weeks)

1. Early—fever, headache, neck stiffness, vomiting
2. Later—psychiatric symptoms, altered consciousness, convulsions

Localizing symptoms

3. Altered behaviour, hallucinations, temporal lobe seizures—Herpes simplex encephalitis
4. Rashes—preceding illness (e.g. measles, varicella, post-infectious encephalomyelitis); concurrent (e.g. West Nile virus encephalitis)

Also

5. Recent vaccination (vaccinia, nervous tissue rabies vaccine)
6. Current seasonal epidemic (arthropod-borne encephalitides)
7. Travel history—to endemic area (e.g. Central Europe/Scandinavia—tick-borne encephalitis)

Examination

1. Vital signs—temperature, pulse rate, blood pressure, respiratory rate, Glasgow Coma Scale
2. General
   - Skin: rashes—West Nile virus, enteroviruses etc.
   - Mucous membranes: cold sores (Herpes simplex encephalitis)
3. Neurological
   - Meningism
   - Ocular fundi—papilloedema indicates raised intracranial pressure, but absence of papilloedema does not exclude this
   - Cranial nerve lesions—most commonly VI (false localizing sign)
4. Other—in post-infectious encephalomyelitis there may be signs of the preceding illness, e.g measles, varicella, mumps etc.

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, Section 1.2

If convulsing, as described in Emergency Medicine, Section 6.5

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

1. Antiviral treatment
   - Aciclovir—where it is affordable, treatment with aciclovir should be started immediately in all undiagnosed cases in which viral encephalitis is included in the differential diagnosis. Specifically, aciclovir is recommended for Herpes simplex, Herpes simiae (B), Herpes zoster, and Epstein-Barr virus encephalitides: dose 10 mg/kg every 8 h by intravenous infusion (reduced in renal impairment)
   - Ribavirin (tribavirin)—for the rare encephalitides associated with RNA virus infections (e,g, Lassa fever, Argentine haemorrhagic fever, Hanta virus, Crimean-Congo haemorrhagic feverm and Rift Valley Fever) ribavirin (tribavirin) has been recommended: 2 g loading dose by intravenous infusion, then 1 g every 6 h for 4 days, then 0.5 g 8 hourly for 6 days
2. Other measures
   - Corticosteroids—sometimes used for post-vaccinal encephalomyelitis (controversial)
   - Reduction of severe intracranial hypertension— intravenous mannitol or mechanical hyperventilation

Key investigations

To establish the diagnosis

1. Epidemiological data (any current epidemics)
2. Lumbar puncture to obtain specimen of CSF— looking in viral encephalitis for:

   Microscopy

   - White cell count—usually raised (but normal in 10–15% of patients with Herpes simplex enceph-alitis at first examination), with lymphocytes and other mononuclear cells predominant except in early infections
   - Gram stain to exclude bacterial meningoencepha- litis

   Biochemical testing

   - Glucose—usually normal or increased, but low levels have been reported
   - Protein—usually elevated into range 0.5–1.5 g/l

   Virology

   - PCR
   - Specific viral IgM (microcapture technique)
   - Viral isolation—e.g. mumps, enteroviruses, lymphocytic choriomeningitis virus
3. Other samples

- Skin lesions—immunofluorescence (Herpes zoster) and electron microscopy (Herpesviruses)
- Nasopharyngeal aspirate—measles
- Stool—enteroviruses
- Serology (acute/convalescent titres)—mumps, Coxsackie viruses, arthropod-borne viruses

Other important tests

1. Full blood count
2. Arterial blood gases (severe cases)
3. CT/MRI—may demonstrate focal lesions (e.g. Herpes simplex encephalitis) or cerebral oedema

Note

The diagnosis of viral encephalitis should not be made too hastily as the differential diagnosis is broad and other treatable causes (e.g. cerebral malaria, bacterial or fungal meningoencephalitides) may be ignored

7.4 Tetanus

See Chapter 7.11.20 in main text

Clinical features

Tetanus, caused by toxins of *Clostridium tetani* in contaminated wounds, remains common in some developing countries but is preventable by vaccination. It is now rare in developed countries but, because it is decreasingly familiar, is less likely to be diagnosed. The case fatality ranges from 20–60%, although in expert hands this may be reduced to 6%, even in severe cases

History

1. Recent wound, especially penetrating, contaminated or with necrosis, is identified in 75–85% of cases

Also

2. Problems in head, neck, mouth—trismus due to a painful local condition is an important differential diagnosis
3. Drugs—a dystonic drug reaction is an important differential diagnosis

Symptoms of tetanus

After an incubation period of usually 6–10 days (less than 15 days in 90% of cases):

- Non-specific—malaise, fever, sweating, and headache
- Suggestive—muscle stiffness (especially of the jaws), spasms, and dysphagia.

Examination

Features of tetanus

1. Muscles
   - Trismus, risus sardonicus, neck retraction
   - Rigidity of erector spinae and abdominal muscles (board-like rigidity)
   - Opisthotonos
   - Tonic contractions/spasms of the stiff muscles
   - Spasms of respiratory muscles and larynx threaten to cause asphyxia
   - Local tetanus may involve only muscles in the region of the wound, e.g. cephalic tetanus
2. Autonomic nervous system
   - Fluctuating heart rate, blood pressure, and temperature with sweating and hypersalivation

   Clinical grading is of prognostic significance:

   - I (mild)—trismus and generalized stiffness without respiratory embarrassment or spasms
   - II (moderate)—marked rigidity, brief spasms, mild respiratory embarrassment, and dysphagia
   - III and IV—frequent prolonged spasms, respiratory embarrassment with apnoeic spells, severe dysphagia. and cardiovascular abnormalities

   Also

   - Features of alternative diagnosis, e.g. local cause of trismus

Note

1. Incubation period less than 4 days and period of onset (trismus to first spasm) less than 48 h are associated with high mortality
2. In developed countries, patients are often elderly (missed childhood vaccination)

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, Section 1.2

If convulsing, as described in Emergency Medicine, Section 6.5

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

1. If apnoeic/asphyxiating/hypoxaemic—emergency tracheostomy, assisted ventilation with oxygen. See Emergency Medicine, section 10.4.2
2. Tetanus immune globulin

In all cases—give before manipulating the wound:

- EITHER equine tetanus immune globulin 10000 units intravenously (beware of anaphylaxis, see Emergency Medicine, section 1.12)
- OR (preferably, if available) human tetanus immune globulin 5000 units intravenously

3. The wound

Antibiotics to sterilize

- EITHER—Metronidazole 500 mg, orally (if possible) or intravenously, three times a day for 10 days
- OR—Benzyl penicillin 2 megaunits intravenously four times a day for 8 days

Thorough surgical débridement of the wound after tetanus immune globulin has been given

4. Other measures

- Sedatives/muscle relaxants
- Diazepam 5–20 mg three times a day by mouth (mild cases) or by continuous intravenous infusion (moderate-severe cases)
- Tracheostomy (moderate and severe cases)
- Neuromuscular blockade (pancuronium/vecuronium) and mechanical ventilation (severe cases)

Further management (severe cases in the intensive care unit)

1. Ventilatory support
2. Control of autonomic nervous system disturbances
   - Hypertension—cautious use of low dose short-acting b-blockers
   - Brady/tachyarrhythmias—treat only if causing significant haemodynamic disturbance, see Emergency Medicine, Section 1.7
3. Prevention of deep vein thrombosis—low molecular weight heparin

Note

Avoid use of excessive doses of diazepam

Key investigations

THE DIAGNOSIS OF TETANUS IS ENTIRELY CLINICAL

1. Wound swab—but failure to culture *Clostridium tetani* from the wound does NOT exclude the diagnosis of tetanus
2. Lumbar puncture—the cerebrospinal fluid is normal

Note

The differential diagnosis includes the many local causes of trismus, dystonic reactions to drugs, tetany, strychnine poisoning, meningitis, and rabies (cephalic tetanus)

Further management

Infection does not confer immunity: give full course of active immunization (tetanus toxoid) after recovery

7.5 Rabies

See Chapter 7.11.9 in main text

Clinical features

Clinical features

Rabies is a zoonotic viral infection of the central nervous system, endemic in domestic dogs and cats, wild carnivores, bats etc., in most parts of the world. It is transmitted to humans by bites of rabid mammals, usually dogs. The case fatality of rabies encephalomyelitis is virtually 100%, but the disease is preventable by modern post-exposure treatment started soon after the bite

History

1. Animal contact
   - History of dog (or other mammal) bite (but may be distant or forgotten, especially with insectivorous bat bites in USA) or a lick by a mammal on broken skin
   - Travel history to rabies endemic area
   - Post-exposure treatment—see Emergency Medicine, section 7.6
2. Incubation period
   - Usually between 20 and 90 days (extreme range 4 days to 19 years)
3. Prodromal symptoms
   - Non-specific—fever, chills, malaise, weakness, tiredness, headache
   - Suggestive—itching, pain, or paraesthesiae at the site of the healed bite wound
4. A few days later
   - Furious rabies—difficulty swallowing (especially water), causing spasms of breathing and great anxiety (with or without pain in the throat)
   - Extreme susceptibility to draughts, causing similar spasms
   - Bizarre behaviour
   - Periods of extreme excitement, hallucinations, terror, aggression with lucid intervals
5. After several more days
   - Lapse into coma and convulsions
   - Sudden death during a hydrophobic spasm
   - Paralytic rabies—ascending weakness with sensory symptoms often starting in the bitten limb; sphincter problems; dysphagia, drooling, and respiratory weakness

Examination

1. Wound
   - Evidence of healed bite
2. Neurological
   - Clinical examination may be normal
   - Excitable behaviour interspersed with lucid intervals
   - Furious rabies—violent, jerky spasms of inspiratory muscles associated with evident terror provoked by attempts to drink or exposure to a draught of air
   - Paralytic rabies—ascending flaccid paralysis with fasciculations, sensory loss, sphincter dysfunction
   - Weakness of muscles of deglutition and respiration
   - Excitable behaviour interspersed with lucid intervals
3. Autonomic nervous system
   - Signs of overactivity—hypersalivation, sweating, labile pulse rate and blood pressure

Immediate management	Although life can be prolonged by invasive, intensive care (tracheostomy, paralysis, mechanical ventilation, cardiac monitoring etc.), the chances of a successful outcome are so low that there is a strong case for palliative care to relieve pain and anxiety
Key investigations	To establish the diagnosis during life 1. Skin punch biopsy (hairy area, e.g. nape of neck) • Detection of virus by direct fluorescent antibody in nerves surrounding hair follicles 2. Saliva • Virus may be isolated 3. Blood • Rabies-neutralizing antibody titre—elevated in unvaccinated patient (but may be negative for 7 days after clinical illness has begun) 4. CSF analysis • May be normal, but protein usually elevated, and may have elevated white blood cell count • Rapid PCR (experimental) • Virus may be isolated • Rabies-neutralizing antibody titre—elevated in unvaccinated patient (but may be negative for 7 days after clinical illness has begun) 5. Other important tests • Given the appalling outcome of rabies it is important to pursue the possible differential diagnosis of a rapidly progressing encephalitis (see Emergency Medicine, section 7.3) if there is ANY doubt about the diagnosis To establish the diagnosis in the biting animal (dog etc.)—brain smear with detection of virus by direct fluorescent antibody or viral isolation. Euthanizing the biting dog and examining its brain immediately is now recommended, rather than observing it for onset of rabid symptoms over a 10-day period
Further management	Attempt to identify/capture/examine (by veterinarian)/test the animal responsible for the bite

7.6 Animal bites/stings

See Chapter 7.11.9 and Chapter 8.2 in main text

Clinical features	A very wide range of animals may inflict bites and stings. Serious consequences may result from trauma, envenoming, allergy or infection

History

1. Timing
   - The event is usually painful and memorable and so precisely timed by the victim.
2. Immediate symptoms—distress associated with a terrifying event and attributable to trauma, envenoming or allergy
   - Trauma
     - Pain, bleeding, dysfunction (depending on site and severity of injury)
   - Envenoming
     - Snake bite

       Local—pain, swelling, persistent bleeding, bruising, blistering, painful enlargement of draining lymph nodes

       Systemic—syncope/collapse (may be early and transient), spontaneous systemic bleeding (gums, nose etc.), vomiting, progressive weakness starting with ptosis, blurred vision, inability to open mouth, swallow, speak etc., generalized muscle aches and tenderness, passage of black urine (rhabdomyolysis)
     - Scorpion sting

       Local—very severe pain, mild swelling
       Systemic—vomiting, sweating, faintness, difficulty with breathing, muscle spasms
     - Spider bites

       Local—pain, sweating and gooseflesh (neurotoxic) or progressive skin changes (red, white, and blue sign; necrotic)

       Systemic—vomiting, faintness, colic and muscle spasms
     - Jellyfish stings

       Local—severe pain, blistering, contact rash
       Systemic—collapse, vomiting
     - Fish stings

       Local—very severe pain
       Systemic—rarely collapse
   - Allergy
     - Hymenoptera stings (bees, wasps, hornets, yellowjackets, ants)

       Local—pain, swelling (may be negligible)
       Systemic—early syncope and collapse, raised, itchy rash, swelling of mouth, lips, tongue, and gums, chest tightness, wheezing, asthma attack, abdominal colic, vomiting, diarrhoea (all of these may develop within a few minutes of the sting)
3. Delayed symptoms—attributable to infection

   Earliest onset at about 12 h (*Pasteurella multocida*) Local—pain, swelling, redness, heat, purulent discharge

   Systemic—sometimes severe generalized symptoms (sepsis)

Examination

1. Vital signs

   Temperature, pulse rate, blood pressure, respiratory rate, Glasgow Coma Scale
2. Trauma

   Injuries to soft tissues, joints, tendons, bones (crush fractures), body cavities (e.g. haemothorax), evisceration, dead tissue, foreign material in the wound(broken teeth, claws, earth etc.). May be severe/life-threatening

   Note that effects of trauma may be associated withe nvenoming and/or allergy and/or infection (e.g. marine coral cuts, stingray, and sea urchin injuries)
3. Envenoming—see History
4. Allergy—features of anaphylaxis (Emergency Medicine, section 1.12)
5. Infection

   Local—pain, swelling, redness, heat, purulent discharge

   Systemic—sepsis syndrome (see Emergency Medicine, section 7.7)

Note

1. Human bites
   - May be of medicolegal significance: document carefully, also any other evidence of injury (sketch and photograph)
   - High risk of infection with group A b-haemolytic streptococci, *Staph. aureus* (40% of wounds), *Haemophilus, Klebsiella, Eikenella corrodens*, and anaerobes
   - May be self-inflicted—typically lips, buccal cavity, fingers, clenched-fist injuries of knuckles
2. Dog, cat/other mammal bites
   - Associated with high risk of infection with a wide range of pathogens, notably *Pasteurella multocida*, *Capnoctyophaga canimorsus*, *Staph. aureus, Clostridium tetani*, and other anaerobic bacteria, rabies virus etc.

Immediate management

First-aid

1. Trauma

   Control pain and bleeding, contain wound with bandaging, give plasma expander if available, transport to medical care
2. Envenoming

   Snake bite

   - Immobilize the patient, especially the bitten limb
   - Avoid harmful remedies
   - Transport the patient to medical care
   - Neurotoxic bites only—pressure immobilization and splinting with a long crepe bandage
   - Venom ophthalmia (spitting cobras and rinkhals)—irrigate affected eye with liberal quantities of bland fluid (e.g. water, milk) and apply 1% epinephrine drops for pain (if available)

   Note

   - Tourniquets, incisions, suction, electric shock, cryotherapy, snake stones etc. should NEVER be used
3. Other bites and stings
   - Fish stings—immerse stung part in uncomfortably-hot but not scalding water (maximum 45°C)
   - Scorpion stings and other painful bites and stings—local 1% lignocaine with digital block or strong systemic analgesia (if available)
   - Jellyfish stings

     Box jellyfish (North Australia, Indo-Pacific)— wash area with dilute acetic acid/vinegar

     Atlantic jellyfish—apply a slurry of baking powder
   - Bee stings—remove the sting as quickly as possible
   - Tick bites—apply surgical spirit to the animal and prise out the mouth parts with forceps

Hospital management

If anaphylaxis, as described in Emergency Medicine, section 1.12

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

If clinical evidence of intravascular volume depletion, establish intravenous access and resuscitate as described in Emergency Medicine, section 3.1

1. Trauma
   - Explore wound under anaesthesia, débriding and removing foreign material.
   - Treat specific injuries to vital structures
   - Delayed primary suture.
2. Envenoming

   Antivenom treatment

   In cases of envenoming by snakes, fish, scorpions, spiders, box jellyfish, and ticks, administer antivenom intravenously (provided that an appropriate specific antivenom is available) if any of the following are present:

   - Paralysis (ptosis etc)
   - Spontaneous systemic bleeding (gums, GI tract etc)
   - Incoagulable blood
   - Shock, ECG abnormalities
   - Black urine (myoglobinuria, haemoglobinuria)
   - Severe/rapidly progressive local envenoming

   Beware of antivenom reactions (anaphylactic or serum): treat/prevent as follows:

   - Treatment with adrenaline (1/1000, 0.3–0.5 ml intramuscularly = 0.3–0.5 mg dose, repeated as necessary) plus anti-H_1 (e.g. chlorpheniramine 10–20 mg IV) plus corticosteroid (e.g. hydrocortisone 5 mg/kg IV) at the first sign of a reaction is preferred to routine prophylaxis EXCEPT in atopic subjects with severe asthma and those who have suffered previous reactions to antivenom. See Emergency Medicine, section 1.12

Key investigations

Trauma

- Appropriate radiological imaging to define extent of the injury

Snake bites

- Simple 20 min whole blood clotting test or rapid coagulation screen
- Stick test urine for blood: positive may indicate red blood cells (?disseminated intravascular coagulation) or myoglobin (rhabdomyolysis)
- Australia only—rapid EIA venom detection kit, using swab from the bite wound
- Tensely-swollen limbs—measure intracompartmental pressure as guide to fasciotomy

Other important tests

- Depending on clinical context/severity—ECG, full blood count, electrolytes, renal and liver function tests, muscle enzymes (creatine kinase), arterial blood gases, chest radiograph

Further management

Trauma (bites by large animals)

1. Definitive wound closure with skin grafts etc.
2. Infection risk
   - Bacterial

     Prophylactic antibiotics for severe/multiple wounds or wounds of the fingers or in response to cultures:

     Amoxicillin/clavulanic acid—(expressed as) amoxicillin 250 mg three times daily by mouth (prophylaxis, mild case) to 1 g three times daily intravenously (treatment, severe case)
     OR

     Second/third generation cephalosporin, e.g.

     cefotaxime 1–2g 6 hourly intravenously
   - Tetanus

     Give tetanus toxoid or, if unimmunized, consider tetanus immunoglobulin
   - Rabies

     Consider possibility of rabies exposure and (if appropriate) give **rabies post-exposure treatment**

     - Thorough wound cleaning—scrub under running tap with soap and water; irrigate with plain water
     - Apply virucidal agent such as 40–50% alcohol or 1% iodine
     - Avoid suturing.
     - Vaccination:
       - Start active vaccination using tissue culture vaccine: dividing one dose (0.5–1 ml) between 8 sites intradermally produces the most rapid antibody response) PLUS
       - Start passive immunization: give equine rabies immunoglobulin, 40 units/kg body weight, OR—preferably if available—human rabies immunoglobulin, 20 units/kg body weight, infiltrate around the wound, with the residue given intramuscularly distant from the site of rabies vaccination

Envenoming

1. Nursing
   - Avoid elevation of the bitten limb
2. Surgery
   - Débridement of necrotic tissue with immediate split skin grafting
   - Avoid hasty and unjustified fasciotomy (especially if the blood is still incoagulable).
3. Myoglobinuric renal failure—try to prevent by correcting hypovolaemia and acidosis and encouraging diuresis (see Emergency Medicine, section 4.2)

7.7 Septic shock

See Chapter 4.4 and Chapter 7.5 in main text

Clinical features	Clinical features
	Septic shock is a condition associated with severe infection in which there is hypotension (systolic blood pressure <90 mmHg) unresponsive to fluids or requiring vasoactive drugs for its correction. The causative septicaemia may be with Gram-positive or Gram-negative bacteria, yeasts, viruses, or protozoa. Failure of one or more organ systems is common

History

1. Systemic features
   - Early—malaise, lethargy, nausea, vomiting, fever, sweating, shivering/rigors
   - Later—restless, anxious, confused, agitated.
   - May develop rapidly (minutes—hours), e.g. meningococcaemia, or gradually
2. Localized features
   - Related to causative infection—e.g pneumonia, urinary tract infection, infected intravascular catheter, meningitis, after large bowel surgery etc.
3. Risk factors
   - Complication of surgery, instrumentation, burns, or other trauma.
   - Complication of preceding illness, e.g 'flu predisposing to staphylococcal pneumonia
   - Travel history—could the patient have malaria? (see Emergency Medicine, section 7.1)

Examination

1. Vital signs
   - Temperature—fever or hypothermia
   - Tachycardia
   - Tachypnoea
   - Hypotension
   - Peripheries warm (vasodilated) or cold and cyanosed (vasoconstricted)
   - Glasgow Coma Score
2. Evidence of the causative infection
   - Complete physical examination to look for focus of infection. Do not forget to examine the back and perineum/rectum (localized abscess).
3. Evidence of organ failure
   - Respiratory—central cyanosis (check pulse oximetry), crackles. Risk of adult respiratory distress syndrome (ARDS)
   - Renal – low urine output. Risk of prerenal renal failure or acute tubular necrosis
   - Liver—jaundice
   - Neurological—confusion
   - Haematological—abnormal bleeding/gangrene of extremities

Notes

1. Look for evidence of predisposition to infection—elderly, immunosuppressed, asplenic, malignant disease, artificial heart valve, prosthetic material etc.
2. Streptococcal toxic shock syndrome—erythematous rash, local severe pain and swelling (necrotizing fasciitis/myositis)
3. Staphylococcal toxic shock syndrome—diarrhoea, myalgia, rash (desquamating), often associated with menstruation/tampon use

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%

If clinical evidence of intravascular volume depletion, establish intravenous access and resuscitate as described in Emergency Medicine, section 3.1

1. Fluid/circulatory
   - 500 ml crystalloid IV every 30 min until central venous pressure is 8–12 mmHg
   - If mean arterial pressure <65 mmHg—give vasopressors
   - If mean arterial pressure >90 mmHg—give vasodilators
   - Central venous oxygen saturation <70% (measured in blood from pulmonary artery or central venous catheter)—transfuse packed red cells to increase haematocrit to at least 30% and give dobutamine initial dose 2.5 µg/kg/min intravenously, increasing until central venous oxygen saturation is 70% or higher
2. Respiratory
   - Consider early intubation and mechanical ventilation
3. Antibiotics

Give broad-spectrum, empirical treatment

Community-acquired septicaemia:

- Aminoglycoside (e.g. gentamicin 5 mg/kg intravenously once daily, assuming normal renal function) + broad-spectrum penicillin (e.g. amoxicillin, 500 mg 8 hourly to 1 g 6 hourly, intravenously)
  OR
- Broad-spectrum cephalosporin (e.g. cefotaxime, 1 g 12 hourly to 2 g 6 hourly, intravenously)

Hospital-acquired septicaemia:

- Aminoglycoside (e.g. gentamicin 5 mg/kg intravenously once daily, assuming normal renal function) + broad-spectrum anti-Pseudomonal penicillin (e.g. Tazosin® 2.25–4.5 g [= Piperacillin 2–4 g + tazobactam 250–500 mg] 6 hourly intravenously)
  OR
- Ceftazidime, 1 g 12 hourly to 2 g 8 hourly, intravenously
  OR
- Meropenem 500 mg–1 g 12 hourly intravenously
  OR
- Imipenem with cilastatin, 500 mg–1 g (of imipenem) 6 hourly intravenously

Pseudomonas infection suspected:

- Aminoglycoside (e.g. gentamicin 5 mg/kg intravenously once daily, assuming normal renal function) + broad-spectrum anti-Pseudomonal penicillin (e.g. Tazosin® 2.25–4.5 g [= Piperacillin 2–4 g + tazobactam 250–500 mg] 6 hourly intravenously)

Gram positive infection suspected:

- Add flucloxacillin 1–2g 12 hourly intravenously
  OR
- Vancomycin 1g 12 hourly intravenously (assuming normal renal function)

Anaerobic infection suspected:

- Add metronidazole 500 mg 8 hourly intravenously

Meningococcaemia

- Benzylpenicillin 2.4 g 4 hourly intravenously
  OR
- Cefotaxime 2 g 6 hourly intravenously

Streptococcal toxic shock syndrome

- Benzylpenicillin 1.2–2.4 g 6 hourly intravenously, or Cefotaxime 2 g 6 hourly intravenously
  PLUS
- Clindamycin 600–1200 mg 6 hourly intravenously

Note

1. Aminoglycosides, vancomycin—dosage dependent on renal function; always monitor levels
2. Other aspects
   - For patients with shock, acidosis, oliguria, or hypoxaemia with evidence of end organ dysfunction—consider recombinant human activated protein C
   - Supportive treatment for specific organ failure—mechanical ventilation, renal replacement therapy (haemofiltration, haemodialysis)
   - Surgical—e.g. urgent fasciotomy and débridement for streptococcal necrotizing fasciitis/myositis
   - Strict normalization of blood glucose between 4.4 and 6.1 mmol/l using intravenous infusion of Actrapid insulin on sliding scale

---

Key investigations

To establish the source of infection

1. Blood culture
2. Other cultures as determined by clinical signs or imaging, e.g. needle aspiration of fluid collections

Other

3. Full blood count—leucocytosis or leucopenia
4. Electrolytes, renal and liver function tests, glucose, clotting screen, muscle enzymes (creatine kinase, ?rhabdomyolysis)
5. Arterial blood gases—pH, *p*O2, *p*CO2, base excess

8 Psychiatry

8.1 Acute alcohol withdrawal

See Chapter 26.3 and Chapter 26.7.3 in main text

Clinical features	**History** Related to alcohol withdrawal 1. Agitation and anxiety 2. Tremor 3. Sweating 4. Insomnia 5. Nausea and vomiting 6. Hallucinations—tactile, visual, auditory 7. Grand mal seizures. Also 8. Drinking history—how much alcohol does the patient usually drink? Have they recently been drinking particularly heavily, or have they stopped?
	Examination Related to alcohol withdrawal: 1. Agitation and anxiety 2. Confusion 3. Tremor 4. Sweating 5. Tachycardia and hypertension Related to clinical context: 6. Cardiovascular—look for evidence of intravascular volume depletion and/or dehydration 7. Consider other complications of alcoholism • Wernicke's encephalopathy: • Ophthalmoplegia • Horizontal and vertical nystagmus • Weakness/paralysis of lateral rectus muscles • Weakness/paralysis of conjugate gaze • Ataxia—predominantly affecting stance and gait, often without clear-cut intention tremor • Acute liver failure • Chronic liver disease and its complications 8. Consider other causes of an acute confusional state–see Emergency Medicine, section 6.2 9. Nutritional status
Immediate management	1. Sedation • Patient can take oral medication—reducing schedule of chlordiazepoxide, e.g. 30 mg four times daily (day 1); 20 mg three times daily and 30 mg at night (day 2); 10 mg three times daily and 20 mg at night (day 3); 5 mg three times daily and 10 mg at night (day 4); 5 mg in the morning and 10 mg at night (day 5); 5 mg at night (day 6), then stop • Patient cannot take oral medication—clomethiazole (chlormethiazole), 0.8% solution, initially 2.5–7.5 ml/min (20–60 mg/min) until light sleep is induced from which the patient can easily be roused, with the rate of infusion then reduced to the lowest possible to maintain this state. Note—careful monitoring for respiratory depression is required: resuscitation facilities must be available. Switch to oral sedation when possible 2. Thiamine—give parenteral thiamine immediately, usually in combination with other vitamins B and C as PabrinexÔ I/V high potency, 2–3 pairs of ampoules intravenously over 10 min every 8 h (each pair of ampoules contains ascorbic acid 500 mg, anhydrous glucose 1 g, nicotinamide 160 mg, pyridoxine hydrochloride 50 mg, riboflavin 4 mg and thiamine hydrochloride 250 mg in a total of 10 ml). Note—facilities for treating anaphylaxis should be available Then 3. Glucose—treat/prevent hypoglycaemia. • DO NOT GIVE GLUCOSE BEFORE THIAMINE—DANGER OF PRECIPITATING WERNICKE'S ENCEPHALOPATHY • If hypoglycaemic—give 50 ml of 50% glucose (dextrose monohydrate) intravenously. IF IN DOUBT, TREAT • If not hypoglycaemic—start 5% dextrose infusion at 50 ml/h to prevent hypoglycaemia (if hyponatraemic used reduced volume of more concentrated dextrose solution)
Key investigations	**To establish the diagnosis** Acute alcohol withdrawal is a clinical diagnosis **Other Important tests** Depending of clinical context, consider as for acute confusional state—see Emergency Medicine, section 6.2
Further management	1. After 2 days, switch from intravenous to oral vitamin replacement, e.g. thiamine 50 mg once daily + Vitamin B tablets, Compound, Strong, 1–2 tablets three times daily + Vitamin C 100 mg once daily 2. Other aspects: as for acute confusional state—see Emergency Medicine, section 6.2—except avoid antipsychotics which lower seizure threshold 3. Long term—measures to help alcoholism

8.2 Drug overdosage

See Chapters 8.1 in main text

Clinical features

History

The overdose

1. Nature, time and quantity of drug ingested
2. Circumstantial evidence
3. Concurrent alcohol consumption

Also

4. Assessment of intent
5. Past medical history, medications and allergies
6. Past psychiatric history

Note

Be cautious in accepting the patient's account at face value. Assume that overdoses of multiple drugs are likely

Examination

Initial survey

1. Airway, breathing, circulation
2. Reagent stick test for blood glucose (?hypoglycaemia)
3. Check for small pupils and slow respiratory rate (?opioid overdose)
4. Check temperature (?hypothermia)
5. Check Glasgow Coma Score (see Table 18)

Further examination

6. Look for features indicated in Table 20.

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Nurse in recovery position if Glasgow Coma Score impaired

Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%.

Consider oropharyngeal airway or cuffed endotracheal tube depending on level of consciousness

ECG monitor—but do not treat arrhythmias unless these are associated with profound hypotension

Establish intravenous access

1. If hypoglycaemic—give 50 ml of 50% glucose (dextrose monohydrate) intravenously. IF IN DOUBT, TREAT
2. If possibility of opioid overdose—give naloxone 0.8–2 mg intravenously, repeated at intervals of 2–3 min to a maximum of 10 mg. IF IN DOUBT, TREAT
3. If hypothermic—start rewarming

Prevention of drug absorption—see Table 21

Specific antidote (if available)—see Table 22

If in doubt—discuss management with a Poisons Centre: the following single number for the UK National Poisons Information Service directs the caller to the relevant local centre: 0870 600 6266

Key investigations

To establish the diagnosis

1. Serum drug levels, e.g. paracetamol, salicylates, iron, theophylline, lithium
2. Save serum sample for measurement of other toxins after discussion with clinical chemist, e.g. paraquat

Note

Record time of blood sampling accurately on specimen tube and in notes

Other Important tests

1. Electrolytes, glucose, renal, liver and bone function tests, full blood count, clotting screen
2. ECG

Consider

3. Arterial blood gases
4. Carboxyhaemoglobin level
5. Chest radiograph—look for evidence of aspiration or pulmonary oedema
6. Abdominal radiograph

See Table 23

Further management

1. Dependent on the nature of overdose taken
2. As dictated by psychiatric condition (if any)

9 Other conditions

9.1 Disseminated intravascular coagulation

See Chapter 22.5.5 and Chapter 22.5.6 in main text

Clinical features

Disseminated intravascular coagulation (DIC) is a systemic disorder in which haemorrhage (main problem in 90% of cases) and thrombosis can occur at the same time. It involves the generation of intravascular fibrin and the consumption of procoagulants and platelets. May be acute or chronic (only acute discussed here)

History
Presence of DIC

1. Bleeding
   - Skin—extensive superficial bruising; oozing from venepuncture/intramuscular injection sites, around indwelling catheters/tubes
   - Mucosa—mouth, nose, gastrointestinal tract, (lungs), (renal tract)
   - Internal—brain, other organs
2. Thrombosis
   - Microthrombotic lesions
   - Skin—often on fingers/toes
   - Internal organs—dysfunction of brain, kidneys, lungs

Related to cause of DIC

1. Sepsis—bacterial, viral, fungal, parasitic (malaria)
2. Major trauma—including burns, surgery
3. Toxins—e.g. venoms (see Emergency Medicine, section 7.6)
4. Obstetric—placental abruption, eclampsia, amniotic fluid embolism
5. Cancer—metastatic carcinoma of stomach, colon, pancreas, breast, lung; mucin-secreting adenocarcinomas; leukaemia (especially acute promyelocytic leukaemia)
6. Blood transfusion—incompatible, massive
7. Liver disease—acute hepatic failure
8. Others—heatstroke (see Emergency Medicine, section 9.3), prosthetic devices (e.g. shunts, ventricular assist devices)
9. Idiopathic—purpura fulminans

Examination

1. Vital signs
2. Evidence of bleeding or thrombosis
3. Related to possible cause (see above)

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Underlying cause
   Treat aggressively
   Give broad-spectrum antimicrobials to cover sepsis if diagnosis not clear (see Emergency Medicine, section 7.7)
2. When diagnosis of DIC established by laboratory testing, give (as appropriate)
   - Fresh-frozen plasma—to keep prothrombin time and activated partial thromboplastin time below a value 1.5 times the upper limit of control values
   - Cryoprecipitate/fibrinogen concentrates—to keep fibrinogen levels >1g/l
   - Platelets—to keep platelets >50×109/l
   - Blood (packed red blood cells)—to keep haematocrit >0.30

Note

1. If the patient continues to bleed/clot 4–6 h after initiation of treatment of underlying cause and the supportive measures described above, then—ONLY WITH EXPERT HAEMATOLOGICAL ADVICE—consider:
   - Antithrombin III, 100 U/kg intravenously over 3 h (loading dose), then continuous infusion of 100 U/kg/24h. Used in moderate/severe DIC when levels of antithrombin III are very low
   - Heparin, 20000–30000 units/24h, by continuous intravenous infusion—to inhibit further thrombogenesis. Used when thrombosis is the main clinical problem
2. Possibility of adrenal infarction (Waterhouse Friederichson)—give steroid (e.g. hydrocortisone 50–100mg 6hourly intravenously) if circulatory compromise

Key investigations

To establish the diagnosis
There is no single diagnostic test for DIC: look for the following

1. Appropriate clinical context
2. Platelet count—decreased
3. Prothrombin time and activated partial thromboplastin time—both increased
4. Fibrinogen/fibrin degradation products (FDPs) and/ or D-dimer—both present/elevated

Other haematological features that may be present include

1. Antithrombin III level—reduced: useful test for diagnosis and therapeutic monitoring
2. Fibrinogen—reduced
3. Fibrinopeptide A—breakdown product of fibrinogen, elevated
4. Thrombin time—prolonged
5. Blood film—may show red cell fragmentation/microangiopathic haemolytic anaemia

Other Important tests
Dependent on clinical context

Further management

Dependent on clinical context

9.2 Sickle cell crises

See Chapter 22.4.7 in main text

Clinical features

History

There are several clinical conditions

1. Pain crisis—severe pain in limbs, hips, back, chest or abdomen
2. Chest/lung syndrome—breathlessness, pleuritic chest pain
3. Brain/neurological syndrome—epileptic fits, transient ischaemic attacks, strokes And less commonly in adults
4. Aplastic crisis—presents with breathlessness and fatigue. Usually seen in children. Associated with parvovirus infection
5. Sequestration crisis—presents with profound anaemia. Usually seen in babies and young children when the spleen and/or liver enlarge rapidly due to trapping of red blood cells. Hepatic sequestration can occur in adults
6. Priapism
   Also
7. Previous sickle cell crises.
8. Precipitating factors—extremes of heat and cold, infections/fever (often upper respiratory tract, 'flu), heavy exercise, emotional stress, any situation producing hypoxia
9. Family history—patterns of crises may follow through generations

Note

1. The patient or their relatives/friends generally know that they have sickle cell disease and are often knowledgeable about the condition
2. The pain is
   - Genuine
   - Excruciating
   - Varies in character and location

Examination

1. Airway, breathing, circulation
2. Glasgow Coma Scale
3. Vital signs—pulse rate, blood pressure, respiratory rate, temperature Note particularly
4. General examination—pallor
5. Chest—local tenderness and signs of infection.
6. Bones—tenderness
7. Liver or spleen—look for enlargement due to hepatosplenic sequestration (particularly in children, uncommon in adults)
8. Priapism.
9. Infection—fever may be the only sign Remember that there may be no localizing signs

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

1. Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%. Monitor with pulse oximeter.
2. Fluid—establish intravenous access (may be difficult, asking patient's advice on best site is often helpful) and give 1 litre of 0.9% saline rapidly, then repeat 4– 6 hourly for duration of crisis (assuming satisfactory urine output)
3. Analgaesia
   - Intravenous e.g. (1) diamorphine by slow intravenous injection at 1 mg/min, usual maximum initial dose is 5 mg, but may be repeated if necessary, or morphine by slow intravenous injection at 2 mg/min, usual maximum initial dose is 10 mg, but may be repeated if necessary. Both to be accompanied by appropriate antiemetic, e.g. metoclopramide 10 mg IV over 1–2 min, or cyclizine 50 mg IV over 1–2 min
   - Intramuscular/subcutaneous—if it is not possible to establish intravenous access, then give diamorphine (0.05 mg/kg) or morphine (0.1 mg/kg) subcutaneously, repeated after 1 h if necessary
4. Warmth—wrap in warm blankets if the patient feels cold
5. Antibiotics—e.g. amoxicillin 500 mg intravenously every 8 h + benzypenicillin 1.2 g intravenously every 6 h
6. Prophylaxis against venous thromboembolism—give low molecular weight heparin, e.g. enoxaparin 20 mg subcutaneously once daily

Key investigations

To establish the diagnosis

Sickle cell crisis is a clinical diagnosis

Other Important tests

1. Full blood count, reticulocytes, group and save
2. Electrolytes, renal and liver function, glucose
3. Cultures—blood, sputum, urine, throat swab
4. Arterial blood gases
5. Chest radiograph—may show widespread patchy infiltrate that is difficult to distinguish from infection
6. HbS level (percentage of total Hb)—if exchange transfusion considered
7. Abdominal radiograph, serum amylase (abdominal syndrome)
8. Serology to detect acute parvovirus B19 infection (aplastic crisis)

Notes

Other investigations as dictated by clinical context, e.g.

CT scan brain if focal neurological signs

Do not order plain radiographs of all sites of pain

Further management

Seek expert advice

Chest syndrome with hypoxia, neurological symptoms or priapism (also seek urological advice) are all indications for exchange transfusion to reduce the HbS to <30% of total Hb

Consider hydroxyurea to reduce frequency of crises

9.3 Heat stroke

See Chapter 8.5.1 and Chapter 26.6.1 in main text

Clinical features

Hyperthermia is a failure of thermal homeostasis that allows the core temperature to rise above 40°C. It can result from exposure to environmental heat with/without prolonged physical exercise (especially if heat dissipating mechanisms are impaired) and/or from increased metabolic heat production. Heat stroke is hyperthermia with severe central nervous system abnormalities such as delirium, convulsions, or coma. Its case fatality ranges from 17–70%

History

Predisposing factors

1. Exposure to high ambient temperature ± high humidity (e.g. in a heatwave)
2. Prolonged strenuous physical exercise at any ambient temperature, especially if insulation from clothing is excessive and the patient is unacclimatized
3. Drugs
   - Neuroleptic malignant syndrome—psychiatriac/ recreational dopaminergic drugs, e.g. phenothiazines, thioxanthene, butyrophenones, amphetamines
   - Malignant hyperpyrexia—occurs in people with a rare genetic predisposition (autosomal dominant) when exposed to various inhaled or local anaesthetic agents
4. Previous history of heat intolerance

Symptoms

Heat exhaustion

1. General—irritability, weakness, lethargy, fatigue, dizziness, headache, muscle cramps/myalgias
2. Gastrointestinal—nausea, vomiting, diarrhoea
3. Respiratory – hyperventilation/tachypnoea
   Heatstroke
   Any or all of the symptoms of heat exhaustion, plus
4. CNS dysfunction—impaired judgement, abnormal behaviour, disorientation, hallucinations, confusion, convulsions, loss of consciousness

---

Examination

1. Vital signs—core (rectal) temperature 40° or more (by definition), hypotension, tachycardia, tachypnoea
2. Related to temperature control mechanisms
   - Sweating—present (>50% cases)or absent (<50%). Hot dry skin is a late finding
   - Piloerection
3. General—weakness, dehydration, bleeding (disseminated intravascular coagulation)
4. Neurological—impaired consciousness (Glasgow Coma Scale), seizures, opisthotonus, decerebrate rigidity, cerebellar dysfunction, oculogyric crises, fixed dilated pupils
5. Signs of predisposing condition—e.g. obesity, skin disease, thyrotoxicosis

---

Note

Muscular rigidity is a feature of neuroleptic malignant syndrome and malignant hyperpyrexia but not of heatstroke

---

Immediate management

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2
Oxygen, high flow with reservoir bag if needed, to achieve PaO_2 >92%
If clinical evidence of intravascular volume depletion, establish intravenous access and resuscitate using isotonic saline as described in Emergency Medicine, section 3.1

1. Cooling
   Should be done rapidly
   Remove to shade or cooler place
   Remove clothes
   - External methods
     Tepid spongeing and fanning; ice packs to neck, axillae, groin; cover with wet sheet—as available
     Hypothermia bed/blanket
     Immersion in cold water with vigorous
     massage—effective at lowering body temperature but associated with more complications than evaporative cooling and not generally recommended
   - Internal methods
     Ice water gastric lavage, ice water rectal lavage, ice water intraperitoneal lavage, mechanical ventilation with cooled gases, cardiac bypass— anecdotal success reported for these treatments
2. Monitor urine output—consider urethral catheter
3. Correct fluid, electrolyte and acid-base abnormalities (see below)
4. Malignant hyperpyrexia and neuroleptic malignant syndrome
   - Stop drug/anaesthetic
   - Treat muscle spasms/rigidity—give dantrolene sodium by rapid intravenous injection, 1 mg/kg repeated as required to a cumulative maximum of 10 mg/kg

---

Notes

1. In the field—stop exertion at the first sign of heat exhaustion, remove excess clothing, move into shade, encourage oral fluids
2. Do not give salicylates—which do not reduce body temperature and may exacerbate coagulopathy
3. Do not give paracetamol (acetaminophen)—which does not reduce body temperature and may worsen hepatic damage

---

Key investigations

Heat stroke is a clinical diagnosis

Important tests

1. Electrolytes and renal function—risk of hypokalaemia, hyponatraemia, hypocalcaemia, hypomagnesaemia, hypophosphataemia, impaired renal function (hyperkalaemia if renal failure and rhabdomyolysis)
2. Glucose—may have hyperglycaemia; also risk of hypoglycaemia
3. Full blood count—high haematocrit indicates haemoconcentration
4. Liver blood tests—elevated transaminases almost always found in heatstroke and indicate hepatotoxicity and/or muscle damage
5. Muscle enzymes—elevated creatine kinase indicates muscle damage (rhabdomyolysis)
6. Albumin/serum proteins—elevated values indicate haemoconcentration
7. Coagulation tests—evidence of DIC (see Emergency Medicine, sectioin 9.1)
8. Amylase—?pancreatitis
9. ECG, troponin—evidence of myocardial damage
10. Arterial blood gases—?lactic acidosis

Other tests that may be indicated include

1. Chest radiograph—?aspiration
2. CT scan head—?alternative cause of CNS dysfunction

Further management

1. Monitor results of active cooling
   - Beware of seizures (see Emergency Medicine, section 6.5)
   - Beware of cardiac arrhythmias—only treat if causing significant haemodynamic compromise (see Emergency Medicine, section 1.7)
2. Supportive care as appropriate
   Respiratory failure—consider intubation and mechanical ventilation
   Circulatory failure—treat hypotension with volume repletion and, if necessary, vasopressor drugs
   Renal failure—in case of rhabdomyolysis, prevent renal damage by correcting acidosis and hypovolaemia and promoting diuresis (see Emergency Medicine, section 4.2)
   Sodium depletion (hyponatraemia, muscle cramps)—sodium repletion with isotonic saline

Note

After recovery—advice to prevent recurrence

9.4 Hypothermia

See Chapter 8.5.2 in main text

Clinical features

History

Two distinct contexts

1. Cold exposure, in patient of any age
2. Multifactorial cause, often in the elderly patient
   - Immobility/falls
   - Cognitive impairment
   - Alcohol
   - Vasodilating drugs
   - Autonomic dysfunction, eg. diabetes mellitus
   - Poor socio-economic conditions

Note

Elderly patients with hypothermia have often been found on the floor at home following a fall

Examination

Initial survey

1. Airway, breathing, circulation
2. Reagent stick test for blood glucose (?hypoglycaemia)
3. Check for small pupils and slow respiratory rate (?opioid overdose)
4. Temperature—using a low-range rectal thermometer: <35°C (by definition).
5. Check Glasgow Coma Score (see Table 18)

Futher examination

1. General appearance—cold, pale mottled skin (whereabouts on the body, if anywhere, does the skin feel warmer?). At 32–35°C, shivering; at <32°C, muscular rigidity
2. Cardiovascular—bradycardia and hypotension
3. Respiratory—look for evidence of aspiration, pneumonia or pulmonary oedema
4. Neurological
   - May range from mild inco-ordination to confusion, lethargy, and coma. Pupils may be dilated and nonreactive
   - Focal/lateralizing signs may indicate stroke that has precipitated hypothermia
5. Endocrine—could the patient be hypothyroid?

Immediate management

Depends on the clinical context

If cardiorespiratory collapse, as described in Emergency Medicine, section 1.2

Treat for hypoglycaemia and/or opioid overdose if appropriate

The patient with hypothermia of gradual onset (usually elderly, usually multifactorial cause)

1. Re-warm—slowly in warm room covered with a blanket or 'Bair hugger' (do not use foil blankets which retard re-warming)
2. Oxygen—give oxygen as necessary to keep PaO_2 >92%
3. Fluids—establish intravenous access. Note risk of pulmonary oedema, hence do not infuse fluid rapidly. If hypotensive, infuse 1 litre 0.9% saline over 2 h, checking for lung crackles and/or worsening gas exchange as this progresses. Repeat or slow rate of infusion as determined by clinical response
4. ECG monitoring—risk of ventricular tachycardia/ fibrillation
5. Antibiotics—as appropriate for pulmonary infection, which is common in this context, e.g. cefotaxime 1 g 12 hourly intravenously

The patient with cold exposure or severe hypothermia (<30°C) or with hypothermia of any cause complicated by life threatening arrhythmia
Re-warm—rapidly, using both:

1. Active external re-warming—apply heat to body surface, e.g. hot water bottles/warmed IV bags (not too hot, must be comfortably bearable against your own skin) in groins and axillae, warmed blankets, radiant heaters
2. Active core re-warming
   - Non-invasive—give warmed (42–46°C) humidified oxygen and warmed (43°C) intravenous fluids
   - Invasive—gastric, colonic, bladder, and peritoneal lavage with warmed (43°C) 0.9% saline solutions

Notes

1. Patients with hypothermia are best managed in an ICU setting: they may require treatment of arrhythmia and/or ventilatory support
2. Arrhythmias
   - Avoid use of catecholamines (arrhythmogenic)
   - Only treat if life-threatening (ventricular fibrillation or asystole)—For VF, attempt defibrillation up to three times, but not more until core temperature >30°C. The drug of choice is probably bretylium 5–10 mg/kg intravenously over 15–30 min, repeated after 1–2 h to total dose of 30 mg/kg. Magnesium sulphate (8 mmol of magnesium) given intravenously over 10–15 min (repeated once if necessary) has also been reported to be effective. Lignocaine (lidocaine) is not effective in hypothermic VF, and the International Liaison Committee on Resuscitation guidelines suggest avoiding this drug, also epinephrine and procainamide, because of the risk of accumulation to toxic levels
3. Diagnosis of death—this can be difficult. Patients with severe hypothermia can appear clinically dead. Resuscitative efforts must continue until the core temperature is 30–33°C, i.e. THE PATIENT IS NOT DEAD UNTIL THEY ARE WARM AND DEAD

Key investigations	**To establish the diagnosis** Hypothermia is defined as a core temperature <35°C

Other important tests

1. Full blood count, electrolytes, glucose, renal and liver function tests—note that severe hyperkalaemia is common in profound hypothermia. Serum potassium must be monitored closely during rewarming, even if initially normal
2. Calcium (low), amylase (high)—in pancreatitis, an important complication of hypothermia
3. Thyroid function tests—?hypothyroid
4. Arterial blood gases—to look for hypoxia and/or acidosis
5. ECG—look for sinus bradycardia, J wave ('junctional' wave—a broad slurred deflection that is superimposed on the distal limb of the QRS complex), prolonged QT interval. Note that the muscular tremor of shivering can lead to artefact on the ECG, which should not be confused with ventricular fibrillation
6. Chest radiograph—look for aspiration, pneumonia, pulmonary oedema

Further management	Dependent on the cause of hypothermia. Prevention of recurrence is likely to require socio-economic intervention in the elderly, e.g. provision of heating, increased supervision

10 Practical procedures

10.1 Central vein cannulation, arterial cannulation and invasive monitoring

10.1.1 Femoral vein cannulation

The optimum position is with the patient supine, but their head and torso can be propped up to an angle of 15 to 30° if this is more comfortable. The key landmark is the femoral pulse, which should be palpated one finger-breadth below the crease of the groin. The femoral vein lies one finger-breadth medial to the femoral artery (the mnemonic NAVY, Nerve Artery Vein Y-fronts, can be useful in remembering the anatomy). The needle should therefore enter the skin one finger-breadth medial to the femoral artery and one finger-breadth below the groin crease (Fig. 1). It should be advanced in the line of the leg, angled rostrally at about 60° to the skin, and with its bevel pointing forwards. When the vein is punctured the guidewire should pass directly up the femoral vein and into the inferior vena cava.

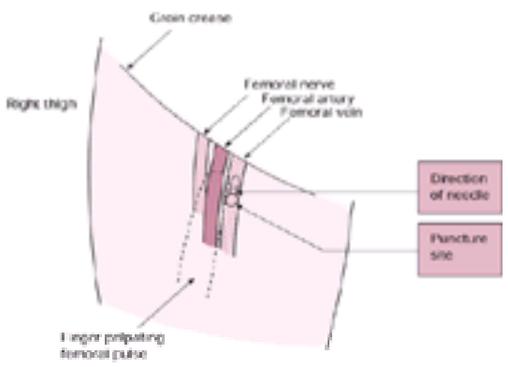

Fig. 1 The approach to the femoral vein.

10.1.2 Internal jugular vein cannulation

10.1.2.1—The low lateral approach

The patient is supine with the head turned away from the side of the puncture. A towel may be placed under both shoulders to extend the neck. After preparation of the skin and drapes, and insertion of local anaesthetic, the bed is tilted to a 25° head down position. The needle is inserted just lateral to the posterior border of the clavicular head of the sternocleidomastoid muscle, about one finger-breadth above the clavicle, with its bevel pointing caudally. It is then advanced parallel to the line of the clavicle and just behind the sternocleidomastoid muscle. The internal jugular vein, which lies superficially at this point, is cannulated close to its junction with the subclavian vein (Fig. 2(a)). As soon as the vein is entered the needle is angulated caudally to ease cannulation, the guidewire passing directly into the innominate vein. The risk of complications was lower with this technique than for any other method of central venous cannulation used in one series of over 5400 cases (see Chapter 16.1).

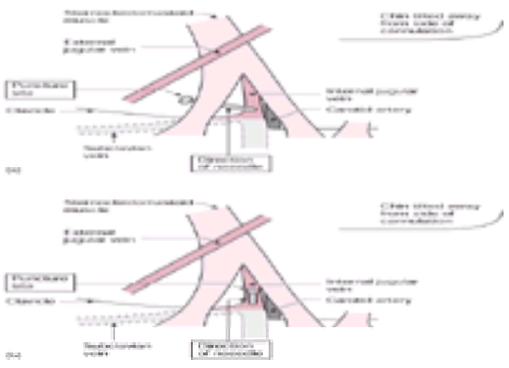

Fig. 2 (a)The low lateral approach to the internal jugular vein. (b)The axial approach to the internal jugular vein.

10.1.2.2—The axial approach

The patient is positioned as described for the low lateral approach to the internal jugular vein (Fig. 2(b)). The needle is inserted in the centre of the triangle defined by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle itself. It should be angulated caudally, at about 60° to the skin, and in a line pointing towards the ipsilateral anterior superior iliac spine.

10.1.3 Subclavian vein cannulation

10.1.3.1—The infraclavicular approach (Fig. 3(a))

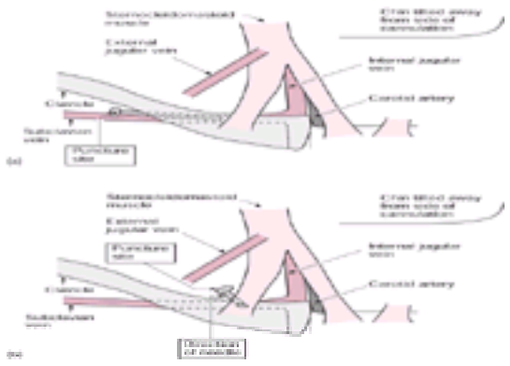

Fig. 3 (a)The infraclavicular approach to the subclavian vein. (b)The supraclavicular approach to the subclavian vein.

The patient is positioned as described for the low lateral approach to the internal jugular vein, excepting that instead of a towel being placed under both shoulders it should be positioned under the spine, allowing the shoulders to retract to reduce the risk of pneumothorax. The needle enters the skin below the mid-point of the lower border of the clavicle and is advanced under the clavicle towards the upper edge of the junction of the clavicle with the manubrium.

10.1.3.2—The supraclavicular approach (Fig. 3(b))

The patient is positioned as described for the infraclavicular approach to the subclavian vein. The needle is inserted into the angle between the superior border of the clavicle and the posterior border of the clavicular head of sternocleidomastoid and advanced caudally, medially and ventrally.

10.1.4 Pulmonary artery flotation catheter

Central venous cannulation should be performed as described above (section 10.1.2 and section 10.1.3) and a pulmonary artery (PA) catheter introducer inserted. Ensure that the balloon at the end of the PA catheter inflates completely and uniformly, and then slowly advance the catheter whilst watching the pressure trace on the monitor. The balloon should be inflated when the

catheter is advanced and deflated whenever the catheter is withdrawn. Pressure traces corresponding to the right atrium, the right ventricle and the pulmonary artery should be seen (Fig. 4). As a rough guide, the waveform should change for every 10 cm that the catheter is advanced. Inflation of the balloon when the catheter is in a medium sized pulmonary artery allows it to 'wedge' and occlude distal flow. To obtain valid readings, the catheter tip should reside in a region of the lung where pulmonary venous pressure exceeds alveolar pressure. The pressure recorded at the tip of the catheter (pulmonary capillary wedge pressure, PCWP) provides indirect measurement of the left atrial pressure, which reflects left ventricular end-diastolic pressure if the chamber is not diseased. Values for cardiac output and mixed-venous blood chemistries may also be directly measured. A number of variables such as systemic vascular resistance and left ventricular stroke work may be derived from values measured with a PA catheter.

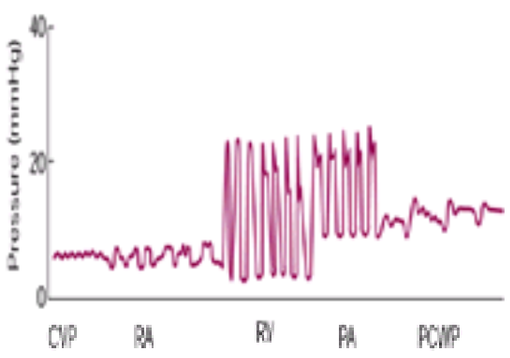

Fig. 4 Pressure tracings obtained on insertion of a pulmonary artery flotation catheter. CVP, central venous pressure, RA, right atrium, RV, right ventricle, PA, pulmonary artery, PCWP, pulmonary capillary wedge pressure.

10.1.5 Arterial puncture/cannulation

Before attempting to puncture or cannulate the radial artery, check the patency of the ulnar artery by applying pressure to the radial artery and asking the patient to clench their fist firmly. On relaxing the fist, the hand should pink up within 10 s (Allen test).

A 25G needle (orange) is perfectly adequate to obtain an arterial blood gas (ABG) sample from a radial artery. 18G (green) or 23G (blue) is needed for a femoral sample. Use either a preheparinized ABG syringe or draw up 1 ml of 1000 u/ml heparin into a syringe and then completely expel the heparin.

Lay the index and middle fingers of your non-dominant hand along the line of the artery as a guide (Fig. 5). For radial and brachial samples, hold the syringe at 45 to 60° to the skin and slowly advance in the line of the artery. For femoral samples, hold the syringe at 90° to the skin. A flash of blood into the syringe indicates successful puncture. Some syringes will fill to a predetermined volume, others require aspiration of 1 to 2 ml.

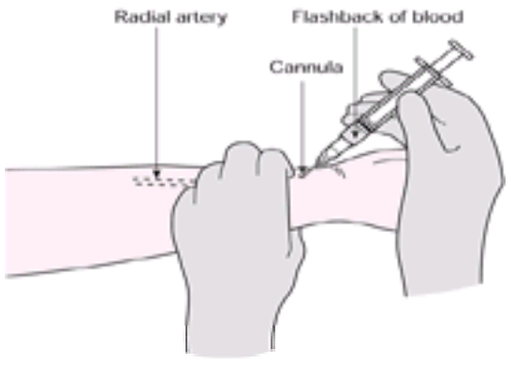

Fig. 5 Puncture of the radial artery.

After successful arterial puncture, press on the site for 3 min (5 if anti-coagulated) to prevent haematoma formation.

Arterial cannulation may be performed either with a cannula over a needle (similar to a venflon) or with a Seldinger technique. After preparation of the skin and insertion of local anaesthetic, the method of arterial puncture should be as described above, with the exception that for all arterial cannulations the needle should be inserted at 45° to the artery. Once arterial puncture has been confirmed, the cannula should be advanced over the needle, or the guidewire passed directly into the artery and the cannula then advanced over the guidewire.

10.2 Cardiac procedures

10.2.1 DC cardioversion

Synchronized cardioversion is the treatment of choice for symptomatic tachyarrhythmias. Conscious patients must be anaesthetized or sedated. Suitable monitoring and facilities for dealing with cardiac arrest should be available. Modern defibrillators incorporate a switch that allows the shock to be synchronised with the R wave of the ECG to reduce the risk of inducing ventricular fibrillation. Gel pads should be applied to the chest wall and cardioversion carried out in the same manner as for defibrillation. The energy required depends on the underlying rhythm. Synchronization means that there may be a delay between pressing the defibrillator buttons and the discharge of the shock when the next R wave occurs.

10.2.2 Cardiac pacing (temporary)

Indications for emergency/acute temporary cardiac pacing are shown in Table 24.

10.2.2.1 External (transcutaneous) pacing

10.2.2.1.1 Percussion pacing Percussion pacing can be used as a temporising measure in some patients with profound bradycardia causing clinical cardiac arrest. It is particularly useful for ventricular standstill where P waves are visible on the ECG. A series of gentle blows should be applied to the lower left sternal edge using the closed fist. Using trial and error, a site can sometimes be found which results in stimulation of the ventricular myocardium. If percussion does not produce a cardiac output, orthodox pacing or CPR should be instituted immediately.

10.2.2.1.2 Transcutaneous pacing Most modern transcutaneous pacing systems are integrated with an ECG monitor/defibrillator. Pacemaker electrodes should be placed in either an anterior-posterior position or in the conventional anterior-lateral configuration. The pacemaker should be set to demand pacing to prevent a stimulus from falling on the T wave following a sponteaneous heart beat, with the rate set at 60 to 90/min for adults. The pacemaker current should be set at the lowest setting and gradually increased to obtain capture of the myocardium and a palpable pulse. The current required to obtain capture is generally in the range 50 to 100 mA and will produce painful contraction of the patient's skeletal muscle. Conscious patients will require analgesia and/or sedation. If capture of the myocardium does not occur, alternative electrode placement should be tried.

Transcutaneous pacing is only a temporizing measure and arrangements should be made for urgent transvenous pacing.

10.2.2.2 Transvenous pacing (ventricular)

Temporary transvenous pacing can be achieved after cannulation of any central vein, but is most easily performed via the right internal jugular, right subclavian or right femoral vein, which can be cannulated as described in section 10.1.1, section 10.1.2 and section 10.1.3.

The conventional Seldinger technique of guidewire and dilators is used to allow placement of a sheath (preferably haemostatic) of sufficient size to accept passage of the pacing wire in the vein that has been cannulated. The pacing wire is passed down the sheath and advanced towards the heart, the aim being to maneouvre it under fluoroscopic guidance into a position where its tip is at the apex of the right ventricule, angulated slightly downwards. Key aspects of the technique are shown in Fig. 6. Common problems and their solutions are described in Table 25.

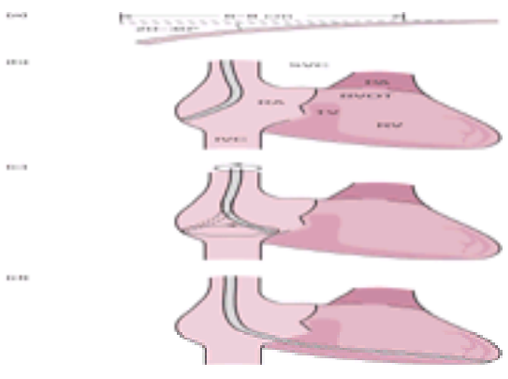

Fig. 6 Correct positioning of the electrode is helped if there is a 20 to 30° curve at the tip of the pacing wire. Mould the electrode to this shape using your fingers: it may need to be bent or straightened depending on its packaging. (a). Advance the wire until it lies vertically in the right atrium. It will usually assume a position where its tip points towards the free wall on the right side (b). Rotate the wire between your index finger and thumb until it points towards the patient's left (c). When it has done so, advance the wire steadily: it should pass through the tricuspid valve and along the floor of the right ventricle to the apex (d). SVC, superior vena cava; RA, right atrium; IVC, inferior vena cava; TV, tricuspid valve; RV, right ventricle; RVOT, right ventricular outflow tract.

After positioning the pacing wire, set the pacemaker to a rate of 70/min, or 10/min above the patient's ventricular rate, and to deliver a pulse of 3 V (or as directed by the manufacturer). A correctly positioned electrode should 'capture', such that each pacing spike is followed by a ventricular complex on the ECG. Establish the voltage threshold by gradually turning down the amplitude of the voltage delivered until capture is lost, which will usually be in the range 0.7 to1.0 V. To allow a safety margin, it is then appropriate in most circumstances to set the pacemaker to deliver a voltage of at least twice the threshold. Sensing can be checked only if there is spontaneous ventricular activity: this is best done by setting the pacemaker rate to between10 and 20/min below the spontaneous ventricular rate and looking on the ECG monitor and the pulse generator for evidence of pacing inhibition. Sensitivity is usually set to to its maximum. Common problems and their solutions are described in Table 26.

When the pacing wire is positioned appropriately and pacing is established, carefully remove the introducer sheath (in most cases), secure the wire with a strong suture (usually 2/0 silk), loop it once or twice on the skin, and then dress with a clear adhesive dressing.

10.2.3 Pericardiocentesis

Cardiac tamponade is the indication for pericardiocentesis as an emergency. Unless the patient is *in extremis* the procedure should, whenever possible, be performed with echocardiographic guidance by an operator experienced in the technique, as follows:

1. Two-dimensional echocardiography is used to assess the size, distribution and haemodynamic effect of the effusion.
2. The ideal entry site for pericardiocentesis is the point on the skin where the effusion is closest to the transducer and the fluid accumulation is maximal. The distance from the skin to the pericardial space is estimated, with the needle trajectory defined by the angulation of the hand-held transducer. A straight path that best avoids vital structures (also the internal mammary artery, which lies 3 to 5 cm lateral to the sternal margin) is chosen.
3. After preparation of the skin and insertion of local anaesthetic, a 16 to 18 gauge polytef-sheathed (or similar) needle attached to a saline-filled syringe is advanced in the predetermined trajectory, with continued gentle aspiration as it moves forward. On entering the pericardial fluid, the needle is advanced approximately 2 mm further, when the sheath is advanced over the needle and the steel core withdrawn.
4. The position of the sheath in the pericardial space can be confirmed by injecting 5 ml of agitated saline through it, whilst observing the pericardial space with 2D-echocardiography (optional).
5. Intrapericardial pressure can be directly measured with a manometer (optional); pericardial fluid can be sent for diagnostic tests (optional).
6. A guidewire is advanced through the polytef sheath, which is removed over the guidewire. A small stab incision of the skin is made at the entry site, following which dilators are used to allow the insertion of a larger sheath (6–8 F) through which a pigtail angiocatheter can be introduced. After the pigtail catheter has been inserted the introducer sheath is removed, leaving only the smooth-walled pigtail catheter in the pericardial space. (Note that this technique is preferred to that of introducing the pigtail catheter directly over the guidewire because the catheter tip can occasionally pull the guidewire out of the pericardial sac, particularly if this is sclerotic.)
7. Pericardial fluid is drained completely by syringe suction and the pericardial catheter is secured to the chest wall by suture and appropriate dressing.
8. If left on continuous drainage, pericardial catheters become plugged. It is therefore better to perform intermittent aspiration, every 4 to 6 h or as clinically indicated, leaving the catheter flushed with saline in between times. It can be removed when drainage has been reduced to less than 25 to 30 ml/day and follow-up echocardiography shows no significant residual effusion (sooner if the catheter is causing problems).

   If the patient is *in extremis* and/or echocardiography (with appropriate expertise) is not available, then a 'blind' subxiphoid approach is most often used:

1. Sit the patient up at an angle of 45°.
2. Insert the needle 3 cm below the xiphisternum at an angle of 30 to 45° to the skin and advance, applying gentle suction all the time (as above), in a line towards the patient's left shoulder.
3. If the needle touches the heart, it will usually provoke ectopic beats. Some authorities recommend that the aspiration needle is attached to the 'V' lead terminal of an ECG cable (using insulated wire with a clip on each end, or simply with sticky tape) to allow continuous monitoring. If the needle touches the heart, then the character of the ECG changes, most particularly with the appearance of gross ST-segment elevation if the needle touches the right or left ventricle.
4. When fluid is obtained, proceed as described above.

10.3 Arterial blood gases (Table 27)

10.4 Airway and respiratory procedures

10.4.1 Mechanical support of ventilation

10.4.1.1 Continuous positive airways pressure

Continual positive airway pressure (CPAP) exerts a dilating force on the upper airway (hence its use in obstructive sleep apnoea), and also recruits collapsed alveoli and increases functional residual capacity. This improves lung compliance, reducing the work of breathing, which is a benefit in a range of clinical circumstances.

CPAP can be used for patients with acute or acute on chronic hypoxaemia who are not exhausted or in ventilatory failure (meaning elevated *p*CO2), e.g. acute pulmonary oedema, postoperative atalectasis, pneumonia. It is not appropriate and is contraindicated for patients who are too obtunded to cooperate, who are unable to protect their airway, who have haemodynamic instability or life-threatening arrhythmias, life-threatening hypoxaemia, or exhaustion.

CPAP is applied via a tight fitting face or nose mask, the usual range for pressure being 2.5 to 10 cmH2O. Once applied, patient comfort, respiratory rate and arterial blood gases should be monitored. Some patients are unable to tolerate the face mask: gastric distension, vomiting, aspiration, eye irritation, conjunctivitis, and facial-skin necrosis are other complications.

10.4.1.2 Non-invasive positive pressure ventilation

Masks that are used for CPAP can also be used to provide non-invasive positive pressure ventilation (NIPPV, often more simply referred to as NIV). The difference between the two treatments is that in CPAP a constant pressure is applied to the airway, but no airflow occurs in the absence of respiratory muscle activity. By contrast, in NIV a pulse of positive pressure is applied to assist respiration, the usual arrangement being that this is triggered by a sensor that detects a fall in pressure in the facial mask when the patient initiates a breath. If a positive pressure is also applied in the expiratory phase (EPAP) in addition to the pulse delivered to support inspiration, then then this is known as bilevel pressure support (BIPAP).

Contraindications for and complications of NIV are the same as those for CPAP.

10.4.1.3 Invasive ventilation

Invasive ventilation may be applied via a tracheal tube or tracheostomy. Ventilation can be adjusted by altering the minute volume (respiratory rate × tidal volume). Oxygenation is adjusted by altering inspired oxygen concentration and positive end-expiratory pressure (PEEP, which acts in a similar manner to CPAP by recruiting collapsed alveoli and reducing the work of breathing). Most ventilators for adults are volume generators that deliver a fixed tidal volume regardless of changes in lung mechanics. If the lungs become stiffer, then inflation pressure will increase to deliver the same tidal volume.

The change from inspiration to expiration is usually time cycled; that from expiration to inspiration is usually either time cycled or triggered by the patient if they are breathing spontaneously. The following values can be used as a guide when initially setting up a ventilator for an adult:

- Tidal volume should be 10–15 ml/kg
- Respiratory rate 10–12/min
- Ratio of inspiratory to expiratory time (I:E ratio) set at 1:2, but for patients with chronic obstructive pulmonary disease or asthma, a smaller I:E ratio is often used (e.g. 1:3) to prevent gas trapping and hyperinflation.
- Concentration of inspired oxygen depends on the clinical context: the patient with normal lungs who requires respiratory support because of respiratory muscle weakness does not need a high *F*iO2 (start with say 28 per cent), whereas the patient with severe problems with gas exchange, eg. bilateral pneumonia or acute respiratory distress syndrome, will require a high *F*iO2 (start with say 60–80 per cent).

Once ventilation is established, the various parameters should be adjusted (and others added, e.g. CPAP) according to the patient's clinical condition and the results of repeated measurement of arterial blood gases.

10.4.2 Management of the airway

10.4.2.1 Endotracheal intubation

Endotracheal intubation remains the gold standard for airway management as it provides a method of oxygenating and ventilating the patient, whilst securing the airway from vomitus and secretions.

Intubation should be preceded by ventilation with high concentration oxygen. The neck should be slightly flexed and the head extended (an assistant holding the neck in a neutral position if trauma to the cervical spine is suspected). The mouth should be inspected for loose teeth or dentures, which should be removed, as should any secretions or vomitus (by suction). A trained assistant should apply cricoid pressure to prevent passive regurgitation.

The laryngoscope should be introduced over the right side of the tongue, moving the tongue to the left. The tip of the blade should be positioned in the valecula (between the epiglottis and the base of the tongue) and lifted upwards and away from the operator to expose the vocal cords (Fig. 7(a)). The endotracheal tube should be introduced so that the cuff is positioned just beyond the cords (Fig. (b)).

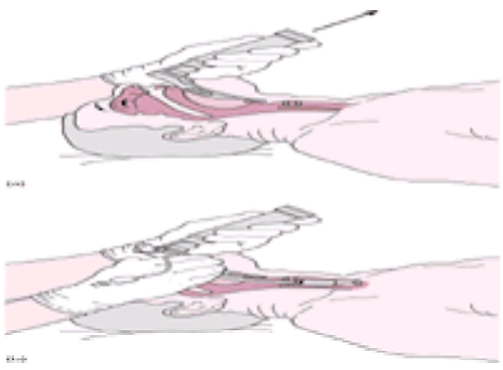

Fig. 7 (a) Position of the laryngoscope before insertion of the endotracheal tube. (b) Placement of the endotracheal tube.

After successful intubation, the patient should be ventilated with high concentration oxygen, the endotracheal tube secured and the tube cuff inflated. Positioning of the endotracheal tube should be confirmed by listening over the apices and the bases of the lungs, and over the stomach. If available, an end-tidal carbon dioxide monitor should be attached to the endotracheal tube.

10.4.2.2 Laryngeal mask airway

The laryngeal mask airway (LMA) is used widely in routine anaesthetic practice and is increasingly used for immediate airway management in cardiac arrest. Pulmonary aspiration associated with the use of a LMA is uncommon provided high inflation pressures are avoided.

The patient should be supine with the neck slightly flexed and the head extended (an assistant holding the neck in a neutral position if trauma to the cervical spine is suspected). The LMA should be held like a pen, and introduced into the mouth with the distal aperture facing towards the patient's feet. The tip should be applied to the palate and advanced until it reaches the posterior pharynx. The LMA is then pressed backwards and downwards until the resistance of the hypopharynx is felt (Fig. 8), when the cuff of the LMA should be inflated. If insertion is satisfactory, the end of the LMA will rise slightly. Positioning of the LMA should be confirmed by listening over the apices and the bases of the lungs, and over the stomach. If available, an end-tidal carbon dioxide monitor should be attached.

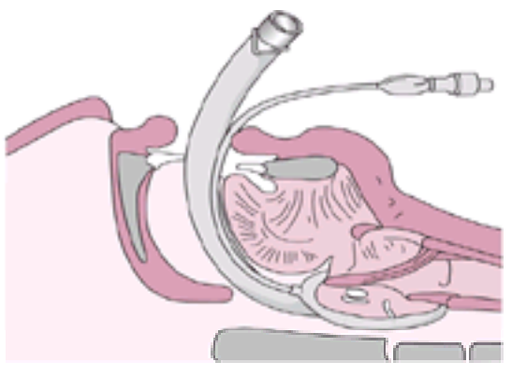

Fig. 8 Laryngeal mask airway inserted into the hypopharynx. The inflated cuff surrounds and isolates the entrance to the larynx.

10.4.2.3 Cricothyroidotomy

10.4.2.3.1 Needle cricothyroidotomy Insertion of a needle or a cannula (typically a large bore intravenous cannula) through the cricothyroid membrane is a useful emergency technique that allows short-term provision of oxygen until a definitive airway can be placed. The cannula should be connected to high flow oxygen with either a Y connector or a side hole cut into the tubing between the cannula and the oxygen supply (Fig. 9). Intermittent insufflation can be achieved by closing the Y connector or side hole with a thumb for one second and then releasing it for three seconds. Inadequate exhalation leads to accumulation of carbon dioxide, hence this technique of ventilation can only be used for 30 to 45 minutes.

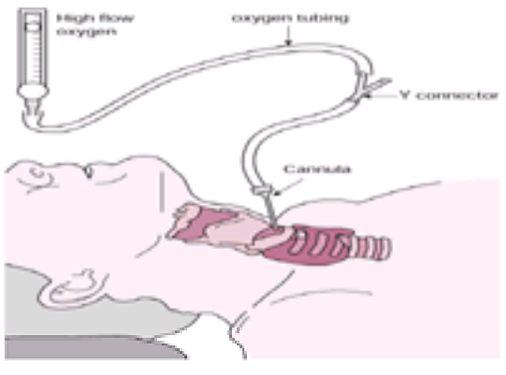

Fig. 9 Oxygenation via a cannula through the cricothyroid membrane.

10.4.2.3.2 Surgical cricothyroidotomy The skin over the cricothyroid membrane should be cleaned and local anaesthetic inserted (in patients who are conscious). A horizontal skin incision is made and extended through the cricothyroid membrane (Fig. 10). A curved haemostat (forceps) is then used to dilate the opening and a small, cuffed endotracheal tube or tracheostomy tube inserted. The position of the tube should be confirmed by auscultation of the lungs and over the stomach, and the tube then secured.

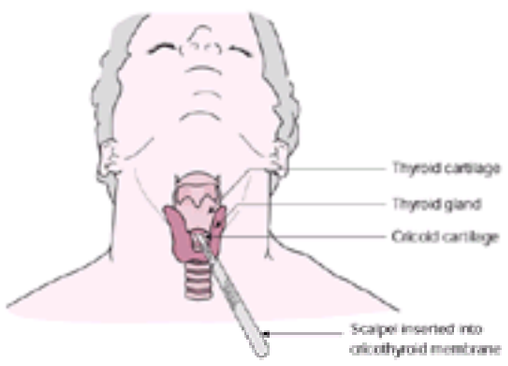

Fig. 10 Technique of surgical cricothyroidotomy.

10.4.3 Percutaneous procedures on the chest

10.4.3.1 Chest decompression

The rapidly deteriorating patient with clinical signs of a tension pneumothorax requires immediate needle decompression of the chest. The second intercostal space on the side of the tension pneumothorax should be identified, and an over the needle cannula or any hollow needle should be inserted in the midclavicular line, directing it just superior to the rib into the intercostal space. Listen for a sudden escape of air when the needle enters the pleural cavity. The cannula should be secured and arrangements made for an intercostal drain to be inserted as soon as the tension pneumothorax has been decompressed.

10.4.3.2 Chest aspiration

Chest aspiration may be considered for any symptomatic spontaneous pneumothorax, irrespective of its size. The advantages over intercostal tube drainage are that, if successful, needle aspiration means a shorter hospital stay, less pain, and less scarring.

The British Thoracic Society guidelines recommend an anterior approach using the second intercostal space in the midclavicular line. Other authors recommend a posterior approach, with the patient in a sitting position with the arms gripping the knees, and using the secone, third, or fourth intercostal space medial to the scapula.

The skin should be prepared and local anesthetic infiltrated down to the pleura. A 16 G cannula is inserted perpendicular to the skin and just over the superior border of the rib. The cannula is then connected to a three-way tap, the second port of which is connected to a 50 ml syringe, and the third to a length of tubing that runs to open under the surface a container of sterile water (Fig. 11). Aspiration should be continued until either resistance is felt or the patient coughs excessively.

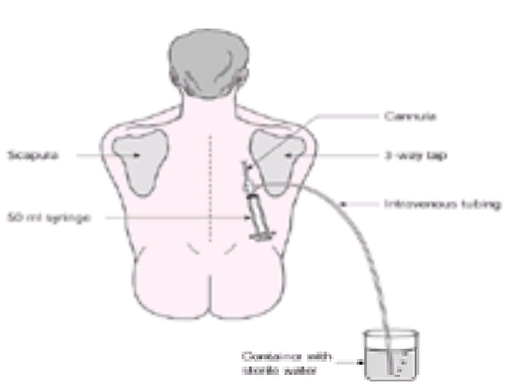

Fig. 11 Chest aspiration (posterior approach).

The success (or otherwise) of aspiration can be determined by repeat chest radiography. The procedure may be repeated if not successful or if the pneumothorax recurs. Success is less likely for older patients and in those with chronic lung disease or recurrent pneumothorax, also after aspiration of more than 2.5 litres.

10.4.3.3 Chest drain

Always confirm the correct side for chest tube insertion. The usual site is the fourth to sixth intercostal space anterior to the midaxillary line. Position the patient supine with the head of the bed slightly elevated and the patient's arm behind their head. Clean and drape the area for tube insertion.

Infiltrate local anaesthetic down to the parietal pleura (10–20 ml of 1 per cent lignocaine). Make a 2 to 3 cm transverse incision at the site and blunt dissect through the subcutaneous tissues, just over the superior surface of the rib. Puncture the parietal pleura with the end of the dissection forceps and insert a gloved finger into the incision to ensure that the pleural space has been entered.

Remove the trocar from the intercostal drain and slide the drain over your finger into the pleural cavity, when 'fogging' of the tube should be seen. Connect the end of the intercostal tube to an underwater-seal apparatus and confirm correct placement by ensuring that the fluid level is swinging with respiration.

Insert two 3/0 monfilament sutures at 90° to the line of the skin incision, one on either side of the chest drain, but do not tie them. They will be used to close the skin when the chest drain is removed (and are much better than a purse string suture, which produces an unsighly scar, for this purpose). Suture the tube in place with a separate 1/0 or 2/0 silk suture, tied around it as many times as its length allows. If the skin incision is gaping on either side of the drain, close this with one or more 3/0 sutures. Place a gauze dressing around the site and secure with strong tape, wrapping some of this around the tube to secure it firmly.

Obtain a chest radiograph to confirm satisfactory placement and effect of the chest drain.

10.5 Lumbar puncture

Ensure that there are no contraindications to lumbar puncture (LP), namely raised intracranial pressure, bleeding tendency, local sepsis, posterior fossa or spinal cord mass lesion.

The patient should be positioned on the bed (Fig. 12(a)) with their knees drawn up towards the chest to open the space between the spinous processes and with their

spine parallel to the bed. Prepare and drape the skin and locate the puncture site (L3/L4 or L4/L5).

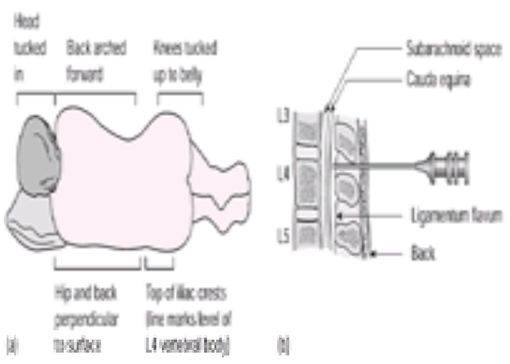

Fig. 12 (a) The patient should lie curled up to increase the spave between the vertebrae. (b) The needle should be slowly advanced until it penetrates the ligamentum liavum.

Anaesthetize the skin and subcutaneous tissues using 5 to 10 ml of 1 per cent lignocaine. Insert the LP needle at 90° to the skin. Advance slowly, aiming between two spinous processes (Fig. 12(b)). As the needle enters the dural space, there is a slight loss of resistance. Remove the stylet and ensure that CSF drips freely from the needle. If it does not, insert the stylet and advance the needle a few millimetres then check again.

Check the opening CSF pressure using a manometer (normally 6–15 cmH_2O) then collect CSF samples. The red cell count in consecutive samples can sometimes help to distinguish subarachnoid haemorrhage from a bloody tap, but this is not always reliable and the sample should also be examined for xanthochromia (oxyhaemoglobin and bilirubin) when subarachnoid haemorrhage is possible. Always send blood samples for glucose and protein estimation at the same time, the CSF glucose concentration normally being 60 to 80 per cent of the blood level.

The patient should be asked to remain lying flat for 2 to 4 h to reduce the severity of post-LP headache.
