Immunoglobulin receptors on the surface of B cells are able to recognize soluble antigens and so initiate the process of B-cell activation and differentiation. During differentiation, naïve B cells become antibody secreting plasma cells. In addition, there is endocytosis of antigen bound to surface immunoglobulin, and processed antigen in the form of small peptides is re-expressed on the surface of the B cell in the context of MHC class II molecules. Thus B cells act as antigen-presenting cells and recruit T-cell help. The signals and soluble factors that result from such T-cell help drive the B-cell process of affinity maturation and memory formation. This takes place in the germinal centres of lymph nodes where there is intimate contact between B cells, T cells, and dendritic cells. It is here that memory B cells are formed and then migrate to the bone marrow, spleen, and the submucosa of the respiratory tract and gut. On re-encounter with antigen, memory B cells undergo rapid activation and differentiation into plasma cells and secrete large amounts of switched, high-affinity antibody.

Thus, the ideal vaccine antigen will lead to the activation, replication, and differentiation of T and B lymphocytes. Ideally, the antigen will persist, conformationally intact, in lymphoid tissue to allow the continuing production of cells that secrete antibody of high affinity and the generation of memory cells.

Vaccine antigens

The ideal vaccine antigen is safe with minimal side-effects, promotes effective resistance to the disease (although it does not necessarily prevent infection), and promotes immunity that is lifelong. It needs to be stable and remain potent during storage and shipping and also has to be affordable to allow widespread use. Most currently licensed vaccines contain live or killed bacterial or viral constituents, bacterial polysaccharides, or bacterial toxoids (Table 1).

Live vaccines are ideal for certain diseases as replication in the body mimics natural infection thereby inducing appropriate and site-specific immunity. Live vaccines must be attenuated to produce the beneficial effects of inducing immunity without the danger of clinical disease. Some live vaccines may be spread from person to person and thus enhance herd immunity although such spread may endanger immunocompromised individuals in whom live vaccines should be avoided. Live vaccines are inherently less stable than killed vaccines and the possibility of reversion of vaccine virus to wild type exists (as in polio). Killed vaccines do not carry the risk associated with person-to-person spread and are inherently more stable, but often require two or three doses to induce optimal immunity, especially when used in the first year of life.

New developments in vaccine antigens

Developments in molecular biology have begun to revolutionize the field of vaccine science and provide a glimpse of the future when traditional reliance on live attenuated viral vaccines or purified bacterial or viral products as vaccine antigens may be reduced. The first licensed vaccine to contain recombinant genetic material was the hepatitis B vaccine. Despite the licensing of highly effective plasma-derived hepatitis B vaccines in the early 1980s, fears about safety and their high cost led to the search for other hepatitis B vaccines. Several vaccine manufacturers used recombinant DNA technology to express hepatitis B surface antigen in other organisms, which has led to the development of new vaccines.

Recent developments have focused on the use of DNA as a vaccine antigen. The utility of naked DNA as a vaccine antigen was discovered by chance in 1989 during a gene therapy experiment when it was shown that a gene inserted directly into a mammalian cell could induce the cell to manufacture (express) the protein encoded by that gene. In early experiments, DNA was injected directly into muscle and the resulting immune response was measured (see Fig. 1).

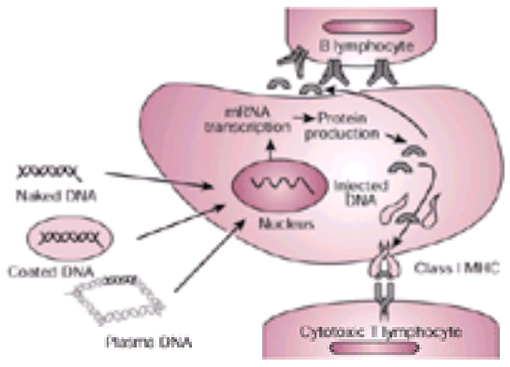

Fig. 1 Injection of DNA encoding a foreign protein can elicit antibodies and a cytotoxic T-lymphocyte response.

DNA vaccines can induce protective immunity in animals to a variety of pathogens, but data in humans are limited. As DNA has the theoretical potential to be incorporated into the host genetic makeup and subvert the genetic working of cells, safety concerns have delayed studies in humans. Phase I studies, however, have assessed DNA vaccines designed to protect against hepatitis B, herpes simplex type 1 and 2, HIV, influenza, and malaria. So far clinical trials have proved disappointing, either because the level of the response was inadequate or because excessive doses of DNA were required to achieve an adequate response. To improve the response to DNA vaccines, a number of newer techniques have been developed. These include:

1. Incorporation of DNA into microprojectiles that are then shot into the target cell via the skin (the so-called 'gene gun' technique).
2. The coating of DNA with cationic lipids or other material that neutralizes its charge; the lipids facilitate cellular uptake and membrane transfer.
3. Delivery of DNA by incorporating it into a viral delivery system using disabled viruses.
4. Delivery of DNA by incorporation into a bacterial delivery system such as attenuated *Salmonella typhimurium*.
5. Delivery of DNA together with traditional adjuvants such as alum.
6. Improving immunogenicity by including a cytokine gene in the plasmid, adjacent to the gene encoding the protective antigen. Local expression of the appropriate cytokine (for example granulocyte–macrophage colony stimulating factor) may augment the immune response in a fashion similar to that seen with adjuvants.
7. Combination of 'priming' immunization with DNA vaccine with subsequent 'boost' with recombinant vaccine.

The huge potential of DNA vaccines, which offer the promise of cheap and stable vaccines that do not require a cold chain for distribution, will stimulate further development of these exciting products.

New developments in vaccine delivery

Research into different routes of vaccine delivery has been driven by the limitations of the parenteral route. These include the difficulty associated with the use of live viral vaccines in the first 6 to 9 months of life (due to the neutralizing effect of passively transferred maternal antibody) and the difficulty and expense of delivering mass immunization by injection. Mucosal delivery of vaccine via the intranasal route has been studied for a number of antigens including measles, influenza, rubella, varicella, and *Streptococcus pneumoniae*. The induction of local immunity for pathogens that either enter the body via the nasopharynx (measles, influenza) or are commonly carried in the nasopharynx (*S. pneumoniae*) is attractive.

Edible vaccines are attracting increasing attention, providing as they do both a means of antigen production and delivery. Studies in animals and Phase I studies in humans have demonstrated their potential. Mice fed with potatoes expressing a non-toxic fragment of the cholera toxin developed mucosal antibodies to the toxin which reduced diarrhoea on challenge with whole cholera toxin. Humans fed raw potatoes expressing the B subunit of enterotoxigenic *Escherichia coli* also showed mucosal immune responses and an increase in neutralizing antibody levels. There are some problems with stability, but edible vaccines are a potentially simple and convenient method of vaccine delivery on a wide scale.

The aim of immunization programmes

Once a vaccine has been developed and shown to be effective it can be used in different ways. Many vaccines are used selectively in groups of the population who are at increased risk of infection (for example because of occupation or travel) or of the severe consequences of the disease that results from infection (because of an underlying medical condition for example). Other vaccines are employed for mass immunization targetting the whole population. Mass immunization can aim to eradicate, eliminate, or to control an infectious disease. Eradication, the state where a disease and its causal agent have been removed from the natural environment, has been achieved only for smallpox. Once eradication has been certified, mass immunization programmes can cease and resources can be transferred to other programmes.

The next target for the WHO is the global eradication of poliomyelitis. Characteristics that favour eradication are the absence of an animal host, the absence of a carrier state, and lifelong protection from vaccination. Poliovirus infection has now been eliminated from the Pan American and Western Pacific WHO Regions although there was a recent resurgence in Haiti. In recently endemic countries, wild poliovirus transmission has been interrupted by a series of National Immunization Days—where live attenuated polio vaccine is delivered to a high proportion of the childhood population on a single day. In 1997, almost 450 million children under 5 years of age were immunized during National Immunization Days. In addition to the resources within each country, this effort has required massive financial support from international donors. Between 1988 and 1998, the number of reported cases of polio worldwide had fallen from 35 251 to 3228 and only three major foci of transmission remain—South Asia and West and Central Africa.

For some infections, eradication by immunization is not possible. A good example is tetanus where the agent is distributed widely in the environment. For these programmes, the aim is to control infection to the point where it no longer constitutes a public health burden. To maintain control, immunization will need to be continued indefinitely.

For diseases that are transmitted from person to person, a good immunization programme provides protection by conferring both individual and herd immunity. For many vaccines, herd immunity can be achieved by vaccinating a high proportion of the childhood population—older individuals are generally immune from previous natural infection. If such a situation can be sustained, transmission of the infection may be interrupted and elimination or eradication becomes possible. If vaccine coverage or efficacy is suboptimal, however, then, in the absence of natural transmission, the number of susceptible people will gradually increase. Eventually the proportion of susceptible people (those who did not receive vaccine or who failed to respond to it) may reach a level sufficient to support an epidemic. Although the size of these epidemics may be small by prevaccine standards, the average age of those infected will be higher than in the prevaccine era. For infections that have more severe consequences in older individuals the morbidity associated with such outbreaks can be substantial. A tragic example of this has been recently observed in Greece where mass vaccination with rubella in childhood has been recommended since 1975. Implementation was poor, however, and during the 1980s coverage was below 50 per cent. The low level of coverage, however, was sufficient to interrupt transmission for several years. By the time rubella infection recurred in 1993, a high proportion of pregnant women were susceptible to rubella and an epidemic of congenital rubella syndrome occurred.

The Expanded Programme of Immunization

In 1974, the WHO, in recognition of the major contribution of vaccines to public health, launched the EPI. At the start of the programme fewer than 5 per cent of the world's infants were immunized against the six target diseases—diphtheria, tetanus, whooping cough, polio, measles, and tuberculosis. Between 1990 and 1997, around 80 per cent of the 130 million children born each year were immunized by their first birthday—preventing around 3 million deaths each year. Each year, over 500 million immunization contacts occur with children and these have provided an opportunity for the delivery of other primary health care interventions.

During the 1990s, EPI has added immunization against yellow fever and hepatitis B to its target (see Table 2) The introduction of these vaccines, however, has been less impressive, particularly in those poorest countries in greatest need. Of 33 African countries at risk of yellow fever, only 17 have included the vaccine in the childhood schedule. By 1998, hepatitis B vaccine had been incorporated into the national programmes of 90 countries, but it is estimated that 70 per cent of the

world's hepatitis B carriers live in countries without programmes. The major barrier to using new vaccines in the developing world is likely to be sustainable funding.

Delivery of immunization programmes

For mass immunization to achieve its aims, high and uniform coverage of immunization must be reached and sustained. Coverage of immunization is associated with a variety of factors including sociodemographic characteristics of the population, organization of health services, knowledge among health professionals, and parental attitudes.

Sociodemographic factors that may influence vaccine coverage include deprivation, maternal education, and family size. Centrally co-ordinated health services with few barriers to access and standard record systems with facilities for call and recall are likely to achieve higher vaccine coverage. Health professionals with accurate knowledge of the indications and true contraindications to immunization are important. Excessive lists of contraindications for DTP immunization in the newly independent states of the former USSR contributed to a massive resurgence of diphtheria in the early 1990s. The number of cases rose from 2000 in 1990 to over 47 000 in 1994; 2500 deaths from diphtheria occurred between 1990 and 1995.

Whether or not parents decide to have their children vaccinated depends on their perceptions of the severity of the disease and of the safety and effectiveness of the vaccine. Knowledge of parental perceptions can be used successfully to target health promotion campaigns. When coverage is high, the incidence of vaccine preventable disease declines and parental perception of the severity of that disease may decrease. In this situation, concerns about the safety of vaccine become paramount and can lead to a decline in vaccine coverage. Such a situation arose in the United Kingdom in the early 1970s when concern about the safety of pertussis vaccine led to a fall in vaccine coverage. This resulted in resurgence of disease with consequent mortality and morbidity (see Fig. 2). Over the next decade, vaccine coverage improved again and the incidence of disease fell to the lowest levels ever.

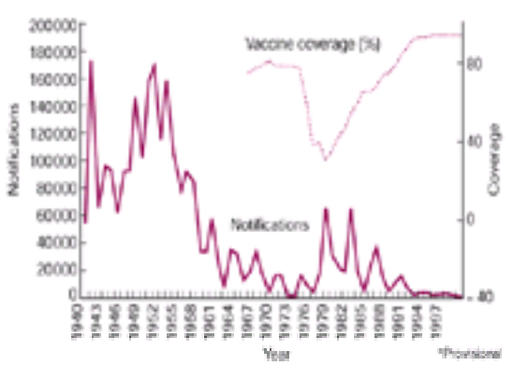

Fig. 2 Whooping cough cases and vaccine coverage in England and Wales between 1940 and 1998.

A more recent example of where largely unsubstantiated concerns about vaccine safety have damaged the success of a vaccination programme have occurred in France. Anecdotal reports of multiple sclerosis following hepatitis B vaccine produced a fall in vaccine coverage in France. Although the number of reports were in line with expected numbers, in October 1998, the French Ministry of Health decided to suspend the schools programme but to continue immunization in general practice. Three case–control studies failed to confirm the link and it is clear that the risk of hepatitis B infection always outweighs the potential risk of adverse events. The WHO and the national committees of several neighbouring countries have reviewed the data and concluded that there is no evidence of a causal association. Despite this, coverage of hepatitis B vaccine has continued to fall in France and in French-speaking Belgium.

In the United Kingdom, speculation that the combined measles–mumps–rubella (**MMR**) vaccine produced bowel problems which in turn could result in autism was published in *The Lancet* in February 1998. This anxiety was based upon a case-series of only 12 patients and the validity of the study was questioned in an accompanying editorial. Subsequent population-based studies of children with autism in the United Kingdom have failed to demonstrate a link with measles-containing vaccines - a finding which is supported by data from Finland. Despite the lack of scientific evidence, a majority of mothers in the United Kingdom now believe the MMR vaccine to be unsafe. This, together with a low proportion of mothers who believe that measles is a severe disease, has resu1ted in a small but sustained fall in MMR vaccine coverage in the United Kingdom.

Evaluation of immunization programmes

Evaluation of an immunization programme may include the measurement of vaccine coverage, surveillance of disease incidence, assessment of prevalence of immunity, and the monitoring of adverse events.

Vaccine coverage

Timely measurement is important for monitoring trends in vaccine coverage and to identify pockets of low coverage. Low coverage may be apparent before any increase in disease incidence is observed. Since the late 1970s, three outbreaks of poliomyelitis have been observed amongst groups with religious objection to immunization in The Netherlands. Despite national coverage of 96 per cent for MMR vaccine, the same group has recently been the focus of a large epidemic of measles. Between April and December 1999, 1750 cases of measles occurred in The Netherlands compared with only nine in the whole of 1998.

Disease surveillance

Once an immunization programme has been implemented, disease incidence data can be used to monitor the effectiveness of that strategy. For example, the dramatic decline in the incidence of invasive *Haemophilus influenzae* infection described in both The Netherlands and the United Kingdom can be used to demonstrate the impact of conjugate vaccination. The age distribution of infection may change as children above or below the target age will form an increasing proportion of those infected. Various epidemiological methods, including case–control studies, cohort studies, and the screening method, can be used to estimate the efficacy of the vaccine in the field.

Seroprevalence studies

Seroprevalence studies are used to assess population immunity to infection. Such immunity results either from immunization or from natural infection. This can detect groups including a high proportion of susceptible individuals who may be the focus of future outbreaks. In 1991, seroprevalence studies in the United Kingdom identified that a large proportion of school-age children was susceptible to measles and therefore that an epidemic of measles was likely. A large campaign was mounted to immunize children from 5 to 16 years of age in November 1994. The number of cases of measles fell rapidly and remained at low levels over the next 5 years.

Adverse events

Monitoring of adverse events is important in maintaining public confidence in an immunization programme and for detecting rare events that could not be identified before licensing the vaccine. The detection of such events may lead to the withdrawal of certain vaccines. In August 1998, rotavirus vaccine was licensed for use in the United States and recommended for mass immunization of infants. During prelicensing studies, five cases of intussusception had been reported in around 10 000 recipients, compared with only 1 in almost 5000 controls; this difference was not statistically significant. During postlicensing surveillance, however, 15 cases were reported to the Vaccine Adverse Event Reporting System. On 22 October 1999, a review of scientific data concluded that there was an increased frequency of intussusception in the 1 to 2 weeks after vaccination which led to withdrawal of the vaccine in the United States.

7.8 Travel and expedition medicine

C. P. Conlon and D. A. Warrell

United Kingdom citizens make 56 million visits abroad each year, 8 per cent of these to developing countries which carry a higher risk of illness (600-fold risk in Mexico, 1835-fold in the Indian subcontinent) than travel to continental Europe (for example, to France).

Pretravel advice

This can be obtained from medical practitioners interested in travel medicine, embassies of the countries to be visited, travel agencies, organizations, specialist travel clinics, and the internet (see below). Members of immigrant communities in Western countries, especially from the Indian subcontinent and West Africa, are vulnerable to endemic diseases, including malaria and typhoid, when they return on holiday to their country of origin, perhaps to visit their families. This group of travellers is less likely to receive good pretravel advice and perhaps less willing to seek or accept it. A certificate of vaccination against yellow fever may be needed for entry to some countries. Details of other immunizations, allergies, blood group, and regular medications should also be carried by the traveller. Adequate insurance is essential. The geographical area to be visited, the age and health of the traveller, and any special risks of the journey (for example, mountain climbing) are taken into account. In remote areas or those with inadequate health facilities the travel insurance policy must cover repatriation.

General advice about health

The basic first-aid kit should include: a topical antiseptic solution; bandages; plasters; proprietary drugs for pain relief, diarrhoea, dyspepsia, allergy, and itch; sunscreen preparations; water purification tablets; and insect repellents.

For motion sickness, antiemetic drugs such as cyclizine are effective, but they may cause sedation and a dry mouth. Long-acting transdermal skin patches containing scopolamine are preferable. Long-haul air flights lead to jet lag: sleep disturbance, fatigue, a feeling of light-headedness and unreality, and poor concentration. These symptoms may be attributable to a 'hangover' if excessive alcohol has been drunk on the flight! A short-acting benzodiazepine, such as temazepam, taken for the first couple of nights after flying, helps to re-establish a regular sleeping pattern. Some travellers have found that melatonin is helpful (Chapter 12.13), but a recent trial demonstrated no efficacy for this product. People with diabetes may need advice on adjusting their insulin regimen or diet for changes in time zones.

Climatic and environmental extremes

At high altitudes, snow blindness and severe sunburn can occur under clear skies even at very low ambient temperatures. Those going to high altitudes should acclimatize slowly and build up their level of physical activity gradually (see Chapter 8.5.4). They should be aware of the symptoms and signs of altitude sickness. Acetazolamide ('Diamox'), in an adult dose of 250 mg twice a day, starting 12 h before starting the ascent, is effective prophylaxis for mild mountain sickness, especially if the traveller has to ascend rapidly (e.g. flying from sea level to more than 3000 m). But gradual ascent, allowing acclimatization is preferable and, if severe symptoms develop, there is no substitute for rapid descent. In the tropics, heat, dehydration, and salt depletion may cause problems. Several days of relative inactivity are needed to acclimatize safely to hot climates.

Strict food and water hygiene are important in countries with relatively poor sanitation. 'Boil it, peel it, or forget it'; is a useful adage for the traveller. Water purification tablets and many types of portable water filters are available. Beverages made with boiled water are generally safe, whereas bottled water and, particularly, ice cubes are unreliable. Treated water should be used even for tooth cleaning.

In many developing countries, blood-borne pathogens, such as hepatitis B and C viruses, human immunodeficiency virus (**HIV**), human T-cell leukaemia/lymphoma virus type 1 (HTLV-1), and, in some areas, malaria, trypanosomiasis, and other infections are prevalent. Screening of donated blood may not be rigorous and needles are commonly reused, sometimes without adequate sterilization. As a result, travellers have been advised to take 'AIDS kits', usually containing needles, cannulas, intravenous giving sets, syringes, and artificial plasma expanders. These are too bulky and expensive for most travellers, but it is worth taking a few 21-gauge needles and 10-ml syringes in case blood must be taken for a laboratory test or an injectable drug is needed. A covering letter from a doctor may allay the suspicion of customs officials that they are to be used for drug abuse.

Travellers seem to become unusually disinhibited and foolish and are particularly likely to engage in promiscuous unprotected sexual activity, especially if they are taking alcohol or other recreational drugs. Since sexually transmitted diseases, including HIV, are highly prevalent in many holiday resorts (not only in prostitutes), good-quality condoms, often not available when travelling, should be carried and used.

Patients with chronic illnesses, such as diabetes or asthma, should take plenty of their current medications as these may not be available abroad. It is a good idea to carry separate supplies in case of luggage loss or theft.

Immunizations

The record of routine childhood immunizations should be reviewed. Many adults will require booster doses for tetanus, polio, and diphtheria.

Yellow fever is only endemic in tropical Africa and South America, not in Asia. Recently, a Belgian tourist acquired fatal yellow fever in The Gambia, emphasizing the continuing importance of this immunization. Cholera vaccine is no longer recommended by the World Health Organization as its adverse effects outweigh its usefulness, but a new oral vaccine is promising. Other immunizations may be recommended after considering the travel itinerary and risk of exposure (Table 1).

The risk of hepatitis A in developing countries ranges from 300 to 2000/100 000 unprotected travellers per month of stay. Active immunization is safe, effective, and durable (see Chapter 7.10.19).

In the 'meningitis belt' of sub-Sahelian Africa, from Senegal east to the Sudan, and in some other areas, dry season meningococcal meningitis outbreaks are so common that immunization is recommended.

Pre-exposure rabies vaccination is being used increasingly. Although the risk of transmission is fairly low, the lack of effective treatment for rabies encephalitis and the fear engendered by a dog bite justifies considering immunization.

Plague vaccine is effective but may give rise to serious side-effects. An alternative in endemic areas is prophylactic or postexposure doxycycline treatment (see Chapter 7.11.16). Anthrax is endemic in many tropical countries, but, despite anxieties raised by its use for bioterrorism in the United States, vaccination or chemoprophylaxis are unnecessary. Japanese (B) encephalitis vaccine is safe and there is a risk of infection in many parts of Asia (see Chapter 24.14.2). Hepatitis B is a risk for medical staff, whose work involves contact with human blood and to those receiving unscreened blood transfusions in some developing countries (see

Chapter 7.10.19). It is also a risk of unprotected sexual activity.

Prevention of malaria

Both travellers and non-specialist physicians must be educated about the prevention and recognition of malaria (see Chapter 7.14.2).

Travellers' diarrhoea (Table 2)

This is the most common health problem of travellers. Symptoms are usually mild, lasting only about 3 to 5 days, but holiday and business plans may be disrupted. The most common cause is enterotoxigenic *Escherichia coli* (**ETEC**). *Salmonella* spp., *Campylobacter* spp., *Shigella* spp., and other pathogenic *E. coli* are also common. Protozoan pathogens, such as *Giardia lamblia, Entamoeba histolytica*, *Cryptosporidium parvum*, and viruses are less common causes. Fish and shellfish poisoning cause similar symptoms starting within minutes or hours of exposure.

Strict food and water hygiene reduces the risk of gastroenteritis. Heating water to 100 °C will kill most pathogens, as will chemical treatment with chlorine or iodine (iodine is contraindicated in pregnant women and some patients with thyroid disease). Water filters are useful additions. Antimicrobials such as co-trimoxazole, doxycycline, and the 4-fluoroquinolones are protective to some extent but are not cheap, may cause side-effects, cannot be taken for prolonged periods, and may encourage antimicrobial resistance. Colloidal bismuth salts are cheaper, safer, and reasonably effective, but the large volumes are inconvenient. An effective vaccine against ETEC may soon be available.

Treatment is by maintaining an adequate fluid intake and using sachets of oral rehydration salts that can be made up with boiled water. Eating solid food may stimulate bowel action by the gastrocolic reflex. Antidiarrhoeal agents, such as codeine phosphate, imodium, or loperamide, often relieve symptoms sufficiently for normal activities to be continued. Short courses of empirical antimicrobials, for example ciprofloxacin (500 mg for 3 days, adults only), can be useful, particularly for patients with underlying diseases. Localized abdominal pain or bloody diarrhoea are indications for seeking medical help immediately.

Immunocompromised travellers

Except for asplenic patients, immunocompromised travellers—including those who have received radiotherapy for lymphomas—should not be given live vaccines such as yellow fever, oral polio, and oral typhoid. Killed or synthetic vaccines are safe. Those patients with mild to moderate immune suppression, including those with early HIV infection, will probably make a reasonable response to immunization; those with more severe immunosuppression may still make a useful, though less durable, response. Influenza, pneumococcal, and *Haemophilus influenzae* b (**Hib**) conjugate vaccines are recommended, as the risk of respiratory infection and bacteraemia is increased. Gammaglobulin is the preferred prophylaxis against hepatitis A in these patients, as the response to hepatitis A vaccine may be unreliable. Asplenic individuals should be on prophylactic antibiotics, such as amoxicillin, particularly if travelling, and should be dissuaded from travelling to areas with high rates of malaria transmission.

Immunocompromised patients should carry antimicrobials with them for treating respiratory or gastrointestinal infections, should seek medical help when abroad, and should carry a letter from their physician outlining their condition and medication.

Pregnant travellers

Commercial airlines will not normally convey a woman who is 36 weeks or more pregnant without a covering letter from her physician. Insurance to cover the costs of delivery abroad should be considered.

The risk–benefit assessment of immunizations and chemoprophylaxis is of particular importance for the pregnant woman and the fetus. Live vaccines should be avoided, but if there is a genuine risk of yellow fever the vaccine should be given as there is no recognized associated teratogenicity. Inactivated polio vaccine may be given parenterally and tetanus immunization is safe. Heat-killed typhoid vaccine is best avoided as it might cause a febrile reaction, stimulating premature labour. However, the modern polysaccharide capsular Vi vaccine should be safe. Pneumococcal, meningococcal, and hepatitis B vaccines are safe in pregnancy, as is gammaglobulin.

Malaria is specially dangerous in pregnant women (see Chapter 7.14.2). Chloroquine and proguanil are safe chemoprophylactic drugs, and quinine, in normal therapeutic doses, is safe for treatment. Mefloquine is best avoided in pregnancy. Pregnant women should take special care with food and drink when abroad, as dehydration may threaten the fetus. There are concerns about congenital goitre when pregnant women use iodine to purify water—the maximum recommended daily intake is 175 µg. Loperamide as an antidiarrhoeal agent is safe, but antimicrobials such as tetracyclines and quinolones should be avoided.

Extremes of age

Young children should have completed their routine immunizations before travelling. Malaria chemoprophylaxis is recommended for all ages. Yellow fever vaccine should only be given to children older than 9 months as a few cases of vaccine-associated encephalitis have occurred in younger children. Most other vaccines, including rabies, are safe. Hepatitis A is rarely symptomatic in children under 5-years old. Families planning to live in developing countries should be offered BCG vaccination for their children to reduce the risk of tuberculous meningitis.

The elderly should have the same immunizations as younger adults and should take antimalarial drugs. They are more prone to respiratory infection and should, therefore, be given influenza, pneumococcal, and *Haemophilus influenzae* vaccines. Jet lag and changes in time zones may be very disturbing. Older people are more likely to have an underlying medical condition requiring medication. It is important that sufficient supplies of medicines are taken abroad and that the patient has a detailed list of these medicines and their dosages, in case the tablets are lost or stolen, and the name and contact address of their physician at home in case of emergency.

Explorers and expeditions

Because of their adventurous aims, expeditions are likely to involve exposure to greater environmental extremes and hazards than ordinary travel. Expeditions usually take place in areas remote even from rural health centres, and so a greater responsibility for dealing with medical problems will devolve on the expedition members. The explorer's greatest fear may be to fall victim to a lethal tropical disease or an attack by a wild animal, but the reality is more mundane: road traffic accidents, mountaineering disasters, drowning, and attacks by humans. Prevention and treatment of medical problems must be planned well in advance. Detailed advice and information can be obtained from a number of organizations, such as the Expedition Advisory Centre of the Royal Geographical Society in London (Tel: 0207–581–2057; Fax: 0208–584–4447), from clubs specializing in mountaineering, cave exploring, diving, and other activities, and from books, journals, and websites. All expeditions should have a designated medical officer and all their members should receive first-aid training, aimed ideally at the particular needs of the expedition. The basics are clearing the airway, controlling bleeding, treating shock, relieving pain, and moving the injured person without causing further damage. Expedition medical kits should be more comprehensive than those carried by ordinary tourists and travellers. Lists of essential drugs are given in Anderson and Warrell (2002). Scissors, and a generous supply of large triangular and crêpe bandages, adhesive plasters, and an 'AIDS kit', to reduce the risk of infection from dirty needles and intravenous fluids are important. Lightweight emergency insulation must be taken if there is any risk of exposure in severe weather conditions, a lightweight collapsible stretcher for mountaineering, and an adequate water supply must be assured or taken if the expedition is into desert areas. A covering letter on official notepaper, signed by a doctor, may be helpful in getting drugs, even apparently innocuous ones such as codeine, through Customs (for example, the Russian Federation) and explaining the need for needles and syringes. The medical facilities nearest to the site of the expedition must be identified and contacted in advance. An emergency plan must be drawn up for the first-aid treatment and evacuation of severely ill or injured expedition members. In some areas, 'Flying doctor' and air evacuation services (such as AMREF in East Africa) are available. Medical insurance must be generous and comprehensive, to include repatriation of the injured. Before leaving their home country, expedition members should have a thorough dental check and treatment for outstanding medical or surgical problems. Control of chronic medical problems such as diabetes mellitus, hypertension, and asthma should be stabilized. In selecting members for an expedition, the most important attributes are experience, possession of the necessary skills (for example, diving and mountaineering), physical fitness, and proven psychological stability under stress. It is advisable always to appoint a reliable local agent in the country where the expedition will take place.

Illness in returning travellers

Details are needed about the countries visited, activities while travelling, immunizations, and antimalarials taken. Common problems are fever, rash, diarrhoea, and eosinophilia (Table 3, Table 4, and Table 5).

In travellers with acute diarrhoea, a dietary history, assessment of hydration state, stool microscopy and culture, abdominal films, and sigmoidoscopy may be needed. There are many possible causes (see Table 2). Patients with chronic diarrhoea may be infected with *Giardia* spp., *Cryptosporidium* spp., *Entamoeba histolytica*, shigellae, or salmonellae. Investigations should include a search for *Clostridium difficile* and its toxin, especially if the patient took antimicrobials while abroad. A minority of patients may develop a postinfective enteropathy, the most common problem being a secondary lactose intolerance. Rarely, bacterial overgrowth or tropical sprue develop.

The commonest causes of eosinophilia are allergy and helminths (see Table 5).

7.9 Nosocomial infections

I. C. J. W. Bowler

Definitions

Hospital-acquired or nosocomial (Greek voso_oμeiov, hospital) infections are distinct from community-acquired infections. They may affect patients and hospital staff. A useful epidemiological tool for the study of these infections is to define them as any infection manifesting more than 48 h after admission. However, some nosocomial infections may not be so easily identified as hospital acquired; for example hospital-acquired hepatitis B infection may not become clinically apparent until months after the patient has been discharged because of the prolonged incubation period. **Iatrogenic infections** are acquired as the direct consequence of a therapeutic intervention (e.g. insertion of a urinary catheter). **Opportunistic infections** are caused by organisms that do not ordinarily harm healthy people; they occur in people with impaired defences. **Endogenous (autogenous) infections** are produced by the patient's normal flora, while **exogenous infections** result from transmission of organisms to the patient from elsewhere. Although in practice it may not always be possible to distinguish endogenous from exogenous infections, this differentiation must be attempted because of important implications for control. Rapid changes in health-care provision in hospitals mean the frequency and nature of nosocomial infection are also changing. The increasing trend to early discharge, particularly for surgical patients, can lead to an under assessment of the burden of nosocomial infection. New interventions provide new opportunities for infection. For instance flexible endoscopes, which have revolutionized the investigation and management of a wide variety of diseases, can transmit Hepatitis B between patients if they are not decontaminated.

Nosocomial infections are preventable. Systematic surveillance to assess the size of the problem and an organized programme aimed at preventing or minimizing the impact of nosocomial infection should be an important part of the hospital's quality assurance system. Hospital managers must ensure appropriate staffing and resources. The programme involves surveillance, feedback of data on infections to staff, plans for outbreak management, and agreed policies for antibiotic prophylaxis, the management of patients with infections, and for carrying out procedures likely to increase the risk of infection. Staff should be educated, through an organized teaching programme, and results should be systematically audited.

Scale and costs of nosocomial infections

The World Health Organization (WHO) recognizes the serious global problem of nosocomial infections. Epidemic nosocomial infections frequently receive greater attention because of the alarm caused by the obvious spread of an infectious disease. A common point source or person-to-person spread are usually involved. Immediate application of control measures to prevent transmission often curtails such outbreaks. However, only about 3 per cent of nosocomial infections are accounted for by epidemic infection. Prevention of the other 97 per cent of (endemic) nosocomial infections requires a systematic approach based on careful surveillance. Host susceptibility, the infectious risk of medical procedures, and the type of hospital environment (e.g. intensive care units) are responsible. The risk of endemic nosocomial infections is reduced, for example, by using prophylactic antibiotics for contaminated surgical procedures.

Rates of nosocomial infections between 5.7 and 8 infections per 100 admissions have been reported. The urinary tract, surgical wounds, and the lower respiratory tract are the most common sites, in that order (Table 1). In the United States, it is estimated that, of 200 000 deaths in patients with nosocomial infections, 20 000 were directly attributable to the infection. In a further 60 000, it contributed to death. Costs were estimated at $4.5 billion in the USA in 1992 and approximately £120 million in England and Wales in 1987, based on an average additional stay of 4 days for each hospital-acquired infection. These are likely to be underestimates. The WHO published comparative world-wide costs in 1984 based on an extra 5 days of admission per infection and a minimum cost of a hospital stay, per day, of $45.00 (Table 2). For developed countries, this hospital stay cost is too low.

Host factors

The principal risk factor is the severity of the underlying disease (e.g. neutropenia, organ system failure). In multivariate analysis, the number of medical diagnoses on admission, especially diabetes, renal failure, or alcohol abuse, are most strongly associated with risk. Treatment itself may lower host defences, for example surgical incisions, bladder catheterization, mechanical ventilation, and neutropenia following cancer chemotherapy. Pathogens are able to form biofilms on the increasingly used prosthetic devices (totally implantable, e.g. hip replacement, or transcutaneous, e.g. intravascular devices) subverting normal host clearance mechanisms.

Patients with similar clinical problems, who are likely to share similar risk factors for infection, tend to be nursed together for convenience but the introduction of a micro-organism into such a group can infect a number of patients. A good example is the rapid spread of small round structured virus gastroenteritis in geriatric wards. A poorly maintained hospital environment is a threat to vulnerable patients; an example is outbreaks of legionellosis in units caring for patients with solid organ transplants, resulting from defective ventilation and hot water systems.

Micro-organisms

Bacteria (*Escherichia coli, Staphylococcus aureus, Enterococcus* spp., *Pseudomonas* spp., and coagulase-negative staphylococci, in decreasing order of frequency) are the most important. Viruses, fungi, and protozoa play a minor part.

Whether endogenous or exogenous, the organisms causing nosocomial infection are usually part of a patient's colonizing flora. It may be difficult to distinguish infecting from colonizing organisms using bacteriological tests alone. They are frequently multidrug resistant. Empirical antibiotic therapy must accommodate the shift towards more resistant colonizing flora occurring in hospitals, particularly in burns and intensive care units. For example *Pseudomonas aeruginosa*, methicillin-resistant *Staph. aureus* (MRSA), and enterococci exhibit multiresistance to antimicrobials, making them difficult and expensive to treat.

Principles of hospital infection control

The main goal of hospital infection control is to prevent nosocomial infection. First, hospital-acquired infections must be identified as endemic or epidemic by clinical and epidemiological investigations. The identification and typing of isolates causing nosocomial infection allows recognition of organisms that are epidemiologically linked. Invasive multiresistant organisms, such as MRSA, often require infection control measures to prevent their spread, and so minimize the use of expensive, sometimes toxic, antibiotics required for their prophylaxis and treatment.

Epidemic outbreaks are usually amenable to measures that interrupt the spread of infection, such as use of gowns and gloves and careful hand washing by those attending patients. Transfer of colonized or infected patients to a single room or an isolation ward is a physical means of preventing spread. Patients infected with the same organism can be grouped together and attended to by a cohort of nurses not involved with uninfected patients. Identification of additional carriers and elimination of colonization may be necessary for some epidemic outbreaks. Controlled trials demonstrating the efficacy of such measures have not been made, but

many observational studies support their use.

Endemic nosocomial infections are less straightforward to control. The size of the problem may not be apparent because attack rates in individual units may be low or because some infection is seen as a normal consequence of certain interventions. It is important that information about endemic infections is collected systematically, analysed, disseminated, and discussed so that preventive strategies can be improved. Control measures are applied to selected patients according to risk; for example correctly timed antimicrobial prophylaxis and meticulous sterile technique in prosthetic joint replacement surgery.

Site of nosocomial infections

Urinary tract

A bacterial count of 10^5 organisms or more per ml in cultured urine indicates infection. However, counts as low as 10^2 organisms/ml are included by some. Urinary-tract infection accounts for 30 to 40 per cent of all nosocomial infections. Most patients remain asymptomatic, but 20 to 30 per cent develop the symptoms of urinary-tract infection, about 1 in 100 of whom develop bacteraemia. Causes of nosocomial urinary-tract infections are listed in Table 3.

Indwelling urinary catheters account for 80 per cent of nosocomial urinary-tract infections; 50 per cent of patients catheterized for longer than 7 to 10 days develop bacteriuria. Most of the others result from instrumentation of the urinary tract. The main source of organisms is the periurethral flora. Bacteria gain access to the bladder, usually by spreading up the outside of the lumen of the catheter. Occasionally, infection is acquired exogenously during an epidemic of nosocomial infection. Most symptomatic or bacteraemic infections occur within 24 h of the organisms gaining access to the bladder. Early recognition, by daily urine culture, of a urinary-tract infection before it becomes symptomatic is not helpful.

Treatment is with broad-spectrum antimicrobials administered empirically after obtaining appropriate cultures and later adjusted after receiving results of bacteriological studies. Asymptomatic patients need not be treated.

Since the important risk factor is the duration of catheterization, prevention is by avoiding catheterization or reducing the period of catheterization. Catheters should be inserted aseptically, and closed sterile drainage systems, uninterrupted gravity drainage, or intermittent or suprapubic catheterization employed. Prophylactic antimicrobial treatment is not useful.

Surgical wound infection

One acceptable definition requires the presence of a purulent discharge in, or exuding from, a wound. *Staph. aureus* (15–33 per cent of all wound infections) and *E. coli* (12–19 per cent) are leading causes. Many other aerobic and anaerobic bacterial may be implicated.

The main risk factor is the degree of wound contamination at operation. Operations may be 'clean' (e.g. herniorrhaphy), 'clean contamination' (e.g. appendicectomy which requires incision of bowel), or 'contaminated' (e.g. gross spillage from the gastrointestinal tract during surgery). *Staph. aureus* causes most infections complicating clean surgery. 'Contaminated' surgery is associated with polymicrobial infections, especially with *E. coli* and mixed anaerobes. Other risk factors include the length of the operation, obesity, a remote infection, and underlying disease. Most wound infections follow direct inoculation of organisms into the wound at surgery or spread of bacteria to open wounds such as burns.

Wound infections present with local symptoms and signs (pain, erythema, pus, dehiscence) with general features of infection such as fever. Appropriate cultures, including blood cultures, are taken, pus is drained, and broad-spectrum antimicrobials are given empirically, directed at the likely flora but later adjusted according to bacteriological results. Prevention is by meticulous aseptic surgical technique. Prophylactic antimicrobials, given no more than 2 h before the surgical incision, are indicated for clean-contaminated and contaminated procedures, and in clean surgery when a prosthesis is inserted (e.g. vascular grafting).

Nosocomial pneumonia

Pneumonia is defined clinically by production of purulent sputum, chest signs, a fall in arterial PO_2 and the appearance of new infiltrates on the chest radiograph not ascribable to pulmonary emboli, collapse, or pulmonary oedema. Between 0.55 and 1.5 per cent of patients admitted to hospital develop lower respiratory-tract infections. Crude case fatalities of between 20 and 30 per cent are quoted but death may be due to underlying disease. Intubated and ventilated patients have the highest risk of acquiring pneumonia. Bacteria colonizing the gastrointestinal and upper respiratory tracts are probably aspirated. This flora is often acquired after admission to hospital. Organisms cultured from bronchoscopic samples are listed in Table 4.

Culture of expectorated sputum or tracheal aspirate is poorly predictive of the bacterial cause of nosocomial pneumonia, which is best determined by quantitative culture of specimens obtained by sampling the terminal airways (e.g. by bronchoalveolar lavage). Initially, broad-spectrum antimicrobials appropriate for likely infecting flora should be given empirically. Once the susceptibility of the causative pathogen has been determined, specific antimicrobial treatment can be instituted. Selective decontamination of the digestive tract has reduced occurrence of nosocomial pneumonia but there has been no reduction in the mortality of ventilated patients. Epidemic nosocomial pneumonia usually results from bacterial contamination of respiratory equipment such as nebulizers, ventilators, or bronchoscopes and can be prevented by cleaning and disinfection of the equipment and hand washing after patient contact.

Intravascular device-associated infections

The most important result of intravascular device-associated infection is bacteraemia, varying in incidence from about 0.04 per cent for subcutaneous central venous ports, to about 0.2 per cent for peripheral intravenous cannulae, and approximately 10 per cent for central venous haemodialysis catheters.

Duration of intravascular cannulation is the greatest risk factor. Bacteria usually gain access to the blood by direct spread from the skin surface along the subcutaneous catheter tunnel to its tip in the blood vessel. Bacteraemia from intraluminal bacteria results from contamination of connecting devices. This is particularly important in catheters with subcutaneous cuffs, such as Hickman catheters, where the periluminal route of infection is less likely. The leading organisms causing intravenous device-related sepsis are *Staph. aureus, Pseudomonas* spp., and *Candida* spp. In patients with haematological malignancies, coagulase-negative staphylococci and enterococci are also frequently implicated.

Line-related sepsis presents with local inflammation or signs of thrombophlebitis but usually with features of bacteraemia. Blood cultures are obtained, the affected catheter is removed and cultured, and empirical antimicrobials are given. Sometimes, long-term intravenous catheters, such as Hickmen lines, can be 'sterilized' by giving parenteral antibiotics down the line. Exit site infections involving these devices can usually be treated with antibiotics with the line *in situ*. Tunnel infections usually require line removal for resolution. Prevention is by using aseptic technique when inserting catheters, maintaining a high standard of line care, and removing catheters as soon as possible. The insertion site should be disinfected with a reliable disinfectant such as an iodine-containing agent, 70 per cent alcohol, or 2 to 4 per cent chlorhexidine. At the time of insertion the operators should wash their hands and for long-line insertion, wear sterile gloves, gown, face mask, and hat. Removal of peripheral intravascular devices should be considered after 3 days. Central venous catheters are usually only removed if blocked or suspected as a source of sepsis. The skin at the exit site should be checked daily and the device removed if sepsis is suspected. Subcutaneous tunnelling, insertion of a subcutaneous cuff (Hickman line), burying them subcutaneously (e.g. portacaths), and incorporating antimicrobials on to the surface of the device can all reduce the infection rate significantly. Replacing the entire intravenous delivery set every 72 h is sufficient to reduce sepsis secondary to intraluminal contamination of 'giving' sets.

Prosthetic device-related infection

Infections of prosthetic devices such as heart valves, vascular grafts, cerebrospinal fluid shunts, artificial lenses, and joints are usually caused by the normal skin flora, for example coagulase-negative staphylococci. The devices become coated with a layer of host-derived macromolecules such as fibronectin and fibrin which have specific adhesion receptors for bacteria, particularly staphylococci. Once attached, these organisms multiply on the surface of the coated prosthesis forming a biofilm in a state physiologically different from rapidly dividing, 'free' micro-organisms. They are inherently more resistant to antimicrobials, which explains the frequent failure of antimicrobial treatment. Bacteria gain access to prosthetic devices by direct inoculation, usually at surgery, or by settling on a prosthesis after bacteraemic spread. Direct inoculation at surgery is responsible for prosthetic-device infections occurring more than 1 year after insertion since the organisms involved are usually

skin commensals of low virulence. Except for organisms that are exquisitely susceptible to antimicrobials, these infections are seldom cured with antimicrobial agents. Surgical removal of the device is frequently necessary. However, infection of artificial lenses in the eye are frequently cured by antimicrobial treatment.

Prevention is by avoiding contamination of the wound at surgery, by using strict aseptic surgical technique. Sometimes, as when inserting prosthetic joints, there is an advantage in providing operating theatres with ultra-clean air. Prophylactic antimicrobials reduce the risk of some prosthetic devices becoming infected during insertion.

Antibiotic-associated diarrhoea

Up to 30 per cent of patients treated with antibiotics will develop diarrhoea as a result of the disturbance of the complex gut flora. In a few, loss of 'colonization resistance' predisposes to acquisition of *Clostridium difficile*. Faecal/oral colonization by this organism is usually harmless, but in about a third, particularly the elderly, the organism may overgrow, produce a cytotoxin and causing colitis. The clinical picture varies from mild diarrhoea with fever to fulminating toxic megacolon requiring colectomy. *Clostridium difficile* related diarrhoea entails a delay in discharge of about 3 weeks. Since attack rates in the elderly are around 5 per cent, the disease can have a major impact on hospital resources. Diagnosis is by detection of the cytotoxin in stool, but the test has poor disease specificity since toxin may be found for many weeks after full recovery. Patient management includes adequate rehydration, avoiding drugs which inhibit gut motility, and stopping the provoking antibiotics. More severe cases will require metronidazole or vancomycin given by mouth and surgical review. Prevention is by restricting the use of antibiotics according to agreed and audited protocols. Hand washing after patient contact, isolation of patients with diarrhoea, and cleaning the ward environment are employed on microbiological grounds, despite a lack of prospective studies showing their efficacy.

Nosocomial bacteraemia

Bacteraemia may occur secondarily to the infections mentioned above. The incidence is approximately 3/1000 hospital discharges. The case fatality is about 40 per cent, but varies with the severity of the underlying disease, being as low as about 2 per cent in obstetric patients. The focus must be identified and, if possible, removed surgically. Appropriate antimicrobials are given after obtaining blood and other relevant cultures.

Other nosocomial infections

These include viral infections such as varicella-zoster, hepatitis C, hepatitis B, Norwalk, and rotaviruses, bacterial infections such as tuberculosis and legionellosis, and fungal infections such as aspergillosis.

7.10.1 Respiratory tract viruses

Malik Peiris

Introduction

Infections of the respiratory tract are one of the most common afflictions of mankind. In economically developed countries, acute respiratory infections account for 20 per cent of all medical consultations, 30 per cent of work absences, and 75 per cent of antibiotic prescriptions. Viruses account for the majority of acute respiratory infections, although when they occur, bacterial infections tend to be more severe. Longitudinal family studies suggest that an individual has on average 2.4 respiratory viral infections per year, a quarter of them leading to a medical consultation. With the exception of influenza, these infections are not a major cause of mortality in the developed world, but it is estimated that they contribute to 20–30 per cent of the 4.5 million deaths annually associated with acute respiratory infection in the developing world.

The term 'respiratory virus' is imprecise, but for the purpose of this discussion it will include those that have the respiratory tract as their primary target. Taxonomically, they belong to diverse virus families (Table 1) and are global in distribution. Other viruses cause systemic disease with respiratory tract involvement as part of an overall disseminated disease process in immunocompetent (e.g. measles, Hantavirus pulmonary syndrome) or immunocompromised (e.g. cytomegalovirus) patients. These are dealt with elsewhere.

A respiratory virus may cause a range of clinical syndromes. Conversely, a respiratory syndrome may be caused by more than one virus. The major viral respiratory syndromes and their common aetiological agents are shown in Table 2. The pattern seen in tropical countries is similar, a notable difference being the role of measles as a major cause of lower respiratory tract infections and fatality.

The anatomical demarcation between upper and lower respiratory tract infections is the larynx. Influenza and adenoviruses are well-recognized lower respiratory tract pathogens in adults as well as in children. Respiratory syncytial virus and parainfluenza viruses, hitherto diseases associated mainly with children, are now being increasingly recognized as important lower respiratory tract pathogens in adults and the elderly.

Transmission

The routes of respiratory virus transmission are through direct contact, contaminated fomites, and large airborne droplets (mean diameter >5 μm, range of transmission <1 m). Influenza may be spread over longer distances by small particle aerosol (mean diameter <5 μm), but even here, direct contact, fomites, and large droplets are more important. Adenoviruses are transmitted by the faeco-oral route as well as by direct contact and large droplets.

Factors increasing transmission of respiratory viruses include the time of exposure, close contact (e.g. spouse, mother), crowding, family size, and lack of pre-existing immunity (including lack of breast-feeding). School-age children often introduce an infection into the family and the commencement of school term may affect transmission patterns in the community. Infected children shed higher titres of viruses than adults. The duration of virus excretion is shown in Table 1. Infectivity usually precedes the onset of clinical symptoms. Immunocompromised patients shed virus for a longer time.

Seasonality

Some respiratory viruses have a predictable seasonality, which varies regionally. For example in temperate regions, influenza A is a typically winter disease while in tropical regions it is a spring/summer disease (e.g. Hong Kong) or occurs all year round (e.g. Singapore, India). Similarly, respiratory syncytial virus (RSV), a primarily winter disease in temperate countries, is a summer disease in Hong Kong. Rhinoviruses occur year round (with increases in the spring and fall) in temperate climes while adenoviruses have no predictable seasonality. The basis for seasonality is unclear but climatic factors such as high humidity may help virus survival and transmission. Factors affecting population congregation such as commencement of school-term and seasonal effects on social behaviour may also play a role.

Laboratory diagnosis

A well-collected specimen is the first (and often most important) determinant in successful laboratory diagnosis. Nasopharyngeal aspirates (secretions aspirated from the back of the nose into a mucus trap) or nasopharyngeal washes are superior to nasopharyngeal or throat swabs for the isolation of many respiratory viruses. They offer the advantage that rapid ('same day') diagnosis for a number of viruses is possible provided the appropriate methods are available. Swabs for viral culture are

placed in viral transport medium immediately upon collection and kept cool (around 4°C) until processed. More invasive specimens such as endotracheal aspirates, brochoalveolar lavage or lung biopsy, when available, usually provide better information. However, the likely site of pathology must be kept in mind—the more invasive specimen is not always better.

The laboratory methods used for detecting a virus in the clinical specimen/s are viral culture, antigen detection, and, more recently, nucleic acid detection. Serology is an option for diagnosing some respiratory virus diseases, but is impractical for others such as rhinoviruses where the large number of antigenically distinct serotypes have no common immunodominant antigen/s. On the other hand, adenoviruses (or influenza viruses), though having many antigenic types or variants, have common antigen/s and a single antigen can detect serological responses to many of them. IgM assays are not routinely available for diagnosis of respiratory viral diseases and paired sera are required so that significant increases in antibody titres can be documented. Complement fixation tests are widely used for this purpose though their sensitivity is not ideal. Haemagglutination inhibition tests are more sensitive for diagnosis of influenza and ELISA tests (though still only available in research settings) provide better sensitivity for diagnosis of RSV and parainfluenza infections.

'Near patient testing' is becoming a reality for some viruses (e.g. influenza) with availability of tests that can be performed in a general practice setting. These become more relevant with the greater availability of antiviral drugs.

Rhinoviruses

Rhinoviruses are adapted to replicate at temperatures of 33–35°C, as found in the external airways. There are over 115 distinct serotypes, but only a few will circulate in a region at any given time. Most rhinoviruses use ICAM-1 on the cell surface as the receptor for attachment but a minority of rhinoviruses use other receptors.

Epidemiology

Rhinoviruses remain one of the most common infections of humans, with 0.5 infections per person per year being a conservative estimate. Secondary attack rates in a family setting may be around 50 per cent overall and 70 per cent in those who are antibody negative.

Immunity

In experimental challenges, immunity is serotype specific, and homologous type specific protection lasts for at least 1 year and correlates with serum IgA, IgG, and secretory IgA antibody levels.

Pathogenesis

Viral replication occurs predominantly in the ciliated epithelial cells of the nasopharynx. The structure of the epithelium is preserved. Mucosal secretions associated with coryza appear to be due to the release of inflammatory mediators and neurogenic reflexes.

It was thought that the preference of the virus for a lower temperature for replication restricted it to the upper respiratory tract, however, this is not strictly true. The temperature of the mucosa of the trachea and bronchi is also lower than core body temperature and does not preclude rhinovirus replication. The virus has been isolated from the lower respiratory tract (including bronchial brushings) and viral RNA has been demonstrated by in situ hybridization in bronchial epithelial cells. Rarely, the virus has been isolated from post mortem lungs of immunocompromised patients.

Clinical manifestations

Rhinorrhoea, nasal obstruction, pharyngitis, and a cough are common features of rhinovirus infections. Fever and systemic symptoms are rare, but more common in the elderly in whom disease can be more severe. Rhinoviruses are a major cause of exacerbations of asthma and chronic obstructive respiratory disease. Lower respiratory tract symptoms are uncommon in the healthy young adult, but may occur in children (bronchiolitis), the immunocompromised, and the elderly.

Treatment and prevention

There are no established antiviral drugs for treatment. Topical interferon-a prevents symptoms if given before onset of disease, but cannot be used for prophylaxis over prolonged periods because of side effects. A viral capsid-binding agent (pleconaril) blocks viral attachment and uncoating and is undergoing clinical trials at present. Antibiotics are ineffective in preventing bacterial complications of the common cold. Mucopurulent discharges are part of the natural course of the common cold and are not an indication for antimicrobial treatment, unless it persists (e.g.>10 days). Given the large number of rhinovirus serotypes, vaccination is not an option.

Coronaviruses

There are two distinct serotypes of respiratory coronavirus—0C43 and 229E. They cannot be cultured from primary specimens and laboratory investigations rely on serology or molecular methods which are only available for research.

Epidemiology

Infection occurs in early childhood and 85 to 100 per cent of adults have antibody to both virus types.

Immunity

Volunteer reinfection studies show that 1 year after initial infection protection from reinfection and illness following a challenge from the homologous virus is incomplete.

Pathogenesis

In common with rhinoviruses, coronaviruses induce little or no damage to the respiratory mucosa. The mucosal discharge is caused by the release of mediators from affected host cells.

Clinical findings

Coronaviruses typically cause upper respiratory tract infections and the common cold. Involvement of the lower respiratory tract is probably more frequent than with rhinoviruses. The virus contributes to exacerbation of asthma in children and adults, but is less important in this role than rhinoviruses. Coronaviruses are also significant pathogens of the elderly.

Treatment and prevention

There are presently no options for antiviral treatment or prevention.

Adenoviruses

Adenovirus subgroups A to D cause respiratory, ocular, hepatic, genitourinary, or gastrointestinal system disease in immunocompetent or immunocompromised individuals. Only respiratory diseases are considered here.

Productive replication and excretion of infectious virus can occur for a prolonged period (see below). In addition, adenoviruses can establish chronic persistence or

'latency', the virological basis and clinical significance of which is poorly understood.

Epidemiology

Adenovirus infections are common during childhood (usually serotypes 1, 2, 5 in early childhood, 3 and 7 during school years or later), but continue to occur throughout life. Reinfection with the same serotype occurs but is usually asymptomatic. Serotypes 1,2,5, and 6 are typically endemic, types 4 and 7 more typically associated with outbreaks, and type 3 can occur in either situation.

Clinical features

Adenovirus respiratory illness often leads to upper respiratory tract disease with coryza and sore throat. Fever may last up to 2 weeks. The sore throat may be exudative and clinically difficult to differentiate from streptococcal infection. Adenoviral infection may present as pharyngoconjunctival fever. Otitis media is a complication in children. Unlike other respiratory viral infections, adenoviruses may be associated with elevated white blood cell counts (>15 × 10^{9}/l), C-reactive protein, or ESR and thus more easily confused with bacterial diseases.

Though uncommon, pneumonia may occur sporadically or in epidemics (caused by serotypes 4 and 7 for example), particularly in closed communities such as the military where stress and physical exertion may predispose to lower respiratory tract involvement. Community outbreaks of adenoviral pneumonia have been reported. Radiological appearance varies from diffuse to patchy interstitial infiltrates and pleural effusion may be present. Adenovirus type 7 pneumonia can lead to permanent lung damage, including bronchiectasis, bronchiolitis obliterans, and unilateral hyperlucent lung syndrome.

Adenoviral infection may disseminate and present as 'septic shock' in the newborn baby. Manifestations in the immunocompromised patient includes hepatitis (especially in liver transplant recipients), colitis, and haemorrhagic cystitis (in renal and bone marrow transplant recipients) in addition to pneumonia. The serotypes associated with disease in these patients may differ from those typically found in the immunocompetent patient, and include the subgroup B2 serotypes 11, 34, and 35. With improving control of other common viral diseases of the immunocompromised (e.g. cytomegalovirus), the role of adenoviruses infections is being increasingly appreciated.

Isolation of an adenovirus from a clinical specimen presents a challenge in interpretation. Adenoviruses are excreted for a prolonged period after initial infection, especially, but not exclusively, from faeces. In children, one-third of patients shed viruses longer than 1 month and 14 per cent longer than 1 year. The clinical significance of a positive result depends on the specimen, the method, and the serotype. Isolation of viruses from the respiratory tract carries greater significance than that from faeces. Patients who have symptomatic adenoviral diseases have higher viral loads than those with asymptomatic carriage. Thus, a rapidly growing virus, a positive antigen detection test (both reflecting higher virus load), or a detectable serological response all point to greater clinical significance. Antigen detection applies only to nasopharyngeal aspirates or bronchial washings.

The above guidelines may not apply to immunocompromised patients who may be infected with unusual serotypes. The presence of the virus in multiple body sites or in peripheral blood possibly points to clinical significance, although further data are needed.

Treatment and prevention

Most adenoviral infections in immunocompetent patients are self-limited and require no specific therapy, however, some infections, especially but not exclusively in the immunocompromised, are severe and life threatening. Ribavirin, vidarabine, cidofovir, and ganciclovir are active against adenoviruses *in vitro.* There are anecdotal reports of their therapeutic use with variable success. However, there are no clinical trials on which to base firm recommendations.

Live attenuated oral vaccines containing serotypes 4 and 7 (associated with outbreaks in military conscripts) are safe and effective, but not licensed for general use.

Respiratory syncytial virus (RSV)

Respiratory syncytial virus (RSV) infects human and non-human primates and was first isolated from a chimpanzee with a 'cold'. Related viruses affect cattle and sheep but do not directly affect humans. The virus has two surface glycoproteins on its envelope (G and F) and the immune responses to them correlate with protection. Two subgroups (A and B) are recognized on the basis of antigenic differences of the G glycoprotein.

Epidemiology

Over two-thirds of infants acquire RSV infection during the first year of life. Of patients hospitalized with RSV disease, 75 per cent are younger than 5 months. The peak of morbidity occurs around 2 months of age, a time when passive maternal antibodies protect against most other viral infections. Primary infection does not lead to solid immunity and reinfection is common. The first reinfection can still be associated with lower respiratory tract involvement. Subsequent reinfection occurs throughout life leading to asymptomatic or upper respiratory tract infections. However, significant diseases may result in the immunocompromised or elderly.

Immunity

Both antibody and cell mediated immunity are important in protection. Antibody to the G proteins prevents attachment of viruses to the cellular receptor, but immunity to the F protein is required to prevent cell to cell spread via fusion of virally infected cells. Cell mediated immunity is important in eliminating established viral infection.

Pathogenesis

The virus leads to a ballooning degeneration of the ciliated epithelial cells, lymphocytic infiltration, and necrosis of the epithelium. There is oedema and increased secretion from the mucous cells and the formation of plugs of mucous and cellular debris in the bronchioles. This results in obstruction and air trapping leading to collapse or over-distension of the distal alveoli. Cells throughout the respiratory tract are affected but the alveoli are spared unless there is RSV pneumonia. Degranulation products of mucosal eosinophils and mast cells and cytokines released by infected macrophages contribute to disease pathogenesis. The cell-mediated immune response contributes to immunopathology in some circumstances. For example when patients with severe combined immunodeficiency and chronic RSV infection receive a bone marrow transplant (for correction of the immunodeficiency), engraftment may be associated with exacerbation of the lung pathology, sometimes with fatal consequences.

Severe RSV bronchiolitis is strongly associated with subsequent childhood asthma. RSV appears to promote type-1 hypersensitivity responses following subsequent exposure to unrelated antigens.

Clinical features

RSV infections of infants may lead to bronchiolitis and pneumonia. Bronchiolitis in infants is associated with expiratory wheeze, subcostal recession, hyperinflation of the chest, nasal flaring, and hypoxia with or without cyanosis. Fever is not prominent in half of the patients. Complete obstruction of a small airway leads to subsegmental atelectasis. Apnoea may occur (particularly in premature infants or in those <3 months of age) and may precede the development of bronchiolitis. Interstitial pneumonitis is uncommon but carries a bad prognosis. Otitis media is a common complication of RSV infection in children. Infants at highest risk from severe RSV disease are those under 6 months, those with pre-existing congenital heart disease, chronic lung diseases (e.g. bronchopulmonary dysplasia), and those born premature.

Infection in adults is often asymptomatic or leads to upper respiratory tract infection. During the RSV season, it is an important cause of lower respiratory tract infection in adults and the elderly—estimated to cause 2 to 9 per cent of the hospitalizations and deaths associated with pneumonia in the elderly. Much of this morbidity is clinically indistinguishable from influenza.

RSV (as well as parainfluenza and influenza) infections in the immunocompromised patient can be life threatening. They usually occur during community outbreaks, but a significant proportion are nosocomially acquired. Once infected, immunocompromised patients have a prolonged period of viral shedding and pose a risk of

transmission to other high-risk patients. The disease typically commences as an upper respiratory tract infection but may progress to involve the lower respiratory tract with more serious consequences. Factors that increase risk of disease progression appear to include bone marrow transplant recipients who acquire the infection in the period prior to engraftment and oncology patients with neutrophil counts less than 0.5×10^{6}/l. Those immunocompromised by HIV appear to tolerate community acquired respiratory viruses better than oncology patients and transplant recipients. This may, however, reflect inadequacy of data rather than reality.

Treatment and prevention

Ribavirin has activity against RSV *in vitro.* Aerosol administration is recommended because it results in much higher concentrations in the respiratory tract than can be achieved by intravenous administration. A number of controlled clinical trials in patients with severe RSV disease have reported clinical benefits associated with its administration by small particle aerosol via a mist tent, mask, oxygen hood, or ventilator, but these findings remain controversial.

In adult bone marrow transplant recipients, an uncontrolled study of ribavirin together with intravenous immune globulin (selected batches with high neutralizing antibody titre) appeared to be beneficial when compared to historical controls. More information is required for deciding the best management strategy.

Monthly intravenous administration of human hyperimmune RSV immunoglobulin during the RSV season, protects against disease of the lower respiratory tract and otitis media in patients with pre-existing risk factors, but is not yet widely available. It did not confer benefits to children with cyanotic heart disease and is not recommended for this group. Side-effects included reversible fluid overload, decrease in oxygen saturation, and transient fever. High titre RSV intravenous immunoglobulin by itself is ineffective in treatment of established RSV disease.

Candidate vaccines for RSV are undergoing clinical trials at present but none is yet available for routine use. Experience of early trials with inactivated RSV vaccines that led to enhanced RSV disease, rather than protection, continues to haunt the field.

Parainfluenza virus

Parainfluenza viruses, despite their name, are not related to influenza viruses, and are more akin to respiratory syncytial virus with which they are classified. They carry two envelope glycoproteins; HN containing both haemagglutinin and neuraminidase activity and F carrying fusion activity.

Epidemiology

The total impact on hospitalization of children by all four types of parainfluenza viruses taken together is comparable to that of RSV but, in contrast to RSV, their impact is in later infancy and childhood. In temperate countries, parainfluenza virus type 3 occurs annually and infects two-thirds of all infants in their first year of life. Parainfluenza type 1 and 2 tend to occur in alternate years and infection is acquired more slowly over childhood. Reinfection with parainfluenza viruses occurs, but rarely leads to lower respiratory tract infection.

Pathogenesis

The virus is confined to the respiratory epithelial cells, macrophages, and dendritic cells within the respiratory tract. Dissemination, even in immunocompromised patients, is rarely documented.

Immunity

Reinfection with parainfluenza viruses continues throughout life. Presence of virus specific IgE in nasopharyngeal secretions has been implicated in the development of parainfluenza croup or bronchiolitis.

Clinical features

Parainfluenza type 1 predominantly causes croup, while type 2 and 3 also cause bronchiolitis and pneumonia. Croup (or laryngotracheobronchitis) is associated with fever, hoarseness, and a barking cough and may progress to inspiratory stridor due to narrowing of the subglottic area of the trachea. The differential diagnosis is epiglottitis due to *Haemophilus influenzae* type b. Parainfluenza type 4 infection is rare, but causes bronchiolitis and pneumonia in children, often in those with underlying disease.

Reinfection in adults, when symptomatic, is a coryzal illness with hoarseness being prominent. Parainfluenza viruses (type 3 in particular) are significant causes of lower respiratory tract disease in adults when the virus is active in the community.

Parainfluenza viruses cause problems in immunocompromised patients (see section on RSV). Lower respiratory tract involvement is associated with wheezing, rales, dyspnoea, and diffuse interstitial infiltrates, and a fatal outcome in one-third of patients. When pneumonia occurs, the histological appearance of the lung is that of a giant cell or an interstitial pneumonia.

Treatment and prevention

The need for specific antiviral therapy arises, particularly in the immunocompromised. Ribavirin is effective *in vitro* but there are no controlled trials documenting its clinical efficacy. There are anecdotal reports of clinical efficacy as well the lack of it.

There are no options for prevention at present, either using vaccines or passive immunization. A live attenuated bovine-derived vaccine strain is currently undergoing clinical trials.

Influenza viruses

Influenza viruses contain a segmented RNA genome. Types A, B, and C are antigenically distinct; of these, types A and B are important in human disease. The viral envelope contains two glycoproteins, the haemagglutinin (H) and neuraminidase (N), which are critical in host immunity. Influenza viruses are designated by the virus type, place of isolation, strain designation, year of isolation, and the H and N antigen subtype, for example A/Sydney/5/95 (H3N2).

Epidemiology

The H and N genes of influenza types A, B, and C undergo mutational change resulting in the emergence of antigenic variants ('antigenic drift'). Every few years, a variant successful in evading the prior immunity of the human population emerges, to cause a global epidemic.

Fifteen H and 9 N subtypes of influenza A are found in aquatic birds, the natural reservoir of the virus. Human influenza A viruses in the first half of this century carried H1N1 surface antigens. In 1957, this virus acquired the genes for different H and N antigens (H2N2) by reassortment of its segmented genome with an avian virus ('antigenic shift'). The human population had no immunity to these new antigens and the virus caused the 'Asian flu' pandemic. A similar reassortment event gave rise to the H3N2 virus and the 'Hong Kong influenza' pandemic of 1968. While all three influenza pandemics this century resulted in significant morbidity and mortality, the toll exacted by the 'Spanish flu' of 1918 was horrendous—over 20 million deaths, greater than that of both World Wars combined. Since influenza B and C have no significant zoonotic reservoirs, antigenic shift and pandemics do not occur.

Avian viruses (e.g. subtype H5N1, H9N2) can occasionally infect humans without undergoing prior reassortment with existing human strains. The H5N1 virus that recently emerged in Hong Kong clearly had the potential to cause disease of unusual severity. However, such non-reassorted avian viruses do not appear to be efficiently transmitted between humans, a prerequisite for a pandemic virus. What might have happened had the H5N1 virus had the opportunity to undergo reassortment and adapt to transmission in humans is too horrifying to contemplate.

Pathogenesis

Viral replication occurs in the columnar epithelial cells leading to its desquamation down to the basal cell layer. The pathology involves the entire respiratory tract. Infection results in decreased ciliary clearance, impaired phagocyte function, and increased adherence of bacteria to viral infected cells, all of which promote the occurrence of secondary bacterial infection.

While there are differences in viral virulence (e.g. current H1N1 strains cause milder disease than H3N2), pre-existing cross-reactive immunity is a major determinant in reducing disease severity. Virus dissemination outside the respiratory tract is uncommon in humans, though it has been occasionally detected in the brain, heart, and fetus.

Immunity

Infection by an influenza virus results in long-lived immunity to homologous reinfection. However, the continued antigenic change in the virus allows it to keep ahead of the host immune response. Cross-immunity to 'drifted' strains within the same H or N subtype may provide partial protection, but there is little cross protection between different subtypes. Local and systemic antibody responses and cytotoxic T cells contribute to host protection.

Clinical features

Influenza ranges from asymptomatic infection, through the typical influenza syndrome, to the complications of influenza. While it cannot always be distinguished from other viral infections on clinical grounds, the typical influenza syndrome is relatively characteristic. It is associated with fever, chills, headache, sore throat, coryza, non-productive cough, myalgia, and sometimes prostration. The onset of illness is abrupt and the fever lasts 1 to 5 days. The pharynx is hyperaemic but does not have an exudate. Cervical lymphadenopathy is often present and crackles or wheezing are heard in around 10 per cent of patients. While the acute illness usually resolves in 4 to 5 days, the cough and fatigue may persist for weeks thereafter.

Common (>10 per cent of symptomatic patients) complications of influenza include otitis media (in children) and exacerbation of asthma, chronic obstructive airways disease, and cystic fibrosis. Less common complications are acute bronchitis, primary (viral) and secondary (bacterial) pneumonia, myocarditis, febrile convulsions, encephalopathy, encephalitis, and myositis (especially in patients with influenza B infection). Age, prior immunity, virus strain, the presence of underlying diseases, pregnancy, and smoking all influence morbidity and severity.

Treatment and prevention

Antiviral therapy

Antiviral drugs with proven clinical efficacy for treatment of influenza A are amantadine, rimatadine and a new class of antivirals, the neuraminidase inhibitors (e.g. zanamivir, oseltamivir). The neuraminidase inhibitors are also active against influenza B, while amantadine and rimatadine are not. All these drugs have maximal efficacy if administered early (within the first 48 h) in the illness.

Rimatadine has fewer neurological side-effects than amantadine. The former is mainly eliminated by the liver while amantadine is excreted by the kidney, a point relevant for patients with compromised renal or liver function. These drugs may be used for containing institutional outbreaks. However, the prophylactic efficacy may be lost if the index case is also treated, probably due to the emergence and transmission of resistant strains.

Preliminary data suggests that antiviral resistance may be less of a clinical problem with the neuraminidase inhibitors. Zanamivir is administered by inhalation, oseltamivir orally. There is limited clinical data suggesting efficacy of aerosolized ribavirin in therapy of influenza A and B.

Aspirin should be avoided in children with influenza because of the increased risk of Reye's syndrome.

Vaccines

Influenza vaccines contain antigens from the two subtypes of human influenza A (H3N2 and N1N1) and B viruses. To keep abreast of change in the surface antigens of the virus, its composition must be modified on an annual basis and annual reimmunization is required. To make global recommendations on vaccine composition and to maintain surveillance for emergence of influenza viruses with pandemic potential, the World Health Organization maintains a global network of collaborating laboratories.

Vaccines in use hitherto have been made from egg-grown viruses and contain: (a) inactivated whole virus, (b) detergent-treated virus (split virus vaccines), or (c) purified surface antigens (subunit of surface antigen vaccines). Split virus and subunit vaccines are associated with fewer side-effects in children (<12 years) and are therefore preferable. Previously unvaccinated children require two doses at least 1 month apart, whereas a single dose appears adequate for adults. These vaccines are generally safe, the most common side-effect being soreness at the injection site lasting a few days. Efficacy is best when there is a good antigenic match between the vaccine and outbreak virus. Immunogenicity and clinical protection are better in healthy young adults compared to patients with chronic renal failure, the immunocompromised, and the elderly (all groups most at need of the vaccine). However, the vaccine is still effective in reducing influenza and pneumonia-related hospitalization and mortality in the elderly and is cost-saving. In young adults, vaccination is associated with decreased absenteeism from work. The duration of protection is limited and therefore vaccine administration should be timed to precede the expected peak of influenza activity.

Influenza vaccine is recommended to those groups at highest risk of morbidity. Recommendations vary from country to country, but they usually include patients in chronic care facilities (especially the elderly), those with chronic cardiopulmonary, lung, or renal diseases, diabetes mellitus, haemoglobinopathies, and the immunocompromised. Some countries, such as the United States, extend the recommendation to all persons over 65 years, pregnant women who will be in the second or third trimester during the influenza season, children receiving long-term aspirin therapy (potentially at risk from Reye's syndrome if they acquire influenza), health-care workers (particularly those in contact with the high-risk patient groups above), and household members of persons in high-risk groups. Currently, there is no consensus on the use of influenza vaccine in HIV infected patients.

An intranasally administered, cold-adapted, live attenuated vaccine has undergone clinical trials with promising results and may in future offer advantages of easier administration and greater patient acceptability.

Nosocomial infection

Respiratory viruses are efficient nosocomial pathogens. Although influenza and RSV are the most notorious, even rhinoviruses cause problems when transmitted to immunocompromised patients. Though paediatric units face the brunt of the problem, adult wards are not exempt. Transmission may occur from patient to patient, patient to staff, and staff to patient, with visitors making their own contribution.

While transmission occurs by large respiratory droplets gaining access to the mucosa of a susceptible individual, their dispersal range is short (<1 m). Much of the transmission occurs by direct hand contact. Adherence to strict hand-washing is the most critical preventive measure. Gloves are useful in reinforcing the 'hand-washing message', but will only be effective if they are changed between patients. Cohorting infected patients, either by symptoms (during the outbreak season) or by rapid viral diagnostic results, is useful. Influenza A vaccination of health-care workers, especially those caring for high-risk children, is to be recommended. Staff education is vital, including awareness of the fact that some of these viruses manifest themselves as a mild 'cold' in adults, and that infected staff members can transmit to patients under their care.

7.10.2 Herpesviruses (excluding Epstein–Barr virus)

J. G. P. Sissons

Human herpesviruses

General introduction

The family of Herpesviridae is widely distributed in the animal kingdom. More than 100 herpesviruses have been isolated from humans, primates, and other mammals, and from reptiles and fish. Comparative sequence analysis suggests they have been coevolving with their individual hosts for millions of years. To date, eight human herpesviruses have been identified, as summarized in Table 1. Herpesviruses have been assigned to three subfamilies, the alpha-, beta-, and gammaherpesvirinae, on the basis of shared genomic and biological properties. All the herpesviruses are characterized by a linear double-stranded DNA genome, contained inside an icosahedral capsid, which is surrounded by a protein tegument and an outer lipid envelope containing virus glycoprotein spikes. They are large viruses whose genomes consist of unique segments of DNA flanked by repeat sequences and encode most of the proteins needed for replication. Although differing in many of their biological properties, all herpesviruses share an important biological feature: their capacity to produce latent infection in their natural host, during which the viral genome persists in cells as a closed circular episome, only a limited subset of virus genes being expressed. Although individual viruses establish latency in different types of cell, this property is key to their ability to produce persistent lifetime infection of the host, and thus to persist in the population. The individual human herpesviruses, and their associated diseases are described in the succeeding chapters: these diseases may result from primary infection, or reactivation of the virus from latency, and tend to be more severe in immunosuppressed patients. The gammaherpesviruses can induce cell transformation and are associated with specific tumours.

Herpes simplex virus infections

Historical introduction

Herpes is a word derived from the Greek meaning to creep or crawl, apparently used since antiquity to describe the evolution of the skin lesions caused by herpes simplex virus (**HSV**) and varicella zoster virus (**VZV**). HSV was the first of the herpesviruses to be isolated, during the 1930s, after the infectious nature of the mucous membrane lesions it causes had been demonstrated by transmission to animals in 1919. The serological distinction of the two types of HSV, HSV-1 and HSV-2, and the association of HSV-2 with genital herpes was made in the 1960s. HSVs are now some of the most intensively studied human viruses.

Aetiology

HSV has a genome size of 150 kbp and codes for some 80 proteins. The genomes of HSV-1 and HSV-2 are largely colinear, but have different restriction

endonuclease sites. Gene expression occurs in three temporally regulated phases of immediate-early, early, and late genes. Immediate-early proteins are largely regulatory proteins which prepare the cell to produce further virus, the early genes code particularly for enzymes involved in the replication of virus DNA, and the late genes for the structural proteins of the virion. Antigenic differences in the surface glycoprotein G are used to distinguish between HSV-1 and HSV-2. Release of progeny virus is normally accompanied by host-cell death—that is, the infection is lytic. The virus infects a relatively wide range of cells *in vitro*, and can also infect experimental animals thereby allowing studies of its pathogenesis.

Epidemiology

HSV is a ubiquitous virus, widely distributed in all populations of the world. Although the virus can produce experimental infections of animals, there are no natural animal hosts and humans are the only reservoir for the virus. Transmission occurs by direct contact of a susceptible individual with infected secretions from an HSV carrier. This is usually via transmission from oral, genital, or skin lesions to mucous membranes or abraded skin of the recipient. HSV carriers can excrete virus asymptomatically, and 1 to 15 per cent of adults excrete HSV at any one time. The prevalence of infection is conventionally assessed by the demonstration of antibody to HSV-1 or HSV-2. The prevalence of HSV-1 increases with age, although the time of acquisition of HSV-1 antibody varies depending on socioeconomic factors. There is a higher seroprevalence in lower socioeconomic groups in early life: 70 to 90 per cent of individuals have antibodies by the age of 10 years, whereas only about 30 per cent of higher socioeconomic groups have antibody by this time. By mid-life 80 to 90 per cent of all individuals have antibody to HSV-1.

HSV-2 infection is usually acquired through sexual contact: consequently seroconversion correlates with the onset of sexual activity, and there is a progressive increase in seroprevalence to HSV-2 beginning in adolescence. The number of sexual contacts is a major risk factor for acquisition of HSV-2. Cumulative seroprevalence rates in adults vary from 10 to 80 per cent depending on the population and risk factors.

HSV can be transmitted to the neonate by infection (usually HSV-2) from maternal genital secretions at the time of delivery. Neonatal HSV infections usually occur in children born to mothers who are asymptomatic excretors of the virus and have no history of genital herpes.

Pathogenesis

HSV infects and replicates in epithelial cells at the site of inoculation on to mucous membranes or abraded skin, with an incubation period of between 4 and 6 days before clinical lesions appear. There is a marked local inflammatory response, but viraemia and dissemination may occur in the immunocompromised host. Following local epithelial replication, HSV enters the peripheral sensory nerves innervating the site of epithelial replication, and ascends the axons by retrograde transport to reach the dorsal root ganglia, or the trigeminal ganglion in the case of oral or conjunctival inoculation. The virus then becomes latent in sensory ganglia, but, despite extensive study, the mechanism of virus latency remains uncertain. Latent HSV-DNA is in an inactive state with minimal gene expression. RNA species called 'latency-associated transcripts' (**LATs**) are the only detectable transcripts. LATs have no detectable protein product and their deletion from the genome does not prevent the establishment of latency, although reactivation is impaired. Latent HSV is carried for the lifetime of the host, but may reactivate in response to certain stimuli including stress, menstruation, ultraviolet light, and immunosuppression. Upon reactivation, infectious virus is produced, travels down peripheral nerves by anterograde transport, and replicates in epithelial cells at the nerve ending. The neuronal latency of HSV and VZV is an extremely effective method of virus persistence. Latent virus in neuronal cells appears to be inaccessible to the immune response, and as it does not replicate, is not susceptible to the action of antiviral drugs. In addition to specific antibody, normal HSV carriers mount a cytotoxic T-lymphocyte response to the virus, which is presumed to control reactivation at local sites. HSV encodes genes which interfere with antigen processing by the class I MHC pathway, and are presumed to help the virus to evade the T-cell immune response. There is no good evidence that the immune response to HSV of people who have symptomatic reactivation episodes differs from that of asymptomatic carriers.

Clinical features

Primary infection with HSV is often asymptomatic: in a recent study of sexually active subjects, only 60 per cent of primary infections with HSV-1, and 40 per cent with HSV-2, were symptomatic. HSV-1 is the predominant cause of orofacial infections and HSV-2 the predominant cause of genital HSV infection, but the clinical manifestations overlap.

Gingivostomatitis

This is the commonest clinical form of primary infection with HSV-1. It is most often seen in children and has an incubation period of 2 to 12 days. Primary infection may be associated with a considerable systemic reaction, with fever, sore throat, pharyngeal oedema, and redness. Painful vesicles appear a few days later on the pharynx and the oral mucosa, lips, and the skin around the mouth: there may be cervical lymphadenopathy. Affected patients may have difficulty in eating, and the lesions last from 3 days to 2 weeks. The differential diagnosis includes other causes of pharyngitis including bacterial pharyngitis and herpangina (due to coxsackie A virus infection): anterior vesicles and ulceration affecting the lips and skin around the mouth are more suggestive of HSV infection. Stevens–Johnson syndrome and severe aphthous ulceration may appear similar, and staphylococcal impetigo affecting the skin around the mouth can give a similar external appearance, but is not associated with oral ulceration.

Reactivation of HSV may give rise to recurrent orolabial lesions: appearing as intraoral mucosal ulcers, but more frequently as the classical 'cold sore' on the lips or skin around the mouth (Plate 1). Patients may first experience a tingling sensation in the area of impending ulceration 1 to 2 days prior to the appearance of vesicles. The lesions usually recur in the same site in individual patients. Around 25 per cent of HSV-1 seropositive people develop recurrent orolabial lesions: the majority have only one or two reactivation episodes per year, although a minority (less than 10 per cent) have more than one attack a month. These episodes are not associated with systemic symptoms and diagnosis is usually straightforward.

Infection at other cutaneous sites

Herpetic whitlow

HSV infection of the finger (herpetic whitlow) may complicate primary oral or genital herpes by autoinoculation of virus, or may occur through occupational exposure (for instance, in nursing, medical, and dental staff). There is oedema, erythema, and local tenderness of the infected finger. Lesions at the fingertip may be confused with pyogenic bacterial paronychias and incised (which is contraindicated for herpetic whitlow, and may even spread infection).

Herpes gladiatorum

This is a term which refers to mucocutaneous HSV infection occurring by transmission of infection through skin trauma, resulting from wrestling or other contact sports.

Eczema herpeticum

HSV infections of the skin are more severe in patients with pre-existing skin disease. In patients with eczema, burns, or other blistering skin diseases, HSV infection may become disseminated.

Cutaneous HSV infection can be confused with herpes zoster, although the latter is usually easy to diagnose by its unilateral dermatomal distribution.

Herpes simplex and erythema multiforme

About 15 per cent of all cases of erythema multiforme are preceded by a symptomatic attack of recurrent herpes simplex, and in susceptible individuals the characteristic rash can be induced by the intradermal inoculation of inactivated herpes simplex virus antigen. The rash of erythema multiforme starts several days after the onset of the herpetic vesicles, and in severe cases can involve the mucous membranes (Stevens–Johnson syndrome). The frequency of these attacks can be reduced by aciclovir prophylaxis.

Keratitis

HSV keratitis is characterized by the acute onset of pain, blurred vision, conjunctival injection, and dendritic ulceration of the cornea. HSV keratitis can cause corneal blindness and its treatment is urgent. Topical aciclovir is the drug of choice, for topical steroids may make the infection worse. HSV can also cause an acute necrotizing retinitis, usually seen in immunosuppressed subjects such as those with HIV infection, but rarely in immunocompetent people.

Genital herpes

Primary genital HSV infection is sexually transmitted and may be associated with systemic symptoms such as fever, headache, and myalgias. Symptoms tend to be more severe in women than in men. There is local pain and itching, dysuria, and vaginal discharge with inguinal lymphadenopathy, with vesicles and ulcers on the vulva, perineum, vagina, and cervix, and sometimes on the skin of the buttocks (Plate 2). In males, primary HSV lesions are seen as vesicles on the shaft or glans of the penis and there may be an associated urethritis. Most genital HSV infections are due to HSV-2, with a variable smaller proportion due to HSV-1. Only 40 per cent of primary HSV-2 genital infection is symptomatic: in patients who have had prior HSV-1 infection, the symptoms of primary genital herpes tend to be less severe. HSV has been isolated from the urethra in 5 per cent of women with the 'urethral syndrome', in the absence of obvious genital lesions. Other manifestations of genital tract disease due to primary HSV infection are, rarely, endometritis and salpingitis in women, and prostatitis in men.

HSV proctitis may follow rectal intercourse. There is anorectal pain and discharge with ulcerative lesions visible on sigmoidoscopy. Perianal lesions are seen in immunosuppressed patients, and spreading perianal HSV infection and HSV proctitis occur in patients with human immunodeficiency virus (**HIV**) infection.

Recurrent genital herpes is frequent in the first year following primary genital infection (90 per cent for HSV-2 and 55 per cent for HSV-1). Thereafter the recurrence rate tends to decrease with time and is around 3 or 4 attacks per year for HSV-2, but less for HSV-1. Severe recurrent genital herpes is particularly troublesome to women.

Complications of primary genital HSV infection include a sacral radiculomyelitis with urinary retention and hyperaesthesia of the perineal area, which usually resolves over several weeks. Aseptic meningitis requiring admission to hospital occurs in up to 7 per cent of women and 2 per cent of men, although suggestive symptoms are more common. Occasionally, and more seriously, transverse myelitis may occur.

HSV encephalitis (see also Viral infections of the CNS)

Encephalitis is the most serious type of disease produced by HSV in the normal immunocompetent host, and has an estimated annual incidence of 2 or 3 cases per million of population. It is the commonest identified cause of acute sporadic encephalitis in Western countries, with the great majority of cases due to HSV-1. There is a reported biphasic age incidence, with higher rates between the ages of 5 and 30 and in those over 50 years. The clinical presentation is that of a focal encephalitis, with an acute onset of fever, confusion and unusual behaviour, impaired consciousness, and possibly focal neurological abnormalities. However, as there are no clinical features specific to HSV encephalitis, the diagnosis should be considered in any patient who presents with clinical features that could indicate an encephalitis.

The cerebrospinal fluid (**CSF**) shows lymphocytic pleocytosis, although neutrophils and red cells may also be present, with a raised protein level. Computed tomographic (**CT**) scans of the brain may show changes in the temporal lobe: magnetic resonance imaging (**MRI**) is a more sensitive method of detection. The electroencephalogram (**EEG**) classically shows spike- and slow-wave activity localized in the temporal lobes. The most definitive way of establishing the diagnosis is by brain biopsy: in the original trial of aciclovir for the treatment of HSV encephalitis, brain biopsy was an entry criterion and confirmed the diagnosis in only 50 per cent of clinically suspected cases. Brain biopsy is very rarely used now, since the advent of non-toxic effective chemotherapy for HSV. There is good correlation between a positive polymerase chain reaction (**PCR**) test for HSV-DNA in the CSF and the diagnosis of HSV encephalitis by brain biopsy and virus isolation. Evidence for intrathecal production of specific HSV antibody is also diagnostic, but as it usually becomes positive a week after onset, PCR-based diagnosis is more useful. Serum or CSF titres of antibodies to HSV do not usually increase in the first week of the illness. In practice, the diagnosis is established by a compatible clinical picture, evidence of characteristic temporal lobe involvement on CT or MRI imaging and EEG, and by PCR-based detection of HSV-DNA in the CSF.

The pathogenesis of HSV encephalitis remains uncertain. Up to half of patients have primary infection and in the rest the disease is presumed to result from reactivation. However, where HSV has been isolated from the brain and the mouth simultaneously in the same patient, the two isolates differ by restriction endonuclease analysis in about 30 per cent of the patients, suggesting a new exogenous virus infection in an already seropositive patient. HSV-DNA can be detected in the brain at autopsy of normal virus carriers, but the factors precipitating HSV encephalitis are not known. Immunosuppression is not usually associated with HSV encephalitis, which predominantly affects normal immunocompetent adults, and very rarely patients with advanced HIV infection. The pathology is that of a focal haemorrhagic necrotizing encephalitis, affecting the temporal lobes.

Treatment

Treatment should be started immediately with intravenous aciclovir (in doses as given below) in any patient in whom HSV encephalitis is clinically suspected, without waiting for confirmation of the diagnosis. Prior to effective antiviral therapy, the mortality from HSV encephalitis was over 70 per cent with very few patients making a full neurological recovery. Intravenous aciclovir was established to be more effective than the previous best therapy of vidarabine in a randomized trial reported in 1986. Mortality in the aciclovir-treated group was 28 per cent, although a lower Glasgow Coma Score on entry carried a higher risk of mortality. However, only 38 per cent of those who received aciclovir had fully recovered at 6 months: there is thus still a high incidence of permanent neurological events, particularly seizures, defects of memory, and personality changes and the prognosis of HSV encephalitis remains serious.

Meningitis

HSV can cause an aseptic meningitis which is quite independent of, and not associated with progression to, HSV encephalitis. The commonest association is with primary genital HSV-2 infection: the incidence of proven HSV meningitis is 7 per cent in women, and 2 per cent in men, with primary genital HSV. There is a pleocytosis, usually lymphocytic, but neutrophils may predominate in early meningitis. HSV may be isolated from CSF by culture, but is now more reliably detected by PCR for HSV-DNA.

In a high proportion of patients with Mollaret's meningitis (a recurrent aseptic meningitis of unknown aetiology), HSV-DNA is reported to be detectable in cerebrospinal fluid by PCR.. The role of HSV in this syndrome remains uncertain.

An association of HSV with Bell's palsy has been reported, but a recent Cochrane review considered the evidence was inconclusive.

Neonatal HSV infection and pregnancy

The incidence of neonatal HSV infection is approximately 1 in 3500 deliveries per annum in the United States, but appears to be rarer in the United Kingdom at 1.65 in 100 000 live births. About 70 per cent of cases are caused by HSV-2 and result from fetal acquisition of HSV-2 from maternal genital secretions during delivery. Most infants with neonatal HSV are born to mothers without clinically evident HSV infection. The risk of transmission from a woman with symptomatic primary HSV infection is about 50 per cent, and 20 per cent from a woman with clinically evident recurrent HSV-2 infection. A small proportion (about 10 per cent) of infections are acquired postnatally by contact with other family members with active lesions.

Neonatal HSV infection appears as lesions on the skin, eye, and mouth or may present as encephalitis or disseminated visceral infection. Although initial superficial infection may progress to visceral infection, visceral infection can present with no evidence of cutaneous lesions, and the diagnosis should be considered in severely ill neonates. Untreated, visceral infection has a high mortality (around 60 per cent).

Primary infection in early pregnancy can lead to congenital HSV infection. This is rare, but can produce serious congenital abnormalities.

HSV in the immunosuppressed patient

HSV infections in immunosuppressed subjects are usually due to reactivation rather than primary infection. They tend to be more severe, are more likely to progress, and take longer to heal than in the normal immunocompetent host. Clinical manifestations in patients with HIV infection include severe perineal, orofacial, and oesophageal infection. HSV pneumonitis, hepatitis, and colitis are also described in immunosuppressed patients.

Pathology

The histological appearance of HSV infection is identical whether infection is primary or recurrent. There is ballooning of infected cells with condensed chromatin in the cell nuclei. Intranuclear inclusion bodies (Cowdrie type A bodies) may be seen and multinucleated giant cells form. VZV produces similar appearances.

Laboratory diagnosis

Definitive diagnosis is made by isolation of virus: swabs from vesicular fluid or other body fluids in virus transport medium can be inoculated into tissue culture and typical cytopathic effects seen. Virus from vesicle fluid can also be identified rapidly as a herpesvirus by electron microscopy after negative staining. The use of PCR-based techniques to detect viral DNA is becoming more widespread. It is particularly applicable to the detection of HSV-DNA in cerebrospinal fluid.

Serological tests for antibody to HSV are only useful in making a retrospective diagnosis. Seroconversion provides proof of primary infection and absence of antibody to HSV-1 or HSV-2 rules out a diagnosis of recurrent HSV infection. However, making a diagnosis of reactivation by demonstrating rising antibody titres is of limited value.

Treatment

The introduction of aciclovir heralded a new era of targeted antiviral drugs and superseded other drugs previously used for the treatment of HSV infections such as vidarabine and idoxuridine. Aciclovir is an acyclic nucleoside which is preferentially phosphorylated in HSV-infected cells by the virus-encoded thymidine kinase to aciclovir monophosphate. Cellular kinases then phosphorylate the aciclovir monophosphate to the triphosphate, which is incorporated into nascent HSV-DNA where it acts as a chain terminator; aciclovir also directly inactivates the HSV-DNA polymerase. Two newer related drugs with the same mechanism of action are famciclovir, a prodrug of penciclovir, and valaciclovir, the valyl ester of aciclovir, which has greater bioavailability and requires less frequent dosage. All these drugs are relatively free of side-effects, although intravenous aciclovir can crystallize in the renal parenchyma and produce renal impairment: it should be given by infusion over 1 hour, and patients should be adequately hydrated. The doses should be reduced in patients with renal impairment.

Primary mucocutaneous infection

In primary oral and genital infection aciclovir 200 mg, 5 times daily, given orally for 10 to 14 days from the onset, reduces the severity of infection, the duration of symptoms, and the duration of viral shedding. There is little evidence that treatment of primary infections reduces the incidence of subsequent symptomatic reactivation episodes. If swallowing is difficult, intravenous aciclovir (5 mg/kg, every 8 h) may need to be given. Famciclovir, 250 mg thrice daily, or valaciclovir, 500 mg twice daily, are alternatives.

Symptomatic reactivation of mucocutaneous infection

Treatment of recurrent infections in the immunocompetent host is often unnecessary as the symptoms are usually very mild. However, aciclovir can shorten the duration of symptoms if it is given very early in the course of the recurrence, preferably during the prodrome before vesicles appear. Oral aciclovir is effective and anecdotal reports suggest that topical aciclovir is effective symptomatically. The same dosage as above for treating a primary infection can be given for 5 days: famciclovir and valaciclovir can be used as alternatives.

Long-term suppressive therapy

This can be considered in immunocompetent patients with genital herpes who have frequent reactivation episodes. Trials of aciclovir in recurrent genital herpes have shown that a dose of 400 mg twice a day significantly reduces the frequency of attacks. However, patients may be able to find a lower effective dose, and in some 200 mg daily prevents attacks. Although it is advised that treatment is discontinued for a month every 6 to 12 months, there is little evidence that resistant virus is a problem in this population. Valaciclovir, 500 mg daily, or famciclovir, 250 mg twice daily, are alternatives.

CNS infection

For HSV encephalitis intravenous aciclovir (10 mg/kg, every 8 h for 10–14 days) should be given to any patient in whom the diagnosis is clinically suspected (see above).

For HSV meningitis intravenous aciclovir (5 mg/kg, every 8 h) can be used with conversion to oral valaciclovir (1 g, twice daily) when improvement occurs, for a total of 10 days.

Systemic infection in the immunosuppressed

Oral treatment as for primary HSV can be used for mild mucocutaneous infection, but for more severe infection and for visceral involvement intravenous aciclovir 5 mg/kg every 8 h should be used. After resolution, continued prophylaxis is usually necessary until immunocompetence is restored, particularly in patients with HIV.

Aciclovir resistance

Resistance of HSV to aciclovir develops readily *in vitro* but is clinically rare: it is due to mutations in the HSV thymidine kinase or DNA polymerase gene. It is seen almost exclusively in immunocompromised patients who have received prolonged aciclovir prophylaxis, especially those with HIV infection, and is manifest as unresponsive or worsening HSV disease despite treatment with aciclovir. There is usually cross-resistance to famciclovir and valaciclovir, and intravenous foscarnet (more usually used to treat human cytomegalovirus infection, see the HMCV section) is the most useful alternative drug for use in severe infection due to resistant HSV.

Prevention and control

There is no vaccine yet available for HSV, although several candidates are approaching phase III trials. There is particular interest in the use of vaccines for postinfective immunization to reduce the frequency of recurrent genital HSV attacks (which has been shown to be possible experimentally in guinea-pigs).

Special problems in pregnant women

Prevention of neonatal HSV infection is best achieved by preventing genital HSV infection late in pregnancy. There is no reason to give aciclovir prophylactically to women with a history of recurrent genital herpes who are asymptomatic, as the incidence of neonatal HSV infection is low in their children. However, women with clinically apparent genital herpes during the last trimester (and probably at any other time in pregnancy) can be treated with aciclovir (although the drug is not licensed for treatment in pregnancy). Women with no clinical lesions may have a vaginal delivery, but the presence of active lesions at the time of labour is regarded as an indication for Caesarean section. Babies born to mothers with clinically apparent genital HSV infection or with a history of recurrent genital HSV infection should be screened for HSV by cultures from the nasopharynx and eyes after birth.

Proven neonatal HSV infection should be treated with high-dose intravenous aciclovir (60 mg/kg per day in three divided doses for 21 days).

Varicella zoster virus infection

Historical introduction

There are clinical descriptions of varicella (chickenpox) and herpes zoster (shingles) in very early medical literature, although the skin lesions of herpes simplex and herpes zoster were grouped together under the term 'herpes'. The similarities between the exanthematous rashes associated with smallpox and with varicella meant they were not distinguished until the latter part of the nineteenth century. Because of its characteristic clinical appearance in a dermatomal distribution, shingles was recognized as a discrete entity in the early Greek literature: the term 'zoster' is said to derive from the Greek term for a girdle, and shingles from the Latin *cingere* meaning to encircle. Von Bocquet in 1892 observed that children developed varicella after contact with adults who had herpes zoster, and in 1925 it was shown that vesicular fluid from patients with zoster produced chickenpox in susceptible individuals when directly inoculated. The idea that zoster resulted from reactivation of latent virus remaining in the individual following childhood varicella was put forward by Garland in 1943, and was strengthened by the work of Hope-Simpson, a British general practitioner. Varicella zoster virus (VZV) was isolated in 1958, and Weller and colleagues showed the similarity of the viral isolates from varicella and zoster. Identity by restriction endonuclease analysis has been shown between the isolates from chickenpox and from later zoster in the same individual, although this was an immunocompromised patient: the long interval between the two illnesses in normal subjects means such studies have never been conducted in this population.

Aetiology

VZV is structurally similar to other members of the Herpesviridae family. The genome is a linear double-stranded DNA of 125 kilobase pairs. The virus is closely cell-associated and spreads from cell to cell in tissue culture. VZV is an alphaherpesvirus, and encodes sets of genes which are largely colinear to those of HSV, and are also expressed in immediate-early, early, and late phases.

Epidemiology

VZV only infects humans, who are thus the only reservoir. The virus is presumed to spread by the respiratory route. Varicella is predominantly a disease of childhood affecting both sexes: 90 per cent of cases occur in children under the age of 13. The incubation period of varicella from exposure to VZV to development of the initial rash is about 2 weeks (with a range of 10–20 days). Patients with varicella are infectious for about 48 h before the vesicles appear, and remain so for 4 or 5 days afterwards until all the vesicles have crusted over. Secondary attack rates in susceptible contacts where there is an index case in the household are between 70 and 90 per cent. The prevalence of VZV varies in different ethnic groups. After 15 years of age only about 10 per cent of subjects in Europe are seronegative for, and consequently susceptible to, infection, although in tropical countries only 50 per cent of young adults may be seropositive. Varicella in adulthood is uncommon in Europe, with less than 2 per cent of all cases occurring in patients older than 20 years.

After primary infection, VZV becomes latent in dorsal root ganglia. Reactivation appears clinically as herpes zoster (shingles), which is a common disease that can affect all age groups but particularly the elderly: about 20 per cent of the population will experience an attack. There is no evidence that exposure to people with active VZV infection predisposes to herpes zoster in their contacts, but a seronegative subject may catch varicella from contact with the vesicles of a patient with shingles. As nosocomial varicella infection is well recognized, isolation of patients with varicella and immunocompromised patients with herpes zoster should be ensured in hospitals. Local unidermatomal zoster is less likely to cause infection and consequently to need isolation. Subclinical infection is unusual and accounts for less than 5 per cent of all infections, but the disease may be mild and in some surveys only 10 per cent of people with a negative history were in fact seronegative for VZV. One attack of chickenpox usually confers life-long immunity.

Pathogenesis

Upon primary infection, initial virus replication probably occurs in the epithelial cells of the upper respiratory tract mucosa, followed by a phase of viraemia during which VZV can be isolated from leucocytes. This blood-borne spread is associated with the production of the disseminated rash. In the skin, the virus infects capillary endothelial cells and adjacent fibroblasts and epithelial cells. During the viraemic phase virus may spread to visceral organs, the lung including alveolar epithelial cells, and transient subclinical hepatitis is probably a normal feature of varicella. Infection of the brain can occur, and VZV encephalitis may be a feature of primary infection, particularly affecting the cerebellum. The encephalitis usually recovers completely (unlike that associated with HSV), and it has been suggested it may have an immune-mediated pathogenesis. Following recovery from primary infection, the virus persists for life in a latent state in dorsal root ganglia. VZV reaches the ganglia by retrograde axonal transport from the lesions in the skin during primary infection, and all dorsal root ganglia and the trigeminal ganglion can potentially carry latent VZV in neurones and possibly in satellite cells.

As for other herpesviruses, the host response is critical in containing the initial infection. The cellular immune response is of particular importance since varicella may be progressive in patients with severely impaired T-cell immunity. Both CD4 and CD8 cytotoxic T lymphocytes specific for VZV are present in normal people carrying latent VZV. The cellular immune response presumably plays a part in controlling reactivation, since impaired T-cell immunity is associated with an increased risk of developing zoster, with zoster in multiple dermatomes, and with cutaneous dissemination of reactivated virus. The increasing risk of herpes zoster with age may reflect waning cellular immunity to VZV.

Clinical features

Primary infection and varicella (chickenpox)

The most striking feature of varicella is the rash, which is centripetal (mainly on the trunk) in distribution (Plate 3). Initially, lesions are present on the face and scalp, before progressing to the trunk and later to the limbs. A macular erythematous rash, papules, and vesicles may all be present together. Individual lesions progress from being papular to vesicles to pustules and then crust over. The scabs normally separate after 10 days without scarring. The systemic symptoms associated with varicella vary considerably. In the majority of children there is a mild illness with fever. Adults characteristically have a more severe illness with myalgias, headache, arthralgias, malaise, and higher fever, with the complications listed below. Symptoms may precede the rash by 1 to 2 days.

The principal complications of varicella in the immunocompetent person are pneumonitis and encephalitis.

Pneumonitis

A prospective study showed that 6 per cent of young adults with chickenpox had respiratory symptoms, but 16 per cent had changes on chest radiography, although the rate of admission to hospital with pneumonia in adults with varicella is only about 0.3 per cent. Patients present with dyspnoea, cough, hypoxia, and bilateral infiltrates on the chest radiograph occurring 1 to 6 days after the appearance of the rash. Hypoxia may be more severe than expected from the physical signs or the chest radiograph. The interstitial pneumonitis can progress to respiratory failure requiring artificial ventilation and intensive care, but it is more commonly transient and resolves completely within 2 to 3 days. Varicella pneumonia is said to be commoner in smokers. Fatalities do occur but the great majority of patients survive, and VZV pneumonia is not associated with long-term respiratory problems. Benign nodular calcification throughout the lung occasionally follows.

Encephalitis

Central nervous system involvement during varicella infection most commonly presents as an acute cerebellar ataxia within a week of the onset of the rash, although it may present as late as 21 days after the rash: it resolves completely over 2 to 4 weeks. A frequency of 1 in 4000 cases of children under the age of 15 years has been quoted. The cerebrospinal fluid of these patients shows a lymphocytosis and elevated protein concentration.

A more serious encephalitis can occur in between 0.1 and 0.2 per cent of cases of varicella. This begins earlier in the course of infection than the cerebellar ataxia, with headache, vomiting, confusion, and impaired consciousness. There is evidence of diffuse cerebral oedema but no defined pattern of CT or MRI abnormality. The encephalitis may be progressive and the mortality is between 5 and 20 per cent with neurological sequelae in up to 15 per cent of survivors.

A meningitis can occur with varicella. Other rare neurological complications reported include optic neuritis, transverse myelitis, and Reye's syndrome.

Other complications

Other complications of primary VZV infection include acute thrombocytopenia with petechiae and purpura and haemorrhage into vesicles and other haemorrhagic manifestations. The platelet count can remain low for weeks after the illness has resolved. Secondary infection of the skin lesions with *Staphylococcus aureus* or *Streptococcus pyogenes* can occur. Purpura fulminans is a rare complication associated with arterial thrombosis and haemorrhagic gangrene. Nephritis and arthritis have been reported as rare complications and myocarditis, pericarditis, pancreatitis, and orchitis are even more rare.

Special problems in pregnant women

Varicella in pregnant women can be severe, with a quoted maternal mortality of 1 per cent. Varicella in the first trimester can cause 'varicella embryopathy': in affected infants there may be a scarred atrophic limb, microcephaly, and cortical atrophy, as well as eye defects, including chorioretinitis, micro-ophthalmia, and cataracts. The autonomic nervous system may be damaged. Varicella embryopathy is rare in recent reported series, giving a risk of about 1 to 2 per cent in mothers with varicella in the first 20 weeks of pregnancy. Varicella zoster immune globulin (**VZIG**) should be considered for pregnant women in contact with varicella (see below), and varicella during pregnancy should be treated with aciclovir on a named patient basis. Neonatal varicella occurs in babies whose mothers contract varicella just prior to or after delivery, and is more severe when the maternal onset is from 2 days before to a week after delivery.

Herpes zoster

The clinical syndrome associated with reactivation of VZV from sensory ganglia is herpes zoster (shingles). This typically presents with pain followed by erythema and vesicular lesions occurring in a dermatomal distribution. The thoracic dermatomes, especially T5 to T12, are involved in about 50 per cent, lumbosacral dermatomes in about 16 per cent, and cranial nerves, mainly the Vth, in 14 to 20 per cent of patients. The first symptoms are usually paraesthesias and shooting pains in the affected dermatome, which precede the eruption of vesicles by several days and occasionally a week or more. Erythematous maculopapular lesions then appear and quickly evolve into a vesicular rash, nearly always in a unilateral dermatome with no vesicles beyond the midline. The vesicles usually form scabs after 3 to 7 days and these separate after 2 weeks or so. There is a risk of secondary infection, particularly with *Staphylococcus aureus*. There may be malaise and low-grade fever, but there are usually no abnormalities of laboratory investigations, although up to 40 per cent of patients with uncomplicated zoster may have lymphocytes and elevated protein concentrations in the CSF. Involvement of the mandibular branch of the Vth cranial nerve can give intraoral lesions on the palate, floor of the mouth, and tongue. Involvement of the geniculate ganglion results in the Ramsay Hunt syndrome, with pain and vesicles in the external auditory meatus, a loss of taste in the anterior two-thirds of the tongue, and a lower motor neurone VIIth cranial nerve palsy.

Complications of zoster

Ophthalmic zoster

VZV reactivation from the trigeminal ganglion can affect the ophthalmic division of the trigeminal nerve resulting in ophthalmic zoster (Plate 4). The features include conjunctivitis, anterior uveitis, a keratitis, and sometimes iridocyclitis with secondary glaucoma and panophthalmitis. However, these latter sight-threatening complications of ophthalmic zoster are unusual. A rare association of ophthalmic zoster is granulomatous cerebral angiitis, which can be associated with arterial thrombosis: cerebral angiography shows segmental narrowing in cerebral arteries on the side of the ophthalmic zoster. CT scanning may show cerebral infarcts, particularly in the distribution of the middle cerebral artery.

Motor zoster

Weakness or paralysis can sometimes be associated with zoster, and is due to involvement of the anterior horn cells in the same segment of the spinal cord as the involved dorsal root ganglion. Depending on the segment involved, this can lead to a monoparesis affecting the upper or lower limb or to diaphragmatic palsy (with involvement of C5/6). Paralysis usually recovers completely, although the outlook for recovery of facial nerve palsy is more variable. It is suggested VZV may be responsible for some cases of 'idiopathic' VIIth nerve (Bell's) palsy.

Autonomic zoster

Lumbosacral herpes zoster can be associated with a neurogenic bladder and acute retention of urine, which may be accompanied by haemorrhagic cystitis due to vesicles on the bladder wall. Intestinal ileus and obstruction may occur.

Zoster meningoencephalitis

A meningoencephalitis may accompany zoster at any site and is characterized by impaired consciousness, headache, photophobia, and meningism. The interval from the onset of skin lesions to symptoms of encephalitis is around 9 days, but may be as long as 6 weeks. Symptomatic encephalitis usually lasts around 2 weeks and is nearly always followed by full recovery without neurological sequelae.

A transverse myelitis, although rare, can occur at any level of the spinal cord.

Postherpetic neuralgia

The incidence of postherpetic neuralgia rises with increasing age of the patient. It is uncommon in young people, but can occur in 50 per cent of patients over the age of 50 years. It is characterized by pain in the affected dermatome persisting for 1 month or more after the acute attack of zoster has resolved. The pain may be steady and burning or paroxysmal and stabbing in nature: it may occur spontaneously or be triggered by stimuli such as temperature or touch.

Zoster sine herpete

This term refers to a syndrome characterized by radicular pain, similar to that experienced in zoster, but without any antecedent skin lesions of zoster. It was originally applied to patients who did have obvious zoster, but had dermatomal pain in areas distinct from those areas where there was rash: however, subsequently it has usually been applied to patients with radicular pain and no rash at all. There are more recent reports describing the use of PCR testing for the detection of VZV-DNA in the CSF of patients with presumed zoster sine herpete. The literature is anecdotal, and it is difficult to regard zoster sine herpete as a diagnostic entity unless there is good evidence for VZV involvement, for instance as shown by the detection of VZV-DNA in CSF and/or blood mononuclear cells. It should be kept in mind, however, as a possible explanation for radicular pain of unknown cause: any possible mechanism is speculative.

Varicella zoster virus infection in the immunosuppressed patient

In patients with immunosuppression, particularly of cellular immunity, varicella can be much more severe (Plate 3). The skin lesions are more diffuse and can take up to three times as long to heal. There may be visceral dissemination to the lungs, liver, and central nervous system. Patients with lymphomas being treated with chemotherapy are particularly susceptible.

Herpes zoster in immunosuppressed patients is also more severe than in normal subjects. Prior to the availability of effective antiviral therapy, skin lesions were more extensive and could take several weeks longer to heal. Dissemination, presumably due to viraemic spread, with widespread skin lesions as in varicella, occurs in 10 to 40 per cent of patients. Cutaneous dissemination is more likely to be associated with visceral dissemination to the same sites as those associated with varicella.

Patients with HIV infection and the acquired immunodeficiency syndrome (**AIDS**) are prone to multidermatomal zoster, which can be one of the defining features of AIDS.

VZV retinitis

This presents with pain and blurred vision in one eye, with progressive necrotizing retinitis seen on ophthalmoscopy. Adjacent cutaneous zoster indicates the diagnosis, but occasionally VZV retinitis can present in immunocompetent patients as the sole manifestation of VZV reactivation. VZV retinitis may be difficult to distinguish from cytomegalovirus (**CMV**) retinitis. A severe form of the disease, seen particularly in patients with HIV infection, is known as progressive outer retinal necrosis: it is associated with a high incidence of retinal detachment and may require treatment with ganciclovir as aciclovir is often ineffective.

Differential diagnosis

Varicella is usually recognized relatively easily. Other causes of a vesicular rash are generalized herpes simplex in the immunosuppressed patient and enterovirus disease, particularly hand, foot, and mouth disease due to coxsackievirus infection, but the rash on the hands and feet is unlike that of varicella which has a centripetal distribution. Human cases of infection with animal pox viruses (monkey pox and camel pox) have rarely been described.

Pathology

Histological appearances of VZV infection are similar or indistinguishable from those of HSV infection.

Laboratory diagnosis

The diagnosis of varicella and herpes zoster are usually made on clinical criteria alone. Virus can be seen in vesicular fluid by electron microscopy or isolated in culture. Serological diagnosis of varicella can be made by demonstrating seroconversion or VZV-IgM antibody. Urgent serology is needed to confirm the seronegative status of contacts at risk of severe VZV infection, to determine the need for VZV immunoglobulin (see below). PCR-based tests for the detection of VZV-DNA are available, and are most useful in testing CSF in cases of suspected central nervous system disease.

Treatment

Pruritus may be alleviated in patients with chickenpox by calamine lotion and antihistamines. Fingernails should be closely cut to minimize scratching. Skin care is important to prevent secondary bacterial infection in patients with varicella and zoster. Aspirin should be avoided in children with chickenpox because of the risk of Reye's syndrome. Strong analgesia may be needed in patients with zoster.

VZV is sensitive to the nucleoside analogues, aciclovir (aciclovir), famciclovir, and valaciclovir: as for HSV, VZV encodes a thymidine kinase which preferentially phosphorylates these drugs in infected cells. The median 50 per cent inhibitory concentration of aciclovir against HSV is 0.1 µmol/l, but it is 2.6 µmol/l against VZV and consequently 800 mg orally is necessary to achieve inhibitory concentrations against VZV.

Treatment recommendations for varicella and herpes zoster are summarized in Table 2.

Varicella

Whether to treat normal children with varicella (who are the great majority of patients) has been much debated. The argument can be made that it is not possible to predict which child may have a severe case and the disease is not always mild. Therapy with aciclovir is safe and, although it has been suggested that widespread treatment with antivirals might result in viral resistance or failure to develop normal immune responses, there is no evidence of this in controlled trials. Treatment with aciclovir begun within 24 h of the onset of rash leads to a 25 per cent decrease in the duration and severity of chickenpox. The argument for treating all adolescents and adults is easier, as chickenpox is more severe for them than it is for young children. Chickenpox in neonates, children with leukaemia, and transplant recipients, should always be treated with aciclovir: intravenously administered aciclovir limits the visceral spread of the virus if given immediately on diagnosis. Treatment in these immunosuppressed patients can be changed from intravenous to oral aciclovir once the fever has settled, if there is no evidence of visceral varicella.

Herpes zoster

The major justification for the antiviral treatment of herpes zoster in immunocompetent patients has been to limit postherpetic neuralgia. Although there are difficulties in accurately and objectively quantifying the pain of postherpetic neuralgia, trial data indicates that acyclovir, valaciclovir, and famciclovir can limit the duration of zoster-associated pain and that valaciclovir is slightly more effective. Acyclovir, valaciclovir, and famciclovir accelerate the healing of cutaneous lesions by 2 days over placebo. Valaciclovir and famciclovir have the advantage of more convenient dosage, as well as being probably slightly more effective.

Patients with zoster over the age of 50 are at the highest risk of postherpetic neuralgia and should consequently be offered antiviral treatment. Patients younger than this may warrant treatment if they have marked pain. All patients with ophthalmic zoster should be treated with antiviral agents, even if they present relatively late, as acyclovir reduces the incidence of keratitis. Immunosuppressed patients with herpes zoster should receive intravenous acyclovir to prevent cutaneous and visceral dissemination of VZV. Valaciclovir and famciclovir may be used if zoster presents in a localized form in less severely immunosuppressed patients.

Corticosteroids have been advocated in patients with herpes zoster, in order to reduce the severity of postherpetic neuralgia. However, in recent trials the addition of oral prednisone to aciclovir resulted in a slightly increased rate of healing of skin lesions but did not affect the incidence of postherpetic neuralgia. The place of corticosteroids thus remains unproven.

Prevention and control

Varicella zoster immune globulin (VZIG), prepared from high-titre immune human serum, has been shown to prevent or ameliorate varicella in seronegative individuals at high risk, such as immunocompromised patients and pregnant women. Seronegative immunodeficient patients (including those on high-dose corticosteroid treatment) and pregnant women with definite contact with varicella are candidates for VZIG administration. It should be administered within 10 days (preferably 2–4) of exposure. Neonates whose mothers have had varicella less than a week before delivery or within 28 days after delivery are also recommended for VZIG administration.

A vaccine is available for VZV. This is the Oka strain of VZV, which is a live attenuated vaccine developed in Japan. It induces 90 per cent protection from natural varicella when administered to non-immune immunosuppressed individuals (such as patients with leukaemias and lymphomas treated with chemotherapy), but it can produce a vaccine-induced rash in up to 40 per cent of such recipients. In immunized healthy children the risk of subsequent varicella after community exposure is reduced to less than 5 per cent, and vaccine-induced rash is much less common (about 5 per cent of recipients). This vaccine is licensed in Japan, some European countries, and the United States, where it is recommended for routine immunization in children aged between 12 and 18 months, but not in the United Kingdom where it is available on a named patient basis only for use in non-immune immunosuppressed subjects. Trials are in progress to assess whether postinfective immunization with the vaccine can diminish the incidence of zoster in those over the age of 50 years: it has already been shown to boost pre-existing cell-mediated immunity to VZV in this age group.

Nosocomial transmission of VZV from those patients with varicella who require admission to hospital is a significant risk as 10 per cent of adults are seronegative. The nursing and management of inpatients with varicella should be restricted to those staff known to be seropositive for VZV. Patients with varicella in hospital should ideally be isolated in negative-pressure rooms to prevent airborne transmission.

Human cytomegalovirus infection

Historical introduction

The syndrome of congenital cytomegalovirus infection 'cytomegalic inclusion disease' was described in children with fatal infection in 1904, but the intranuclear inclusions were attributed to a protozoan parasite. In 1921, the pathologist Goodpasture suggested the inclusions in the parotid glands of infants were caused by a virus, because a filterable agent produced similar histology in guinea-pig salivary glands, and the lesions were attributed in 1926 to 'salivary gland virus'. Human cytomegalovirus (**HCMV**) was finally isolated in 1956, and so named by Weller for the characteristic 'owl's eye', or cytomegalic, inclusions it produces in the nucleus of

infected cells.

HCMV produces little morbidity in the immunocompetent, but can produce severe disease in the fetus if infection is acquired *in utero*, and in the immunosuppressed patient.

Aetiology

HCMV is the largest human herpesvirus with a linear double-stranded DNA genome of 250 kb encoding over 200 proteins. It can be grown in tissue culture in human fibroblasts. Mammalian cytomegaloviruses are species-specific, and so HCMV cannot be studied in animal models. The most widely studied laboratory strain, AD169, shows significant genomic variation from recent clinical isolates which possess an additional 15 kb of DNA. They can infect and replicate in macrophages, which are probably an important site of latency for this wild-type virus. HCMV replicates slowly compared to other herpesviruses: gene expression occurs in sequential immediate-early, early, and late phases.

Epidemiology

Following primary infection, HCMV persists for life as a latent infection with periodic asymptomatic excretion of virus in saliva, breast milk, urine, semen, and cervical secretions. Infection is spread by close contact with these body fluids. In less developed countries HCMV is usually acquired in childhood and seropositivity is nearly 100 per cent in young adults. In more developed countries seropositivity increases with age, but seroprevalence is higher in lower socioeconomic groups. Overall, about 50 per cent of adults are seropositive. During childhood, HCMV is acquired from breast milk or contact with other infected children excreting virus in their saliva or urine: studies in day nurseries have shown transmission between children as well as to susceptible adult carers. Later, sexual transmission becomes a major route of infection: seroprevalence approaches 100 per cent in homosexual men and sex workers.

Blood and blood products from seropositive donors can transmit HCMV. Transfusion recipients at risk of HCMV disease now usually receive screened seronegative blood, otherwise the risk of transfusion-related HCMV infection is 2.5 per cent per unit of blood. Transmission results from virus in leucocytes, but leucodepletion of blood (now being widely adopted as a preventive measure against transmissible spongiform encephalopathies) greatly reduces the risk of HCMV transmission. Finally, solid organ and bone marrow transplants from seropositive donors can transmit HCMV, and produce particularly severe disease in seronegative recipients.

Pathogenesis

Current evidence suggests myeloid lineage cells are a principal site of HCMV latency, and that virus may be reactivated when monocytes acquire a permissive phenotype as they differentiate into macrophages. Other cells, including endothelial cells and possibly epithelial cells, may also be sites of latency.

The immune response is critical in controlling infection in the normal host. Normal immunocompetent infected individuals mount a strong T-cell response, with very high frequencies of cytotoxic (CD8+) T lymphocytes in the peripheral blood particularly targeted at the HCMV major tegument protein (pp65) and the major immediate-early protein (IE1). Impairment of this response is associated with the risk of disseminated infection. HCMV possesses at least four genes whose products interfere with the class I MHC antigen-processing pathway, and a number of other potential 'immune evasion' genes, which may help the virus reactivate by delaying immune recognition of infected cells. Natural killer cells may be active early in the infection. Antibody probably limits the blood-borne dissemination of HCMV, as maternal IgG appears to be especially important in preventing viral transmission to the fetus. Subclinical reactivation occurs requently in the normal host but is controlled by the immune response. Immune deficiency, particularly of the T-cell response, as occurs with iatrogenic or disease-induced immunosuppression, may allow uncontrolled replication and result in HCMV disease. Pathology is presumably produced by direct cytopathic effects of the virus, although indirect effects produced by soluble virus-encoded proteins or the host response are also possible. The presence of HCMV in a diseased organ does not necessarily implicate the virus as a cause of disease, because reactivation of virus may sometimes be non-pathogenic and a 'bystander' effect to some other pathogenic process.

This difficulty in unequivocally attributing disease to HCMV is illustrated by its postulated role in arterial disease. HCMV has been detected in atherosclerotic lesions by immunohistology. A more recent study associated HCMV with the smooth muscle cell proliferation responsible for coronary artery restenosis following angioplasty, although subsequent reports failed to confirm this. Other microbial agents have now been described in atherosclerotic lesions in humans, and Marek's disease virus (also a herpesvirus) is associated with atherosclerosis in chickens. The association thus remains plausible but speculative.

Clinical features of HCMV disease

Primary infection in immunocompetent subjects

Primary infection in children and adults is asymptomatic in most cases, but HCMV can produce an illness clinically indistinguishable from infectious mononucleosis caused by primary Epstein–Barr virus (**EBV**) infection, characterized by fever, myalgia, cervical lymphadenopathy, and mild hepatitis. Tonsillopharyngitis is much less common than in primary EBV infection, and lymphadenopathy and splenic enlargement are less prominent features. The fever lasts 2 to 3 weeks, but it can persist for up to 5 weeks. In more developed countries an increasing proportion of HCMV seroconversion illness is seen in older adults, and the diagnosis should still be considered in patients over 50 or 60 years of age. Myocarditis, pneumonitis, and aseptic meningitis are rare complications. A proportion (5–10 per cent) of patients with Guillain–Barré syndrome (**GBS**) show serological evidence of primary HCMV infection: they are more likely to have antibodies to the GM2 ganglioside than other patients with GBS, and a causal relationship is postulated.

Primary HCMV infection acquired from blood transfusion is characterized by a similar clinical picture occurring 3 to 6 weeks after transfusion, and is usually self-limiting in the normal host. The distinction of primary HCMV infection from other causes of mononucleosis syndromes (such as EBV and toxoplasmosis) depends on serological testing (the Paul-Bunnell and Monospot tests are negative in HCMV mononucleosis).

HCMV disease in the immunosuppressed patient

HCMV produces its most severe disease in immunosuppressed patients, particularly solid organ and bone marrow transplant (**BMT**) recipients, and those with AIDS, all characterized by impaired T-lymphocyte function: this strongly supports the importance of T cells in controlling infection.

Disease in solid-organ transplant recipients

The risk of HCMV disease is three- to fivefold greater in a seronegative recipient receiving a graft from a seropositive donor than in a seropositive recipient, and disease is much more severe. Many centres 'match' seronegative donors to seronegative recipients, although this is often thwarted by organ shortage. Disease presents with specific organ involvement not seen in the normal subject. Interstitial pneumonitis due to HCMV carries a poor prognosis; gastrointestinal disease includes oesophagitis, gastritis and peptic ulceration, and colitis; HCMV retinitis may occur in severely immunosuppressed patients. HCMV has been reported to be associated with increased graft rejection and renal artery stenosis in renal transplant recipients, with accelerated coronary artery stenosis in heart transplant recipients, and with 'vanishing bile duct' syndrome in liver transplant recipients. However, none of these associations is definitively established as causal.

Disease in bone marrow transplant (BMT) recipients

HCMV disease is a major problem in allogeneic BMT recipients, with a 30 to 50 per cent incidence of clinically significant infection. It is a lesser problem in autologous BMT. Seropositivity in donor or recipient, or both, carries a risk of HCMV disease, but the risk can be eliminated when both donor and recipient are seronegative if HCMV seronegative blood products are used to support the patient. Pneumonitis is the most serious manifestation of HCMV infection after BMT, occurring in 10 to 15 per cent of allogeneic BMT recipients, with a mortality of 80 per cent without antiviral therapy. There is interstitial pneumonitis in the absence of any other identifiable pathogen, with increasing arterial hypoxaemia, and progression to respiratory failure. It is suggested that graft-versus-host disease (**GvHD**) may contribute to the lung injury in HCMV pneumonitis in BMT recipients. The relationship of HCMV to GvHD is controversial, with propositions that HCMV may predispose to GvHD, and vice versa.

Disease in patients with AIDS

HCMV disease is one of the most frequent opportunistic infections in patients with advanced HIV infection, of whom 40 per cent develop sight- or life-threatening HCMV disease. A CD4 count below 50/µl carries a high risk of disease, although the widespread use of antiretroviral therapy in developed countries means that relatively few patients now have such low CD4 counts, and the incidence of HCMV disease in patients with AIDS has consequently declined significantly.

HCMV retinitis was seen in up to 25 per cent of patients with AIDS prior to effective antiretroviral therapy (Plate 5). Characteristically, haemorrhagic retinal necrosis spreads along retinal vessels and threatens sight when disease encroaches on the macula. Patients present with visual impairment and have an increased risk of retinal detachment and haemorrhage: hence those with low CD4 counts should undergo regular examination of the optic fundi to detect retinitis before it becomes symptomatic. Diagnosis is made by the ophthalmological detection of typical retinal changes, preferably with accompanying evidence of HCMV viraemia. Without treatment, HCMV retinitis almost invariably progresses to affect both eyes and destroy vision.

HCMV is reported to produce a diffuse encephalitis in AIDS patients but, although the virus is sometimes seen in neuronal cells at autopsy, encephalitis attributable to HCMV is relatively rare in clinical practice in comparison to the other causes of encephalitis in those with AIDS. HCMV can also produce a progressive radiculopathy causing low back pain, which radiates to the area supplied by the affected spinal nerve root, and the development of flaccid paraparesis.

In the gastrointestinal tract, HCMV is associated with oesophagitis, gastritis, and enterocolitis. Virus can be seen in biopsies from these sites, usually in shallow ulcers.

HCMV pneumonitis is rare in patients with AIDS, suggesting there must be additional factors to account for its frequency in BMT recipients.

Congenital and neonatal HCMV infection

HCMV infection of the neonate may be congenital from intrauterine infection, perinatal transmission during birth, or postnatal from breast milk. The frequency of congenital HCMV infection in developed countries is around 0.5 to 1 per cent of live births: it results from either primary maternal infection in pregnancy, or from reactivation of HCMV during pregnancy in a previously infected mother. The risk of primary maternal infection in pregnancy is about 1 per cent, and it carries a 40 per cent risk of congenital infection. Fetal infection is more likely to occur, and to be severe, when a seronegative mother acquires primary infection in early pregnancy. The risk of symptomatic congenital infection from reactivation of maternal HCMV in pregnancy is much lower, although not absent. Pre-existing maternal immunity limits spread to the fetus.

Approximately 5 to 20 per cent of congenitally infected babies are symptomatic at birth: the higher figure applies to babies of mothers with primary infection, who are also more likely to have serious disease. In its most severe form congenital HCMV infection is associated with microcephaly, chorioretinitis, nerve deafness, hepatitis with jaundice and hepatosplenomegaly, and thrombocytopenia with petechiae: such classical 'cytomegalic inclusion disease' has a high mortality, and 80 per cent of all infants symptomatic at birth who survive have serious sequelae such as mental, visual, and hearing impairment. However, the majority of congenitally infected babies are asymptomatic at birth: only 5 to 15 per cent subsequently develop sequelae on long-term follow-up, the commonest being sensorineural deafness, which occurs in isolation in otherwise normal babies.

Perinatal or postnatally acquired HCMV infection is rarely symptomatic or associated with long-term sequelae, if the mother is seropositive.

Malignancy

Although associations between HCMV and malignancy have been postulated in the past, there is currently no good evidence to associate the virus with any human malignancy.

Pathology

On light microscopy, typical HCMV-infected cells appear large with a relative reduction in cytoplasm, and nuclei that contain prominent intranuclear inclusions, surrounded by a clear halo (described as 'owl's eye' inclusions). These cells contain replicating virus and are associated with active infection and disease. They are diagnostic when seen in biopsies of affected organs. In patients dying of severe disease, histological evidence of HCMV involvement can be found in most organs, whereas it infects a restricted range of cells *in vitro*.

Laboratory diagnosis

Primary infection is usually diagnosed by the detection of IgM antibody to HCMV in the absence of IgG antibody: there is a marked atypical lymphocytosis (mainly due to increased CD8+ T cells) but heterophile antibody (as detected in primary EBV infection by the Monospot or Paul-Bunnell tests) is absent. Serology is of limited use in confirming HCMV disease in the immunosuppressed patient: IgG antibody is a useful marker of HCMV carriage, but titres do not rise reliably in disease. IgM antibody is found during primary infection, and also sometimes with reactivation in patients who are immunosuppressed. Culture of virus from urine may only indicate asymptomatic reactivation; culture from the blood buffy coat is more definitively associated with HCMV disease as virus can never be cultured from the blood of normal HCMV carriers, and culture from an organ site (such as bronchoalveolar lavage fluid) may indicate locally active disease. Rapid culture methods, such as the **DEAFF** (detection of early antigen fluorescent foci, by a monoclonal antibody against an immediate-early viral protein) or shell vial tests facilitate virus isolation. The HCMV antigenaemia assay detects the presence of the HCMV pp65 protein in peripheral blood neutrophils (where it may be taken up passively, rather than expressed by natural infection): the number of positive cells correlates with the level of viraemia. PCR-based techniques are increasingly used to detect and quantitate the HCMV load in blood or plasma, and in many laboratories are now the standard assay for detecting HCMV. As virus can never be detected in plasma (as opposed to leucocytes) in normal carriers, the presence of HCMV-DNA in plasma indicates active viral replication. Detection of virus in biopsy specimens by histological and immunohistological techniques implies organ disease due to HCMV.

In practice, HCMV disease is usually diagnosed by the combination of an appropriate clinical syndrome, and HCMV detection in blood or plasma, or in biopsies from involved organs, in the absence of any other likely causal microbial pathogen.

Treatment

Several drugs are now available for the treatment of disease due to HCMV. Aciclovir has little *in vitro* activity against HCMV, which, unlike HSV, does not possess a thymidine kinase (see above), and has no place in its therapy (although it is used in prophylaxis—see below). Ganciclovir, another nucleoside analogue, is monophosphorylated in infected cells by the *UL97* gene product of HCMV, and is active against HCMV: its most limiting side-effect is myelotoxicity with leucopenia and thrombocytopenia, but it has many other potential side-effects including azoospermia in males. Intravenous administration is necessary since an oral form of ganciclovir has bioavailability of only about 10 per cent, restricting its use to prophylaxis (oral valganciclovir, a new valyl ester of ganciclovir, has much higher bioavailability: it also produces equivalent plasma concentrations to intravenously administered ganciclovir, which initial trials suggest it may replace). Resistance to ganciclovir results from mutations in the drug target, the HCMV-DNA polymerase, or in the *UL97* gene, and is seen mainly in AIDS patients in whom prolonged use is necessary. An alternative drug to ganciclovir is foscarnet (trisodium phosphonoformate), which is a competitive inhibitor of the viral DNA polymerase and shows no cross-resistance with ganciclovir. This also has to be given intravenously and its side-effects include renal impairment and hypocalcaemia. Cidofovir, a nucleotide analogue acting on the viral DNA polymerase is also licensed for use in the United Kingdom, but is highly nephrotoxic (probenecid has to be given concurrently to prevent irreversible renal damage) and therefore relatively little used.

Primary infection

In the immunocompetent host, this requires no specific antiviral treatment.

HCMV disease in the immunosuppressed (due to primary or secondary infection, or reactivation)

This is usually treated with ganciclovir or foscarnet for 2 to 3 weeks of full-dose induction intravenous therapy: for ganciclovir this is 5 mg/kg body weight every 12 h;

and for foscarnet 60 mg/kg every 8 h. Secondary prophylaxis may well be needed if immunosuppression persists (see below).

HCMV pneumonitis in BMT recipients

HCMV pneumonitis responds poorly to ganciclovir or foscarnet alone, but the combination of full-dose ganciclovir with intravenous immunoglobulin has been shown to reduce mortality. Although specific anti-CMV immunoglobulin was initially used, recent trials suggest normal pooled intravenous immunoglobulin is equally effective. Many centres monitor BMT recipients, especially of allogeneic grafts, for CMV viraemia and if detected commence 'pre-emptive therapy' with ganciclovir prior to the development of symptomatic or obvious organ disease.

HCMV retinitis in patients with AIDS

This is treated with an induction course of ganciclovir or foscarnet (both drugs have also been used in combination). Continued prophylaxis is needed to prevent relapse unless significant recovery of the CD4 count can be induced with antiretroviral therapy: for this, intravenous ganciclovir—5 mg/kg per day for 5 days per week—is effective, but high-dose oral ganciclovir (1000 mg three times per day) may be adequate if retinal disease is peripheral to the macula. Given the difficulty of these regimes, implantable intraocular devices giving a sustained release of ganciclovir into the vitreous humor have also been used. The use of combination antiretroviral therapy in HIV-infected patients is associated with a much improved long-term control of HCMV infection.

However, the syndrome of 'immune recovery vitritis', characterized by posterior segment inflammation, can occur in patients with inactive treated CMV retinitis as their CD4 count reconstitutes on antiretroviral therapy.

Congenital HCMV infection

In a phase II evaluation of ganciclovir (8 or 12 mg/kg body weight daily for 6 weeks) for the treatment of symptomatic congenital HCMV infection, excretion of CMV in the urine decreased: however, after cessation of therapy viruria returned to near-pretreatment levels. Hearing improvement occurred in 5 out of 30 babies at 6 months or later, suggesting some efficacy, but the role of antiviral therapy in congenital HCMV infection remains to be established.

Prevention and control

The problem posed by HCMV in immunosuppressed patients has led to several approaches to prophylaxis.

Antiviral prophylaxis

Ganciclovir has been used for primary prophylaxis in solid-organ and BMT recipients, particularly those at high risk of disease (seronegative recipients of a seropositive graft, or seropositive recipients), and in AIDS patients with less than 100 CD4 cells/μl. Oral ganciclovir has been shown to be effective in many of these settings. Despite their limited *in vitro* activity against HCMV, and lack of efficacy as therapy, oral aciclovir and valaciclovir have also been shown to provide significant prophylaxis against HCMV disease in renal transplant recipients. Moreover, valaciclovir prophylaxis was also associated with a lower rate of graft rejection. This evidence, combined with their lack of toxicity compared to ganciclovir, has led to their widespread use.

Passive immunization

CMV hyperimmune globulin has been reported to reduce the risk of HCMV disease in renal transplant recipients but is expensive and little used in practice.

There are initial reports that HCMV-specific T-cell immunity can be reconstituted in BMT recipients by the adoptive transfer of virus-specific T lymphocytes from the immune donor, but this is still a research therapy.

Active immunization

A live laboratory (Towne) strain of HCMV has been tested as an experimental candidate vaccine in renal transplant recipients and found to have some evidence of protective immunity, perhaps equivalent to having previous natural HCMV infection. However, there is currently no available licensed vaccine, although some candidates are in early development.

Special problems in pregnant women

Pregnant women who are seronegative should avoid contact with possibly infected children in day nursery settings, although this may be impractical. This population would be the target for a vaccine were one available. Ganciclovir must not be used in pregnancy.

Human herpesvirus-6 and -7

Human herpesvirus-6

Introduction

Human herpesvirus-6 (**HHV-6**) was originally isolated in 1986 from cultured human lymphocyte lines and initially named 'human B lymphotropic virus'. However, it was subsequently shown to be tropic principally for T cells, although it can also replicate in macrophages, glial cells, and EBV-transformed B cells. HHV-6 is widely distributed in humans and primary infection is associated with roseola infantum (also known as exanthem subitum or sixth disease), an aetiological association first described in Japanese children by Yamanishi and colleagues in 1988.

Aetiology

HHV-6 has typical herpesvirus morphology and is genetically classified in the betaherpesvirus subfamily. Two groups of HHV-6 isolates, HHV-6A and HHV-6B, are now clearly distinguished by their genetic sequence and some variation in their biological properties. HHV-6B is associated with roseola, whilst HHV-6A has not been clearly associated with human disease.

Epidemiology

There is high seroprevalence of HHV-6 in all populations. More than 90 per cent of children are seropositive at 2 years of age. The virus (usually the HHV-6B variant) can be detected in peripheral blood mononuclear cells by PCR in nearly all healthy people. It is most probably transmitted via maternal saliva, although intrauterine and perinatal transmission could occur. The virus is not detectable in breast milk.

Pathogenesis

Upon primary infection with HHV-6, the virus probably replicates in regional lymphoid tissue in the oropharynx and can be found in circulating lymphocytes. HHV-6 replicates *in vitro* in CD4+ T-cell lines. However, during persistent infection in a normal adult, the virus can be detected by PCR in both CD4+ T cells and in monocytes/macrophages in peripheral blood. Monocytes/macrophages are probably the principal site of carriage during persistent infection. The mechanism of viral latency is uncertain. HHV-6 induces CD4 expression on $CD4^-$ lymphocytes, and *in vitro* may thus facilitate HIV entry into previously $CD4^-$ cells.

Although HHV-6 cannot normally be isolated in culture from the peripheral blood of normal individuals, it is easy to detect HHV-6 DNA in the peripheral blood of immunosuppressed subjects: this and other evidence indicates immunosuppression is associated with reactivation of HHV-6. Mechanisms by which HHV-6 may

produce clinical manifestations remain unclear.

Clinical features

Primary infection with HHV-6 in young children is associated with roseola and also with a febrile illness without rash.

Roseola infantum (exanthem subitum, sixth disease)

Roseola is an acute illness of infants and young children, characterized by 3 to 5 days of high fever with upper respiratory tract symptoms and sometimes cervical lymphadenopathy. As the fever defervesces, a rash appears and lasts for 1 to 3 days. The rash is diffuse, macular or maculopapular, and appears similar to that of rubella. The illness is accompanied by mild atypical lymphocytosis and there may be neutropenia. Rarely, infections are complicated by febrile convulsions, meningitis, encephalitis, and hepatitis, which is usually mild but occasionally severe.

Roseola has been estimated to occur in only 10 to 20 per cent of children, as primary HHV-6 infection is commonly subclinical.

Febrile illness

Fever without rash is a more usual manifestation of primary HHV-6 infection than roseola. In one major study of 1600 children under the age of 3 years presenting to a North American hospital emergency department with acute febrile illness, 10 per cent of cases were ascribed to primary HHV-6 infection. In children between the ages of 6 and 12 months within this study, 20 per cent of acute febrile illness was due to HHV-6, but only 17 per cent of all these children with documented primary HHV-6 infection had clinical roseola.

Febrile convulsions

There is accumulating evidence that HHV-6 has a major association with febrile convulsions in young children. In the study quoted above, 13 per cent of all the children under 3 years of age had febrile convulsions associated with acute HHV-6 infection, and the infection was reported to account for one-third of all febrile seizures in children up to the age of 2 years. It is believed that this association is not solely because HHV-6 induces high fever, but because it also specifically infects the nervous system. HHV-6 DNA can be detected in the cerebrospinal fluid of children with primary infection.

HHV-6 infection in immunosuppressed patients

A number of studies have shown increases in antibody titres to HHV-6 and increased HHV-6 DNA levels in peripheral blood by PCR in immunosuppressed solid-organ and bone marrow transplant recipients. In bone marrow transplant recipients, HHV-6 has been associated with fever, skin rash, graft-versus-host disease, encephalitis, delayed engraftment, marrow suppression, and pneumonitis: however, it is not clear whether HHV-6 plays a specific aetiological role in these syndromes. In the case of pneumonitis, BMT recipients have higher levels of HHV-6 DNA in the lung, but other opportunist infections such as human cytomegalovirus were not always excluded as the cause.

There is good evidence that HHV-6 reactivates in patients with advanced HIV infection and AIDS. However, there is no firm evidence for any HHV-6 associated disease in patients with AIDS.

In summary, current evidence suggests HHV-6 is infrequently associated with disease in immunosuppressed patients, but that it could be responsible for occasional cases of pneumonitis in BMT recipients.

Other disease associations

Some studies have associated HHV-6 with the chronic fatigue syndrome and with multiple sclerosis. The present consensus is that there is no convincing evidence for any significant aetiological association between HHV-6 and these illnesses.

Malignancy

HHV-6 DNA has been detected in the blood of patients with a number of lymphoproliferative disorders, but this probably reflects reactivation rather than any causal association with the tumour. There are reports of HHV-6 DNA being detected in some tumours, such as the nodular sclerosis variant of Hodgkin's disease, but there is no convincing aetiological association between HHV-6 and any tumour.

Differential diagnosis

Primary HHV-6 infection may be confused with many febrile childhood illnesses associated with a rash. The rash associated with roseola may mistakenly be attributed to sensitivity to recent antibiotic treatment. Other virus infections (EBV, HCMV) may also be associated with atypical lymphocytes and a mononucleosis syndrome.

Pathology

HHV-6 replicates in cells of central nervous system origin, particularly glial cell lines, *in vitro*. HHV-6 DNA can be detected in the brain of apparently normal individuals, suggesting viral persistence in the central nervous system. No distinctive histopathology has yet been attributed to HHV-6.

Laboratory diagnosis

Commercial assays for HHV-6 antibody do not distinguish between antibody to HHV-6A and HHV-6B and may cross-react with antibodies to HHV-7. Seroconversion is evidence of primary infection. IgM assays for HHV-6 antibody are not reliable indicators of primary infection as some HHV-6 carriers may have IgM antibody periodically.

Although HHV-6 can be cultured from peripheral blood mononuclear cells during acute primary infection, few laboratories will undertake this. PCR-based techniques for the detection of HHV-6 DNA in plasma and cerebrospinal fluid are the method of choice for clinical diagnosis, and are becoming increasingly available.

Treatment

HHV-6 sensitivity to antiviral drugs corresponds to the sensitivity of cytomegalovirus. Thus, HHV-6 replication is inhibited *in vitro* by ganciclovir and foscarnet but not aciclovir, but there are no controlled clinical trials of these agents. Their use may be considered for an immunosuppressed patient in whom HHV-6 associated pneumonitis is suspected.

Prevention and control

There is currently no place for measures to prevent HHV-6 transmission. It seems unlikely there will be a case for the development of a vaccine because infants may be infected so early in life, while they still have maternal antibody.

Special problems in pregnant women

Nearly all pregnant women will be carriers of HHV-6. There is no evidence to associate HHV-6 with a specific risk to the fetus or neonate.

Human herpesvirus-7

Human herpesvirus-7 (HHV-7) was isolated in 1990. It is also a betaherpesvirus, similar to but distinct from HHV-6. HHV-7 predominantly infects CD4+ T cells and can be reactivated from latency upon T-cell activation.

Although there is serological cross-reactivity between HHV-6 and HHV-7, the evidence is that HHV-7 infects nearly all humans during childhood (but later than HHV-6), with greater than 90 per cent of children being infected by the age of 5 years. The virus is excreted in saliva.

HHV-7 has been associated with some cases of roseola, and in a Japanese study was reported to cause roseola in infants who had already had a previous episode of roseola proven to be due to HHV-6. The similarity between HHV-7 and HHV-6 suggests that they may be associated with a similar range of diseases, but the association with roseola is the only one so far identified.

The best method of diagnosis is by PCR on serum or CSF. Laboratory tests for HHV-6 often also test for HHV-7 in a multiplex PCR. In the absence of any disease associations, apart from that with roseola, there is no reason to consider any treatment for HHV-7.

Human herpesvirus-8

Introduction

Human herpesvirus-8 (HHV-8) is the most recently isolated of the human herpesviruses. In 1994 Chang and colleagues, using the technique of representational difference analysis (which selectively amplifies DNA present in diseased tissue, but not the corresponding normal tissue), reported the detection of novel DNA sequences with homology to herpesviruses in Kaposi's sarcoma tissue. This herpesvirus is most closely related genetically to a well-characterized simian herpesvirus (herpesvirus saimiri) and less so to EBV, and it was consequently assigned to the g2-herpesvirus subfamily. It was initially named Kaposi's sarcoma-associated herpesvirus (**KSHV**), but was subsequently designated HHV-8. Current culture techniques are unreliable, but the virus can be detected by PCR. Serological assays depend on the use of infected cell lines or synthetic antigens from predicted open-reading frames. The seroepidemiology, biology, and disease associations of the virus are still being analysed, but HHV-8 is clearly closely associated with Kaposi's sarcoma, a tumour which has long been suspected of having a viral aetiology, with primary effusion lymphoma, and with Castleman's disease. Reported associations with multiple myeloma and other cancers are unconfirmed.

Aetiology

HHV-8 has the characteristic morphology of a herpesvirus. The viral genome is composed of a 141-kbp long unique segment flanked by multiple 801-bp direct repeats. Sequence analysis suggests that HHV-8, like other herpesviruses, is an ancient human virus, with several major subtypes reflecting the migrationary divergence of human populations. HHV-8 contains eight genes homologous to mammalian genes encoding cell-cycle regulatory proteins (the cyclins), chemokines, and inhibitors of apoptosis. Comparative genetic analyses show a high rate of amino acid variation in *ORF-K1* and another gene, *K15*. Analysis of the variable genes indicates there are at least four virus subtypes, A–D. On the evidence to date the normal cellular site of latency of HHV-8 almost certainly includes the B cell.

Epidemiology

The emerging epidemiology of HHV-8 suggests it is less ubiquitous than other human herpesviruses. Initial serological assays using indirect immunofluorescence on infected cell lines to detect antibodies to a latent nuclear antigen (**LANA**), give a seroprevalence of approximately 80 per cent in patients with Kaposi's sarcoma, and 25 to 30 per cent in HIV-positive homosexual men without Kaposi's sarcoma. Seroprevalence in normal adults is reported as being more than 50 per cent in African adults in West Africa, 20 per cent in Black South African blood donors, and less than 5 per cent in blood donors in the United Kingdom and United States, with intermediate rates in Italy and other Mediterranean countries. Seroprevalence in HIV-positive and -negative adults in Uganda was equal at 53 per cent. HHV-8 can be detected by PCR in nearly all cases of Kaposi's sarcoma, so the failure of this assay to detect antibody in all cases of Kaposi's sarcoma implies it has limited sensitivity. An assay using lytic-cycle antigens gave higher rates of seroprevalence, but these may result from cross-reaction with EBV antibodies. Newer assays using multiple HHV-8 antigens are currently being applied.

The normal route of transmission of the virus is unknown, but sexual transmission occurs between homosexual men. A LANA-based assay detected seroconversion to HHV-8 in HIV-infected homosexual men at a median of 33 months before they subsequently developed Kaposi's sarcoma. HHV-8 infection in children correlates with seropositivity in their mothers, but whether this reflects vertical or horizontal transmission is unknown.

Pathogenesis

There has been much uncertainty over the cell of origin of Kaposi's sarcoma, but the spindle cells of which the tumour is largely composed are thought to be of lymphatic endothelial origin. In Kaposi's sarcoma tumour tissue, HHV-8 DNA and LANA are present in every spindle cell, suggesting an aetiological role for the virus.

In HIV-associated Castleman's disease, the HHV-8 LANA antigen is present in immunoblasts in the mantle zone of the tumour. HHV-8 is present in the tumour cells of all cases of primary effusion lymphoma so far studied, although so also is EBV. HHV-8 latently infected cell lines derived from these tumours can be induced *in vitro* to release infectious virus, and are used to detect antibodies to the virus.

These clear associations of virus DNA with tumour cells suggest a definite oncogenic role for HHV-8. The possession of the genes encoding cyclin and antiapoptotic protein homologues suggests they may be involved in cellular transformation and oncogenesis by HHV-8.

It has been suggested that HHV-8 may be involved in the pathogenesis of multiple myeloma. The virus has been reported in bone marrow dendritic stromal cells of myeloma patients, but not in myeloma cells; however, this putative association remains speculative. The individual HHV-8 subtypes are not associated with any distinct pathology.

Clinical features

Apart from these malignancies, the only reported clinical syndrome accompanying primary or reactivated HHV-8 infection is fever and bone marrow failure in immunosuppressed transplant recipients.

Kaposi's sarcoma

Kaposi's sarcoma manifests clinically as purplish brown macules, papules, or plaques. It is described in four characteristic clinical settings: the classic form in elderly Mediterranean or Jewish males, the endemic African form (accounting for 10 per cent of cancer in equatorial Africa), in patients with immunodeficiency states such as transplant recipients, and the AIDS-associated form. The classic and African forms are characterized by lesions on the extremities, systemic and mucosal involvement is rare, and the disease is indolent. In immunosuppressed patients (other than those with AIDS) lesions are more widespread and more rapidly progressive, although visceral involvement is still unusual, and lesions may regress if immunosuppressive drugs are stopped. AIDS-associated Kaposi's sarcoma is seen predominantly in homosexual men in Western countries, but is commonly associated with heterosexually acquired HIV infection in African countries: it is characterized by widespread cutaneous lesions with involvement of the oral mucosa (Plate 6), and visceral lesions may occur in the lungs or gastrointestinal tract. Progression can be much more rapid than the other forms. HHV-8 has been isolated from all these forms of Kaposi's sarcoma.

Primary effusion lymphomas

Previously known as body cavity-based lymphomas, these are a rare and aggressive type of B-cell lymphoma presenting in patients with AIDS as lymphomatous effusions of the peritoneal, pleural, or pericardial spaces, usually with no identifiable tumour mass. HHV-8 is present in the tumour cells of all cases so far studied, although so also is EBV.

Castleman's disease

Also known as angiofollicular lymph node hyperplasia, Castleman's disease can be localized and is amenable to curative excision. However, a multicentric form is seen particularly in HIV-infected patients and is more aggressive: HHV-8 is found in a high proportion of these multicentric cases, especially those associated with HIV.

Pathology

No distinctive histopathology, independent of the pathology of the tumours with which it is associated, has been identified as attributable to HHV-8 infection in cells.

Laboratory diagnosis

HHV-8 can best be detected by PCR-based tests. Antibody assays are described above, and may become commercially available in the near future.

Treatment

Assays based on the HHV-8 infected lymphoma cell lines suggest that HHV-8 replication is moderately sensitive to foscarnet, ganciclovir, and cidofovir. It has been suggested that patients with AIDS treated with foscarnet and ganciclovir may have been less likely to develop Kaposi's sarcoma. There is no established use of antiviral drugs in treating HHV-8 tumours.

The treatment of Kaposi's sarcoma is discussed in Chapter 7.10.24. Kaposi's sarcoma confined to the skin can be treated with radiotherapy or with intralesional interferon-alpha. More widespread cutaneous or visceral disease can be treated with single-agent or combination chemotherapy.

Kaposi's sarcoma lesions may regress with antiretroviral treatment, possibly due to the improved cellular immunity that occurs with a reduction of the HIV load.

Prevention and control

Given limited knowledge of the epidemiology and disease associations of HHV-8, no prevention or control measures are used. No special problems of infection have been identified in pregnant women.

Cercopithecine herpesvirus-1 (herpes B virus)

Introduction

Cercopithecine herpesvirus-1 is the formal name now given to herpes B virus (also previously known as herpesvirus simiae, a term no longer used), whose natural hosts are members of the *Macaca* genus of Old World monkeys. It produces minimal disease in its natural host, but its transmission to humans results in a high incidence of severe disease. Although more than 30 other herpesviruses have been isolated from non-human primates, none of these have been unequivocally associated with a disease in humans. The virus was first isolated in 1932 from the brain of Dr WB who died of encephalitis after a bite from a macaque monkey (hence the name herpes B virus). There have since been about 45 cases of human infection resulting from accidental transmission from captive monkeys.

Aetiology

Herpes B virus is an alphaherpesvirus closely related to HSV and appears to behave in an analogous manner to HSV in its natural primate host. Herpes B virus can also infect and produce disease in other non-human primates and small mammals.

Epidemiology

Herpes B virus is enzootic in Old World macaque monkeys, principally rhesus (*Macaca mulatta*) and cynomolgus (*Macaca fascicularis*) macaques. The epidemiology in its primate host is similar to that of HSV in humans, with 80 per cent or more of natural and captive adults monkeys being infected. Infected monkeys may develop vesicular oral lesions and can shed virus intermittently from oral, conjunctival, and genital secretions.

Rhesus and cynomolgus macaques have been quite widely used in medical research, particularly for polio vaccine development during the mid-1950s and for studies of retroviruses from the late 1980s following the AIDS epidemic. Nearly all the reported human cases resulted from occupational exposure through bites and scratches in workers handling monkeys, but transmission from needlestick injuries and a splash in the eye have also been reported. One case of human-to-human transmission apparently occurred by inoculation on to inflamed skin.

Two clusters of infections have been described in the United States (in 1987 and 1989), the earlier one involving the case of human-to-human transmission. A seroprevalence study of over 300 monkey handlers revealed no seropositive subjects, and asymptomatic infection documented by seroconversion appears to be extremely uncommon.

Clinical features

The incubation period from occupational exposure to the development of symptoms has been 3 to 5 days in most cases, but it can range from 3 to 30 days. Cutaneous vesicles may occur at or near the site of inoculation accompanied by regional lymphadenitis. A prodrome of fever, malaise, headache, and abdominal pain occurring in the first 2 weeks is common, but the dominant and characteristic feature of reported cases is a progressive myelitis and encephalitis. Herpes B virus produces a multifocal haemorrhagic myelitis and encephalitis. Visceral spread is recorded in fatal cases. Before the advent of aciclovir and later antiviral drugs, the mortality rate was 70 per cent.

It is not clear whether herpes B virus can establish latency and then reactivate in humans. Viral shedding has recurred when antiviral treatment was stopped relatively early, so most patients have been maintained on antivirals for long periods.

Laboratory diagnosis

Herpes B virus is a category IV pathogen and only a few designated laboratories can undertake culture and isolation of the agent. In the United Kingdom the designated laboratory is at the Central Public Health Laboratory, Colindale, London, and in the United States at the South West Foundation for Biomedical Research, San Antonio, Texas. Suspected infected monkeys should be bled to determine seropositivity. Serodiagnosis in humans is made difficult because of antigenic cross-reactivity between herpes B virus and herpes simplex virus. The inoculation site should preferably be biopsied for possible culture and analysis. PCR-based methods are available in specialized centres and are the standard for definitive diagnosis.

Treatment

Suspected injuries from macaques carry the risk of herpes B virus infection, although most captive macaque colonies are now maintained free of the virus. A suspected contaminated wound should be debrided and cleaned with chlorhexidine or iodine soap. There may be a case for initiating immediate antiviral treatment if infection in the monkey is suspected or for a deep wound. Otherwise presumptive therapy may be initiated if the monkey is subsequently shown to be positive for herpes B virus, although the report of transmission by an eye splash favours early presumptive treatment.

Aciclovir and ganciclovir both inhibit herpes B virus replication *in vitro*. For presumptive therapy, oral aciclovir 800 mg, 5 times daily, or preferably valaciclovir in

equivalent dose can be given for at least 2 weeks.

If symptomatic disease is suspected, intravenous aciclovir should be used (10 mg/kg body weight every 8 h for peripheral disease, and 15 mg/kg every 8 h for central nervous system involvement). If progression occurs, ganciclovir (5 mg/kg every 12 h) should be considered as an alternative. Treatment has been associated with limitation of disease and recovery in some patients.

Prevention and control

Those working with macaques should follow standard procedures to avoid infection. Screening of newly imported monkeys, and the creation of colonies of macaques free of herpes B virus, are now becoming standard practice.

7.10.3 The Epstein–Barr virus

M. A. Epstein and Dorothy H. Crawford

Background

The virus

Epstein–Barr virus (**EBV**), discovered in 1964, is one of the eight herpesviruses of man. It consists of an outer envelope, a protein capsid, and an inner double-stranded linear DNA genome.

Viral infectious cycle

Natural infection is limited to man and susceptible target cells are circulating B lymphocytes and, in certain circumstances, squamous epithelial cells of the oropharynx. Lytic infection of these cell types leads to production of viral progeny and cell death. The virus also causes a latent infection of B cells *in vivo* and can transform normal B lymphocytes *in vitro* into continuously growing, latently infected, immortalized lymphoblastoid lines. Specific sets of virus-coded proteins are expressed in each type of infection.

Virus-coded proteins

EBV-coded proteins are categorized according to the time of their appearance during the infectious cycle as latent, early, or late antigens. Most elicit cytotoxic T-cell responses and serum antibodies; both are important for controlling the infection and the latter are used in diagnosis.

General epidemiology

The virus is widespread in all human populations. Primary infection usually occurs in early childhood, at which age it is clinically silent, but leads to the generation of antibodies to the virus-determined antigens and of specific cytotoxic T lymphocytes. A lifelong carrier state ensues, in which both humoral and cellular immune responses are maintained continuously. The virus persists as a latent infection in a few circulating B lymphocytes and as a productive, lytic infection in intraepithelial B cells of the mouth and pharynx, and perhaps also the urogenital tract and salivary glands. EBV is shed into the buccal fluid in considerable amounts in about 20 per cent of those who have been infected and in small amounts in the remainder; the virus has also been detected in genital secretions. Virus in the buccal fluid provides the main source for transmission of the infection in the population; in children this occurs via droplets or when objects are casually contaminated with saliva and sucked, whereas amongst the sexually active, transmission is by salivary transfer during kissing. In developing countries, 99.9 per cent of children are infected by the second to the fourth year of life but in industrialized countries with high standards of hygiene many do not meet the virus as young children. The percentage of teenagers or young adults remaining free of infection in Western societies depends on socio-economic group—the higher the standard of living, the greater the percentage; 50 per cent of very affluent young adults may escape childhood infection (Fig. 1).

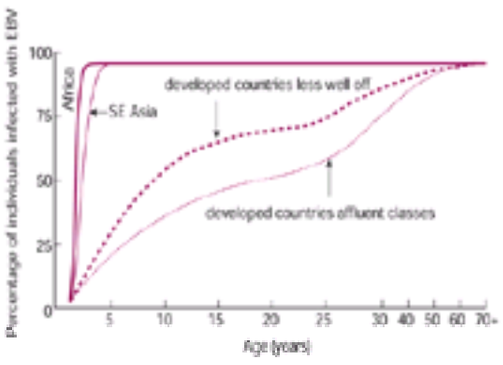

Fig. 1 Comparison of the ages at which individuals in different populations become infected with EBV. In developing countries, almost all children have acquired the virus by 2 to 4 years of age, depending on geographical region. In developed countries with high standards of living and hygiene, the time of infection is delayed for many, more markedly among the affluent than the less well off. Amongst the very rich, as many as 50 per cent may reach adolescence or young adulthood without having encountered the virus and will undergo delayed primary infection with a high risk that this will be accompanied by the symptoms of infectious mononucleosis. (Reprinted with permission from Epstein MA (2002). Infectious mononucleosis. In: *Encyclopedia of life sciences*, vol. 10, pp.211–16. http://www.els.net/, London: Nature Publishing Group.)

Infectious mononucleosis

Infectious mononucleosis occurs in about 50 per cent of those who miss EBV infection in childhood when, sooner or later, they undergo delayed primary infection; the other 50 per cent of delayed infections are symptom free. Because teenagers and young adults in the affluent classes of Western countries escape infection as children, infectious mononucleosis is a disease of upper socio-economic groups; conversely it is exceptionally rare in developing countries (Fig. 1). Although most cases occur in adolescents and young adults, children and the middle aged may sometimes develop the disease, and rarely also the elderly. Infectious mononucleosis is associated with kissing and is acquired when a healthy carrier, who is shedding virus in his/her saliva, passes this during close buccal contact directly into the oropharynx of a partner who has not been primarily infected in the usual way as a child. This explains why case-to-case infection and epidemics are not seen and why the incubation period, perhaps 30 to 50 days, is difficult to calculate. Primary EBV infection giving infectious mononucleosis-like symptoms may also be transmitted by blood transfusion or organ grafting from an infected donor to a previously uninfected recipient.

Symptoms

Classic infectious mononucleosis may follow some days of vague indisposition or may start abruptly. It presents with sore throat, fever with sweating, anorexia, headache, and fatigue, together with malaise quite out of proportion to the other complaints. Dysphagia may be noticed and also brief orbital oedema. Erythematous and maculopapular rashes occur in a small number of untreated patients, but in many more who have been taking ampicillin for sore throat before infectious mononucleosis has been diagnosed. Tonsillar and pharyngeal oedema can rarely cause pharyngeal obstruction (Fig. 2).

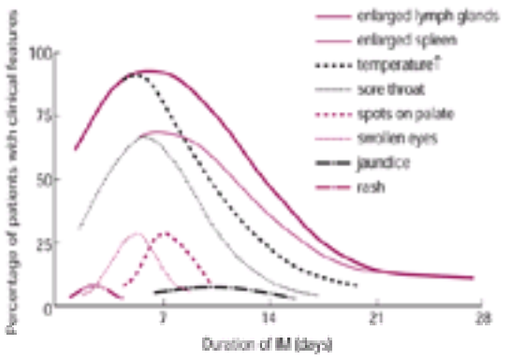

Fig. 2 Percentage of patients with infectious mononucleosis showing various clinical features during the course of the disease, and the timing and average duration of each. (Reprinted with permission from Epstein MA (2002). Infectious mononucleosis. In: *Encyclopedia of life sciences*, vol. 10, pp.211–16. http://www.els.net/, London: Nature Publishing Group.)

Signs

The fever may rise to 40°C but high levels and swings are not seen. There is redness and oedema of the pharynx, fauces, soft palate, and uvula, and about half the patients develop greyish exudates. Generalized lymphadenopathy is almost always present, most marked in the cervical region; the glands are symmetrical, discrete, and slightly tender, and are accompanied by splenomegaly in about 60 per cent of cases and an enlarged liver in 10 per cent. There is usually a moderate bradycardia. Besides the rash, characteristic palatal enanthematous crops of reddish petechiae are found in about one-third of patients, and jaundice occurs in about 8 per cent (Fig. 2).

Clinical course

Mild cases may resolve in days, but 1 to 2 weeks is more usual, followed by a period of lethargy. The duration of this convalescence is influenced by psychological factors, particularly the speed with which patients are encouraged to resume full activity. About 1 case in 2000 may continue in a truly chronic or recurrent form for several months or years, and here exhaustive investigations have shown immunological defects. Most other cases of so-called chronic infectious mononucleosis are in reality manifestations of 'chronic fatigue syndrome', but it is highly controversial as to whether this is a true entity rather than a form of depression or a belief disorder; credible connections with EBV have not been established. In contrast, there is an extremely rare, genetically determined, X-linked, lymphoproliferative condition (XLP disease, or Duncan syndrome after one of the first families to be recognized) in which the affected young males of certain kindred die from infectious mononucleosis owing to a specific inability to respond normally to EBV during primary infection; the disease progresses inexorably, with necrotic destruction of vital organs and multisystem failure. There is evidence that an aberrant immune response to EBV in XLP results in unregulated cytotoxic T-cell activity being directed against the normal cells of vital organs instead of targeting solely on EBV-infected cells displaying EBV antigens. The gene responsible for this defect has recently been cloned.

Complications

Minor non-specific complications may occur; rare more serious complications include secondary bacterial throat infections, traumatic rupture of the enlarged spleen, asphyxia from pharyngeal oedema, massive hepatic necrosis, Guillain–Barré syndrome, and autoimmune manifestations such as thrombocytopenia and haemolytic anaemia.

Differential diagnosis

Classic infectious mononucleosis is diagnosed on the basis of the clinical picture considered in conjunction with serological and haematological laboratory investigations (see below). An infectious mononucleosis-like disease can occur in primary cytomegalovirus infection and in toxoplasmosis, but in both conditions the sore throat is much less severe and with cytomegalovirus the lymphadenopathy may be minimal or absent.

Laboratory diagnosis

A rapid screening test (Monospot test) can be used to detect the presence of heterophil antibodies in the patient's serum. Although these heterophil antibodies are not directed against viral-coded proteins they are present in up to 85 per cent of acute infectious mononucleosis sera. Cases of Monospot-negative infectious mononucleosis tend to be those outside the classic 15- to 25-year age range, and false-positive tests may occur in pregnancy and autoimmune disease. However, the presence of serum IgM antibodies to EB virus capsid antigen (**VCA**) are diagnostic of infectious mononucleosis. An additional important feature of infectious mononucleosis is the presence of lymphocytosis of up to $15 \times 10^{9}/1$, with the majority of cells having an 'atypical' morphology.

Treatment

Bed rest and aspirin for headache and pharyngeal discomfort are the only treatments required. When the fever resolves the patient should be encouraged to get up and resume some activities as fast as is practicable, but violent exercise should be avoided for 3 weeks after an enlarged spleen ceases to be palpable. Only complications need active therapy: splenic rupture requires surgery, bacterial infections call for appropriate antibiotics, airway obstruction must be relieved by tracheostomy, and corticosteroids should be given for life-threatening pharyngeal oedema and for neurological and haematological complications.

Pathogenesis

Why children do not have symptoms during primary EBV infection whereas adolescents and young adults frequently react by developing infectious mononucleosis is not fully understood. The immunological reactions of young adults on first encountering EBV are more exuberant than those of children reflecting physiological differences in responsiveness. The mode of infection and consequent size of infecting dose also play an important part; children come into contact with small amounts of virus in saliva from a shedder in droplets or casually contaminating some sucked object, whereas a young person may take in large amounts of virus-containing saliva from a carrier during kissing so that virions reach susceptible cells in large numbers. Intraepithelial B cells become productively infected in infectious mononucleosis and at this stage EBV can easily be found in patients' saliva. The newly replicated virus infects masses of B lymphocytes which are released from the throat into the blood and lymphatics from where they accumulate in lymphoid tissue throughout the body. In response, there is a generation of even greater numbers of cytotoxic T cells specifically directed against EBV-determined antigens displayed by the infected B lymphocytes. An exaggerated immunological response thus underlies the changes seen in infectious mononucleosis since all these lymphoid cells present in the circulation, in lymph nodes, in tonsils, in lymphoid centres in the mouth and pharynx, and in spleen and liver are responsible for causing the sore throat, fever, malaise, lymphadenopathy, and hepatosplenomegaly by immunopathological mechanisms.

Endemic (or 'African') Burkitt lymphoma

The classic form of this B-cell tumour, first described by Burkitt in 1958, is found in certain parts of Africa and Papua New Guinea where the temperature does not fall below 16°C or the annual rainfall below 55 cm. Endemic Burkitt lymphoma is distinct from the 'Burkitt-like' tumours that occur sporadically everywhere in the world (sometimes called 'American' Burkitt lymphoma) and that have a different age incidence, anatomical distribution, and response to therapy, and arise from B cells with different phenotypic characteristics.

The association between EBV and endemic Burkitt lymphoma is so close that it is generally accepted that the virus is an essential link along with cofactors in a complicated chain of events which leads to the malignancy. Hyperendemic malaria has been identified as the important cofactor, and its spread by anopheline mosquitoes requiring warmth and moisture explains the climate dependence of Burkitt lymphoma.

Burkitt lymphoma is a disease of childhood, is extremely rare over the age of 14 years, and in the endemic areas it is more common than all other childhood tumours added together.

Symptoms

The tumour is usually multifocal and the symptoms depend entirely on the anatomical location. Jaw tumours are present in 70 per cent of patients, are the usual presenting feature, may be multiple in up to all four quadrants, and are almost always accompanied by tumours elsewhere. They give a rapidly growing mass with loosening of teeth and exophthalmos from orbital spread. Abdominal tumours involve retroperitoneal nodes, liver, ovaries, intestines, and kidneys. Burkitt lymphoma sometimes presents in thyroid, the adolescent female breast, testicles, and salivary glands; extradural tumours in the spine cause rapid paraplegia, and skeletal tumours also occur. Characteristically Burkitt lymphoma does not involve the spleen or peripheral lymph nodes.

Signs

The tumours are firm, very rapidly growing, painless, and cause minimal constitutional disturbance. Their sites determine the clinical signs.

Clinical course

Tumour growth is relentless and death ensues within a few months in the absence of treatment.

Differential diagnosis

In endemic areas Burkitt lymphoma can be diagnosed from the clinical picture. Unlike Burkitt lymphoma, retinoblastoma is intraocular, rhabdomyosarcoma is extraorbital and does not involve teeth, nephroblastoma is not multifocal, and neuroblastoma and ovarian tumours can be distinguished histologically. Paraplegia of tuberculous origin causes vertebral collapse and acute transverse myelitis is preceded by pain and fever. Other lymphomas have a markedly dissimilar anatomical distribution.

Laboratory diagnosis

Histological examination of a biopsy sample gives ready confirmation. Antibodies to EBV antigens show a unique pattern and titres rise or fall with disease progression or response to therapy. IgG anti-VCA titres are around 10 times higher than in controls and antibodies to EBV-restricted early antigens (EA-R) and membrane antigens (MA) are also detectable.

Treatment

Surgery and radiotherapy are ineffective, but moderate courses of chemotherapy give excellent results with cyclophosphamide being the drug of choice.

Pathogenesis

The molecular pathways whereby EBV-coded antigens transform normal B lymphocytes *in vitro* into continuously growing immortalized cell lines are partially understood. There are now credible explanations as to how EBV combines with cofactors such as hyperendemic malaria to cause the tumour. The virus is a necessary, but not on its own sufficient, element in the aetiology of the disease.

Lymphoproliferations in immunosuppressed states

In primary and secondary suppression of cellular immunity there is diminished immune control of persisting EBV infection which leads to increased virus replication in the oral cavity, increased numbers of circulating, virus-carrying B lymphocytes, and increased levels of serum antibodies to EBV antigens. This is sometimes described as a 'reactivated infection' although the condition is clinically silent. However, on occasions the loss of control leads to the development of EBV-associated lymphoproliferations.

In transplant recipients

Transplant recipients who receive lifelong immunosuppressive drugs to prevent graft rejection have a 28 to 100 times increased risk of developing lymphoproliferative disease and lymphoma compared with normal controls; most of these conditions are of B-cell origin, contain the EBV genome, and express viral antigens in their cells. Lymphoproliferative disease has two forms. About 50 per cent of cases are associated with primary EBV infection in patients who were seronegative at the time of grafting, occur within the first year after transplantation in a young age group, and have infectious mononucleosis-like symptoms. The remainder of the cases occur in older patients late after transplantation as a localized mass, commonly in the gut, central nervous system, or transplanted organ; biopsy shows large-cell lymphoma, which is usually monoclonal. Reduction of immunosuppressive therapy, with or without acyclovir therapy, is the first line of treatment, with cytotoxic drugs and/or radiotherapy being used only where there is no response or after recurrence. Recently, experimental treatments with EBV-specific cytotoxic T-cell infusions have shown encouraging results.

In acquired immunodeficiency syndrome (AIDS)

Two types of lymphoma are seen in patients with AIDS; large-cell lymphoma and Burkitt lymphoma, and both may be associated with EBV.

Large-cell lymphomas similar to those found in transplant recipients (see above) occur in severely immunocompromised patients with AIDS; their distribution is

extranodal, involving many unusual sites, most commonly the central nervous system. These lymphomas show a strong association with EBV which reaches 100 per cent in cerebral tumours; the progress is rapid, with a mean survival time from diagnosis of 3 to 4 months. Treatment (radiotherapy) is disappointing because patients with terminal AIDS are in such poor general health.

Burkitt lymphoma occurs earlier in the course of human immunodeficiency virus (HIV) disease while the immune system is still relatively intact and is therefore more amenable to treatment. About 50 per cent of these lymphomas contain EBV DNA.

Hodgkin's disease and T-cell lymphomas

There has long been a suspicion that EBV is involved in the induction of Hodgkin's disease because of the similar socio-economic epidemiology of Hodgkin's disease and infectious mononucleosis, and because within 5 years of infectious mononucleosis there is a four- to sixfold increase in the likelihood of developing Hodgkin's disease. There is now evidence that in Hodgkin's lymphomas EBV DNA is carried and expressed in both the Reed–Sternberg and the mononuclear Hodgkin's cells. These findings are as yet insufficient to implicate EBV in the aetiology of Hodgkin's disease, but point to the need for further investigation. A similar situation exists with oral T-cell lymphoma in patients with AIDS, and nasal T-cell lymphomas.

Nasopharyngeal carcinoma

This tumour is restricted to the postnasal space where it arises from squamous epithelial cells. The tumour is seen rarely throughout the world but has a remarkably high incidence in southern Chinese, and in the Inuit and related circum-Arctic races. In high incidence areas, nasopharyngeal carcinoma is the most common cancer of men and the second most common of women. A rather high incidence of nasopharyngeal carcinoma is seen amongst Malays, Dyaks, Indonesians, Filipinos, and Vietnamese people, and a medium-high incidence belt stretches across North Africa, through the Sudan, to the Kenya highlands. The tumour usually occurs in middle or old age, but in North Africa it has bimodal age peaks, one involving young people up to 20 years of age and a second much later in life. Irrespective of geographical region, nasopharyngeal carcinoma cells always carry the EBV genome.

Symptoms

Nasopharyngeal carcinoma causes nasal obstruction, discharge, or bleeding; deafness, tinnitus, or earache; headache; and ocular paresis from tumour spread to involve cranial nerves. Patients may present with a single symptom caused locally by the tumour or with several symptoms, and about one-third complain only of cervical lymph-node enlargement due to metastatic spread from an occult primary tumour.

Signs

Direct spread from the primary tumour may involve the soft tissues, bone, parotid gland, buccal cavity, and oropharynx. The neoplasm may extend into the nasal fossas, the paranasal sinuses, or the orbit, and can invade the eustachian canal or the parapharyngeal space where cranial nerves IX, X, XI, and XII can be involved. Invasion of the skull or cranial foramina may damage cranial nerves II, IV, V, and VI. Lymphatic spread causes enlarged cervical lymph nodes and subsequently extends to the supraclavicular glands. If bloodborne metastases occur, they are most frequent in the bones, liver, and lungs, but may be in any organ.

Clinical course

Untreated nasopharyngeal carcinoma progresses inexorably to death.

Differential diagnosis

Nasopharyngeal carcinoma must be distinguished from other tumours of the nasal cavities, namely adenocarcinomas, sarcomas, malignant lymphomas, and rare malignancies such as chordoma, teratoma, and melanoma.

Laboratory diagnosis

The diagnosis of nasopharyngeal carcinoma is made histologically on a biopsy sample either from the primary tumour or from an enlarged cervical lymph node. In addition, serum antibody titres to EBV antigens show a characteristic reaction pattern—IgG and IgA antibodies to VCA and diffuse early antigen (EA-D) are raised, with the titre correlating with the tumour burden. Uniquely, IgA antibodies to VCA and EA are also found in the saliva from patients.

Treatment

Nasopharyngeal carcinoma responds well to radiotherapy, which is the treatment of choice. In the earliest stages of the disease, radiotherapy gives 5-year survival rates of 50 per cent or more, and of those surviving 5 years, 70 per cent remain permanently free of relapse. More advanced stages of nasopharyngeal carcinoma have correspondingly worse prognoses.

Pathogenesis

EBV is now widely accepted as necessary for the causation of nasopharyngeal carcinoma, but is not sufficient on its own. Besides the racial predisposition there is also a genetic predisposition since southern Chinese people with an A2BW36 haplotype are four to six times more likely to have nasopharyngeal carcinoma than those without. Epidemiological studies suggest that important environmental cofactors associated with the Chinese way of life play a role and two likely candidates are: traditional herbal medicines, taken as snuff, and containing tumour-promoting substances of phorbol ester type; and traditional salt fish which has been shown to contain carcinogenic nitrosamines.

Hairy leukoplakia in AIDS

This lesion occurs in people with HIV and in other immunosuppressed individuals; it usually presents as painless white patches on the tongue or on the lateral buccal mucosa. The lesions are slightly raised, poorly demarcated, and have a 'hairy' or corrugated surface; the patches are usually multiple and measure up to 3 cm in diameter.

The squamous epithelial cells of this condition contain large amounts of actively replicating EBV, providing an unusual example of the production of the virus by such cells. Treatment with acyclovir arrests the EBV replication and the lesions regress, but only for as long as the drug is continued.

Smooth muscle tumours and gastric carcinoma

Recently EBV has been implicated in various types of gastric carcinoma and in leiomyomas and leiomyosarcomas in children immunosuppressed by AIDS or after organ transplantation. Much further study of these relationships is required.

7.10.4 Poxviruses

Geoffrey L. Smith

Poxviruses are large DNA viruses that replicate in the cell cytoplasm. The most infamous was variola virus, which caused smallpox, a disease responsible for devastating epidemics with up to 40 per cent mortality. Smallpox was eradicated (1977) by immunoprophylaxis with vaccinia virus, a related orthopoxvirus. Poxvirus infections in humans have since been restricted to molluscum contagiosum and rare zoonoses such as monkeypox, cowpox, orf, pseudocowpox, yaba tumour virus, and tanapox.

Classification

The chordopoxviruse subfamily is subdivided into eight genera, of which the orthopoxviruses have been the most important (Table 1). Viruses within different genera are antigenically distinct, while those within a genus are cross-reactive and cross-protective. Four of the nine poxviruses that infect humans are orthopoxviruses: cowpox, variola, monkeypox, and vaccinia virus. Different orthopoxviruses are distinguishable by their biological properties such as pock type, ceiling temperature on the chorioallantoic membrane, or by the restriction pattern of genomic DNA. Following the sequencing of several virus genomes, species-specific DNA probes are becoming available. Vaccinia virus has no known natural animal reservoir and its origin remains a mystery. It caused human disease only as a rare complication after vaccination against smallpox. Cowpox and monkeypox viruses were named after the species from which they were isolated but the natural reservoir of each virus may be rodents. Infections in cows or monkeys, like the occasional transmission to man, are rare. Cowpox, monkeypox, and vaccinia virus have a broad host range, while variola virus infected only humans and the lack of an animal reservoir aided the smallpox eradication campaign.

Poxvirus biology

Poxviruses replicate in the cytoplasm, encode enzymes for transcription and DNA replication, and have large, complex virions (Fig. 1) and double stranded DNA genomes of 150 to 300 kb. Vaccinia virus is the most intensively studied poxvirus. It encodes about 200 genes of three classes (early, intermediate, and late) that are expressed in a strictly regulated manner. Transcription of each class is dependent upon the prior expression of the previous class.

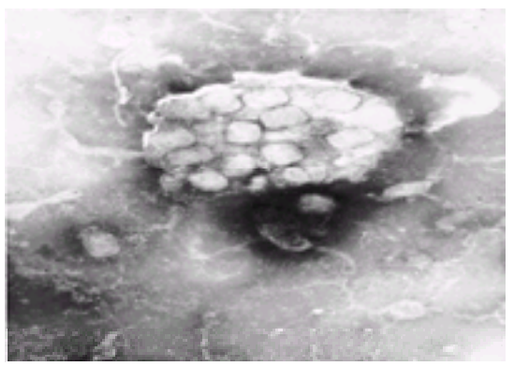

Fig. 1 Electron micrograph of material from smallpox lesion, viewed by negative contrast, showing a clump of poxvirus particles. (By courtesy of the late Henry Bedson.)

Virus morphogenesis is complex (Fig. 2(a)) and produces two forms of infectious virion: intracellular mature virus (IMV) and extracellular enveloped virus (EEV). IMV remains within the cell until it is lysed and forms most of the progeny, whereas EEV is released from the cell before death and represents less than 1 per cent of infectivity (Fig. 2(b)). EEV possesses an additional lipid envelope with which several virus and cellular proteins are associated, giving it distinct immunological and biological properties. EEV is necessary for virus dissemination *in vitro* and within the infected host. Immunity to EEV-specific antigens, which are highly conserved among orthopoxviruses, is required for protection against disease.

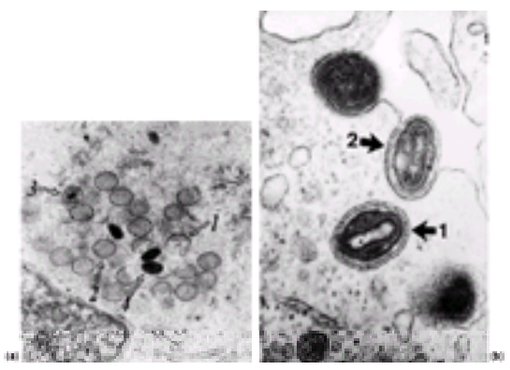

Fig. 2 Electron micrographs showing (a) a cytoplasmic vaccinia virus factory containing maturing virus particles with stages of morphogenesis numbered 1 to 4 and (b) fully enveloped virus particles, one of which is leaving the cell.

Pathogenesis

Poxvirus infections cause a local skin lesion or generalized pustular rash. Detailed experimental analysis of human smallpox was impossible, but generalized poxvirus infections have been studied in experimental models, namely monkeypox in monkeys, rabbitpox (a neurovirulent vaccinia virus) in rabbits, and ectromelia virus in mice. The spread of variola virus in man was probably similar to that of ectromelia virus in mice and is characterized by sequential phases of virus infection, replication, and release accompanied by cell necrosis.

Virus enters through skin abrasions (ectromelia and cowpox) or inhalation of airborne virus and establishes a respiratory infection (ectromelia, rabbitpox, and variola). In smallpox, the respiratory route was most important and sometimes the only possible route of transmission from index cases to contacts; also patients became infectious only after enanthem developed. A respiratory infection was established in the epithelial cells of the alveoli and small bronchioles. Here, alveolar

macrophages became infected and transmitted the virus via lymphatics to the local lymph node, where further virus replication occurred. Virus released into the blood (primary viraemia) was mostly cell-associated and spread to other organs of the reticuloendothelial system, notably the liver, spleen, and lymph nodes.

Extensive replication here released larger amounts of virus into the blood (secondary viraemia) enabling the virus to infect other organs such as the kidneys, lungs, and intestines and to reach the skin and produce the skin lesions with the characteristic centrifugal distribution (Fig. 3) (Plate 1). Lesions started with a papule that became pustular and then crusted. After 2 to 3 weeks the scab was shed leaving a scar. The incubation period of smallpox was approximately 12 days. Symptoms included headache, fever, malaise, vomiting, and, in severe cases, prostration, toxaemia, and hypotension. Delayed onset of the skin eruptions usually correlated with a grave prognosis. Haemorrhagic or flat confluent-type smallpox had very high mortality rates.

Fig. 3 Smallpox in a 9-month-old boy in Pakistan, photographed on the eighth day of the rash. (By courtesy of the World Health Organization.)

The outcome of infection depended upon the age and physiological and immunological status of the patient and the strain of virus. Variola major was more virulent and produced fatality rates in unvaccinated patients of between 5 and 40 per cent, while the milder variola minor, called alastrim in the Americas, caused only 0.1 to 2 per cent mortality. Morphologically, the viruses were indistinguishable, and vaccination with vaccinia virus was equally effective against both. However, alastrim virus was consistently more thermolabile and had a lower ceiling temperature of 37.5°C compared to 38.5°C for variola major, 39°C for monkeypox, 40°C for cowpox, and 41°C for vaccinia virus.

Very young and elderly patients were most susceptible to smallpox and those aged 5 to 20 years most resistant. Pregnancy and immunological deficiency, particularly in cell-mediated immunity, increased the severity of infection. Pregnant women were more likely than any other group to develop haemorrhagic-type smallpox, which was usually fatal. The greater importance of cell-mediated immunity rather than antibody in recovery from poxvirus infections was illustrated in several ways. Firstly, in children with severe defects in cell-mediated immunity there was a progressive and uncontrolled virus replication from the vaccination site that was usually fatal. In contrast, defects in antibody production were usually tolerated if the cell-mediated immune response was normal. Secondly, passive administration of antivaccinia virus serum had little effect on mice infected with ectromelia virus, whereas prior infection with vaccinia virus was protective. Thirdly, in mice infected with ectromelia virus, the effective mechanisms that combated infection in the liver and spleen were operative by 4 to 6 days postinfection and coincided with the maximum levels of cytolytic T cells, but preceded the development of systemic antibody.

The eradication of smallpox

Early attempts to control smallpox relied upon variolation or inoculation, in which material isolated from a mild case of smallpox was administered by sniffing or scratching. This was replaced by vaccination in 1798 after Jenner noticed that milkmaids, who often acquired cowpox infections on their hands from the teats of cows, were protected from smallpox. Jenner infected a boy (James Phipps) with poxvirus material (probably cowpox), derived from a cow via a milkmaid (Sarah Nelmes), and subsequently challenged him with smallpox. Protection was achieved and due to the efficacy and greater safety of this procedure it rapidly replaced variolation. Sometime between 1798 and the twentieth century vaccinia virus replaced cowpox as the smallpox vaccine. In 1959, the World Health Organization (WHO) adopted a recommendation to achieve the global eradication of smallpox. With fresh funding and a plentiful supply of potent freeze-dried vaccine this goal was achieved in 1977. Two years later, the WHO certified that eradication was complete. This triumph of preventive medicine justifies the saying 'prevention is better than cure' but also demonstrates that prevention is best achieved by eradication.

Sequencing of poxvirus genomes

The genomes of vaccinia virus strains Copenhagen, Western Reserve and modified virus Ankara (MVA), variola virus strains India-1967 and Bangladesh-1975, and camelpox virus have been determined. In addition, regions of variola virus Harvey-1947, Garcia-1966, Congo-1970, and Somalia-1977, rabbitpox, and cowpox virus GRI-90 have been sequenced. These analyses showed that the central region of these orthopoxvirus genomes are very closely related with greater than 96 per cent nucleotide identity between vaccinia and variola viruses, but that there is significant divergence in the terminal regions. A notable difference between the vaccinia and variola genomes is the fragmentation of several genes in variola that are intact in vaccinia virus. It is possible that the disruption of genes of an ancestral poxvirus may have contributed to the evolution of variola major as a highly pathogenic virus for man. The retention of these non-functional genes in the variola virus genome suggests that they became non-functional in the relatively recent evolutionary past, and perhaps that variola virus is a 'recent' human pathogen that never became fully adapted to man.

Other poxvirus genomes that have been sequenced are molluscum contagiosum virus, Shope fibroma virus and myxoma virus, yaba-like disease virus, and the *Melanoplus sanguinipes* entomopoxvirus.

Poxvirus expression vectors

Vaccinia virus recombinants expressing foreign genes were developed in 1982 and have become a widely used laboratory expression system and have potential as live vaccines for infectious disease and cancer. Infection with a recombinant vaccinia virus allows expression and simultaneous delivery of the foreign antigen to the immune system. Moreover, the large capacity of vaccinia virus allows expression of multiple foreign genes from a single virus so creating polyvalent vaccines. Safer vaccinia virus strains that do not cause vaccination complications (eczema vaccinatum, generalized vaccinia, progressive vaccinia, encephalopathy (<2 years), or encephalitis (>2 years)) are being developed by deletion of virulence genes from conventional vaccinia virus strains. An alternative strategy is to use poxviruses that establish only abortive infections in human cells, such as MVA or the avipoxviruses fowlpox virus and canarypox.

Human monkeypox

Monkeypox was discovered in captive primates in 1958, but in 1970 was isolated in tropical rain forests of West and Central Africa from humans who had suffered generalized poxvirus rashes visibly very similar to smallpox. The virus is distinct from variola in pock morphology, ceiling temperature, genomic restriction endonuclease pattern, lesion morphology on rabbit skin, and its ability to be passaged indefinitely in mouse brain. However, although monkeypox produced a very similar disease to smallpox in man, person-to-person transmission was too inefficient for establishing epidemics. Thus human monkeypox infections are single or multiple sporadic cases restricted to dense tropical rain forests in Central and West Africa. Clinically, human monkeypox closely resembles ordinary, discrete-type smallpox except that there is a pronounced lymph node enlargement (Fig. 4). Mortality rates in unvaccinated patients between 1970 and 1986 were 11.2 per cent but these were all in children less than 8 years old and the highest rate (18.7 per cent) was in infants less than 2 years. The virus is probably acquired from infected monkeys or rodents such as squirrels.

Fig. 4 Moderately severe monkeypox in a girl of 7 years from Equateur Province, Zaire. (By courtesy of the World Health Organization.)

Cowpox and pseudocowpox

Cowpox virus has a broad host range including cattle, humans, large felines, and even elephants, but it is not enzootic in cattle and its natural hosts are rodents. It is distinguishable from vaccinia virus by the pock type, ceiling temperature, rate of replication in tissue culture, genome size and restriction pattern, and the production of cytoplasmic A-type inclusion bodies. Pseudocowpox is enzootic in cattle, unlike cowpox. Historically, it was important since it was sometimes used mistakenly for vaccination and, being a parapoxvirus, was ineffective in preventing smallpox. Its misuse compromised Jenner's correct assertion that true cowpox was an effective smallpox vaccine.

In man, cowpox produces an acutely inflamed, local lesion, similar to a primary smallpox vaccination. There is usually fever, enlargement of the local lymph nodes, and pain. Unlike vaccinia virus, which occasionally produced a generalized infection, cowpox lesions are always local. Human lesions caused by pseudocowpox virus (milker's nodules) are extremely rare and are less painful than those caused by cowpox.

Tanapox and yaba tumour virus

Tanapox virus was first isolated from the Tana valley in Kenya from humans suffering from localized skin lesions typical of poxviruses (Plate 2). Subsequently, a similar virus was found in humans in Zaire during surveillance for monkeypox. It is a rare zoonosis of monkeys, that in Kenya may have been transmitted by mosquitoes. Serologically, it is related to yaba-like disease virus and yaba tumour virus. In man it usually produces a solitary lesion that is preceded for a few days by a mild fever. The lesion takes 5 to 6 weeks to clear and is distinguished from other poxvirus lesions by its failure to become pustular. This virus cannot be cultured on the chorioallantoic membrane.

Yaba tumour virus is a monkey virus that can cause histiocytomas if injected subcutaneously or intradermally into man. The lesions are not neoplastic and are cleared by the immune response.

Cutaneous poxviruses (orf and molluscum contagiosum)

See Chapter 7.10.25 and Chapter 7.10.26.

7.10.5 Mumps: epidemic parotitis

B. K. Rima

Aetiology

Mumps is an acute, generalized, communicable infection of children and young adults, caused by a paramyxovirus. Almost any organ can be infected—salivary glands, pancreas, testis, ovary, brain, mammary gland, liver, kidney, joints, and heart. Swelling of the face is only one of the symptoms of the disease, albeit the most common and important one for diagnosis.

Epidemiology

The incubation period lies between 14 and 18 days. In any outbreak, 30 to 40 per cent of those exposed infected have subclinical illness. Mumps is highly infectious. Transmission depends on close personal contact with a patient who is excreting virus in the saliva and spreading it in droplets. In the prevaccine era, the peak incidence was in the late winter or early spring, in 3- to 7-year cycles. Most morbidity is associated with meningitis and orchitis. Case fatality is about 2 per 1000.

Virology

Mumps virus (**MuV**) can be grown in tissue cultures of chick embryo, monkey kidney, human amnion, or HeLa cells. Cytopathic changes may be seen as early as 24 h postinfection. With immunofluorescence the virus can be detected in a matter of hours. The virus can also be cultured in the yolk sac or embryonic cavity of chick embryos.

MuV is thermolabile. It can be stored for years at –70°C but infectivity is lost in a few days at room temperature. Treatment with ether or paraformaldehyde inactivates the virus rapidly, but neither of these processes destroys the antigens responsible for the complement fixation, haemagglutination, or reactivity in the skin test.

A patient excretes culturable MuV in the saliva for between 2 and 6 days before parotitis develops and for up to 4 days afterwards. Virus can be cultured from the urine for up to 14 days around the onset of disease. It is almost as easily cultured from ultracentrifugates of urine as from saliva. There is, however, no evidence of viral spread of the virus by urine. During the acute disease MuV can also be cultured from throat washings or a swab of the orifice of Stensen's duct and be detected by reverse-transcriptase polymerase chain reaction (**RT-PCR**), in saliva, throat swabs, and urine. In the blood it can be cultured only for a day or two around the start of disease. Virus can be isolated from cerebrospinal fluid for the first 3 or 4 days of the meningeal illness.

MuV is an enveloped RNA virus with a genome of 15 384 nucleotides. Its inner core is a ribonucleoprotein complex (the nucleocapsid) containing the non-segmented, negative-strand, RNA molecule encapsidated by the major nucleocapsid protein (N). The nucleocapsid has the herring bone structure characteristic of paramyxoviruses (Fig. 1(a)). Attached to this are two further proteins involved in transcription and replication of the RNA genome: the phosphoprotein (P) and the large replicase protein (L). The nucleocapsid is surrounded by a lipid bilayer membrane derived from the host cell (Fig. 1(a) Fig. 1(b)). On the inner leaflet there is a membrane or matrix protein (M) that plays an essential role in virus budding. On the outer surface are two glycoproteins, one carrying the haemagglutinin-neuraminidase activity (HN), the other responsible for fusion activity (F). A non-structural, small, hydrophobic protein (SH) has been described in the membrane of MuV-infected cells. The sequence of the SH protein is hypervariable. This has been exploited in molecular studies of the epidemiology of MuV. The functions of V, and other non-structural protein, and SH are unknown. The gene order (Fig. 1(c)) leads to an expression gradient in which the abundance of mRNAs decreases with increasing distance to the promoter at the 3_ end of the genome so that the N mRNA is more abundant than the L mRNA.

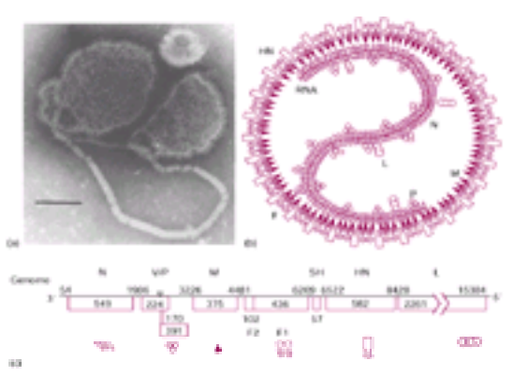

Fig. 1 Structure and genome organization of mumps virus. (a) A disrupted, negatively stained, mumps virion. The viral nucleocapsid protrudes from the particle and the fringe of viral spikes is visible (bar = 100 nm). (b) Diagram of the localization of the nucleocapsid (N), phospho- (P), large (L), matrix (M), haemagglutinin-neuraminidase (HN), and fusion (F) proteins in the mumps virion. (c) Structure of the genome of mumps virus indicating the localization of the genes, the nucleotide number of their starting and stopping position, and (in boxes) the number of amino acid residues in each of the viral proteins.

Pathogenesis and pathology

MuV causes an infection of the upper respiratory tract that spreads to draining lymph nodes. The subsequent viraemia and infection of the lymphocytes and macrophages causes spread to many organs, but because mumps is so rarely lethal, details are scant. Lymphocytic infiltration and destruction of periductal cells lead to blockage of the ducts both in salivary glands and in the seminiferous tubules of the testes. The lymphatics in the tissues surrounding and overlying the parotid glands become obstructed, producing a gel-like oedema that may spread down over the chest wall, especially when the swelling of the salivary glands is severe.

MuV frequently invades the nervous system: changes can be detected by electroencephalography or by examination of the cerebrospinal fluid in at least half the patients. However, in most of these cases there are no neurological symptoms or signs. Mumps virus is one of the most common known causes of lymphocytic meningitis. Neuronal damage probably does occur, explaining the occurrence of quadriplegia or single-nerve paralysis in some patients. Apart from transient weakness of the facial nerve, which may be due to pressure of a swollen gland or damage by mumps virus, these complications are very rare.

Mumps encephalitis is a different entity; cerebrospinal fluid is normal and contains no virus. At autopsy there is perivascular demyelination as in other forms of

postinfectious encephalitis (see Chapter xxxx).

Clinical features and diagnosis

Parotitis

A patient with mumps parotitis may have a fever without rigors (40 to 40.5°C) as well as pain near the angle of the jaw. The face and neck become distorted with swelling. The skin over the gland is hot and flushed but there is no rash, unlike in the swelling of erysipelas. If the swelling is severe, the mouth cannot be opened for pain and tightness, and is dry because the flow of saliva is blocked. This discomfort lasts for 3 or 4 days. Sometimes as one side clears, the parotid on the other side swells. When there is bilateral parotitis, clinical diagnosis is usually obvious. One condition that must be excluded is bull-neck diphtheria (see Chapter 7.11.1), which can look very like mumps.

Rarely, the submaxillary and sublingual salivary glands may also be affected. The symptoms are similar to those in parotitic mumps, but it is difficult or impossible to distinguish the swelling from other forms of submaxillary swellings, especially inflammation of various groups of lymph nodes and Ludwig's angina. In mumps, the neck swelling is ill defined and the angle of the jaw is impalpable. To determine if cervical lymph nodes are swollen from some other cause, the pharynx must be examined carefully. The fauces must be examined for signs of tonsilitis that might cause cervical adenitis. The lymph nodes in contact with the submaxillary and sublingual salivary glands drain the corner of the eye, the side of the nose, the cheeks, the lips, and the floor of the mouth, all of which must be explored, before a diagnosis of submaxillary or sublingual mumps can be made. Laboratory tests are needed to confirm the diagnosis.

In infectious mononucleosis, the glands stand out distinctly and the parotid is not affected. In septic parotitis there is more parotid tenderness; there may be fluctuation, and pus exudes from the orifice of Stensen's duct. Calculus causes spasmodic pain and swelling and may be detected radiographically. Recurrent parotitis and Mikulicz's syndrome are unlikely to be confused with mumps except in the earliest stages, nor are uveoparotid fever and tumours of the gland, as they are chronic conditions.

Orchitis

Orchitis may occur 4 or 5 days after the onset of parotitis. Quite often it occurs without preceding parotitis. It is an acute condition, with chills, sweats, headache, and backache, and a swinging temperature as well as severe local testicular pain and tenderness. The scrotum is swollen and oedematous, and the testicles are impalpable. Usually only one testicle is affected but sometimes both: the second testicle may become affected just as the swelling of the first is subsiding. The illness lasts 3 or 4 days before the swelling begins to subside. Orchitis is unusual before the age of puberty, though it has occurred in young boys and even in infants. In adolescent and young males it develops in 1:5 cases. Some degree of atrophy of the testicle occurs in at least one-third of patients with orchitis. Azoospermia after mumps is rare and only temporary. The fear of sterility after mumps orchitis has been exaggerated, so the doctor can reassure the patient. Orchitis when it occurs without parotitis is difficult to distinguish from gonococcal epididymo-orchitis unless there has been contact with mumps. The rare case of orchitis in infancy may resemble torsion of the testis and perhaps it is safer to operate than risk a serious misdiagnosis.

Meningitis and encephalitis

Lymphocytic or viral meningitis may develop a few days after the start of parotitis, but almost as often it occurs in the absence of parotitis. In the cerebrospinal fluid, protein and lymphocytes are increased. Occasionally the patient develops transient paralysis of limbs. Polyneuritis, neuritis of the trigeminal or facial nerve, and retrobulbar optic neuritis have been described in mumps but all are rare. The meningitis is usually mild and self-limiting. In encephalitis the outlook is different. The patient is confused and may lapse into coma and remain comatose for days, weeks, or months. Almost 2 per cent of the encephalitis cases are fatal.

Other complications

Deafness is sometimes reported after mumps, but it is rarely permanent. Women sometimes complain of ovarian pain during an attack of mumps, but it is rarely as severe as in men with orchitis. There is no evidence that it affects fertility. Mastitis occurs in 15 per cent of the cases, both in females and males, but it is usually mild and fleeting. Mild upper abdominal pain in about 50 per cent of the cases may be related to viral changes in the pancreas. The amount of amylase in duodenal fluid may be less than normal. This is probably caused by a blockage of the ducts in the pancreas. Although there are anecdotal reports of diabetes occurring after an attack of mumps, there is no virological or immunological evidence for a direct link.

Mumps in the fetus and infant

Abortion may occur in women with mumps in the first trimester of pregnancy. It is not common and probably not caused by viral damage to the fetus. The connection between primary endocardial fibroelastosis, which is declining in incidence, and mumps is rather vague, but recent evidence indicates that by RT-PCR viral RNA could be amplified from myocardial samples in more than 70 per cent of the cases. Mumps virus has not been isolated from heart tissue at autopsy and these infants have no mumps antibody in their blood. They may show a delayed hypersensitivity response to the skin test. This has not been explained, but may reflect some immune defect in the fetus which could cause myocarditis and fibroelastosis.

In the normal infant, maternal IgG passes to the fetus and seems to protect the infant against mumps during the first year of life. The typical disease of mumps in infants is a rare clinical finding even in populations with no previous experience of the disease. Orchitis has been reported in infants, and mumps virus may be isolated in vague respiratory infections in infants.

Laboratory diagnosis

In patients without parotitis, especially meningitis, and in the absence of contact history, serological tests, RT-PCR, and virus isolation are the only means of reaching a firm diagnosis. MuV isolation is now rarely used. MuV contains several different antigenic components, which provoke distinct antibodies that are useful for laboratory confirmation. The most important are the HN protein (V antigen) and the N protein (S antigen). S antibody rises in the first 2 weeks of infection but then declines rapidly. V antibody appears at the end of the first week, usually in high titre: it may persist for years and indicates past infection. Neutralizing antibodies also develop. Nowadays, sensitive enzyme immunoassay (EIA) allows early diagnosis by detection of mumps-specific IgM and IgA. IgA can be detected in saliva or mouth washings on about the fourth day after infection, and in the serum early in the disease. Measurement of antibodies in acute and convalescent sera is a reliable method for diagnosis, especially in patients who have no parotitis. Viral antigen produces a tuberculin-like reaction when injected into the skin of people who have been infected with mumps virus before, with or without clinical symptoms. The test is of value in assessing immunity or the need for vaccination.

Treatment

There is no specific treatment. Symptomatic treatment includes simple analgesics, but for the severe pain of orchitis, morphine (15 to 30 mg) may be required for a day or two. Corticosteroids are worth trying in severe cases of parotitis, more especially in orchitis. An adult dose of 60 mg prednisolone daily for 2 or 3 days sometimes gives dramatic relief from pain though it may not reduce the swelling.

Prevention and control

The mainstay of prevention is vaccination of susceptible individuals. Isolation is not effective as the patient has been infectious for days before parotitis occurs and inapparent cases are frequent. Attenuated live vaccine, licensed since 1967, gives 95 per cent seroconversion, and protection lasts for at least 15 years. In developed countries, mumps vaccine is currently given between 14 and 16 months of age as one component of a trivalent mumps/measles/rubella (**MMR**) vaccine, using live attenuated strains of all three viruses. This has succeeded in suppressing the incidence of mumps by more than 98 per cent in the United States and in the United Kingdom. Mumps vaccination is contraindicated in pregnant women and patients with immunodeficiency due to immunosuppressive therapy or disease. However, HIV seropositive children should be vaccinated with the MMR vaccine.

Measles

H. C. Whittle and P. Aaby

Measles is an acute, highly transmissible viral infection of man spread by aerosolized droplets, which causes much death and suffering, especially among children of the so-called Third World. Its severity varies according to host and socioeconomic factors, not to antigenic variation or alteration in virulence of the virus. There is no reservoir of infection other than in man and no evidence of a carrier state. The virus causes a generalized infection coupled with severe immunosuppression. The chief clinical features result from infection of the skin, mucous membranes, and respiratory tract. Attack rates in home contacts are very high (of the order of 90 per cent), subclinical infection is infrequent, and children are the main victims. Long-life immunity follows the disease. Although global coverage by measles immunization in 1998 was 72 per cent, at least 36 million children are infected annually and 1 million die mainly in sub-Saharan Africa where immunization coverage is low.

Epidemiology

The epidemiology of this global infection varies markedly between developed and developing countries.

In the West, most children are infected between 3 and 6 years of age, when they attend nursery and primary schools. Mortality is low (under 0.05 per cent) and morbidity, although considerable when compared to many other common viral infections, is limited. Most cases occur in the winter and spring, with a biannual epidemic pattern. Recently the epidemicity has been influenced by widespread immunization (Fig. 1), which has dramatically reduced both the number of cases and complications. However, even in the United States, which has the longest experience of systematic immunization, there is now evidence of a resurgence of measles with a higher case fatality in non-immunized subgroups of the population, such as religious minorities who do not believe in vaccines, refugees, illegal immigrants, and the poor in the inner cities.

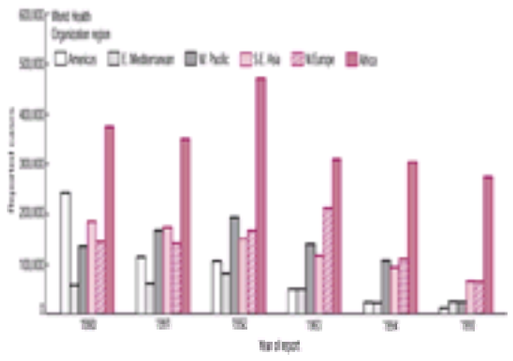

Fig. 1 Reported incidence of measles—World Health Organization regions, 1990–1995.

In the Third World, measles is severe and different: it kills between 3 and 15 per cent of children in the community and some 10 to 20 per cent of those admitted to hospital. Mortality from measles is considerably higher in Africa (5–15 per cent) than in Asia or South America (1–3 per cent); within Africa, West Africa has the highest case-fatality rates. Contrary to the early European experience, when the highest mortality was among the overcrowded urban poor, studies from the developing world indicate a higher mortality in rural rather than urban populations. In communities where females tend to stay at home and are more constrained in their social contacts, mortality is higher in girls than boys. There is a high fatality rate in children with chronic disease, including kwashiorkor, tuberculosis, and human immunodeficiency virus (**HIV**) infection.

There are many reasons for this increase in severity: children are infected at a young age (median age, 12–24 months); severe malnutrition leads to prolonged, severe measles that kills up to 40 per cent of those infected. Overcrowding is another strong determinant of outcome, for secondary and tertiary cases in large families are at great risk of death. Exposure to a large dose of the virus when in close contact with the index case may be an important factor. Furthermore, the severity of measles and the chances of the secondary case dying are dependent on the severity of disease in the index case. Transmission of measles from one sex to the other has been found to increase mortality two- to threefold compared to transmission from the same sex. The high mortality found in West Africa is probably due to the very large, polygamous, and extended families, which increase the risk of intense exposure.

The epidemiology of measles used to vary according to the degree of urbanization, but now the coverage of immunization may be a more important determinant. In remote villages, outbreaks were less frequent and with more susceptible children in each family the risk of intensive exposure and severe disease was increased. These outbreaks resembled the severe epidemics that in the past have devastated the remote island populations of the Faeroes, Fiji, Greenland, and Tristan da Cunha and killed more than 80 per cent of the Inca people in the wake of the Conquistadors in fifteenth-century Middle America. In urban areas, migration, and overcrowding have led to a hyperendemic pattern of infection with a low age of infection but fewer cases per family, the case fatality therefore being lower than in rural outbreaks. Hospital wards and clinics in the developing world are usually important centres of infection; in a hospital in the north of Nigeria, 35 per cent of children with measles had acquired the infection by attending the outpatient clinic 2 to 3 weeks before.

Acute measles is often less severe among children under 6 months of age, among previously immunized children, and among those who have received immunoglobulin when exposed. In these cases the course of infection is characterized by a prolonged incubation period, a short prodrome, mild symptoms, and a favourable outcome. Recent research has provided limited support for the previous belief in a general increase in long-term morbidity and mortality after the first 6 weeks of measles infection. These long-term consequences may have been due to the initial severity of infection as secondary cases have a higher long-term mortality than index cases. However, nowadays in areas with high vaccination coverage the disease is milder. This is particularly true for index cases who tend to be older than the secondary cases and have a lower mortality than uninfected children (suggesting that there is a beneficial effect of mild measles). Long-term morbidity is most likely to be experienced by young children who have severe measles following intensive exposure.

The severity and mortality of measles in developing countries has decreased dramatically as a consequence of measles immunization, which reduces the severity of infection, increases the number of subclinical cases, and lessens the likelihood of transmission. However, even if coverage is maintained, the epidemiology of measles alters as a result of changes in herd immunity from exposure to natural measles, and subclinical infection is important in maintaining protective antibody

levels among vaccinated individuals. Thus, as antibody levels fall and the number of unvaccinated and unexposed subjects rise, there will be an increasing potential for epidemics among young adults. This is particularly true in developing countries where fertility rates are high; for measles is severe in young pregnant women and may attack both mother and child at the same time.

Popular beliefs

In most cultures, measles has a specific local name and is a much feared disease. Popular understanding is centred around the rash, which if it stays within the body will lead to severe disease. This belief has some basis in truth for the prodrome is prolonged in severe cases, and a proportion of deaths reportedly occur before the appearance of the rash during very severe epidemics. Therapeutic practices, such as rubbing the skin with palm oil or kerosene, are aimed at eliciting the rash quickly. In West Africa it is believed that cooling keeps the rash within the body, so the child may be bedded in warm sand or covered with blankets, and is not washed or given cold water to drink. Such customs may aggravate dehydration. In West Africa, as a result of popular awareness of measles, good correspondence exists between parental diagnosis and that based on clinical and immunological assessments. The mother's diagnosis, which can be used for epidemiological surveillance, is nearly always correct.

The virus and its antigens

Measles mainly infects humans, but like the other closely related morbilliviruses (such as rinderpest or canine distemper virus) it is able to cross species to infect other primates and, on occasions, dogs. It contains a single strand of RNA, is highly pleomorphic, and ranges from 100 to 300 nm in diameter. The virus propagates by budding from the cell membrane, from which it acquires an envelope. The membrane of infected cells and the virion envelope contain two surface glycoproteins, the haemagglutinin (**H**) and fusion (**F**) proteins, and a non-glycosylated matrix (**M**) protein, which forms the inner layer. The H protein, which allows attachment of the virus to cells, via the CD46 or CDw150 receptors, is the main target for neutralizing antibodies; the F protein is responsible for fusion and syncytium formation of infected cells. CD46 is a ubiquitous membrane cofactor protein, which together with five other proteins, protects cells from complement activation and lysis. Vaccine strains of measles virus bind to CD46 to downregulate the protein, resulting in complement-dependent cell lysis which limits viral replication. Some wild-type viruses, but not all, bind to the receptor but do not downregulate it, thus preventing lysis and allowing efficient viral replication. The CDw150 receptor (also known as signalling lymphocyte-activator molecule or **SLAM**) is expressed on immature lymphocytes and on effector memory T cells, and is rapidly induced on T and B cells after activation. The internal components or nucleocapsid consist of RNA, the nucleoprotein (**N**), which is the major protein, the phosphoprotein (**P**) and the large protein (**L**). The F protein is remarkably stable, the H protein shows minor antigenic variation, but the N protein, which contains a variable region in the C terminus, is highly divergent among different strains of virus. Genetic analysis of *H* and *N* genes allowed molecular surveillance of the measles virus in the United States, which suggested that the majority of cases were the result of international spread of the virus. There is also variation in the M protein, which some claim is related to persistent infection. The replication and assembly of measles virus is shown in Fig. 2.

Pathogenesis and the immune response

The course of infection and the immune response to this invasion are shown in Fig. 3. The measles virus, which is thermolabile and survives best at low humidities, is spread to susceptible contacts in droplets during sneezing and coughing. First it infects and multiplies in the epithelium of the upper respiratory tract or the conjunctivas. Some 4 to 6 days later the virus is found in the reticuloendothelial tissue of the liver and the spleen after passage through lymph nodes and spread via the blood. Here it multiplies, causing fusion of cells to form giant cells with many nuclei. Viral antigens, which can be found by immunofluorescent techniques in and on the surface of both these cells and lymphocytes, now induce the immune response. First, natural killer cells and cytotoxic T cells mount a cell-mediated reaction that contains the virus and limits its spread within cells. Later, B cells are primed to produce antibody. Defects in the cellular immune system, as in severe malnutrition, cancer or primary immunodeficiencies, allow widespread multiplication of the virus to cause fatal giant-cell pneumonia.

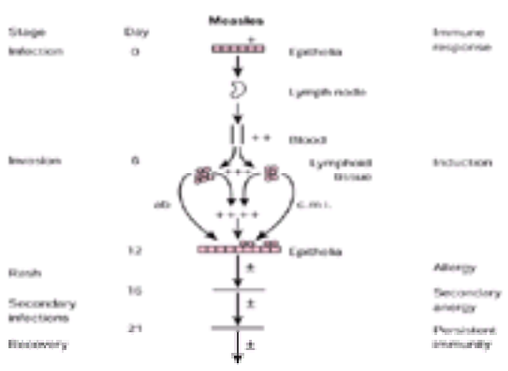

Fig. 3 Pathogenesis of measles. + Denotes amount of virus; ab, antibody. (Reproduced with permission from Parry EHOP (1984). *Principles of medicine in Africa*, 2nd edn. Oxford University Press, Oxford.)

Around day 8, the measles virus is carried by the blood, either free or in mononuclear cells, to the target tissues, which are the epithelia of the eye, lung, and gut. Again, the agent multiplies to cause a bright redness of the mucosa and Koplik's spots (see below), which are foci of viral multiplication. At this stage, measles virus may be cultured from nasopharyngeal secretions, and antigen can be detected by immunofluorescent techniques in the characteristic giant cells of the buccal mucosa, in epithelial cells, and in both B and T lymphocytes in the blood.

The rash, appearing around days 14 to 16, is the sign of a strong and complicated allergic reaction to the virus in the epithelia. The extent and severity of the rash, which reflects the clinical severity of the disease, is determined by the number of target cells infected. Histological examination shows virus in the disrupted epidermis, in the corium, and in capillary endothelium. These tissues are infiltrated by mononuclear cells together with antibody, immune complexes, and complement. An intact cell-mediated immune response is essential to generate the rash and clear the virus, for if impaired, as in the case of children with leukaemia, or occasionally in severe kwashiorkor, the virus multiplies unchecked and no rash appears. Some 2 or 3 days after the start of the rash, around day 17 or 18, the virus can no longer be cultured in the epithelia, for infected cells have been disrupted and the free virus neutralized by antibody. The first antibody to appear is to the nucleoprotein antigens. The second, which is largely responsible for neutralization of the virus, is to the haemagglutinin. Finally, the antibody to the fusion glycoprotein appears in a low titre. This antibody stops cell-to-cell spread of the virus. At this stage the child is markedly immunosuppressed and thus susceptible to secondary infections of the eyes, mouth, gut, and lungs. Latent viruses, such as herpes simplex or cytomegalovirus, may be reactivated and in turn cause further immunosuppression. The delayed

hypersensitivity reaction, as measured by skin tests to old tuberculin or candida antigen, is absent or severely impaired.

By the third week, day 21, as the patient recovers, antibody is in full production. Levels remain elevated for the rest of the patient's life, either because of repeated subclinical infections or because the virus persists in latent form in the spleen and other organs, so stimulating antibody. Occasionally the virus persists in the brain in a damaging form to cause subacute sclerosing panencephalitis (see below). In this rare condition, virus can be isolated from the brain up to 8 years after measles, and antibody levels to all but the M protein antigen are raised in the cerebrospinal fluid and blood. The immune system, for unknown reasons, has failed to clear the virus, which is probably aberrant, for such strains are unable to produce normal amounts of protein.

The mechanisms of immunosuppression are complex. The cytotoxic T-cell response, which is exuberant, may result in the destruction of infected T cells and dendritic cells thus leading to their depletion, deficient antigen processing, and generalized immunosuppression. Crossbinding of the CD46 cellular receptor downregulates IL-12, a crucial cytokine in the development of TH-1 and delayed hypersensitivity responses (Fig. 4). Infection of CDw150+ lymphocytes, which are predominantly of the T_{H0}/T_{H1} type, results in suppression of lymphoproliferation and cell death. Thus measles ultimately dampens the TH1 response, resulting in a skewing towards a TH2 cytokine response and susceptibility to intracellular and other pathogens. However, this immunosuppression may be in the interest of the host by limiting further autoallergic damage of infected tissues.

Pathogenesis in the underprivileged, in the malnourished, and in the HIV-infected

Measles in the children of the Third World, as was formerly the case in the underprivileged in Europe, is severe, prolonged, and carries a high case-fatality rate due to secondary infections. Two explanations are offered. Crowding leads to a high dose of measles virus and also increases the chances of secondary infection. The period of incubation has been found to be short in severe and fatal cases, which is consistent with the emphasis on infecting dose as a mechanism of severe disease. Alternatively, or in tandem, malnutrition diminishes the immune response to the virus, allowing great proliferation of virus and subsequent damage to the host. There is experimental evidence, although only in severely malnourished children with marasmus or kwashiorkor, that the lymphocytes of these patients may be more readily infected during the induction phase. A normal immune response follows, which generates a severe and widespread rash followed by prolonged immunosuppression. Secondary bacterial infections with, for example, *Streptococcus pneumoniae*, or latent infections such as herpes simplex or *Mycobacterium tuberculosis* follow in the wake of this intense immunosuppression, often killing or maiming the child. Virus persists in lymphocytes and epithelial cells for up to 30 days after the start of the rash. Antibody production occasionally fails and secretory IgA is deficient, which may explain why the virus persists for so long in the gut. Anorexia, increased catabolism, protein loss from the gut, and further malnutrition exaggerate the problem, which is worst in the weanling child (Fig. 5).

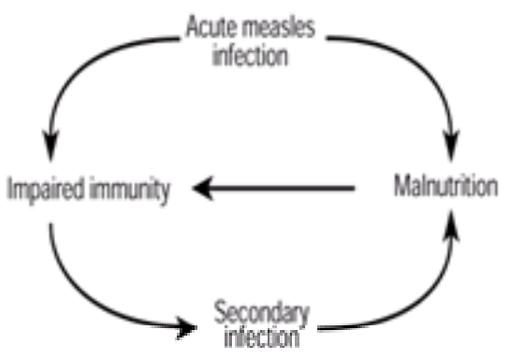

Fig. 5 The complex interaction between infection, nutrition, and impaired immunity seen in measles. (Reproduced with permission from Greenwood BM (1996). The host's response to infection. In: Weatherall DJ, Ledingham JGGL, Warrell DA (1996). *Oxford Textbook Medicine*, 3rd edn, p. 282. Oxford University Press.)

Over 1 million children under the age of 5 years are living with HIV infection in sub-Saharan Africa. The impact of measles and measles vaccination on disease and death in this population will probably depend, as in malnutrition, on the degree of immune damage at the time of infection. The death rate after measles in hospitalized infants is higher in HIV-infected children, and prolonged viral shedding, as detected by the polymerase chain reaction (**PCR**), occurs in the majority of these children. Thus, in regions of high prevalence, HIV-infected children may be important unrecognized transmitters of the virus. Asymptomatic HIV-infected children respond normally to vaccination, but those with **AIDS** (acquired immunodeficiency syndrome) are less likely to respond and may be threatened by persistent infection. Further research is needed on the interaction of the two infections and their impact on the epidemiology and eradication of measles.

Clinical features

There is a spectrum of severity that ranges from mild in the privileged and well nourished to severe in the blatantly malnourished or immunosuppressed. However, the rule is not inviolate and other factors such as the age and dose of infection are probably as important in determining the severity of disease. Measles, often severe, occasionally infects unvaccinated young adults or individuals who have lived in isolated communities. The clinical features of measles and some complications are shown in Fig. 6 and discussed below.

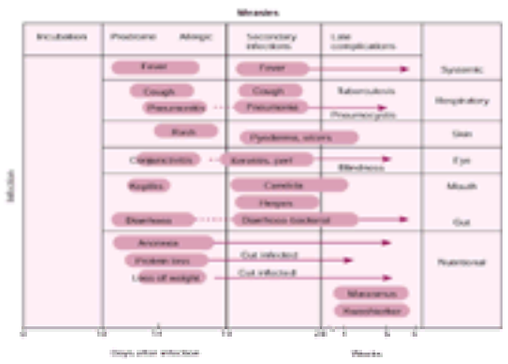

Fig. 6 Clinical features of measles and some of its complications. (Reproduced with permission from Parry EHOP (1984). *Principles of medicine in Africa*, 2nd edn,

Oxford University Press, Oxford.)

Prodrome (days 10–14)

A diagnosis of measles is often missed at this stage, when fever coupled with a runny nose, and sometimes complicated by convulsions, is the main feature. Other signs are mild conjunctivitis, red mucosa, Koplik's spots, and diarrhoea. Koplik's spots are found in the buccal mucosa. They are 'small irregular spots of bright-red colour; in the centre of each spot is seen a minute bluish-white speck'. A useful diagnostic test is to scrape the buccal mucosa with a spatula, place the scraping on a microscope slide, stain with Leishman's stain, and examine for giant cells under a microscope. The prodrome is prolonged in severe cases, and reduced in individuals with modified measles due to maternal antibodies or the prophylactic use of immunoglobulin.

Rash (days 14–18)

The morbilliform rash first appears on the forehead and neck and then spreads, over a period of 3 to 4 days, to involve the trunk and finally the limbs (Plate 1).

In children in Africa and other parts of the developing world the rash is often red, confluent, raised, very extensive, and sometimes accompanied by bleeding into the skin and gut (Plate 2). Later the rash blackens, then the skin peels causing extensive desquamation. Other epithelial surfaces are inflamed, the severity matching that of the rash. Cough, a cardinal sign, may be hoarse and coupled with inspiration difficulty if the larynx and trachea are inflamed. Signs of pneumonitis are apparent, which in severe cases may cause cyanosis or be complicated by mediastinal and subcutaneous emphysema. Conjunctivitis, especially in those who are vitamin-A deficient, can be severe; enteritis may cause profuse diarrhoea with a resulting loss of protein, and malabsorption of food and water. The mouth is painful and red, which adds to the misery of the child, who becomes anorexic and may even refuse to suck the breast. In the uncomplicated case, as is usual in the West, the convalescent period is short, usually lasting less than a week. Complications should be suspected if fever persists while the rash is fading or desquamating.

Complications

Early complications (days 18–30)

As a result of the widespread, severe allergic reaction to the measles virus signified by the rash, the patient is left severely immunosuppressed and is susceptible to infection.

Pneumonia

This causes the most deaths (Table 1) and is heralded by a rise in fever, leucocytosis, and respiratory difficulties. Lobar pneumonia is usually caused by *S. pneumoniae*, but bronchopneumonia, which is more common, results from other bacteria, such as *S. aureus*, or secondary viral infections with, for example, herpes simplex or adenovirus. A variety of other organisms such as Gram-negative bacteria, cytomegalovirus, fungi, *M. tuberculosis*, and *Pneumocystis carinii* should be considered as potential lung pathogens in the malnourished or immunocompromised child.

Stomatitis and enteritis

Chronic diarrhoea and a sore mouth caused by candidal infection are common complications of measles in children in the Third World. The gut is often superinfected with *Bacteroides* spp., *Escherichia coli*, *Pseudomonas* spp., and *S. aureus*, which results in malabsorption and protein loss. Deep ulcers caused by herpes simplex virus erode the corners of the mouth, gums, and inner surface of the lips causing much misery, illness, and pain (Plate 3).

Eye infections

Corneal ulceration leading to impaired vision or blindness is common after measles, especially in malnourished and vitamin A-deficient children (Plate 4). Several studies from Africa have shown that more than half of childhood blindness is related to measles. The mechanisms are still under discussion. In northern Nigeria, herpes simplex was found in 47 per cent of active corneal ulcers after measles, and measles virus in 12 per cent: the children often had evidence of oral herpes. In a study in Tanzania, blindness precipitated by measles was associated with vitamin A deficiency (50 per cent), *herpes simplex* infection (21 per cent), and the use of traditional eye medicine (17 per cent).

Skin and other infections

Pyoderma is common after measles. In the malnourished patient, deep eroding ulcers may bore through the skin even into bone. When originating in the mouth they are know as cancrum oris or noma (Plate 5). Otitis media is also common.

Encephalitis

This is a rare, but much feared, complication found in approximately 1 to 2 per 1000 cases. The onset is usually between 4 and 7 days after the start of the rash, but, rarely, it may occur within 48 h or up to 2 weeks from the onset. In addition to seizures, there is often fever, irritability, headache, and a disturbance in consciousness that may progress to profound coma. The disorder is probably attributable to a neuroallergic process: lymphocytes from the cerebrospinal fluid have been shown to respond to myelin basic protein, as in experimental allergic encephalomyelitis. The virus cannot be isolated from cerebrospinal fluid, which contains lymphocytes and raised levels of IgG but normal levels of measles antibody. Mortality and morbidity is high: 10 to 15 per cent of victims die and 25 per cent of children are left with permanent brain damage. Treatment is supportive; dexamethasone has no convincing beneficial effect.

Late complications

Malnutrition

This is the most frequent complication, for children of the developing world often lose a lot of weight during measles and may take many weeks to regain it. Those originally underweight, who have had severe measles, are at greatest risk, for anorexia in these children is prolonged, much protein is lost from the gut, and secondary infections, which lead to marasmus or marasmic kwashiorkor, are frequent. Measles has been shown to persist in the epithelia and lymphocytes of the severely malnourished for 30 or more days after the rash.

Persistent infection

Pneumonitis

A giant-cell pneumonia is found in patients with defects in cell-mediated immunity; children with leukaemia or kwashiorkor are particularly vulnerable as are those with symptomatic HIV infection. The lung disease may develop weeks after measles, and in most cases the rash of measles has been absent and thus the diagnosis may not be suspected. The diagnosis is made by virological and/or histological examination of lung tissue. Most of these children die.

Subacute sclerosing panencephalitis (SSPE)

Persistent measles virus infection is responsible for this rare, progressive disease of the brain, which is found in 0.1 to 1.4 per million children after measles. The virus is detected in the brain by electron microscopy and by immunofluorescent methods, and has only been isolated using cocultivation techniques. The child with SSPE has usually experienced normal measles, albeit at a young age, 5 to 10 years earlier. The first indication is a disturbance in intellect and personality; behaviour

disorders and deterioration in school work are frequently mentioned. There then follows, over a period of weeks and months, myoclonus-like seizures, signs of extrapyramidal and pyramidal disease, and finally a state of decerebrate rigidity followed by death. The electroencephalogram shows a characteristic regular series of high-amplitude, spike-like waves. Very high titres of measles complement-fixing and haemagglutinin-inhibiting antibody are present both in serum and cerebrospinal fluid; the haemagglutin-inhibiting antibody is probably produced within the nervous system. Treatments for SSPE have included the use of transfer factor, plasmapheresis, and antiviral drugs, but to no avail.

Multiple sclerosis, autism, Crohn's disease

There is no convincing evidence that measles virus or immune responses to it have a causative role in these diseases. The alleged association between the measles, mumps, and rubella (**MMR**) vaccine, autism, and Crohn's disease was based on weak science and has now been convincingly refuted by larger and stronger epidemiological studies. Subsequent molecular studies have failed to confirm the original finding of measles virus and genomic RNA in diseased bowel.

Diagnosis

This is primarily clinical, although signs may be less clear-cut in vaccinated subjects. Thus in areas of high vaccine coverage the detection of measles-specific IgM antibody by enzyme-linked immunoassay (**ELISA**) or, better still, the detection of measles antigen in saliva or urine may clinch the diagnosis if the rash is mild or atypical. Subclinical measles is common in vaccinated children after exposure to measles: the diagnosis is made by detecting a fourfold or greater rise in measles antibody within 2 to 6 weeks of exposure. It is not clear if such cases are infectious.

Treatment of measles and its complications

No effective antimeasles drug exists, yet some children do benefit from treatment in hospital. The following criteria indicate severe measles and a need for hospital admission: a widespread, confluent rash darkening to deep red or purple; signs of laryngeal obstruction; subcutaneous emphysema; marked dehydration; blood in the stool or more than five stools a day; convulsion or loss of consciousness; severe secondary pneumonia; corneal ulceration; or severe ulceration of the mouth and skin. These signs should be taken particularly seriously when the child is underweight or frankly malnourished.

Hydrate the child orally or intravenously. Treat lobar pneumonia with benzylpenicillin, and bronchopneumonia with combined antibiotics such as gentamicin and cloxacillin, or with co-trimoxazole. Antibiotic eye ointments relieve discomfort and possibly prevent secondary infections of measles conjunctivitis. Antibiotics (topical and systemic) and vitamin A should be given routinely for the treatment of eye ulcers. If *herpes simplex* virus is the cause, use aciclovir topically or, when severe, systemically. Candidal infections of the mouth or gut often respond dramatically to nystatin. Feeding, by tube if necessary, needs careful planning and presentation, for the anorexic infected child will be in severe negative energy balance due to a greatly increased catabolic rate. Case fatality rates are 30 to 50 per cent lower in those children in hospital treated with vitamin A. This should be given orally at the time of diagnosis in a dose of 100 000 IU for children below 12 months of age and in a dose of 200 000 IU for older children. If eye signs of vitamin A deficiency are present, the initial dose should be repeated the next day and again 1 to 4 weeks later.

No specific effective treatment for encephalitis or SSPE exists.

Prevention

Passive immunization with human immunoglobulin is highly effective if given within 2 or 3 days of exposure, in a dose for children of 0.2 ml/kg. Immunoglobulin should be given to those in whom vaccination is contraindicated: children immunosuppressed by kwashiorkor, by malignancies such as leukaemia or lymphoma, or by steroids or cytotoxic drugs. Passive immunization may also be used to protect pregnant women, those with active tuberculosis, and those with AIDS.

The currently used vaccines are live strains, attenuated by culture in chick fibroblasts. The complications of vaccination are few and generally mild. Fever of moderate severity is infrequent, and a mild rash with some signs of upper respiratory tract infection occurs rarely. Encephalitis or SSPE is exceedingly rare after vaccination. Underweight children respond normally to the vaccine, as do ill children attending the outpatient department and those on the ward. As clinics and hospitals are major sites of transmission of the virus in the developing world, all susceptible children in these places—unless seriously immunocompromised because of, for example, leukaemia, kwashiorkor, or AIDS—should be vaccinated.

The first measles vaccines introduced in the United States and Europe in the 1960s were inactivated with formalin. Although they produced high levels of H antibody, they failed to raise antibody to the F protein. This gave poor protection, and on exposure a severe local reaction at the site of injection or a bizarre form of measles resulted. The rash was unusual, having urticarial and vesicular features, fever was high, oedema of the limbs frequent, and severe pneumonia present. This syndrome is still occasionally seen in adults who were vaccinated with killed vaccine during childhood. Rhesus macaques immunized with formalin-inactivated vaccine followed by challenge with measles virus developed an atypical rash and pneumonitis accompanied by immune-complex formation and eosinophilia. This experiment shows that atypical measles results from a non-protective type-2 CD4 T-cell response.

The optimal age for vaccination in the developed world is between 14 and 16 months, when maternal antibody, which neutralizes the virus to cause vaccine failure, has disappeared. This recommendation does not apply to children in the Third World, because there measles infects at an early age. The World Health Organization (**WHO**) recommends vaccination at 9 months of age but, by then, 5 to 15 per cent of children may have had measles. Edmonston–Zagreb, a different strain of vaccine, passaged in human diploid cells, and given in high dose (in excess of 10^5 infectious particles) subcutaneously, has proved to be immunogenic at the age of 4 to 6 months. Subsequently, the WHO recommended its use at 6 months of age in areas of the world with a high incidence of measles occurring below 9 months of age. However, long-term follow-up demonstrated lower survival rates among female recipients of high-titre vaccine than among female recipients of standard-dose measles vaccine. Although the biological explanation for this unexpected finding is unknown, the use of high-titre vaccines is now no longer recommended.

Some scientists have argued that measles vaccines will have a limited impact on childhood survival—for disadvantaged children, saved from measles by vaccination, will only die at a later date from other infections or malnutrition. However, a variety of epidemiological studies has documented remarkable reductions in mortality after standard measles vaccine. In Bangladesh, measles vaccination was associated with a 36 per cent reduction in all-cause mortality from the age of 9 months, despite the fact that acute measles accounted for only 4 per cent of deaths in the community. The reason for this unexpected benefit is unknown but it is not related to the prevention of measles. The benefit is particularly marked for girls and is most likely due to non-specific immune stimulation.

Primary vaccine failure may occur because maternal antibody neutralized the vaccine, or it may be due to heat-inactivation of improperly stored vaccine. Secondary vaccine failure may occur because the children are intensively exposed or because protective antibody levels wane. This has not been a problem in developed countries where most children have received their vaccine after 15 months of age, but in developing countries early vaccination at 6 to 9 months of age may increase the likelihood of antibody concentrations declining to non-protective levels.

Waning immunity may become an increasing problem as vaccine coverage increases: because more mothers will have been vaccinated and since they have not been exposed or had natural measles, they will transmit lower levels of maternal antibody. Thus their babies become susceptible to measles by 3 to 5 months of age. This increases the problem of measles control: the two groups of children, born to vaccinated or naturally infected mothers, will have low or high levels of maternal derived antibody, respectively, and thus will need to be vaccinated at different ages.

...or eradication?

Measles eradication has yet to be made an official global policy. However, several regions are pursuing a policy of measles elimination. The United States has been successful with a policy of obligatory vaccination before school entry. The Pan-American Health Organization (**PAHO**) has pursued a successful but expensive policy of national immunization days for all children aged between 1 and 14 years, high routine vaccination coverage, and periodic follow-up campaigns during which all children aged 1 to 4 years are vaccinated. However, the real test of global measles eradication will be in Europe and Africa. Europe, which at best has a coverage of 85 to 90 per cent, has no tradition of an obligatory use of vaccines and an increasing proportion of the population are averse to vaccination. Africa will be a stern test of the PAHO strategy, for due to political instability it is difficult to maintain a sufficiently high coverage for a long period. In addition, because of high fertility rates there will be a constant renewal of susceptible children, combined with an accumulation of susceptible young adults due to waning immunity.

New vaccines, which can be given in early infancy, or two-dose strategies using the standard vaccine at 6 and 9 months of age, will be necessary to contain measles in the developing world. Coverage of at least 95 per cent of all susceptible children, including those between 3 and 9 months of age, with a vaccine that is at least 95 per cent effective will be necessary if the virus is to be eradicated. Current vaccines do not meet these standards. New vaccines such as the Modified Vaccinia Ankara recombinant virus, a non-replicating mutant of horsepox made to express the F and H proteins, or a DNA vaccine expressing these proteins may possibly fulfil such exacting requirements, for they have been shown to protect macaques from measles. However, in those countries with a high child mortality rate where measles vaccine has been shown to have non-specific beneficial effects, vaccination programmes may need to be continued even if measles is eradicated.

7.10.6.1Nipah and Hendra viruses

James G. Olson

Nipah virus

Introduction

An outbreak of severe, febrile encephalitis associated with human deaths occurred in Malaysia, beginning in September 1998. Initially recognized near Ipoh in the northern state of Perak, it was attributed to an endemic mosquito-borne viral encephalitis caused by Japanese encephalitis virus which is amplified by swine. Veterinary and public health measures for control of Japanese encephalitis failed to have an impact on the encephalitis in humans. In January 1999, the outbreak spread to the state of Negri Sembilan and cases increased dramatically.

Aetiology

A new virus of the family Paramyxoviridae, genus *Megamyxovirus*, shows characteristic syncytia and giant cell formation in Vero cell culture. Nipah virus, named for the location where the first isolate was obtained, is approximately 1.1 µm in length with an average diameter of 21 nm. Extracellular, pleomorphic virus particles average 500 nm but vary greatly in size. Surface projections along the envelope are seen only sporadically and measure 10 nm in length. Nipah virus differs genetically from its closest relative, Hendra virus, at the nucleotide level in the phosphoprotein (11 per cent), nucleoprotein (26 per cent), and matrix protein (31 per cent) genes, respectively.

Epidemiology

Nearly all patients had a history of direct contact with pigs. Exposures were primarily occupational and frequently included close contact with pigs with respiratory disease. Since late 1996, a new disease of swine has spread among pig farms in Malaysia. It was not identified as a new syndrome because morbidity and mortality were not considered excessive, and the clinical signs were not markedly different from those of a range of other swine diseases. Transmission of virus among pig farms was by trade and movement of asymptomatic pigs. Other species have become infected with Nipah virus, but only in circumstances where they were exposed to infected pig farms. Serological studies have implicated two species of pterapid fruit bats (flying foxes) as possible wildlife reservoirs of infection (Plate 1).

Clinical features (see also Chapter 24.14.2)

Nipah virus encephalitis is a severe, acute, febrile disease with prodrome of fever, headache, and drowsiness. On admission, patients have fever (70 per cent), drowsiness (50 per cent), disorientation (18 per cent), neck stiffness (12 per cent), myoclonus (10 per cent), unresponsiveness or coma (9 per cent), and seizures (6 per cent). Most (58 per cent) cerebrospinal fluid white blood cell counts were normal, while cerebrospinal fluid protein levels were increased (68 per cent). Platelet counts were mildly decreased (median, 137 × 10^9/l). Of patients who had CT scans, 16 per cent showed cerebral oedema and 14 per cent had focal hyper densities. MRI scans of brain revealed multiple small hyper intensity signals on T2-weighted images. New findings following admission include hypotension (40 per cent), signs of autonomic dysfunction (26 per cent), seizures (22 per cent), and myoclonus (20 per cent). Almost half (49 per cent) of patients became unresponsive or comatose and 50 per cent required intubation. The case fatality ratio was 43 per cent, with the median time from admission to death of 4 days. Intubation, seizures, myoclonus, hypotension, and autonomic dysfunction were grave prognostic indicators.

Pathology

Histological and immunohistochemical findings at autopsy included a systemic vasculitis with fibrin thrombi and fibrinoid necrosis. Endothelial cells of affected vessels showed occasional multinucleated syncytial giant cell formation. Endothelial cells also showed lytic necrosis and sloughing into the lumen of the blood vessels. In the central nervous system, the vasculitis was diffuse involving cerebral cortex and brain stem and was associated with extensive areas of rarefaction necrosis. In these areas, neuronal degeneration and death, neuronophagia, microglial nodules, and mild perivascular inflammatory infiltrates were present. Eosinophilic, mainly intracytoplasmic, viral inclusions were seen in affected neurons and parenchymal cells.

Laboratory diagnosis

Enzyme immunoassay and immunohistochemical tests for Nipah virus infections are sensitive and specific methods for laboratory confirmation of clinical illness. Viral isolation in Vero cells can be successful using throat washings, serum, and urine from acutely ill patients and from brain of patients who die. Isolation of Nipah virus is not recommended for laboratory confirmation because of the extreme hazard (biosafety level 4) of the virus.

Treatment

Clinical management of patients is primarily supportive. Most patients required intubation. Patients with hypotension were treated with intravenous fluids and pressor agents, while those with seizures and myoclonus received anticonvulsive drugs. Oral tribavirin (ribavirin) was administered to several patients but data are not available on its efficacy.

Prevention and control

Control areas with active disease were identified, all pig farms within the designated areas were culled, and the pigs buried. This broke the cycle of transmission to humans. Serological testing of swine showed that on infected farms most of the adult pig population had been exposed, an observation which formed the basis of a national testing and eradication programme. Serum samples from every pig farm in Malaysia outside the control were sampled twice at a minimum interval of 3 weeks. Nipah virus should be eradicated from the Malaysian pig herd.

Hendra virus

Since its first description in Australia in 1994, there have been two outbreaks of fatal disease in horses and humans in Queensland, caused by Hendra virus (formerly known as equine morbillivirus). This is closely related to Nipah virus (see above) and Menangle virus, which was responsible for disease in pigs and humans in New South Wales in 1997. Clinical features of Hendra virus infection in humans were pneumonitis and meningoencephalitis. The natural hosts of Hendra, Menangle, and Nipah viruses and Australian bat Lyssavirus (see Chapter 7.10.10) are species of flying foxes (genus *Pteropus*). In eastern Australia, 20 per cent of flying foxes (*P. poliocephalus* and *P. alecto*) were seropositive for Hendra virus. In these bats, the disease is usually subclinical. Virus is found in uterine fluid and is transmissible

oronasally to horses, cats, and other mammals.

7.10.7 Enterovirus infections

Ulrich Desselberger and Philip Minor

Enteroviruses are a major group of viruses causing systemic infection in man. They form two genera of the Picornaviridae family (the Enterovirus and Parechovirus genera) and occur in at least 66 serotypes in humans. They infect via the gastrointestinal tract and are mostly clinically inapparent. However, viraemia can be followed by infection of organs distant from the site of entry with often devastating affects in the form of meningitis, encephalitis, myopericarditis, and also rashes and conjunctivitis.

The viruses

Viruses of the Picornaviridae are unenveloped icosahedral particles of 27 to 30 nm in diameter, containing single-stranded RNA of positive polarity and approximately 7.5 kb size as their genome. The nucleic acid is poladenylated at the 3' end and carries a small protein, VPg, covalently linked at its 5' end. The enteroviruses and parechoviruses form two of the six current genera of the Picornaviridae family, the other four being rhinoviruses, cardioviruses, aphthoviruses, and hepatoviruses. Three serotypes of poliomyelitis virus (polio virus), 23 types of Coxsackie A virus, six types of Coxsackie B virus, and various types of enterocytopathic human orphan (echo) viruses are recognized within the enterovirus genus. The parechoviruses comprise echoviruses 22 and 23 and were established as a separate genus on the basis of the highly distinctive nature of the sequence of their genomes. Other classical features of the enteroviruses, such as their stability at acid pH (in contrast to rhinoviruses or aphthoviruses), their buoyant density in caesium chloride gradients, and the nature of their broad clinical effects and persistence in the environment are also shared by the parechoviruses.

The three-dimensional structure of the poliovirus particle has been elucidated by crystallographic analysis. The viral capsid consists of 60 protein subunits, each containing the four unglycosylated viral proteins VP1 to VP4. The capsid proteins are arranged in such a way that VP1 molecules form the apices at the five-fold symmetry axis of the icosahedron whereas two other proteins, VP2 and VP3, are arranged in the centre of the triangular face near the three-fold axis of symmetry. VP4 is an internal protein. All proteins interact with each other. The N terminus of VP4 is myristylated.

Viruses initiate replication by attaching to their cellular receptors, and some of these have been characterized. The poliovirus receptor is a member of the immunoglobulin superfamily. Transgenic mice expressing the human poliovirus receptor become susceptible for poliovirus infection with a pathology similar to that of infected primates. They may eventually replace primates for vaccine testing (see below). Other enterovirus receptors are the decay accelerating factors (DAF; receptor for echovirus 7), implicated in the complement pathway, and the integrin VLA-2 (echovirus 1). Other cell surface molecules may be involved in the virus–cell receptor interactions of many enteroviruses, as the expression of an identified receptor is not always sufficient to make a previously resistant cell line susceptible to productive infection. It is also of interest that some strains of poliovirus, mainly of serotype 2, are able to paralyse mice if injected. The receptor involved in mice has not been identified.

The positive sense RNA genome acts as a messenger molecule. All enterovirus RNAs have a long 5' end untranslated region (UTR) of approximately 750 nucleotides length, containing an internal ribosomal entry site (IRES) which is important for binding of ribosomes and translation of RNA into protein. Downstream of the 5' UTR is a large single open reading frame containing three parts: P1, coding for structural proteins VP1 to VP4; P2, coding for proteins 2A, 2B, and 2C; and P3, coding for proteins 3A to 3D. Protein 3C is a viral protease and protein 3D the RNA-dependent RNA polymerase. P2 and P3 proteins (with the exception of VPg = 3B) are only found in infected cells. The P1 to P3 proteins are synthesized as one large precursor, from which the individual proteins are produced by a complex autocleavage and cleavage cascade. RNAs replicates via double-stranded replicative intermediates. The ratio of positive to negative stranded RNA molecules in infected cells is approximately 100:1. Naked enterovirus RNA is infectious upon transfection, and can be transcribed from full length cDNA clones permitting biochemical manipulation and studies of structure and function at the molecular level.

The extensive antigenic variation of enterovirus capsid proteins allows typing into polio-, Coxsackie-, and echoviruses using type-specific neutralizing antisera, but there is some cross-reactivity. The main antigenic sites are located on all three major virion proteins (VP1–VP3), and some involve sequences from more than one protein.

Comparison of complete RNA genome sequences of many enteroviruses show a very close relationship between some enterovirus and rhinovirus sequences. Within the echoviruses, however, there is great diversity, for example echovirus 22 shows a very low degree of homology with any other enteroviruses.

Four subdivisions of human enteroviruses have been proposed according to genomic relatedness:

- Group 1: polioviruses, Coxsackie viruses A1, A11, A13, A17, A18, A21, and A24;
- Group 2: enterovirus types 68–70;
- Group 3: Coxsackie viruses B1–B6, A9, all echoviruses except types 22 and 23, and enterovirus 69;
- Group 4: Coxsackie viruses A2, A3, A5, A7, A8, A14, and A16, and enterovirus 71.

Hepatitis A virus has previously been designated enteroviruses 72, but is now in its own genus Hepatovirus. Echoviruses type 22 and 23 form the Parechovirus genus.

Pathogenesis

The most widely accepted model of the pathogenesis of enterovirus infection is based on that developed by Bodian for poliovirus, in which the virus infects via the gastrointestinal tract and undergoes primary replication in lymphoid cells lining the alimentary tract (oropharyngeal, intestinal). A viraemic phase follows, allowing infection of distant target organs: spinal cord and brain, meninges, myocardium, skeletal muscles, skin, mucous membranes. Other tissues, for example lymph nodes

and brown fat tissue, can also become infected. Intensive multiplication in the CNS leads to the destruction of motor neurones and results in paralysis.

A slightly different and more subtle model of poliovirus pathogenesis was proposed by Sabin, in which the virus infects the mucosal surface, so accounting for the fact that virus can be shed in faeces long after it has become undetectable in lymphoid tissues and when neutralizing antibody is detectable in the blood. The primary replication creates a viraemia which seeds distant, still unknown, sites and virus replication there results in a second viraemia which may be detected about 1 week postinfection and can lead to systemic infection including CNS involvement.

Shedding of virus occurs from the throat and faeces for many weeks and even months after infection and thus ensures transmission (see below). Virus replication in sites distant from the port of entry normally terminates with the appearance of neutralizing antibody, first IgM at 8 to 12 weeks after infection, and then IgG. Children with B cell immunodeficiencies may develop persistent infections.

Most enterovirus infections are silent or produce a 'minor illness' with the symptoms of a mild upper respiratory tract infection with or without fever. In a minority of infections (1 per cent or less) a systemic 'major disease' may develop:

- paralytic poliomyelitis and aseptic meningitis (polioviruses);
- aseptic meningitis, herpangina, conjunctivitis, hand, foot and mouth disease (Coxsackie A viruses);
- aseptic meningitis, myopericarditis, encephalitis, pleurodynia (Coxsackie B viruses; enterovirus 71);
- aseptic meningitis, rashes, conjunctivitis (echoviruses);
- polio-like illness, aseptic meningitis, hand, foot and mouth disease, epidemic conjunctivitis (enterovirus types 68–71).

Symptoms of clinical illness caused by enteroviruses are summarized in Table 1 and are discussed in more detail below.

Clinical symptoms

Central nervous system infections

Poliomyelitis

While there is evidence of poliomyelitis as an ancient human disease as shown on a funerary stele from Middle Kingdom Egypt, about 1300 BC, there is little documentation of its occurrence until near the end of the nineteenth century, when it appeared in epidemics in children (hence the alternative name 'infantile paralysis'). The appearance of poliomyelitis coincided with improvement in standards of public hygiene and is explained by the consequent exposure of infants to infection at a later age. Maternal antibody is capable of confining infection to the gut, where the virus can persist until the immune response develops to eliminate it. In contrast, when maternal antibody has declined in older infants, the virus can spread to sites outside the intestine, causing paralysis.

Even under modern conditions of hygiene, infection with all three poliovirus types is normally inapparent, but illness with neurological symptoms results in about 1 per cent of infections. This can present as aseptic meningitis with neck stiffness, usually recovering after 10 days (abortive or non-paralytic poliomyelitis). Meningitis is also caused by several other enteroviruses (see below). The more serious presentation is paralytic poliomyelitis, appearing 5 to 10 days after a mild upper respiratory tract infection ('minor illness') and progressing to flaccid paralysis resulting from motor neurone destruction ('major illness'). This may be accompanied by spasms and inco-ordination of non-paralysed muscles. Various forms of the 'major illness' reflect infection of different parts of the CNS. Paralysis of limbs results from destruction of motor neurones in the lower part of the spinal cord ('spinal form'), while the more life threatening bulbar poliomyelitis ('bulbar form') involves infections of the medulla oblongata or bulb. Respiratory functions can be affected in both the spinal and bulbar forms of the disease. Encephalitis is rare. In children under 5 years old, paralysis of one leg is most common; in children 5 to 15 years of age, weakness of one limb or paraplegia are frequent; quadriplegia is most common in adults, often accompanied by urinary bladder and respiratory muscle dysfunction. Muscular function in limbs may return slowly but there is residual paralysis in 90 per cent of survivors. Ten to 25 per cent of paralytic cases have bulbar symptoms with hypertension, shock, and dysphonia. Complications are nosocomial pneumonias (by staphylococci or Gram-negative bacteria), urinary tract infections, and emotional problems. The mortality from paralytic polio is 2 to 5 per cent among children and 15 to 30 per cent among adults. Muscle weakness may develop many years after the initial polio disease (postpolio syndrome or postpolio neuromuscular atrophy). A persistent poliovirus infection as cause of this has been assumed, based on the presence of viral RNA in cerebrospinal fluid and neural tissue. However, such RNA has also been found in patients with other neurological and non-neurological diseases and is therefore less likely to be related to the postpolio syndrome. The alternative view is that the postpolio syndrome is anatomical in origin, such that the initial attack of polio destroys motor neurones and reduces the backup available as the patient ages.

Aseptic meningitis

Aseptic meningitis is the most frequent clinical presentation of enterovirus infection and can be caused by Coxsackie viruses of both groups A and B, and echoviruses, mainly types 4, 6, 11, 14, 16, 25, 30, and 31 (see Table 1). The disease starts with fever, headache, neck stiffness, and photophobia. Sensory or motoric deficits are unusual but confusion is common. The symptoms may persist for 4 to 7 days. The CSF usually shows pleocytosis consisting of 10 to 500 leucocytes per µl, mainly lymphocytes. Polymorphonuclear cells may predominate at the onset, but, should they persist, bacterial infection and possibly abscesses should be considered. The protein concentration in CSF may be normal or slightly increased; the glucose level is normal. Complete recovery is the usual outcome of aseptic meningitis.

Encephalitis

Enterovirus encephalitis is rare but may follow aseptic meningitis. Enterovirus infection in patients with hypo- or agammaglobulinaemia may persist for years with chronic meningitis or encephalitis as sequelae, and a high mortality.

Enterovirus 71 infection which is normally associated with hand, foot, and mouth disease has been found to cause severe meningoencephalitis (with brain stem involvement), polio-like acute flaccid paralysis, and a high case fatality rate in children during several recent outbreaks in Bulgaria, Taiwan, and Malaysia. In some of the fatal cases there may have been coinfections with a species B adenovirus. Enterovirus 71 occurs in three genotypes and is rapidly evolving; it is most closely related to Coxsackie virus A16.

Neonatal infections

Neonatal infection followed by severe, generalized disease may be caused by Coxsackie B viruses and echovirus, mainly of types 6, 7, and 11. These viruses seem to be transmitted late in pregnancy, perinatally, or postnatally by the mother or other virus-infected infants in neonatal wards or special care baby units. The infants develop heart failure due to a severe myocarditis, or a meningoencephalitis. Hepatitis and adrenalitis may also occur. The mortality is high. Viruses may be recovered from brain, spinal cord, myocardium, and liver at autopsy.

Bornholm disease (epidemic pleurodynia)

This is usually caused by Coxsackie B viruses but also by echoviruses of types 1, 6, 9, 16, and 19, and by Coxsackie A viruses of types 4, 6, 9, and 10. The disease can strike families in small outbreaks. It typically starts abruptly with fever and chest pain due to the involvement of the intercostal muscles, or abdominal pain resulting from involvement of muscles of the abdomen. There may be severe frontal headache. The symptoms last 3 to 14 days, followed by complete recovery.

Myopericarditis

Enterovirus-induced myocarditis is mostly due to infection with Coxsackie B viruses in the young. The onset of disease is usually acute, very severe, and may be fatal in neonates, however in adolescents and adults it is normally mild. The virus may persist after the initial infection and cause dilated cardiomyopathy. In fatal cases (usually neonates 2–11 days after onset of disease) there is cardiac dilatation, myocyte necrosis, and an inflammatory reaction. The diagnosis is often difficult, particularly in older patients, as pericarditis, coronary artery occlusion, or heart failure may have been diagnosed initially. Typical clinical findings are often

tachycardia, arrhythmias, murmurs, rubs, and cardiomegaly.

Besides causing acute myocarditis, chronic enterovirus infection can lead to chronic myocarditis and dilated cardiomyopathy, possibly due to immunopathologial mechanisms. In chronic disease, neither infectious virus nor viral antigens are normally detected in heart biopsies; however, viral RNA is regularly found in cardiac muscle, suggesting that the viral genome persists. The true significance of the presence of the viral genome in such cases is still under discussion.

The disease can be produced with Coxsackie B viruses in mice. In this animal model there is also initial viraemia and replication in myocytes, but this is followed by disappearance of infectious virus and destruction of myocytes, possibly by autoimmune mechanisms.

Herpangina

This is caused by Coxsackie viruses of types A1 to 6, 8, 10, and 22. Children and young adults between 2 and 20 years of age are mainly affected. The disease presents with acute onset of fever, sore throat and pain on swallowing, also vomiting and abdominal symptoms. Small vesicular lesions or white papules surrounded by a red halo can be seen on the fauces, pharynx, palate, uvula, and tonsils. The disease is mild and self-limiting.

Exanthemata

Rubella-like rashes can be produced by echoviruses of types 4, 9, and 16, but also Coxsackie viruses A9, A16, and B5. Those usually occur in the summer and may be accompanied by fever, malaise, cervical lymphadenopathy, and aseptic meningitis.

Hand, foot, and mouth disease

A typical distribution of vesicular lesions in hands, feet, and mouth (but also buttocks and genitalia) is produced by infection with Coxsackie virus type A16 and enterovirus 71, less frequently with Coxsackie viruses A4, A5, A9 and A10, B2, and B5. Enterovirus 71 may produce more severe clinical symptoms (see above).

Foot and mouth disease

The aphthovirus causing foot and mouth disease in cloven hoofed animals, is endemic in Africa, Asia, and South America. Virus is secreted before blisters of mouth and feet appear in animals. The zoonosis in humans is very rare, with about 37 recorded cases. Human infection occurs from virus entering through broken skin, drinking unpasteurised milk, or by inhalation of droplets. A 2 to 6-day incubation period is followed by blisters of hands, feet, and mouth, fever and sore throat. Complete recovery ensues. No person-to-person spread is recorded.

Conjunctivitis

Several enterovirus types cause conjunctivitis, often affecting large numbers of people epidemically. Most notable causes are echovirus types 7 and 11, Coxsackie virus A24 and B2, and enterovirus 70 that often produces a haemorrhagic conjunctivitis.

Diabetes and pancreatitis

Insulin-dependent diabetes mellitus (IDDM, or type 1 diabetes) is likely to be an autoimmune disorder in which the insulin-secreting pancreatic islet cells (beta cells) are destroyed. The human disease has long been thought to be caused by infectious agents, particularly since association between enterovirus infection and the development of IDDM has been shown in animal model studies (infection of mice with Coxsackie B3–B5 viruses). However, there is also a strong genetic component in the development of IDDM.

Chronic fatigue syndrome (CFS)

Chronic fatigue syndrome (CFS), also known under the names of myalgic encephalomyelitis (ME), Royal Free disease, Iceland disease, postviral fatigue syndrome, and neuromyasthenia, can occur both sporadically and epidemically. The main clinical feature is excess fatiguability of skeletal muscle, accompanied by pain. Other symptoms include headaches, inability to concentrate, paraesthesia, and impairment of short-term memory. A major problem in diagnosis is a clear definition of the clinical entity. Several virus infections have seemed to precede the development of CFS. Those are mainly enterovirus infections, chronic Epstein–Barr virus (EBV) infection and also infections with *Toxoplasma* and *Leptospira* species. The stringency of the association of chronic enterovirus infection with the appearance of CFS is controversial. A recent report of a joint working group of the Royal Colleges of Physicians, Psychiatrists and General Practitioners has concluded that persistence of enteroviruses is unlikely to play a role in the development of CFS. Similar conclusions have been drawn for the possibility of a causal link between chronic EBV infection and CFS (see Chapter 7.10.3).

Gastroenteritis

Although enteroviruses infect via the gastrointestinal tract and readily replicate there, they very rarely cause diarrhoea. Outbreaks of diarrhoea with echovirus type 11 have been reported. In Japan, an entervirus termed Aichivirus which is proposed as the type species of a new genus of the Picornaviridae family has been identified as the cause of multiple outbreaks of gastroenteritis in humans, mostly associated with the consumption of raw oysters. This virus seems to circulate widely in populations of Japan and other South-east Asian countries, with subclinical infections likely to be common (see Chapter 7.10.8).

Laboratory diagnosis of enterovirus infections

Virus isolation

Virus isolation is an excellent procedure to diagnose enterovirus infections. Virus is shed for weeks, and sometimes months, from the primary infection sites (cells lining the gut, see above). Starting from a few days after infection, virus can be found in concentrations of 10^5 to 10^6 tissue culture infectious doses 50 per cent per g faeces ($TCID_{50}$/g faeces). Throat swabs are also a good source for virus, particularly early in infection and when there are respiratory symptoms. In cases of meningitis, enteroviruses can be propagated in cell culture from the CSF, but the method is much less sensitive than genome detection (see below). Viruses are readily isolated in secondary cultures of monkey kidney cells, or in cultures of permanent cell lines derived from human embryonic kidney, human amnion, or human fetal lung. The cytopathic effect (CPE) produced by enteroviruses is non-specific. Typing of a cytopathic agent is carried out using antiserum pools or in multistep procedures. Most Coxsackie A viruses (with the exception of Coxsackie virus A9) do not grow well in cell culture but can be readily isolated by intracerebral, intraperitoneal, or subcutaneous infection of mice, causing flaccid paralysis and death. In contrast, Coxsackie B viruses cause spastic paralysis. Polio- or echoviruses do not usually grow in mice although polioviruses will replicate in transgenic animals that have appropriate receptors (see above).

Serology

Neutralization assays are the method of choice for typing enteroviruses. These tests are labour intensive and not apt for rapid diagnosis. They are mainly used for seroepidemiological studies. Recurrent enteroviruses infections during a lifetime often result in elevated serum antibody titres which obscure diagnostic changes. Significant antibody rises are therefore rarely observed in paired sera (taken at the onset of and during convalescence from disease).

A Coxsackie B virus-specific IgM test (using an IgM antibody capture technique) has been developed for rapid diagnosis. However, there is cross-reactivity between the IgM responses to different enteroviruses, including different genera of the picornaviruses, and so this test is not very specific. Prolonged presence of enterovirus-specific IgM has also been observed. Thus, in summary, the usefulness of serology for the diagnosis of enterovirus infection is limited.

Genome detection

Hybridization techniques and, more recently, reverse transcription polymerase chain reaction (RT-PCR) techniques have been applied to test for the presence of

enterovirus genomes. This approach has been very productive, particularly in diagnosing CNS infections from CSF specimens, and has become the 'gold standard' of diagnosis, surpassing viral culture. Enterovirus RNAs have also been detected in myocardial biopsies from patients with myocarditis and dilated cardiomyopathy, in muscle of people with inflammatory muscle disease and chronic fatigue syndrome, and in brain biopsies. The significance of these findings is not clear as infectious virus can rarely be isolated, and viral antigen cannot be detected. Highly conserved sequences in the 5' UTR of enterovirus genomes have allowed the design of PCR primers detecting most enterovirus RNAs. As the echovirus 22 genome is very different from that of the other enteroviruses, tailor-made primers have to be added in a multiplex RT-PCR to include these viruses, which occur particularly in neonates and infants. A modified RT-PCR procedure can differentiate between wild-type and vaccine-derived poliovirus infections.

Epidemiology of enterovirus infections

Enteroviruses are mainly transmitted by the faecal–oral route, due to the fact that viruses are shed in faeces for weeks or months after infection. Spread is particularly intense within families, usually starting from young children's primary infection. In temperate climates, there are seasonal peaks (July–September in the northern, and December–February in the southern hemisphere), whereas in subtropical/tropical climates enterovirus infections occur all the year round. The vast majority of primary human enterovirus infections occur during the first decade of life. Type-specific surveillance in several geographical regions has shown that Coxsackie viruses A9, A16, B4, and echovirus types 6, 9, 11, 19, 22, and 30 are most frequently found.

Prevention of enterovirus infections

As there are only three poliovirus types and no significant animal reservoir, it has been possible to develop very successful poliovirus vaccines. In 1954, a formalin-inactivated poliovirus vaccine (IPV) was introduced by Dr Jonas Salk in the United States, and in 1962 Dr Albert Sabin introduced a vaccine consisting of attenuated strains of the three poliovirus types which could be given orally (OPV). Protection by the live-attenuated vaccine is effected mainly at the site of entry by eliciting locally virus-specific IgAs and IgGs. Inactivated vaccine mainly elicits serum IgGs which prevent infection of the CNS and other sites distant of the port of entry by neutralization of viraemic virus. The main characteristics of IPV and OPV are summarized in Table 2.

Inactivated poliovirus vaccine

This vaccine was and is used with high acceptance rates in Scandinavia and Holland and has virtually eliminated poliomyelitis in these countries. There was a small outbreak of poliomyelitis due to poliovirus type 3 in Finland in the early 1980s, which seemed to be possible due to the fact that type 3 antibody levels in the community were comparatively low. However, the poliovirus strain isolated during the outbreak was antigenically unusual and less well neutralized by antisera to the reference strains of type 3 poliovirus. IPV is the vaccine of choice in cases of immunodeficiency.

Live attenuated poliovirus vaccine

This vaccine has a number of advantages compared to the inactivated vaccine as it:

- parallels the natural infection;
- stimulates both local secretory IgA in the pharynx and alimentary tract, and systemic circulating virus-specific IgG antibody;
- is easy to administer as an oral vaccine;
- is more cost effective.

The disadvantage is that in a few cases the attenuated vaccine strains have reverted to virulence. Since the early 1980s, all cases of polio in the United States and Europe were found to be caused by vaccine-related, that is reverted poliovirus, or were imported from endemic countries and were not indigenous, original wild-type strains. The risk of vaccine-associated poliomyelitis is between 0.5 and 3.4 cases per million of susceptible children immunized. Vaccine-related polio is mostly caused by type 2 or type 3 viruses, probably due to the fact that the number of point mutations in type 1 vaccine virus compared to wild type is much higher than in type 2 and type 3 vaccine viruses. However, this finding raises the question of whether oral vaccination should be continued. In the United States, guidelines have been developed recently which replace the oral vaccination programme by a mixed procedure, initially using inactivated vaccine, followed by booster doses of oral vaccine. For a variety of reasons many countries (United States, France, Germany) have either subscribed to the exclusive use of IPV or are likely to do so in the near future. The decision was influenced by the good progress made towards the eradication of polio due to wild-type virus.

OPV is the vaccine of choice for people travelling into poliovirus endemic areas if their immune status is unknown or in doubt. The vaccine should be given at least 2 weeks before departure.

Polio eradication and surveillance

For many years it was thought that the Sabin oral poliovaccines were ineffective in tropical countries. While many reasons were put forward, the lack of impact of polio vaccination programmes was probably due to loss of vaccine potency through failure to maintain storage at cool temperatures, and also the epidemiology of poliovirus infection. In temperate countries, poliomyelitis is seasonal with infections peaking in the summer months. A strategy of vaccination based on immunization of young children at a set age (usually a few months) is therefore able to build up a highly immune population in the winter so that transmission of the wild-type virus becomes more difficult. In tropical countries, where exposure is year round, it is a matter of chance whether a child is first naturally infected, or immunized. This was recognized by Sabin in 1960, but not acted upon until some 20 years later, when the strategy of National Immunization Days was developed in South America. This approach involves immunizing all children below a certain age in a country within a very short period, so that all susceptible children's intestinal tracts are occupied by vaccine virus and are therefore resistant to infection by the wild type. Transmission of wild-type virus is therefore broken, and the virus dies out.

WHO have pronounced the intention of eliminating poliomyelitis due to wild-type virus. The Americas have been free of polio since 1992, but vaccine-derived poliomyelitis occurred in Haiti and the Dominican Republic in 2000/1. The last case of polio in South East Asia occurred in March 1997. In 2000, the Western Pacific Region was declared polio-free by WHO, and polio is now endemic in only 30 countries (Fig. 1). The scale of the undertaking is colossal, and the progress towards eradication is extraordinary. For example in 1992 in China, all children aged 5 or less were immunized over a 1-week period. This amounts to one-quarter of the world's children. At the time of writing, virus was still known to be endemic in India and surrounding countries, countries of West and Central Africa, and of the Eastern Mediterranean region, but eradication before long is a real possibility.

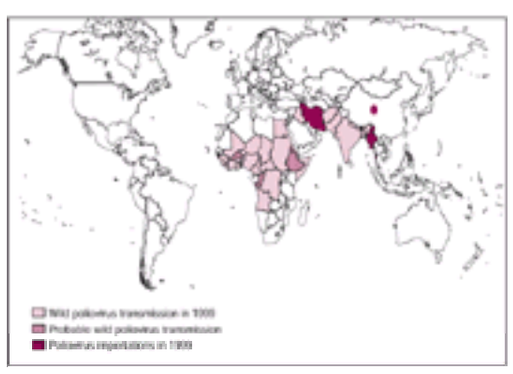

Fig. 1 Countries with known or probable wild poliovirus transmission —World Health Organization, 1999, as of March 2000. (From Centers for Disease Control (2000), with permission.)

Part of the challenge is to demonstrate that the virus has in fact been eliminated, and this depends on rigorous, effective surveillance. One approach is to obtain data on cases of acute flaccid paralysis of whatever cause, including the Guillain–Barré syndrome. All cases should be investigated to see whether they are due to poliovirus infection or not, and it is considered that the background rate in the absence of poliomyelitis should be one case per 100 000 members of the population,

providing a control for the adequacy of the surveillance scheme. Alternative approaches include the investigation of poliovirus isolates to establish whether they derived from vaccine or wild-type strains. There are possible concerns over the adequacy of either approach.

Once wild-type poliovirus has been eradicated, the only sources of the virus will be manufacturers of vaccines, laboratories holding stocks, and recipients of live attenuated vaccine. While manufacturers and laboratory workers can be required to work under high containment level conditions to avoid escape of virulent virus, vaccinees pose a particular problem. The vaccine works by establishing an infection in the recipient but the virus may adapt to the gut and eventually undergo major molecular changes to improve its fitness. In principle, such viruses could spread to others forming a focus for a return of poliovirus infections and poliomyelitis. In practice, the vaccine virus seems to be poorly transmissible compared to the wild type. In countries such as Cuba where it has been given only in the early part of the year as a matter of policy, virus is not detectable after 6 months. Thus, it might be possible to stop vaccinating with no further precautions, as the vaccine strain of poliovirus will die out more rapidly than susceptible individuals will accumulate to provide a population to maintain it. However, people with B cell immunodeficiency can remain infected but apparently healthy for up to 15 years. During this time the virus may adapt to an extent that neurotropism is regained, and an unvaccinated population will again be highly susceptible. The numbers or geographical distribution of such long-term excretors are unknown. One possible approach to the problem would be to use inactivated vaccine for some unspecified period. The fact that serious consideration has to be given to how to deal with the cessation of vaccination is a tribute to the extraordinary progress which has been made towards polio eradication.

7.10.8 Virus infections causing diarrhoea and vomiting

Ulrich Desselberger

Introduction

Acute gastroenteritis and vomiting in humans is a well-characterized clinical entity caused by several different agents (viruses, bacteria, parasites, etc.). Viral gastroenteritis is a global problem, particularly in infants and young children.

Many viruses are found in the gut but not all of them produce acute gastroenteritis (Table 1). Viral infections normally associated with gastroenteritis are caused by: rotaviruses; enteric adenoviruses; small, round structured viruses (**SRSVs**) and classic human caliciviruses; and astroviruses. Other viruses found in the gastrointestinal tract (enteroviruses, reoviruses, non-group F adenoviruses, toroviruses, coronaviruses, parvo-viruses) are not regularly associated with diarrhoeal disease in humans. Finally, there are viruses found in the gut of immunosuppressed patients (most often those with human immunodeficiency virus (**HIV**) infection), including herpes simplex virus (**HSV**), cytomegalovirus (**CMV**), and picobirnaviruses. HIV itself can also infect the gut directly.

Only the major virus groups regularly causing gastroenteritis in man are described here separately. Clinical symptoms, diagnosis, treatment, epidemiology, and vaccine development are reviewed under common headings.

Rotaviruses

Structure

Rotaviruses are the major cause of infantile gastroenteritis worldwide and also of acute diarrhoea in the young of many mammalian species. They are members of the Reoviridae family, with a genome of 11 segments of double-stranded RNA encoding six structural viral proteins (VP1–4, VP6, and VP7) and six non-structural proteins (NSP1–NSP6). The structural proteins VP1–3 are located in the inner or core layer, VP6 forms an inner shell or intermediate layer, and VP7, and VP4 are components of the outer shell or outer layer (VP4 protrudes as spikes). Thus, a double-shelled/triple-layered particle, 75 nm in diameter, appears in a characteristic form on electron micrographs (Fig. 1), the name of the virus being derived from *rota* (Latin = wheel).

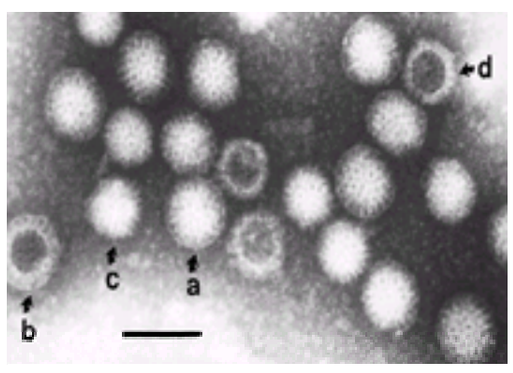

Fig. 1 Rotavirus particles in the faeces of a child admitted to hospital with acute gastroenteritis. Negative staining with aqueous 2 per cent potassium phosphotungstate, pH 7.0. The scale bar represents 100 nm. Four different morphologies of particles are shown: (a) double-shelled (ds) particles containing RNA; (b) ds particle without RNA (empty; core penetrated with stain); (c) single-shelled (ss) particle containing RNA; (d) single-shelled empty particle. (Figure by courtesy of M. Jenkins, Regional Virus Laboratory, East Birmingham Hospital). (Taken from U. Desselberger, Reoviruses. In: *Medical Microbiology,* 14th edition, (eds. D. Greenwood, R. Slack, J. Peutherer), page 620. Churchill Livingstone, Edinburgh, 1992, with permission of the publisher.)

Classification

Rotaviruses are classified according to the immunological reactivities and genomic sequences of three of their structural components.

1. Specific epitopes on the inner-shell protein VP6 allow five groups (A–E) to be distinguished, and two more groups (F, G) probably exist. Within group A rotaviruses, there are at least four subgroups. Group A rotaviruses constitute the vast majority of human infections.
2. Both surface proteins, VP4 and VP7, elicit neutralizing antibodies and thus confer type-specificity. A dual-type classification system has been devised for group A rotaviruses, which differentiates G types (VP7-specific, G for glycoprotein) and P types (VP4-specific, P for protease-sensitive protein)—for example, G1P1A[8] is G serotype and genotype 1, P serotype 1A, P genotype 8. At least 11 G types and 9 P types have been found in humans (see reviews by Estes 1996 and Desselberger 2000). As group A rotaviruses reassort readily in doubly infected cells, various combinations of VP4 and VP7 types occur in natural isolates.

Replication

Rotaviruses replicate in the mature epithelial cells at the tips of the villi of the small intestine. Viruses enter cells either by receptor-mediated endocytosis or directly, and single-shelled subviral particles (devoid of VP4 and VP7) produce and protrude large numbers of mRNAs from all 11 segments into the cytoplasm. Viral proteins are synthesized from mRNAs, and morphogenesis proceeds in a complex fashion. Mature rotavirus particles are released from cells by lysis, resulting in very high concentrations of up to 10^{11} virus particles per ml of faeces at the peak of the acute diarrhoea.

Pathogenesis

The diarrhoea arises by cellular necrosis and atrophy of the epithelium, leading to a reduction in the breakdown and absorption of carbohydrates and to increased osmotic pressure in the gut lumen. The villous damage is repaired by cells emerging and differentiating from the crypts of the gut epithelium, which show a reactive hyperplasia. This is accompanied by increased secretion, which also contributes to the diarrhoea. Several viral proteins have been shown to be determinants of the pathogenicity of rotaviruses and VP4 is of major significance. Most recently, the non-structural protein NSP4 (= VP10) has been characterized as the first viral enterotoxin.

Immune response

A serotype-specific humoral immune response is elicited after neonatal or primary rotavirus infection. However, during the first 2 years of life children are repeatedly infected with rotaviruses, leading to multiple serotype-specific, but also partially heterotypic, protection. The presence of rotavirus-specific secretory IgA coproantibodies seems to correlate best with protection against disease, although the exact correlates remain to be determined. There are also rotavirus-specific cytotoxic T-cell responses whose exact role in immunity is unknown.

Enteric adenoviruses

Structure and classification

Adenoviruses are non-enveloped icosahedral viruses possessing a genome of linear double-stranded DNA approximately 35 000 bp in size. Their capsid is between 70 and 80 nm in diameter and consists of 240 hexons and 12 pentons that stand out as projecting fibres at the corners of the icosahedral virus particle. Human adenoviruses occur in 51 distinct serotypes, ordered in six different subgroups (A–F). Those adenoviruses regularly associated with gastroenteritis are classified as subgroup F, serotypes 40 and 41. Adenoviruses of different groups (causing respiratory tract infections) are also found in the gut, but are not regularly associated with diarrhoea.

Replication

Adenoviruses attach to susceptible cells via the fibre proteins, and enter via receptor-mediated endocytosis. Phased early and late gene transcription of the viral DNA in the cellular nucleus is followed by translation and morphogenesis in the cytoplasm, and numerous particles are released after cell death. The early protein E1A is a potent blocker of apoptosis and of interferon-a and -b expression. Late adenovirus gene expression blocks cellular DNA expression. Some adenoviruses seem to decrease the expression of MHC class 1 antigens on the surface of infected cells, thus reducing susceptibility to adenovirus-specific cytotoxic T cells. There is a serotype-specific humoral immune response providing homotypic protection.

Small, round structured viruses (SRSV)

Structure and classification

These viruses were first recognized as the cause of gastroenteritis during outbreaks in Norwalk, Ohio, in the late 1960s. Norwalk virus (**NV**) particles are spherical and measure 27 to 35 nm in diameter. NV and Norwalk-like viruses (**NLVs**) are all members of the Caliciviridae family. Their 7.7-kb genome consists of single-stranded RNA of positive polarity. Cup-shaped depressions on the surface of virions have given the name to this viral family (Latin *calix* = goblet, cup). Phylogenetic trees of full-length sequences of caliciviral cDNA demonstrate at least three genogroups (Norwalk virus representing genogroup 1; Lorsdale virus, genogroup 2; and Manchester virus, genogroup 3). The SRSVs and typical caliciviruses that infect humans are shown in Table 2. Genogroup 3 viruses have been termed 'classical' caliciviruses as their structure is better preserved on electron microscopy, and the genomes of some show greater homology with several animal caliciviruses which are possible sources of human infection.

Replication

Details of the replication of human caliciviruses can only be deduced from those of animal caliciviruses as there is no reproducible *in vitro* cell-culture system for the human SRSVs. The viruses seem to interact with species-specific receptors and a single protein precursor is co- and post-translationally cleaved in a way similar to that observed in enteroviruses.

Immune response

Although SRSV infections elicit human immune responses, they do not seem to give full protection against subsequent infection. On the contrary, higher pre-existing antibody levels seem to predispose to more severe illness upon reinfection.

Astroviruses

Structure and classification

Astroviruses are members of the newly defined family Astroviridae. They possess a 6.8-kb genome of single-stranded RNA of positive polarity. So far, eight different serotypes have been distinguished, which correlate well with major differences in genome sequences (that is, genotypes).

Replication

Human astroviruses grow well in particular cell cultures. After viral absorption to unidentified cellular receptors and uncoating in the cytoplasm, full-length and subgenomic RNAs are made. These direct the production of protein precursors which are post-translationally cleaved. Replication takes place purely in the cytoplasm.

Illness

The onset of acute viral gastroenteritis follows a short incubation period of 1 to 2 days. It is sudden, with watery diarrhoea lasting between 4 and 7 days, vomiting, and varying degrees of dehydration. Over one-third of children with rotavirus infection have a fever of more than 39 °C. Fewer have a high fever after infection with SRSVs. The duration of diarrhoea after infection with SRSVs is as a rule shorter (1–2 days) than after infection with rotaviruses or enteric adenoviruses (4–7 days). Disease due to SRSV infection may be accompanied by abdominal cramps, headache, and myalgia. In rotavirus infection all degrees of severity are seen. Inapparent infections are not infrequent, particularly in neonates where the infection is caused by so-called 'nursery strains'. It is not clear whether the asymptomatic nature of rotavirus infection in neonates is due to infection with particular strains or depends on the presence of maternal antibodies that provide partial protection. Rotavirus infections are frequently accompanied by respiratory symptoms; but there is no strong evidence that rotavirus replicates in the respiratory tract. In immunodeficient children, chronic gut infections with rotaviruses, adenoviruses, and astroviruses have been observed, accompanied by virus shedding over weeks and even months.

Diagnosis

The diagnosis of rotavirus, astrovirus, and enteric adenovirus infections is relatively easy as large numbers of particles are shed during the acute phase of the illness. In contrast, SRSVs replicate for a shorter period and are shed at lower concentrations. Diagnosis is by electron microscopy of negatively stained specimen

suspensions ('Catch-all method'), by passive particle agglutination tests, virus-specific enzyme-linked immunosorbent assays (**ELISAs**), and more recently by viral genome detection using the polymerase chain reaction (**PCR**) (for adenoviruses) and reverse transcription-PCR (**RT-PCR**) (for rotaviruses, caliciviruses, and astroviruses). The morphological appearances of the main viruses pathogenic for humans are shown in Fig. 2. PCRs are extremely sensitive diagnostic tools, allowing both viral detection and typing. Aliquots of PCR amplicons can also be sequenced and the information used to establish phylogenetic trees. Such trees are becoming increasingly important not only for virus classification but also for epidemiological studies and surveillance (see below).

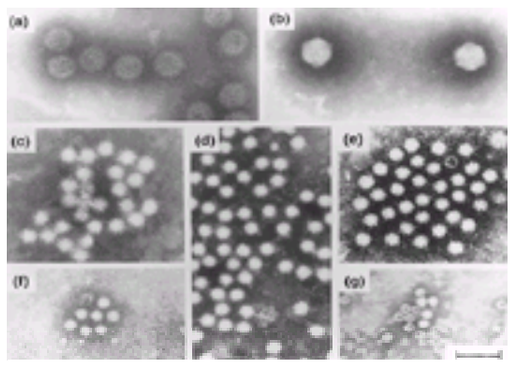

Fig. 2 Electron micrographs of (a) rotavirus, (b) enteric adenovirus, (c) SRSV, (d) calicivirus, (e) astrovirus, (f) enterovirus, and (g) parvovirus. Negative staining with 3 per cent phosphotungstate, pH 6.3; bar represents 100 nm (Figures by courtesy of Dr J. Kurtz, Oxford Public Health Laboratory (astroviruses) and Dr J. Gray, Clinical Microbiology and Public Health Laboratory Cambridge (all other viruses)). Reproduced from *Principles and practice of clinical virology,* 4th edn (eds. A. Zuckerman, J. Banatvala, J. Pattison), p. 236. J. Wiley and Sons, Chichester, 2000, with permission of the publisher.

Treatment

Treatment is mainly by oral rehydration or, in more severe cases, intravenous rehydration. In severe rotavirus infections, treatment with oral immunoglobulins has shown to affect the duration of diarrhoea and virus shedding. This is not, however, a routine treatment. Otherwise treatment is symptomatic, but the use of antimobility drugs (codeine phosphate, diphenoxylate, coperamide) in children is not advised. Specific antiviral agents have been tested in animal models of rotavirus infections but are not used for human treatment.

Epidemiology

Rotaviruses

Rotavirus infections occur endemically worldwide and cause over 800 000 deaths annually in children below the age of 2 years, mainly in developing countries. Therefore development of vaccine candidates has been a major goal since the early 1980s (see below). The epidemiology of rotaviruses is complex. Besides children, elderly patients and patients with immunodeficiencies can be affected. There is a strict winter peak of rotavirus infections in temperate climates, but infections occur year round in tropical and subtropical regions. Transmission is by the faeco-oral route. Nosocomial infections on infant hospital wards occur and are difficult to eliminate. Group A rotaviruses of different G and P types are found to cocirculate in various populations within the same geographical location, and the relative incidence of different types changes over time. Various surveys have shown that usually more than 90 per cent of cocirculating strains in temperate climates are types G1 to G4 and occur in combination with different P types as types G1P1A[8], G2P1B[4], G3P1A[8], and G4P1A[8]. Other G types may also be represented, seen particularly in tropical and subtropical areas but increasingly in temperate climates. For instance, G9 strains have caused outbreaks with increasing frequency in the United States and Europe. Most mammalian, as well as avian species, harbour a large diversity of rotaviruses and may act as a reservoir for human infections. An animal source is suspected for many of the more unusual human group A rotavirus isolates, and possibly for group B rotavirus isolates. The latter caused outbreaks in children and adults in China during the 1980s and have recently been isolated from patients with diarrhoea in Calcutta. Group C rotaviruses are associated with small outbreaks in humans.

Small, round structured viruses

Age-related seroprevalence studies of SRSVs have recently shown that infection is much more frequent and occurs from younger ages onwards than previously thought. Approximately 50 per cent of infants have been infected by the age of 2 years. The rate of inapparent infection is high, particularly in the young. In contrast to rotavirus infections, SRSVs cause outbreaks of acute gastroenteritis, mostly due to contamination of food or water. Contaminated oysters and green salads are often implicated as sources of infection. Outbreaks occur in older children and adults in recreational camps, hospitals, nursing homes, schools, cafeterias, hotels, cruise ships, at banquets, etc. SRSV outbreaks occur worldwide throughout the year, in contrast to the regular winter peaks of rotavirus infections in temperate climates. The viruses are highly infectious and spread rapidly. Transmission is spread by the faeco-oral route and also by projectile vomiting, scattering viruses into the environment by aerosol. At least seven different genotypes cocirculate, which have been confirmed as serotypes. Type 1 and 2 viruses are most frequent.

Astroviruses

Infections with astroviruses occur in infants and the elderly as endemic infections, but they can also cause food-borne outbreaks of diarrhoea. There are at least eight genotypes, correlating well with known serotypes which cocirculate. Serotype 1 is most frequently found, followed by serotypes 2 to 4 at intermediate and serotypes 5 to 7 at low frequencies. Seroprevalence studies have indicated that infection by more than one serotype is not unusual.

Vaccine development

Vaccines have been found to be the best individual and also population-based tools to restrict infection with epidemic viruses. Of the gastroenteritis-inducing viruses, vaccine development has only been intensely directed towards rotaviruses. After many trials with variable success, a live-attenuated, rhesus rotavirus (**RRV**)-based, human reassortant vaccine eliciting immunity to human rotavirus strains G1 to G4 has recently been found to confer significant protection (70–80 per cent) from severe disease including dehydration, whereas protection from infection alone was only moderate (40–50 per cent). This vaccine was recommended by the Advisory Committee on Immunization Practices (**ACIP**) in the United States in 1998. However, after 1.5 million doses had been used, the rare complication of gut intussusception was found to be apparently significantly associated with vaccination. In 1999 the ACIP withdrew the recommendation, and the vaccine has been taken off the market by the manufacturer. Studies of the epidemiological findings and possible mechanisms of pathogenesis are underway.

As a result, other approaches to immunization against rotavirus infection have gained interest, such as the use of virus-like particles obtained from baculovirus-recombinant coexpressed rotavirus proteins, enhancement of rotavirus immunogenicity by microencapsidation, DNA-based candidate vaccines, and possibly 'edible vaccines'.

No vaccines against other viruses causing gastroenteritis in humans have been developed so far. For NV-like viruses this is unlikely to happen, as long-term immunity does not usually seem to follow natural infection.

Outbreak control

Nosocomial rotavirus outbreaks among paediatric populations (on hospital wards and in day-care centres) are common. There have been numerous reports of outbreaks of diarrhoea and vomiting occurring in adults and children due to infections with Norwalk-like viruses, acquired from banquets, travel on cruise ships, cafeterias, schools, hotels, fast-food restaurants, etc.

Outbreak control measures should focus on the interruption of person-to-person transmission and the removal of common sources of infection (food, water, etc.) in

conjunction with measures to improve environmental hygiene (by food-handlers, etc.).

7.10.9 Rhabdoviruses: rabies and rabies-related viruses

M. J. Warrell and D. A. Warrell

Virology

The Rhabdoviridae are a family of more than 100 rod- or bullet-shaped RNA viruses found in vertebrates, insects, and plants (Fig. 1). Two genera infect animals: *Vesiculovirus* and *Lyssavirus*. Vesicular stomatitis virus is a *Vesiculovirus* of cattle and horses, which occasionally causes an influenza-like illness in farmers or laboratory workers. The genus *Lyssavirus* comprises seven genotypes: rabies and six genotypes of rabies-related viruses.

Fig. 1 Rhabdoviruses. Virion of rabies virus. (Electron micrograph by courtesy of Mr C. J. Smale and Dr Joan Crick.)

The rabies virion is approximately 180 × 75 nm. Its core is a single strand of negative non-segmented RNA, associated with a nucleoprotein, a phosphoprotein, and an RNA polymerase to form a helical ribonucleoprotein complex (RNP). This is enveloped in a matrix protein covered by a coat of glycoprotein (G) and host cell-derived lipid. The G protein forms numerous spikes or knobs, 10 nm long, and its composition determines viral virulence.

The virus is readily inactivated by ultraviolet light, drying, boiling, most organic lipid solvents including more than 45 per cent ethanol, soap solution, detergents, hypochlorite, and glutaraldehyde solutions.

Typing by means of monoclonal antibodies or genetic sequencing techniques allows the identification of strains of rabies and rabies-related viruses from different geographical areas and vector species, revealing the diversity of rabies virus strains.

Epidemiology

Rabies is a zoonosis that remains endemic in most parts of the world (Fig. 2). Currently, the following countries are rabies free: Iceland, Norway, Sweden, Finland, Switzerland, Portugal, Italy, Greece, Cyprus and other Mediterranean islands, Singapore, Sabah, Sarawak, Bali, New Guinea, New Zealand, Antarctica, Oceania, Hong Kong islands (but not the New Territories), Japan, South Korea, Taiwan, and Caribbean islands with the notable exceptions of Cuba, the Dominican Republic, Grenada, Haiti, Trinidad, and Tobago. Some other countries have no indigenous rabies but infected animals cross land borders.

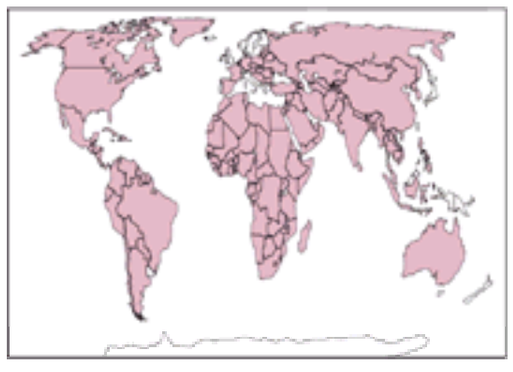

Fig. 2 Global distribution of rabies. Rabies-free areas shown in white.

Primarily an infection of wild mammals, rabies is spread by bites and rarely by inhalation of aerosols in bat caves and by ingestion of infected prey. The ecology of rabies virus can be divided into urban and sylvatic phases, which overlap to a varying extent in different countries.

In a particular area, transmission in the sylvatic phase tends to occur predominantly within a single species in separate ecological compartments. Each vector has a

separate virus strain and a distinctive method of transmission. The wild-mammal reservoir species varies in different geographical areas: in the United States, striped skunks (*Mephitis mephitis*) and to a lesser extent spotted skunks (*Spilogale putorius*) in the central States and California; raccoons in the east; the grey fox (*Urocyon cineroargenteus*) in central areas and red fox (*Vulpes vulpes*) in the east; coyotes in the south; and in the arctic, the fox *Alopex lagopus*.

Bat rabies in the Americas is all due to genotype 1 virus, whereas in the rest of the world bats have rabies-related lyssaviruses. In North America insectivorous bats are the vectors, including the Mexican free-tailed bat (*Tadarida brasiliensis mexicana*), the red bat (*Lasiurus borealis*), the big brown bat (*Eptesicus fuscus*), and the silver-haired bat (*Lasionycteris noctivagans*), whose virus is the main cause of human rabies infections in the United States (see below). Bat infection has been found in every state except Alaska and Hawaii.

The three species of true vampire bats, *Desmodus rotundus*, *Diaemus youngi*, and *Diphylla ecaudata* (Desmodontinae), occur from sea level to over 3500 m but usually below 1500 m, only in Mexico, Central and South America, and some Caribbean Islands (Fig. 3). The common vampire bat, *D. rotundus* is the main vector of vampire bat rabies in Trinidad, Mexico, and Central and South America. Carnivorous bats of the family Megadermatidae, such as the Indian 'vampire' (*Megaderma lyra*), are usually responsible for the myth that vampires occur outside this area. In Latin America vampire bat-transmitted paralytic rabies (derriengue) has locally serious economic consequences. In Brazil 50 000 head of cattle are estimated to die annually.

Fig. 3 Distribution of the three species of true vampire bats (Desmodontinae).

In Grenada and Puerto Rico mongooses (*Herpestes auropunctatus)* are vectors of sylvatic rabies; in most of Africa and Asia, wolves, jackals, and small carnivores of the families Mustelidae and Viverridae (e.g. the yellow mongoose *Cynictis penicillata* in South Africa and the palm civet *Paradoxurus hermaphroditus* in Indonesia); and in Europe, foxes, wolves, raccoon dogs (*Nyctereutes procyonoides*), and insectivorous bats (see rabies-related viruses). There are reports of rabies virus being isolated from wild rodents in many countries including the Russian Federation, Germany, Egypt, Nigeria, Thailand, and the United States, but the significance of this finding is uncertain.

Humans are occasionally infected by wild mammals, but domestic dogs and cats, the principal vectors of urban rabies, are responsible for more than 90 per cent of human cases worldwide. Domestic dogs are the principal reservoir in many parts of Africa and Asia, and in urban areas elsewhere. Rabies control programmes can reduce the risk of rabies in domestic animals to such an extent that wild animals, for example, bats in the United States, become the principal vectors of infection to humans.

Cyclical epizootics of rabies, such as the fox epizootic in Europe, result from an uncontrolled increase in the population of the key reservoir species. This epizootic started in Poland at the end of the Second World War. Initially it advanced at a rate of about 40 km a year across France, but recently has retreated. Although the fox is one of the most susceptible species to rabies, about 3 per cent of animals survive the infection and become immune. In the Caribbean island of Grenada, almost half of the mongooses have serum neutralizing antibody against rabies. Seropositive raccoons, bats, and very occasionally dogs have also been found.

Incidence of human rabies

The true incidence of human rabies throughout the world is not reflected in official figures, such as those reported by the World Health Organization. In 1998, in India alone, the estimated mortality was 30 000, in Bangladesh, it was 2000 ($1.6/10^5$ population) and in Sri Lanka, 110. The true mortalities were probably considerably higher. High mortalities also occur in Nepal, Pakistan, and Ethiopia, but there are very few data from Africa. In the United States in 10 years since 1990, 27 human cases occurred, seven of whom were infected by dogs (two from Asia). Twenty (74 per cent) patients were infected by bats, and 15 (75 per cent) of the bat infections were due to a rabies strain associated with silver-haired (*Lasionycteris noctivagans*) and pipistrelle bats (*Pipistrellus subflavus*). The Russian Federation reported 11 deaths from rabies in 1999. Rabies was eradicated from Britain by 1903 but in November 2002 a man died of European bat lyssavirus infection (see below) in Scotland.

Transmission

Virus can penetrate broken skin and intact mucosa. Humans are usually infected when virus-laden saliva is inoculated through the skin by the bite of a rabid dog or other mammal (Fig. 4). Saliva from a rabid animal can infect if the skin is already broken, by the animal's claws for example. In the United States infective contact with bats may be unnoticed: only one of 20 patients had a history of a bat bite. Animals can be infected through the gastrointestinal tract, but there is no evidence that this happens in humans.

Fig. 4 Child bitten on the face by a rabid dog. This wound carries a high risk of rabies with a short incubation period. (Copyright D.A. Warrell.)

Inhalation of aerosolized virus created by bats' infected nasal secretions may be an important method of transmission among cave-dwelling bats. In Texas, two men died of rabies after visiting caves inhabited by millions of Mexican free-tailed bats, many of which were rabid. Two laboratory workers in the United States developed rabies after inhaling fixed strains of rabies virus during the preparation of vaccines. The accidental use of vaccine in which the virus was not inactivated has led to fixed virus rabies (*rage de laboratoire*): for example, in Fortaleza, Brazil in 1960.

Transmission of rabies from one person to another has been proved in six patients who received infected corneal grafts (Fig. 5). The donors had died of undiagnosed neurological diseases. Twenty-two to 39 days after transplantation, the recipients developed retro-orbital headache on the side of the graft and died of rabies. In a seventh recipient, in Morocco, rabies was prevented by vigorous postexposure prophylaxis. Other infections spread by corneal grafts are Creutzfeldt–Jacob disease and cryptococcosis. Considering that the saliva, respiratory secretions, and tears of patients with rabies contain virus it is surprising that the disease has not been

spread to relatives and nurses.

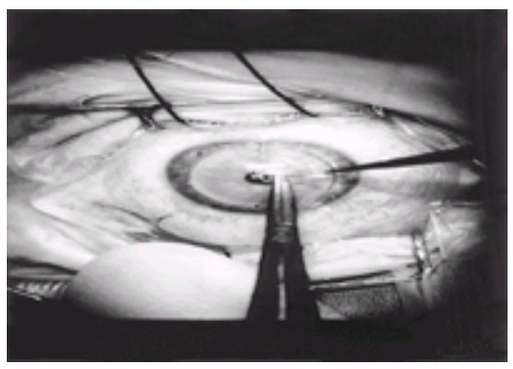

Fig. 5 Corneal transplant graft (by courtesy of Professor A. Bron).

Transplacental infection has been observed in animals but only once reported in humans. A number of women with rabies encephalitis have given birth to healthy babies. The transmission of rabies from mother to suckling infant via the breast milk has been suspected in at least one human case and is well known in animals.

Pathogenesis

The mechanism by which the highly neurotropic rabies virus enters the nervous system, travels into the brain, and out again to many organs is intriguing. The virus may replicate locally in muscle cells or attach directly to the nerve endings. Its preferential attachment to nicotinic acetylcholine receptors at motor end-plates is blocked by a-bungarotoxin, whose structure has a homologous sequence with rabies glycoprotein. Once inside peripheral nerves, virus travels in a retrograde direction within the axoplasm. This progression can be blocked experimentally by local anaesthetics, metabolic inhibitors, and nerve section. No virions are detectable in the axons. A current hypothesis is that the virus travels in an incomplete form, perhaps as naked ribonucleoprotein complexes, at this stage. Rabies virus is experimentally inaccessible to antibodies while inside the peripheral nerve.

On reaching the central nervous system, there is massive viral replication on membranes within neurones and direct transmission of virus from cell to cell occurs across synaptic junctions. There is neuronal dysfunction without significant pathological change. Centrifugal spread of virus from the central nervous system in the axoplasm of somatic and autonomic efferent nerves deposits virus in many tissues including skeletal and cardiac muscle, adrenal medulla, where infection may be clinically significant, and in kidney, retina, cornea, pancreas, and nerve twiglets in the hair follicles (see below). At this stage, productive viral replication occurs, with budding from outer cell membranes in the salivary and other glands. This is the means of the further transmission of rabies by bites to other mammals. In humans, virus is also delivered to the lacrimal glands, taste buds, and respiratory tract. Viraemia has very rarely been detected in animals and is not thought to be involved in pathogenesis or spread.

Immunology

Immunological response to rabies infection in humans

There is no detectable immune response until encephalitic symptoms develop, suggesting that rabies virus avoids or suppresses the immune system. Neutralizing and other antibodies become detectable in serum after about 7 days and in cerebrospinal fluid a little later. They may rise to high levels in patients whose lives are prolonged by intensive care. A small amount of rabies-specific IgM is sometimes detectable, but is not useful as a means of diagnosis.

There is little evidence of a lymphocyte-mediated immune response to rabies encephalitis. A pleocytosis appears in only 60 per cent of patients, with a mean leucocyte count of 75×10^3/mm. Peripheral-blood lymphocyte transformation has been shown in a few patients with furious rabies, but not in those with paralytic disease. Experimentally, in fatal rabies there is suppression of the cytotoxic T-lymphocyte response to unrelated viral antigens and a T-cell response is associated with survival in mice.

Interferon is induced by rabies infection, but appears to be at a very low level in human patients. In animals, latent infections can be reactivated by corticosteroids and stress. This provides a possible explanation for occasional reports of long incubation periods.

Rabies nucleoprotein is a weak superantigen, as it directly stimulates CD4 type 2 T lymphocytes bearing Vb8 T-cell receptors without intermediary antigen-presenting cells. The development of paralytic rabies in mice is dependent on the presence of the specific T-cell receptors. In humans the effect might be an inefficent polyclonal antibody response, preventing a specific immune response and eventually resulting in anergy.

Immunological response to rabies vaccination

Neutralizing antibody may be detectable as early as 7 days after the start of primary immunization. The surface glycoprotein of the virus induces neutralizing antibody, which protects against subsequent challenge with rabies virus in animals. The titre of these antibodies shows a better correlation with protection than any other measure of immune response.

Rabies nucleoprotein antigens also stimulate protective immunity in animals, through non-neutralizing antibody, helper T lymphocytes, and interferon-a induction. This protection is effective against a variety of rabies and rabies-related strains, unlike the glycoprotein-mediated immunity.

In human vaccinees, peripheral-blood lymphocyte transformation occurs in response to a variety of rabies and rabies-related virus antigens. The role of helper and cytotoxic T lymphocytes in protection against disease is unclear.

Neutralizing antibody is undoubtedly protective in the early stages after inoculation of virus, but in experimental animals the 'early death phenomenon' is due to a very low level of rabies antibody which accelerates the terminal phase of the encephalitis.

A low level of interferon may be induced briefly after the first dose of rabies vaccine. In animals, interferon induced by viruses or synthetic inducers, or the administration of exogenous interferon, was effective postexposure prophylaxis against rabies.

Rabies in animals

Any warm-blooded animal (mammal or bird) can be infected with rabies. In dogs the incubation period ranges from 5 days to 14 months, but is usually between 3 and 12 weeks. The first symptom, as in many humans, is intense irritation at the site of the infection. Despite the popular idea of the 'mad' rabid dog, only 25 per cent develop furious rabies. Clinical features include an early and marked change in behaviour, dysphagia, ptosis, altered bark, paralysis of the jaw, neck, and hind limbs (Fig. 6), hypersalivation, congested conjunctivas, pruritus, shivering, trembling, snapping at imaginary objects, pica, and extreme restlessness, causing the animal to wander miles from home. Dogs with furious rabies attack inanimate objects, often seriously injuring their mouths in the process. Virus may be excreted in the saliva 3 days before symptoms appear, and the animal usually dies within the next 7 days. This is the basis for the traditional 10-day observation period for dogs that have bitten humans. There are rare reports, from India, Ethiopia, and elsewhere, of chronic excretion of virus in the saliva of apparently healthy dogs. *Oulou fato* is a clinical variant of canine rabies with apparently reduced virulence for humans, seen in West Africa 50 years ago.

Fig. 6 Dog with paralytic rabies showing paralysis of the limbs and hypersalivation. (Copyright D.A. Warrell.)

Rabid foxes lose their fear of humans and the majority develop the paralytic form of the disease. An extreme degree of furious rabies is seen in 75 per cent of infected cats. Cattle usually develop paralytic symptoms, with dysphagia, hypersalivation, groaning, trembling, colic, diarrhoea, tenesmus, and rectal prolapse. Most other domestic ungulates develop paralytic symptoms. Horses often show furious features with sexual excitement. Most wild animals, like foxes, lose their fear of humans and may appear tame. Rabid skunks, raccoons, badgers, martens, and mongooses may become very aggressive. Dysphagia and inability to drink is common in rabid animals, but they do not exhibit hydrophobia.

Clinical features in humans

The incubation period ranges from 4 days to many years, but it is between 20 and 90 days in three-quarters of cases. It tends to be shorter after bites on the face (average 35 days) than after those on the limbs (average 52 days).

Prodromal symptoms

In many patients, the first symptom is itching, pain, or paraesthesia at the site of the healed bite wound (Fig. 7). Non-specific prodromal symptoms include fever, chills, malaise, weakness, tiredness, headache, photophobia, myalgia, anxiety, depression, irritability, and symptoms of upper respiratory tract and gastrointestinal infections. Subsequently, symptoms of either furious or paralytic rabies will develop, depending on whether the spinal cord or brain are predominantly infected.

Fig. 7 This man developed intense itching in the left leg, provoking scratching and excoriation, 6 weeks after being bitten in that limb by a mad dog. He died with furious rabies a few days later (by courtesy of Professor Sornchai Looaresuwan).

Furious rabies

Furious rabies is the more commonly diagnosed form. Most patients have the diagnostic symptom of hydrophobia: a combination of inspiratory muscle spasm, with or without painful laryngopharyngeal spasm, associated with terror (Fig. 8). Initially provoked by attempts to drink water, this reflex can be excited by a variety of stimuli including a draught of air ('aerophobia'), water splashed on the skin, irritation of the respiratory tract, or ultimately, the sight, sound, or even mention of water. The inspiratory spasm is violent and jerky. The neck and back are extended, the arms thrown up, and the episode may end in generalized convulsions with cardiac or respiratory arrest.

Fig. 8 Hydrophobic spasm in a 14-year-old Nigerian boy with furious rabies. Note the violent contraction of inspiratory muscles: sternomastoids and diaphragm (depressing xiphisternum). (Copyright D.A. Warrell.)

Patients experience hyperaesthesia and generalized arousal, during which they become wild, hallucinated, fugitive, and aggressive, alternating with lucid intervals. Despite these symptoms, attributable to brainstem encephalitis, neurological examination may prove surprisingly normal. Abnormalities include meningism, cranial-nerve lesions (especially III, VI, VII, IX, X, XI, and XII), upper motor-neurone lesions, fasciculation, and involuntary movements. Disturbances of the hypothalamus or autonomic nervous system cause hypersalivation (Fig. 9), lacrimation (Fig. 10), sweating, hypertension or hypotension, hyperthermia or hypothermia, inappropriate secretion of antidiuretic hormone, or diabetes insipidus and, rarely, priapism with spontaneous orgasms. Hypersexuality suggests similar aetiology to Klüver-Bucy syndrome.

Fig. 9 Hypersalivation in a Thai woman with furious rabies. (Copyright D.A. Warrell.)

Fig. 10 Lacrimation in a Thai patient with furious rabies. (Copyright D.A. Warrell.)

Without supportive treatment, about one-third of the patients will die during a hydrophobic spasm in the first few days. The rest lapse into coma and generalized flaccid paralysis, and rarely survive for more than a week without intensive care.

Paralytic or dumb rabies

This is the clinical pattern in less than a fifth of human cases except in the case of vampire bat-transmitted rabies (Fig. 11), which is invariably paralytic. The largest reported outbreak was in Trinidad between 1925 and 1935, when there were 89 human cases; others have been described from Mexico, Guyana, Brazil, Peru, Bolivia, and Argentina. The paralytic form of rabies was also seen in patients with postvaccinal rabies, in the two patients who inhaled fixed virus, and is said to be more likely to develop in patients who have received antirabies vaccine. After the usual prodromal symptoms, especially fever, headache, and local paraesthesiae, flaccid paralysis develops, usually in the bitten limb, and ascends symmetrically or asymmetrically with pain and fasciculation in the affected muscles and mild sensory disturbances. Paraplegia and sphincter involvement then develop, and finally fatal paralysis of deglutitive and respiratory muscles. Hydrophobia is unusual, but may be represented by a few pharyngeal spasms in the terminal phase of the illness. Even without intensive care, patients with paralytic rabies have survived for up to 30 days.

Fig. 11 Vampire bat bite inflicted on the ear of a sleeping child in Tapirái, São Paulo, Brazil (by courtesy of Dr João Luiz Costa Cardoso, São Paulo).

Other manifestations and complications

Respiratory system

Asphyxiation and respiratory arrest may complicate the hydrophobic spasms or generalized convulsions of furious rabies and the bulbar and respiratory paralysis of dumb rabies. Bronchopneumonia is an expected complication and a primary rabies pneumonitis may occur. Various abnormal patterns of respiration have been described, including cluster and apneustic breathing. There are some similarities to respiratory myoclonus. Pneumothorax may complicate inspiratory spasms.

Cardiovascular system

A variety of dangerous cardiac arrhythmias has been reported, including supraventricular tachycardias, sinus bradycardia, atrioventricular block, and sinus arrest. Hypotension, pulmonary oedema, and congestive cardiac failure are attributable to myocarditis.

Nervous system

Raised intracranial pressure resulting from cerebral oedema or internal hydrocephalus has been reported in a few cases, but spinal-fluid opening pressure is usually normal and papilloedema rarely found. Evidence of diffuse axonal neuropathy is consistent with histological appearances of degeneration of peripheral nerve ganglia and axons.

Gastrointestinal system

'Stress' ulcers and Mallory–Weiss syndrome are possible explanations for the haematemesis often reported in rabies.

Differential diagnosis

Rabies should be suspected whenever a patient develops severe neurological symptoms after being bitten by a mammal in a rabies endemic area. Some patients fail to remember that they have been bitten. Hydrophobia is pathognomonic of rabies and is unlikely to be mimicked accurately by the hysteric. Inspiratory spasms with

associated emotional response are produced by asking the patient to swallow accumulated saliva or by directing a draught of air on to their face. Patients are sometimes misreferred to otolaryngologists or psychiatrists.

Tetanus, which can also follow an animal bite, is similar to rabies in some respects, especially the pharyngeal form of cephalic tetanus ('hydrophobic tetanus'). It is distinguished by its shorter incubation period (usually less than 15 days), the presence of trismus, the persistence of muscle rigidity between spasms, the absence of meningoencephalitis (cerebrospinal fluid is universally normal), and a better prognosis. Hydrophobia does not occur in other encephalitides; the combination of intense brainstem encephalitis and furious behaviour in a conscious patient would be most unlikely except in rabies. Delirium tremens and some plant toxins (e.g. *Datura fastuosa*) and drugs (phenothiazines and amphetamines) may enter the differential diagnosis.

Paralytic rabies can be confused with other causes of ascending (Landry-type) paralysis. Postvaccinal encephalomyelitis (see below) usually develops within 2 weeks of the first dose of the older types of rabies vaccines. In poliomyelitis, objective sensory disturbances are absent and fever rarely persists after paralysis has developed. Examination of cerebrospinal fluid may help to distinguish acute inflammatory polyneuropathy (Guillain–Barré syndrome). *Herpesvirus simiae* (B virus) encephalomyelitis is transmitted by monkey bites, but the incubation period (3 to 4 days) is usually shorter than in rabies. Vesicles may be found in the monkey's mouth and at the site of the bite, and a diagnosis can be confirmed virologically.

Pathology

The brain, spinal cord, and peripheral nerves show ganglion-cell degeneration, perineural and perivascular mononuclear cell infiltration, neuronophagia, and glial nodules. Inflammatory changes are most marked in the midbrain and medulla (Fig. 12) in furious rabies and in the spinal cord in paralytic rabies. The diagnostic Negri bodies (Fig. 13 and Plate 1) are eosinophilic, intracytoplasmic inclusions predominantly consisting of masses of viral ribonucleoprotein, with a basophilic inner body, containing fragments of cellular organelles including ribosomes and occasional virions. They can be demonstrated by haematoxylin and eosin or Schleiften's stains in histological sections of grey matter in up to 75 per cent of human cases, especially in hippocampal pyramidal cells and cerebellar Purkinje cells.

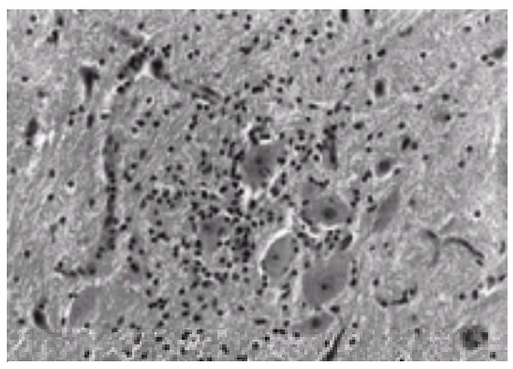

Fig. 12 Inflammatory cells around neurones in the central medulla (para-ambigualis region) of a patient who died of rabies encephalitis (× 400). (Reproduced by courtesy of Dr P. Lewis, London.)

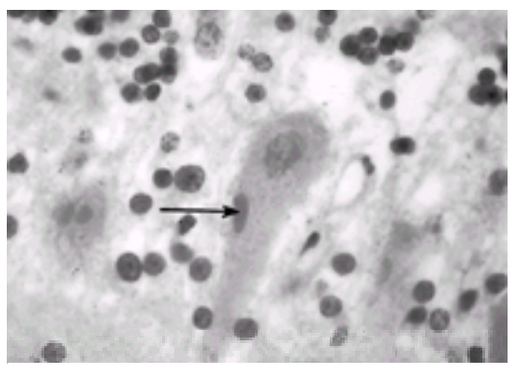

Fig. 13 Street virus in human cerebellar Purkinje cells as seen with the light microscope. Several Negri bodies can be seen (one is arrowed) (× 615). (By courtesy of the Armed Forces Institute of Pathology 73–12330.) (See also Plate 1.)

In view of the appalling prognosis of rabies encephalitis, neuronolysis is often surprisingly mild and patchy, and death can occur without any inflammatory response. Vascular lesions such as thrombosis and haemorrhage have also been described. The brainstem, limbic system, amygdaloid nuclei and hypothalamus appear to be most severely affected. Outside the nervous system, there is focal degeneration of salivary and lacrimal glands, pancreas, adrenal medulla, and lymph nodes. An interstitial myocarditis, with round-cell infiltration, is found in about 25 per cent of cases.

Laboratory diagnosis

A suspect rabid animal that might have infected a patient should be killed and the brain examined without delay. Rabies antigen detection by a direct immunofluorescent antibody test on acetone-fixed brain impression smears is usually used or alternatively, if no fluorescent microscope is available, by rapid enzyme immunodiagnosis. Virus isolation takes up to 3 weeks by intracerebral inoculation of mice, or about 4 days in murine neuroblastoma cell culture.

In humans, rabies can be confirmed early in the illness by demonstration of viral antigen by a direct immunofluorescent antibody test in nerve twiglets in skin biopsies (Fig. 14). This rapid method is positive in 60 to 100 per cent of cases, and no false-positive results have been reported. Antigen can also be detected in brain biopsies but tests on corneal impression smears are usually falsely negative. The polymerase chain reaction is being used increasingly to identify rabies antigen in secretions.

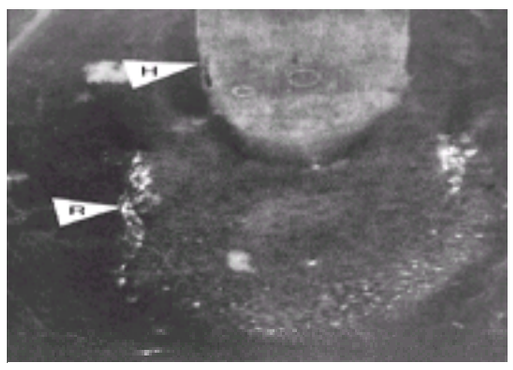

Fig. 14 Diagnosis of human rabies during life. Vertical section through a hair follicle and shaft (H) showing fluorescence of nerve cells around the follicle (R) indicating the presence of rabies antigen (× 250). (Copyright M.J. Warrell.)

During the first week of illness virus may be isolated from saliva, brain, cerebrospinal fluid, and very rarely urine. Rabies antibodies are not usually detectable in serum or cerebrospinal fluid before the eighth day of illness in unvaccinated patients. Antibody may leak into the cerebrospinal fluid in patients with postvaccinal encephalomyelitis, but a very high titre suggests a diagnosis of rabies. A specific IgM test has not proved useful diagnostically.

Treatment

Patients with rabies must be sedated heavily and given adequate analgesia to relieve their pain and terror. If intensive care is undertaken, the aim is to prevent complications such as cardiac arrhythmias, cardiac and respiratory failure, raised intracranial pressure, convulsions, fluid and electrolyte disturbances including diabetes insipidus and inappropriate secretion of antidiuretic hormone, and hyperpyrexia. Antiserum, antiviral agents, inter-feron-a, corticosteroid, and other immunosuppressants have proved useless.

Prognosis

Rabies was formerly regarded as a universally fatal disease, but there are reports of five cases of recovery or prolonged survival, following intensive care. Two patients who recovered had had nervous-tissue vaccine treatment, and the diagnoses were made serologically. Three patients were given pre- or postexposure tissue-culture vaccine and they never recovered from profound neurological deficits.

Despite intensive care, the prognosis of rabies encephalomyelitis is still virtually hopeless. At the time of the bite, however, before virus has invaded the nervous system, correct cleaning of the wound (see below) and the use of optimum postexposure immunization reduce the risk of rabies developing from about 35 to 65 per cent in untreated cases to near zero. The risk varies with the biting species and the site and severity of the bites. It is highest following head bites by proved rabid wolves, when the mortality in unvaccinated people may exceed 80 per cent.

Prevention and control

In countries where rabies is endemic

Control strategy is based on gathering information about the prevalence and host range of rabies in wild and domestic animals. This requires laboratory facilities for confirming the diagnosis. Domestic animals can be protected by yearly vaccination. Dogs are muzzled and kept off the streets; strays are eliminated. People should be discouraged from keeping wild carnivores, such as skunks, raccoons, coatimundis, and mongooses, as pets. Unnecessary contact with mammals should be avoided (e.g. stroking stray dogs, exploring bat-infested caves). Reduction of wild-animal reservoir populations may be attempted, but this is difficult to achieve and likely to cause ecological chaos. An alternative approach is to attempt the vaccination of key reservoir species by using live oral vaccines distributed in bait. An oral vaccinia-recombinant rabies glycoprotein vaccine has successfully controlled fox rabies in Western Europe, and is also used in North American raccoons and coyotes. Rabies is most likely to be controlled or eradicated where the principal reservoir is the domestic dog, as in nineteenth-century Britain, Malaysia, and Japan.

Education and publicity about rabies is always needed. Clinics and dispensaries must be adequately supplied with vaccine and antiserum to provide postexposure prophylaxis, but difficulties over expense, supply, and preservation often preclude this. In dog-rabies endemic areas, pre-exposure vaccination is advisable but rarely used.

In countries where rabies is not endemic

Importation of potential vectors, especially domestic dogs and cats and wild bats and carnivores, should be strictly controlled and, where feasible, imported mammals should be vaccinated against rabies and kept in quarantine for an adequate period.

Postexposure prophylaxis may be required for people who were exposed to the risk of rabies while abroad. Travellers should be educated to seek local medical help if they are bitten, scratched, or licked by animals. Many travellers wait until they return to their homeland, sometimes weeks or months after the bite, before asking for medical advice.

Pre-exposure immunization regimens

Pre-exposure vaccination is the most effective form of rabies prevention. No rabies deaths have been reported in anyone who had pre-exposure vaccine followed by postexposure booster doses. In rabies-free areas it is needed by those who handle imported animals before and during quarantine in kennels, zoos, and laboratories; those who work with rabies virus in laboratories; and those who are resident in or intend to travel to dog rabies-endemic areas. In endemic areas others particularly at risk in certain areas include veterinarians, dog-catchers, cave explorers, naturalists, and animal collectors.

A course of three doses of tissue-culture rabies vaccine (see below) is given on days 0, 3, and 28 (or 21) intramuscularly or 0.1 ml intradermally into the deltoid or the anterolateral thigh in children, preferably into the same limb. If chloroquine is being taken for malaria prophylaxis, or in other cases of suspected immunosuppression, the intramuscular route must be used. If sharing an ampoule for intradermal injections, a sterile needle and syringe must be used for each patient. The neutralizing antibody response is enhanced and prolonged by a booster dose after 1 year. A prompt secondary response to booster injections then occurs after many years. Repeated booster doses are only needed if the risk of infection is high.

The antibody response is so predictable that it need not normally be checked, unless there is immunosuppression. An antibody level above 0.5 IU/ml indicates immunity, and serological monitoring can prevent unnecessary booster doses for rabies laboratory staff and others at continuous risk.

Postexposure prophylaxis

The decision to give postexposure treatment depends on the precise geographical location of the exposure; when it occurred; its severity—whether it was a bite or lick on broken skin; the nature, appearance, behaviour, and fate of the biting animal and if possible, whether it had been vaccinated against rabies within the last year. This information may allow proper assessment of risk; but if there is any doubt the patient should be given full postexposure prophylaxis, even if the bite is several months old.

The aim is to neutralize inoculated virus before it can enter the nervous system. Wound cleaning and active and passive immunization must be implemented as soon as possible.

Wound cleaning

This is effective in killing virus in superficial wounds, but is often neglected. First aid consists of scrubbing the wound with soap and water for several minutes. Foreign material should be removed and a viricidal agent such as povidone iodine, or 40 to 70 per cent alcohol, should be applied liberally. Quarternary ammonium compounds, such as benzalkonium chloride, are inactivated by soap and so are no longer recommended. Hospital treatment of wounds involves thorough exploration, debridement, and irrigation of deep wounds, if necessary under local or general anaesthetic. Suturing should be avoided or delayed and the wound left without occlusive dressings. Attention should be given to tetanus prophylaxis and the range of bacterial and other pathogens, particularly associated with mammal bites. Most of the bacteria are sensitive to amoxicillin/clavulanic acid, cephoxitin, or tetracycline.

Specific prophylaxis

This consists of active and passive immunization. The indications are given in Table 1.

Active immunization

Tissue-culture vaccines

Human diploid cell vaccine (**HDCV**) (Imovax rabies™ Aventis Pasteur), purified chick embryo cell vaccine (Rabipur/Rab Avert™ Chiron Behring), and purified vero cell vaccine (**PVRV**) (Verorab™Aventis Pasteur) are now the tissue-culture vaccines of choice.

The intramuscular postexposure regimen of these vaccines is 5 × 1 ml doses into the deltoid on days 0, 3, 7, 14, and 28, although for PVRV each dose is only 0.5 ml. An economical eight-site intradermal regimen can be used with vaccines which have an intramuscular dose of 1 ml. On day 0, eight intradermal injections of 0.1 ml are given (deltoids, suprascapular, lower-quadrant abdominal wall, and thighs) using a whole ampoule in a Mantoux-type syringe. On day 7, four intradermal injections of 0.1 ml are given (deltoids and thighs), and single intradermal doses of 0.1 ml are given on days 28 and 91. Advantages of the eight-site method are: fewer hospital attendances; a rapid induction of neutralizing antibody, making it the treatment of choice when no rabies immunoglobulin is available; a wide margin of safety; using a whole ampoule on day 0, which avoids sharing ampoules of vaccine between patients during the emergency treatment; and finally, giving a large antigenic stimulus on day 0 gives the best chance of survival to patients who are 'low responders' to the vaccine and to those who fail to return on time for subsequent doses.

The two-site intradermal regimen was designed for use with PVRV. A dose of 0.1 ml for PVRV and 0.2 ml for the other two vaccines is given intradermally at two sites (deltoids) on days 0, 3, and 7 and a one site on days 28 and 90. Both of these intradermal regimens use a similar total amount of vaccine per course, about 40 per cent of that of the intramuscular regimen, but the antibody response following the eight-site method is significantly earlier and higher than that after the two-site regimen.

Side-effects of tissue-culture vaccines are mild and transient: local itching, redness or pain at the site of injection, influenza-like symptoms, and occasionally a rash. More serious allergic reactions include rare, type I immediate hypersensitivity during primary courses. Type III immune-complex hypersensitivity was reported in 6 per cent of those receiving booster doses of HDCV in the United States and consisted of urticaria, rash, angio-oedema and arthralgia 3 to 13 days after injection, but none has been fatal. A few cases of polyneuritis, Guillain–Barré syndrome, or local limb weakness have been reported in patients receiving tissue-culture vaccines. These events are very rare and no more frequent than for other commonly used virus vaccines.

Nervous-tissue vaccines

Semple vaccine, a 5 per cent sheep or goat brain suspension, and suckling mouse brain (Fuenzalida) vaccine are still used in Asia and the latter also in Africa and South America. The abdomen is often used as a suitable target for the daily subcutaneous injections. These vaccines produce neurological reactions, including postvaccinal encephalomyelitis.

Postvaccinal encephalomyelitis

Neurological reactions to nervous-tissue vaccines occur in up to 1 in 220 courses of Semple vaccine, with a 3 per cent mortality, and are an allergic response to myelin and related neural proteins in the vaccine. In Latin America, neuroparalytic reactions complicated 1/7865 to 1/27 000 courses of suckling mouse brain vaccine with a 22 per cent mortality. Most reactions to Semple vaccine affect the central nervous system, whereas at least 70 per cent of those following suckling mouse brain vaccine involved the peripheral nervous system.

The incubation period ranges from 3 to 35 days after the first injection of vaccine, but it is usually between 7 and 14 days. Clinical forms include a rapidly reversible mononeuritis multiplex involving particularly the cranial, radial, brachial, and sciatic nerves; a dorsolumbar transverse myelitis with fever, paralysis, and sensory loss in the lower limbs, with sphincter involvement, loss of tendon reflexes, extensor plantar responses, and severe girdle and thoracic pain; an ascending paralysis (Landry type), which ends in fatal bulbar paralysis in a third of cases; and meningoencephalitic and meningoencephalomyelitic reactions. The overall mortality of these reactions is 15 to 20 per cent. Most survivors make a complete recovery in 2 to 3 weeks, but a few are left with permanent neurological sequelae.

A moderate lymphocyte pleocytosis and elevated cerebrospinal fluid protein is usual. Pathological changes consist of swelling and chromatolysis of neurones with extensive perivascular demyelination and lymphocytic infiltration in the spinal cord. These features resemble experimental allergic encephalitis, postvaccinal encephalomyelitis after vaccinia vaccine, postinfectious encephalomyelitis, and acute multiple sclerosis. Corticosteroids, for example, prednisolone at 40 to 60 mg/day, are thought to be helpful, and the use of cyclophosphamide has been suggested. Vaccination should be stopped as soon as symptoms appear and the course continued with a tissue-culture vaccine.

Passive immunization

Rabies immune globulin (**RIG**) has proved valuable in protection, presumably by neutralizing rabies virus during the first week after initial vaccination, before neutralizing antibody has appeared, and it enhances the T-lymphocyte response to vaccine experimentally. Its use is recommended at the start of all primary postexposure courses of rabies vaccine, but it is vital following severe bites (on the head, neck, hands, and multiple or deep bites).

The dose of human RIG is 20 IU/kg body weight, and 40 IU/kg for equine RIG. Serum sickness has not been reported after human RIG treatment, but hypersensitivity reactions to equine RIG occur in 1 to 6 per cent of those treated; however, these are not reliably predicted by a previous intradermal test. RIG must be given even if the test is positive, and the skin test is unnecessary. Adrenaline should always be available in case of reactions.

The RIG is infiltrated into the tissues around the bite wound, and any remaining is injected intramuscularly into the thigh, not the buttock. If RIG is given hours or days before the first dose of vaccine, the immune response will be impaired. RIG is prohibitively expensive and is not available or affordable to more than 95 per cent of patients receiving postexposure treatment in developing countries.

Postexposure prophylaxis in people who have received previous vaccination

If a complete pre- or postexposure course of a modern potent tissue-culture vaccine has been given, or if the neutralizing antibody level has been over 0.5 IU/ml, only two intramuscular doses of tissue-culture vaccine should be given on days 0 and 3. The first dose of the vaccine can be divided between four or eight intradermal sites on day 0. Passive immunization is not required. Otherwise, full postexposure treatment must be given.

Failures of postexposure prophylaxis

Deaths from rabies have occurred despite vaccine treatment. These may be attributable to the use of low-potency nervous-tissue vaccines, delay in starting vaccination, an incomplete vaccine course, omission of passive immunization, failure to infiltrate RIG around the wound, injection of vaccine into the buttock, or decreased immune responsiveness of the vaccinee. So far, in the few cases in which the virus strain could be typed, tissue-culture vaccine failures could not be attributed to failure of neutralization of the particular infecting strain of virus by antibody induced by the vaccine. However, vaccine protection against rabies-related viruses may be less efficient than against genotype 1 rabies viruses (see below).

A reduced or delayed immune response to vaccine can sometimes be predicted. If treatment is started late (e.g. more than 2 days after exposure), no RIG is available for severe bites, the patient is immunocompromised, or a rabies-related virus infection is suspected, the immune stimulus can be enhanced either by doubling the initial dose of vaccine, or by dividing the first dose of tissue-culture vaccine between eight sites intradermally, as for the economical eight-site regimen (see above).

Rabies-related viruses known to infect humans

Mokola virus, Duvenhage virus, European bat lyssavirus, and Australian bat lyssavirus are rabies-related viruses that have been proved to infect humans. Three genotypes are only found in Africa. Genotype 2, Lagos bat virus has not been detected in humans. Mokola virus (genotype 3) has been isolated from shrews (*Crocidura* spp.) in Nigeria and Cameroon, and mainly from cats in South Africa, Zimbabwe, and Ethiopia. It was isolated from a child with meningitis who recovered, and from another with fatal encephalitis. Duvenhage virus (genotype 4) caused a fatal illness, with clinical features identical to furious rabies, in a South African of that name who was bitten by a bat and had then received a full course of rabies vaccine. The rabies fluorescent antibody test was negative in the Duvenhage case and

weakly positive in the Mokola cases.

Rabid bats had been found occasionally in Europe since 1954. In 1985, a woman was bitten by a rabid, insectivorous bat in Denmark, and an extensive search revealed many rabid bats there and across Europe. The European bat lyssavirus (**EBL**) group comprises genotype 5 (**EBL 1**) and genotype 6 (**EBL 2**), which are each subdivided into phylogenetically distinct groups a and b. The vector species of EBL 1 is *Eptesicus serotinus.* Type 1a is found in Russia, Poland, Germany, Denmark, and the Netherlands; type 1b in France, the Netherlands, and Spain. Two Russian girls died of rabies following bat bites. Myotis bats harbour EBL 2: EBL 2a in the Netherlands and the United Kingdom (three isolates including the human fatality in 2002), and EBL 2b in Switzerland. A fatal human case in Finland was due to EBL 2b.

The identification of a lyssavirus in fruit bats (genus *Pteropus*) in eastern Australia was an unexpected finding in 1996. This Australian bat lyssavirus (**ABL**) (genotype 7) has since caused a fatal rabies-like encephalitis in two women who had handled bats.

The G protein of rabies vaccine strains is very similar to that of all genotype 1 viruses, but shows a variable degree of antigenic homology to rabies-related viruses. Tissue-culture rabies vaccines have not protected animals against challenge with Mokola virus and their effect against Duvenhage virus is uncertain. Protection against EBL viruses may be slightly less efficient, but ABL is closely related to genotype 1 strains and so protection should be undiminished.

7.10.10 Colorado tick fever and other arthropod-borne reoviruses

M. J. Warrell and D. A. Warrell

Within the large family of Reoviridae human pathogens are found in four genera: *Reovirus*, *Rotavirus*, and two arthropod-borne genera *Coltivirus* and *Orbivirus*. Colorado tick fever is a group A coltivirus, together with Eyach virus, from Europe. Group B comprises coltiviruses from South-east Asia and Indonesia and Banna virus from China. This group may be reclassified as the *Seadornavirus* genus. Banna virus has been isolated from patients with encephalitis. The four pathogenic orbivirus serogroups are Kemerovo, Changuinola, Orungo, and Lebombo.

Colorado tick fever

The virus responsible for Colorado tick fever or 'mountain fever' is an 80-nm, double-shelled particle, covered with capsomeres. The icosahedral core contains 12 segments of double-stranded, negative-sense RNA. The virus has the ability to infect human erythrocytes and this may also occur with the other colti- and orbiviruses.

Colorado tick fever is a zoonosis involving hard (ixodid) ticks (principally *Dermacentor andersoni*, but also *D. occidentalis*, *D. variabilis*, *D. parumapertus*, *D. albipictus*, etc.) and wild mammals including porcupines, coyotes, squirrels, chipmunks, deer, mice, and other rodents. Ticks pass Colorado tick fever virus trans-stadially, but not transovarially.

Epidemiology

Colorado tick fever is acquired from tick bites in western and north-western parts of the United States (including California), British Columbia, and Alberta. Very rarely, it has been caused by an infected blood transfusion. Several hundred cases are reported each year in the United States, but the true incidence is thought to be at least 10 times higher than that. Hikers and campers are at special risk in rodent and tick-infested terrain. The prevalence of antibody to Colorado tick fever among shepherds was 32 per cent. The highest incidence is from May to July when ticks are most active. Infection usually confers lasting immunity.

Clinical features

In adults the infection is nearly always mild, but in children it is occasionally severe or even fatal. Three to six days after the tick bite (extreme range, 1 to 19 days) there is a sudden fever with rigors, generalized aches, myalgia, headache, and backache. In half the patients there is a biphasic fever. A maculopapular or petechial rash appears in about 10 per cent of cases and gastrointestinal symptoms in 20 per cent. Laboratory findings include leucopenia with relative lymphocytosis, occasional thrombocytopenia, and mild lymphocyte pleocytosis.

The illness usually resolves in about 10 to 14 days, but convalescence may be prolonged. Severe manifestations include meningism and drowsiness, sometimes associated with gastrointestinal symptoms, spontaneous bleeding, thrombocytopenia, and disseminated intravascular coagulation. Late, possibly immunological effects, include myocarditis, pericarditis, pleurisy, arthritis, and epididymitis. Colorado tick fever infection may precipitate abortion, but the transplacental infection and teratogenic effects reported in mice have not been observed in man.

Diagnosis

Viral antigen may be detected in erythrocytes by immunofluorescence 1 to 120 days after the start of symptoms. Erythrocyte precursors are infected in the marrow, but their survival is apparently not affected. Virus can be isolated from the blood, and if there is central nervous system involvement, the cerebrospinal fluid. Colorado tick fever virus produces a cytopathic effect on several cell lines, but intracerebral injection of ground blood clot, or preferably washed erythrocytes, into suckling mice is more sensitive for diagnostic isolation. An indirect fluorescent antibody test can provide early serodiagnosis, but acute infections can be diagnosed by polymerase chain reaction detection of antigen. Neutralizing antibody and specific IgM enzyme immunoassays become positive after 14 to 21 days and the IgM disappears after 45 days.

Differential diagnosis

Many other tick-borne acute febrile illnesses, some with rashes and nervous system involvement, can be acquired in the endemic area for Colorado tick fever. These include Rocky Mountain spotted fever, tularaemia, Lyme disease, and relapsing fever. Tick paralysis caused by *D. andersoni* and other ixodid ticks presents as a poliomyelitis-like, ascending, flaccid paralysis that is unlikely to be mistaken for the meningitic or encephalitic syndromes of Colorado tick fever.

Treatment

The symptomatic treatment of fever and pain should exclude salicylates in case of thrombocytopenia. Tribavirin (ribavirin) inhibits the replication of Colorado tick fever virus experimentally but its use in humans has not been reported.

Orbivirus serogroups

Kemerovo

The orbivirus serogroup Kemerovo contains three viruses isolated from *Ixodes* and *Hyalomma* ticks in Russia and Central Europe. They cause enign febrile illnesses and, occasionally, meningitis or encephalitis in spring and early summer, when ticks are active. Rodents and birds are involved in the zoonotic cycle. Oklahoma tick fever is another Kemerovo virus rarely causing febrile illness in the United States.

Changuinola

There is a single report of human febrile illness with the orbivirus Changuinola in Panama. The virus has been isolated from phlebotomine flies and mammals in that area.

Orungo

Orungo virus is found mainly in West Africa but also in Uganda and the Central African Republic. Up to 75 per cent of some populations are seropositive. The clinical effects are unknown but fever and diarrhoea occur in some people, perhaps with encephalitis, as in experimental mice. There is no rash or jaundice. It is transmitted

by *Anopheles*, *Aedes*, and other mosquitoes. Monkeys, sheep, and cattle may be infected.

Lebombo

This reovirus was isolated from one febrile child in Nigeria. Lebombo is also found in mosquitoes and rodents.

7.10.11 Alphaviruses

L. R. Petersen and D. J. Gubler

Introduction

The genus Alphavirus of the family Togaviridae comprises 27 registered viruses, 16 of which cause human infection (Table 1). Alphaviruses are lipid-enveloped virions with a diameter of 50 to 70 nm whose genome is a molecule of single-stranded, positive-sense RNA approximately 12 000 nucleotides in length. Most alphaviruses are maintained in nature in complex transmission cycles between wild or domestic animals and one or more mosquito species. Humans become infected from infective mosquitoes that take a bloodmeal. Patients develop high viraemias with some alphaviruses and may contribute to the transmission cycle by infecting mosquitoes. The epidemiology and geographic distribution of the alphaviruses depend on several factors, including the requirements for and presence of suitable amplifying hosts, the presence and feeding behaviour of a suitable arthropod vector, and the frequency of exposure of non-immune reservoir hosts and humans to infected vectors. Alphavirus infections are not communicable.

Most infections in humans are asymptomatic, but alphaviruses can cause a spectrum of clinical illness ranging from non-specific febrile illness, often with rash, myalgia, or arthralgia, to frank encephalitis and death (Table 1). No specific therapy is available. Vaccines for some alphaviruses are used in animals, although none have been licensed for humans.

Laboratory diagnosis

Alphavirus infections are diagnosed serologically by detection of immunoglobulin M (IgM) and G (IgG) responses. All alphaviruses have common antigenic determinants that result in cross-reactions in immunodiagnostic tests. Neutralization tests may be necessary for serological confirmation in areas where multiple alphaviruses are endemic/enzootic. Isolation of virus from acute-phase serum is possible with some alphaviruses, but they are seldom recovered from the central nervous system, including cerebrospinal fluid, except from fatal cases. Virological diagnosis may also be made using polymerase chain reaction and immunohistochemistry on tissue samples.

Specific alphavirus infections

Chikungunya

Aetiology and epidemiology

Chikungunya virus is found in Africa and Asia and is transmitted primarily by *Aedes* mosquitoes. Non-human primates such as monkeys and baboons may be the primary maintenance hosts in sylvan settings in Africa. In urban settings in Africa and Asia, the virus is transmitted from human to human via *Aedes aegypti* mosquitoes. Explosive urban epidemics occur during the rainy season. One epidemic, in Madras in India, caused an estimated 300 000 cases. Serosurveys have shown antibody prevalences greater than 90 per cent in some areas of Africa.

Clinical characteristics

The sudden onset of fever and crippling arthralgia follows an incubation period of 2 to 3 days (range 1 to 12). The fever may remit for 1 to 2 days and then recur ('saddle back' fever). Arthralgias are polyarticular, migratory, and mostly involve the small joints. Papular or maculopapular skin rashes, typically on the trunk and limbs, occur, usually during the second to fifth day of illness. Most infections are probably asymptomatic. Arthralgia may last several months; a few patients may have symptoms 5 years after infection. Children are less likely to present with arthralgia and rash, and more likely to have headache, injected pharynx, and gastrointestinal symptoms.

Diagnosis

Leucopenia is the only likely laboratory finding. Viraemia usually is present in the first 48 h of illness. Haemagglutinin-inhibition and IgM antibodies will be present in nearly all patients by the seventh day of illness. IgM antibodies detectable in serum by IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) may persist 6 months after infection.

Prevention, control, and treatment

Prevention and control can only be achieved by reducing *Ae. aegypti* populations in the large urban centres of the tropics and by avoiding mosquito bites. No licensed vaccines currently exist. There is no specific treatment. Anti-inflammatory drugs may relieve arthralgia. Chloroquine phosphate may be helpful for refractory arthralgias.

Eastern equine encephalitis

Aetiology and epidemiology

The virus is widely distributed throughout North, Central, and South America and the Caribbean; however, little is known about the epidemiology of eastern equine encephalitis outside North America. In the United States, human infections are usually sporadic and small outbreaks occur each summer, mostly along the Atlantic and Gulf Coasts. In recent years, one to 14 cases have been reported annually. In North America, wild birds and *Culiseta melanura* mosquitoes maintain the virus.

Clinical characteristics

The incubation period exceeds 1 week and the onset is abrupt with high fever. About 2 per cent of infected adults and 6 per cent of children develop encephalitis. Eastern equine encephalitis is the most severe of the arboviral encephalitides, with a mortality of 50 to 75 per cent. Symptoms and signs include dizziness, decreasing level of consciousness, tremors, seizures, and focal neurological signs. Death can occur within 3 to 5 days of onset. Sequelae, common in non-fatal encephalitis, include convulsions, paralysis, and mental retardation. Illness due to eastern equine encephalitis in South America appears to be less severe.

Diagnosis

Cerebrospinal fluid pressure may be raised, with slightly increased protein, normal sugar, and up to 2000 cells/mm ^{3}. IgM antibodies are readily detected in serum or cerebrospinal fluid by ELISA. Paired serum samples can be tested by haemagglutinin inhibition, ELISA, or neutralization tests. Horse or pheasant deaths and the proximity to swamps provide clues to the diagnosis.

Prevention control and treatment

Prevention depends on the avoidance of mosquito bites and mosquito control in suburban areas. Inactivated vaccines have been used successfully in horses, and an inactivated vaccine has been used experimentally in laboratory workers and others at high risk of exposure. No specific treatment is available.

Ross River virus

Aetiology and epidemiology

This virus causes 'epidemic polyarthritis' in Australia, south-western Pacific islands, and Fiji. *Ae. vigilax* is an important vector in Australia and *Ae. scutellaris* complex mosquitoes in some south Pacific islands, although the virus has been isolated from more than 30 mosquito species. An epidemic in various Pacific islands in 1979 to 1980 affected more than 50 000 people. An average of 4800 cases is reported annually from Australia. Explosive outbreaks and viraemias in humans suggest virus transmission from human to human by certain mosquitoes.

Clinical characteristics

The illness begins suddenly with arthralgia in the small joints of the hands and feet. A maculopapular rash occurs in about half of patients within 2 days of onset and is most prominent on the trunk and limbs, but can cover the entire body. The rash may progress to small vesicles. Myalgia, headache, anorexia, nausea, and tenosynovitis are common, but the temperature is only slightly elevated. The arthralgia may be prolonged. Symptomatic infection is rare in children.

Diagnosis

Isolation of virus from serum is possible for the first few days of illness. IgM antibodies will be detected by MAC-ELISA within 5 to 10 days of onset. Complement fixation, haemaglutinin inhibition, and neutralization tests may be useful, particularly when paired serum samples are available.

Prevention, control, and treatment

Avoidance of mosquito bites and peridomestic mosquito control can effectively reduce the risk of infection. No specific treatment is available. Non-steroidal anti-inflammatory drugs may relieve symptoms.

Venezuelan equine encephalitis complex

Aetiology and epidemiology

Six subtypes (I–VI) within the Venezuelan equine encephalitis virus complex have been identified. Five antigenic variants exist within subtype I (IAB, IC, ID, IE, IF). These subtypes and variants are classified as epizootic or enzootic, based on their apparent virulence and epidemiology. Epizootic variants of subtype I (IAB and IC) cause equine epizootics and are associated with more severe human disease. Enzootic strains (ID-F, II (Everglades), III (Mucambo, Tonate, Paramana), IV (Pixuna), V (Cabassou), VI (unnamed)) do not cause epizootics in horses, but may produce sporadic disease in man. Large epizootics (IAB and IC) have occurred in equines in northern countries of South America and Central America, sometimes reaching the United States. In 1969 to 1972, a massive epizootic extending from Ecuador to Texas killed more than 200 000 horses and caused several thousand human infections. In 1995, a large epizootic, which began in Venezuela and spread to Colombia, affected thousands of horses and caused approximately 90 000 human infections. Epizootic strains are carried by a wide variety of mosquitoes including *Aedes*, *Mansonia*, and *Psorophora* spp. Horses are the principal amplifying hosts during epizootics but are not amplifying hosts for enzootic transmission. Enzootic strains are maintained in a cycle involving *Culex* (*Melanoconion*) mosquitoes and rodents.

Clinical characteristics (epizootic virus infections)

After an incubation period of 1 to 6 days, there is a brief febrile illness of sudden onset, characterized by malaise, nausea or vomiting, headache, and myalgia. Acute symptoms last 2 to 5 days; generalized asthenia up to 3 weeks. Among those with clinical illness, less than 0.5 per cent of adults and less than 4 per cent of children develop encephalitis. Nausea and vomiting, nuchal rigidity, ataxia, convulsions, paralysis, and death may occur. Long-term sequelae following encephalitis are uncommon.

Diagnosis (epizootic virus infections)

A marked leucopenia is universal, often accompanied by neutropenia and thrombocytopenia, with moderate lymphocytosis in the cerebrospinal fluid. Virus isolation from serum or throat swab is possible within the first few days of illness. Paired sera can be tested by HI and neutralizing tests. Specific IgM can be detected by MAC-ELISA in the second week of illness.

Prevention, control, and treatment

Equine immunization is effective in controlling epizootic disease. Venezuelan equine encephalitis is highly infectious by the aerosol route; many laboratory infections have occurred. Live attenuated and inactivated vaccines have been used in laboratory workers. People in affected areas should avoid mosquito bites. No specific treatment is available.

Western equine encephalitis

Aetiology and epidemiology

This is a complex of closely related viruses found in North and South America, but human disease is rare outside North America and Brazil. Summer outbreaks may be precipitated by flooding, which increases breeding of *Culex* mosquitoes (particularly *Culex tarsalis* in the western United States). Large outbreaks of western equine encephalitis in humans and horses occurred in the western United States in the 1950s and 1960s; however, a declining horse population, equine vaccination, and improved vector control have reduced the reported number of human cases to zero, in most years during the last decade.

Clinical characteristics

The ratio of apparent to inapparent infection in adults is less than 1 in 1000; however, this ratio increases to 1:1 in infants under 1 year of age. Following an incubation period of about 7 days, headache, vomiting, stiff neck, and backache are typical; restlessness and irritability are seen in children. Weakness and hyporeflexia are common. Convulsions occur in 90 per cent of affected infants and 40 per cent of children between 1 and 4 years, but are rare in adults. Recovery in 5 to 10 days is common, but convalescence may be protracted. Although rare in adults and older children, sequelae are common in infants, with half of those with encephalitis left with convulsions, and/or severe motor or intellectual deficits. The case fatality rate is 3 to 7 per cent.

Diagnosis

Clinical laboratory findings in western equine encephalitis are often not remarkable. IgM antibodies are readily detected in serum by ELISA. Paired sera can be tested by HI, IgG ELISA, or neutralization tests. Virus can occasionally be isolated from serum or cerebrospinal fluid.

Prevention, control, and treatment

Prevention of western equine encephalitis relies on mosquito control and the avoidance of mosquito bites. Vaccine is available for horses. An inactivated vaccine has been used for laboratory staff and others at high risk of exposure. No specific treatment is available.

Other alphavirus infections

Barmah Forest virus

Since its first recognition as a cause of human disease in 1988, the geographical distribution of Barmah Forest virus has expanded recently in Australia. It causes sporadic disease and epidemics, with up to 300 serologically confirmed cases. The disease resembles that of Ross River virus infection, although the rash tends to be more florid and true arthritis is less common. The illness is prolonged in some patients. Little is known about the ecology of Barmah Forest virus, although outbreaks have coincided with Ross River virus outbreaks, and the virus has been identified in the same mosquito species.

Mayaro virus

Mayaro virus has been isolated from humans and various mosquito species (mostly *Haemagogus*) in Trinidad, Brazil, Bolivia, French Guiana, Surinam, Peru, and Venezuela. Several outbreaks have been identified, most recently in Venezuela in 2000. The disease is characterized by an abrupt onset with fever, chills, headache, myalgia, and arthralgia, mostly in the small joints of the extremities. A maculopapular rash may occur 2 to 5 days after defervescence. Arthralgia may persist for several months.

O'nyong-nyong virus

From 1959 to 1962, this virus caused epidemics in Uganda, Kenya, Tanzania, and Malawi, involving approximately 2 million people. The virus was isolated in 1978 from *Anopheles funestus* mosquitoes in Kenya after a long period of no apparent o'nyong-nyong virus activity. In 1996 to 1997, an outbreak occurred in Uganda. O'nyong-nyong is closely related to chikungunya and produces a similar illness, although fever is less pronounced and lymphadenopathy is more common. *Anopheles funestus* and *A. gambiae* transmit the virus.

Sindbis

Sindbis virus is widely distributed in Africa, India, tropical Asia, Australia, and northern Europe but is only rarely associated with human disease. The clinical features include fever, rash, arthralgia, myalgia, malaise, and headache. The fever, if present, is not high. The maculopapular rash progresses from trunk to extremities and vesicles can occur on the palms and soles. Virus has been isolated from vesicle fluid.

In northern Europe, symptomatic disease is recognized from Sweden, through Finland, to the former Karelian SSR, where it is known as Ockelbo disease, Pogosta disease, or Karelian fever, respectively. Prominent rheumatic complaints, sometimes persisting for several years, have been noted in Europe and South Africa. The virus has been isolated most often from ornithophilic *Culex* mosquito species. High antibody prevalences in Africa suggest that human exposure is common. Several outbreaks have been noted.

7.10.12 Rubella

P. A. Tookey and S. Logan

Introduction

Rubella infection usually causes a mild exanthematous disease of little clinical significance. However, in early pregnancy, infection may result in multiple congenital abnormalities. As a result of the widespread use of rubella vaccine, congenital rubella is now uncommon in most countries with developed health services.

The enveloped RNA virus of rubella is classified in its own genus, *Rubivirus*, within the family Togaviridae. Little variation has been detected among rubella isolates.

Epidemiology

Humans are the only known host for rubella virus. In temperate zones the infection is seen predominantly in spring and early summer. Before the introduction of rubella vaccine, rubella was endemic in virtually all countries. Epidemics were superimposed on the endemic infection every 4 to 9 years, and pandemics every 10 to 30 years. In most populations, in the absence of a mass immunization programme, around 10 to 20 per cent of women reach child-bearing age still susceptible to rubella infection. Infection is rare in infancy, incidence rises slowly in early childhood and then rapidly, peaking between 5 and 9 years of age.

Postnatally acquired infection

The rash usually begins on the face and spreads to the trunk and then the extremities; the pink maculopapular lesions are initially discrete but later tend to coalesce. The suboccipital and posterior cervical lymph nodes are characteristically enlarged. Mild fever, sore throat, coryza, cough, and conjunctivitis may be present; symptoms are usually mild and last 3 to 7 days. There may be a prodrome with malaise and fever, especially in adults. There is no specific treatment.

Arthralgia is a common complication in older patients, but frank arthritis is unusual; both are normally transient but recurrent or persistent symptoms have been reported, mainly in women. Less common complications include purpura, thrombocytopenia, postinfectious encephalitis, transverse myelitis, and the Guillain-Barré syndrome.

Rubella is clinically indistinguishable from a number of other infections and at least half of all infections are clinically inapparent or non-specific; a history of clinically diagnosed rubella infection is unreliable.

The incubation period is 14 to 21 days. The exact mode of transmission is uncertain but airborne spread by the respiratory route is likely and close contact is usually necessary for transmission. Individuals are infectious from about 5 to 7 days before to 3 to 5 days after the start of symptoms. Infectivity is highest immediately before, and on the first day of, symptoms. Congenitally infected infants shed large amounts of virus from the oropharynx and may be a source of infection for many months.

Infection usually produces lifelong immunity but reinfection has occasionally been reported.

Congenital infection

Congenital rubella is typically associated with cataracts, cardiac anomalies, and sensorineural hearing loss. The teratogenic effects may result in a wide range of defects (Table 1), but sensorineural hearing loss alone or combined with other abnormalities is most common. The earlier the stage of pregnancy at which infection occurred, the more likely it is that the child will have severe, multiple problems. The risk of damage following primary maternal infection in the first 10 weeks of pregnancy is around 90 per cent; this drops rapidly thereafter, and after 16 weeks' gestation even sensorineural hearing loss and growth retardation are rare; no abnormalities have been demonstrated following serologically confirmed maternal infection after 18 weeks' gestation.

Some defects, particularly sensorineural hearing loss, may not develop or reveal themselves until later infancy or childhood. Other reported late-onset problems include diabetes mellitus, thyroid dysfunction, and possibly autism and other behavioural and psychiatric disorders. A rare progressive rubella panencephalitis has been reported.

Maternal rubella infection is not always transmitted to the fetus. Transmission is most likely during the first trimester, the rate then declines until the last few weeks of pregnancy when it rises again. Most prospective studies of the risk to the fetus have been carried out on women with symptoms, but asymptomatic primary infection is thought to carry a similar risk. The risk of transmission following maternal reinfection in the first trimester is estimated to be about 8 per cent, but the likelihood of damage is low. Symptomatic maternal reinfection is rare, but in these circumstances viraemia is more likely and the risk to the fetus may be greater.

The diagnosis of congenital rubella infection is relatively easy if suspected early, but more difficult to confirm later. Virus can be isolated or detected by polymerase chain reaction (PCR) from multiple sites including the oropharynx, urine, and conjunctival fluid during the first months of life; viral shedding occasionally persists for years, but only about 10 per cent of infants are still shedding virus at 12 months. The presence of rubella IgM antibody in early infancy is virtually diagnostic of congenital infection because acquired infection is rare at this age. The presence of IgG antibody alone is not diagnostic since it is likely to indicate passively transferred maternal antibody, but persistence of IgG beyond 6 months is strongly suggestive of congenital infection. When abnormalities present late, a presumptive diagnosis can be made based on a compatible clinical picture and the presence or persistence of rubella IgG antibodies in a young child who has not yet been vaccinated.

Management of rubella-like illness during pregnancy

Routine antenatal rubella testing is not designed to identify infection in pregnancy, and specific diagnostic investigations are needed. Pregnant women with a rubella-like rash should be investigated simultaneously for rubella and parvovirus B19, since they are clinically indistinguishable. Even women previously reported to be immune should be investigated in case of laboratory error or reinfection. Blood should be tested for IgG and IgM antibodies, with a repeat test after 2 weeks if the results are equivocal. Rising IgG or detectable IgM antibody indicates recent infection. Investigations must be done in consultation with a virologist, who should be aware of the date and type of contact, stage of pregnancy, and history of previous immunization and testing.

Vaccination

Three strains of live, attenuated rubella vaccine were licensed in 1969. The RA27/3 strain is commonly used. Protective antibody levels are produced in around 95 per cent of recipients; protection is probably lifelong in most individuals.

In children, rubella vaccine causes few side-effects. Low-grade fever and rash are occasionally reported, and transient arthralgia has been seen in about 3 per cent of vaccinees; there have also been rare reports of myositis and vasculitis. Joint symptoms are common in adult women, affecting up to 40 per cent of vaccinees. They are less frequent and less severe than following naturally acquired rubella infection. Symptoms are generally mild and transient but a handful of cases of apparently

recurrent or persistent arthritis after rubella immunization have been described.

Different vaccine strategies have been pursued. In some countries, including the United States, there was mass immunization of all children early in their second year in an attempt to eliminate rubella from the community. This strategy not only protects those who are vaccinated but also reduces the risk of infection in susceptible pregnant women. However, if there is low vaccine uptake in childhood the spread of wild virus is slowed down but not eliminated: the effect is to push up the peak age of incidence of infection, which could, paradoxically, increase the number of congenital rubella cases.

In the United Kingdom, concern about low vaccine uptake and the duration of vaccine-induced immunity led initially to the adoption of a selective strategy of immunizing schoolgirls after the age of peak incidence. Routine testing and immunization of nursing and other staff who might be in contact with pregnant women was introduced, as well as antenatal screening for rubella susceptibility, with postpartum vaccination of susceptible women to protect subsequent pregnancies. The continued circulation of wild virus ensured that most women were protected by natural immunity acquired during childhood, with most of the remainder being covered by the schoolgirl and adult immunization programmes.

A third method was implemented in Sweden in 1982, when measles, mumps, and rubella (**MMR**) vaccine was introduced for all 1-year olds with a second dose at 12 years in order to reach those who did not receive vaccine previously or failed to respond, and to boost antibody status in the rest.

In 1988, in the United Kingdom, reassuring data on the persistence of immunity after vaccination and high vaccine uptake levels led to the introduction of mass immunization for all children in the second year of life with MMR; in 1996 this was supplemented by a preschool booster, and the schoolgirl vaccination programme was abandoned. Antenatal screening for rubella susceptibility continues, but the delivery of postpartum vaccination is not routinely monitored. Uptake of MMR by the age of 24 months averaged about 92 per cent between 1988 and 1992, but declined to about 88 per cent by 2000. Although the circulation of wild virus has dropped to very low levels since MMR was introduced, if the decline in vaccine uptake is not reversed it is possible that outbreaks of rubella could occur once again, putting susceptible pregnant women at risk.

Vaccination has led to dramatic declines in the numbers of susceptible pregnant women, rubella-associated terminations, and children born with congenital rubella. In the United Kingdom less than five congenitally infected infants were reported on average each year between 1990 and 2000, compared with 58.5 per year in the 1970s (when diagnostic methods and case ascertainment were less efficient). Terminations of pregnancy for rubella disease or contact averaged 612 a year in England and Wales during the 1970s, but during the 1990s the annual average was less than 10.

The strategy to be adopted in any country seeking to control congenital rubella by vaccination must depend on the projected uptake of vaccination and the long-term prospects for continuing the programme. An important element should be the screening and immunization of susceptible health personnel, particularly those in contact with pregnant women.

Vaccination in pregnancy

There have been persistent concerns that the vaccine virus might be teratogenic if given during pregnancy. Although vaccinees cannot infect other susceptible individuals, the virus can cross the placenta. Data pooled from studies of children born to several hundred women inadvertently vaccinated up to 3 months before conception or during pregnancy show less than 3 per cent with serological evidence of congenital infection, and no reported case of abnormalities attributable to congenital rubella. Over 80 of these infants were born to women vaccinated in the month of conception, probably the period of greatest vulnerability. These data suggest that the likely maximum theoretical risk is less than 5 per cent.

7.10.13 Flaviviruses

L. R. Petersen and D. J. Gubler

Introduction

The genus Flavivirus of the family Flaviviridae comprises 68 registered viruses; 35 of which cause natural human infection (Table 1). Flaviviruses are small (37–50 nm), spherical particles whose genome is a molecule of single-stranded, positive-sense RNA approximately 11 000 nucleotides in length. Based on epidemiological and phylogenetic characteristics, the flaviviruses are classified into three groups: those that are mosquito-borne, tick-borne, and those in which no arthropod vector has been demonstrated. All flaviviruses of human importance belong to the first two groups; the last group contains a few viruses found in vertebrates.

Most flaviviruses are maintained in nature in complex transmission cycles between wild or domestic animals and one or more haematophagous arthropod vectors. Humans become infected from infected arthropod vectors that take a bloodmeal, but for most of the flaviviruses, humans do not usually develop high viraemias and are not thought to contribute to the transmission cycle. However, some flaviviruses of world-wide importance, including the dengue and yellow fever viruses, do produce high-level viraemias in humans and can be maintained in urban settings through a mosquito–human–mosquito transmission cycle.

The epidemiology and geographical distribution of the flaviviruses depend on several factors, including the presence of suitable amplifying hosts, the presence and feeding behaviour of a suitable arthropod vector, and the frequency of exposure of non-immune reservoir hosts and humans to infected vectors. Globalization of trade and travel, human population growth, and neglect of mosquito control programmes have produced conditions conducive for increasing incidence and geographic expansion of the flaviviruses. A recent dramatic example is the introduction and subsequent spread of the West Nile virus in the western hemisphere. Flavivirus infections are not communicable.

Flavivirus infection in humans can result in asymptomatic infection or a spectrum of clinical illness ranging from non-specific febrile illness, fever with rash or arthralgia or both, haemorrhagic fever, hepatitis, encephalitis, and death. The same virus can cause a variety of syndromes, and often the majority of those infected are asymptomatic. Although no specific therapy is available, prompt supportive treatment and proper management may substantially reduce mortality from some flavivirus infections. Ribavirin has been shown to have antiviral activity against several RNA viruses, but it has low *in vitro* and *in vivo* activity against flaviviruses.

Laboratory diagnosis

All flaviviruses have common group epitopes on the envelope protein that result in extensive cross-reactions in serological tests. The specificity of antibody detected should therefore be confirmed by cross-neutralization tests in areas where multiple flaviviruses are endemic/enzootic.

The IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) is widely used for diagnosis of flaviviruses. IgM antibody is usually detectable 5 to 8 days after infection. Because detectable IgM antibody persists for one or more months after infection with most flaviviruses, its presence is not confirmatory of current infection. Therefore, people with detectable IgM antibody are considered presumptive cases. Confirmatory laboratory diagnosis of most flaviviruses requires isolation of the virus, detection of specific viral RNA or specific antigen in a clinical sample, or virus-positive immunohistochemistry in autopsy tissues. A four-fold or greater rise in specific neutralizing antibody is confirmatory in some infections.

Important mosquito-borne flavivirus infections

Dengue and dengue haemorrhagic fever

Aetiology and epidemiology

There are four closely related, but serologically distinct dengue viruses, called DEN-1, DEN-2, DEN-3, and DEN-4. Since there is only transient, weak cross-protection among the four serotypes, persons living in an area of endemic dengue can be infected with three, and probably four, dengue serotypes during their lifetime.

Dengue fever is the most widespread and has the highest incidence of all the flaviviruses; with an estimated 50 to 100 million infections, and 200 000 to 500 000 cases of dengue haemorrhagic fever per year throughout most tropical regions of the world depending on epidemic activity (Fig. 1). The case fatality rate of dengue haemorrhagic fever cases averages 5 per cent. Over 2.5 billion people live in areas where dengue is endemic. The transmission cycle of most importance is the *Aedes aegypti*–human–*Ae. aegypti* cycle in large urban centres of the tropics. Multiple virus serotypes often cocirculate within the same city (hyperendemicity), causing periodic epidemics, especially in south-east Asia.

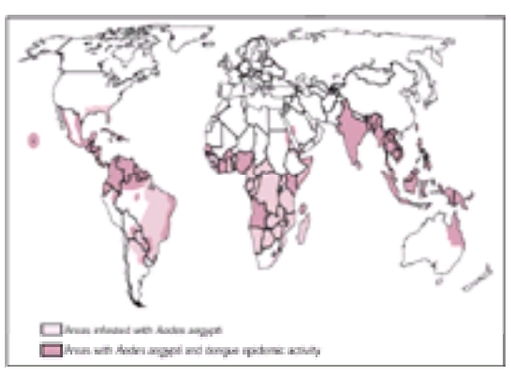

Fig. 1 The geographical distribution of dengue fever.

Humans are infected with dengue viruses by the bite of an infective mosquito. *Ae. aegypti*, the principal vector, is a highly domesticated tropical mosquito that lays its eggs in artificial water containers commonly found in and around homes. The adult mosquitoes rest indoors and prefer to feed on humans during daylight hours, with peak biting activity in the early morning or late afternoon. The adult female mosquitoes are nervous feeders and, if their feeding is interrupted, will return to the same person or different persons to continue feeding. Thus, during a single blood meal, several persons may become infected, making *Ae. aegypti* a highly efficient epidemic vector.

Clinical characteristics

Dengue virus infection in humans causes a spectrum of illness ranging from inapparent or mild febrile illness to severe and fatal haemorrhagic disease. The incubation period averages 4 to 7 days, with a range of 3 to 14 days. There are two major clinical syndromes: classic dengue fever and dengue haemorrhagic fever.

Dengue fever

Classic dengue fever, primarily a disease of older children and adults, is characterized by sudden onset of fever, frontal headache, retro-orbital pain, lumbrosacral pain, severe malaise, myalgias, bone pain, nausea, and vomiting. Patients may be anorectic, have altered taste sensation, and have a mild sore throat. Initial temperature may rise to 41°C and fever may last 2 to 7 days; a relative bradycardia may be present. Up to half the patients may have a transient rash or skin mottling in early illness. Defervescence occurs between days 3 and 6. A second, non-pruritic skin rash, varying in form from scarlatiniform to maculopapular and usually lasting an average of 2 to 3 days, may appear on the trunk, spreading to the face and extremities, sparing palms and soles, and often resolving with desquamation. The fever may rise again (saddleback pattern) with the presence of the rash.

Other findings associated with dengue fever include generalized lymphadenopathy and haemorrhagic manifestations. Skin haemorrhages, including petechiae and purpura, are the most common, along with gum bleeding, epistaxis, menorrhagia, and gastrointestinal haemorrhage. Haematuria is uncommon and jaundice is rare. Clinical laboratory findings include a neutropenia followed by a lymphocytosis, often marked by atypical lymphocytes. Liver enzyme levels may be mildly elevated, but in some patients serum alanine aminotransferase and aspartate aminotransferase levels reach 500 to 1000 U/l. Thrombocytopenia is not uncommon.

Classic dengue fever is rarely fatal, but weakness and depression may last several weeks following the acute illness, particularly in adults. There are no permanent sequelae.

Dengue haemorrhagic fever

During the last 50 years, dengue haemorrhagic fever has been recorded in south-east Asia, where all four dengue serotypes have circulated, but the first epidemic of dengue haemorrhagic fever in the Americas appeared in 1981 in Cuba, associated with the arrival of a new Asian virus of different genotype.

Pathogenesis

The characteristic development of dengue haemorrhagic fever during a heterotypic dengue infection, is presumed to result from pre-existing cross-reactive immunity. Subneutralizing levels of dengue antibodies enhance the infectivity of the virus by increasing the efficiency of binding and uptake of virus–antibody complexes through Fc receptors on blood monocyte or tissue macrophage cells, the chief site of replication in humans. This phenomenon of antibody-dependent enhancement is demonstrable *in vitro.* Cellular components of the primed immune response are probably also involved, and the resulting complement activation and release of cytokines and other mediators cause capillary leakage and coagulopathy, the hallmark of dengue haemorrhagic fever. The contribution of viral factors and variations in the host's immune response to the development of dengue haemorrhagic fever is unknown.

Clinical features

Although dengue haemorrhagic fever can occur in adults, it is primarily a disease of children under the age of 15 years. It is associated with all four virus serotypes. Dengue haemorrhagic fever is characterized by sudden onset of fever, usually lasting 2 to 7 days, and non-specific signs and symptoms. During this acute phase, it is difficult to distinguish dengue haemorrhagic fever from dengue fever and other illnesses found in tropical areas. However, at the critical time of defervescence, signs of circulatory failure or haemorrhagic manifestations may occur, the most common being petechiae, purpuric lesions, and ecchymoses. Epistaxis, bleeding gums, gastrointestinal haemorrhage, and haematuria occur less commonly. In its most severe form, dengue shock syndrome, occurring in approximately one-third of dengue haemorrhagic fever cases, patients experience hypotension, narrowing of the pulse pressure (£ 20 mmHg), and circulatory failure. Patients may complain of abdominal pain shortly before the onset of shock.

Physical findings associated with dengue shock syndrome include cool, blotchy, and congested skin, cyanosis, diaphoresis, tachypnia, and oliguria. Hepatomegaly, pulmonary effusion, and oedema are common, as is leucopenia. By definition, patients with dengue haemorrhagic fever/dengue shock syndrome must have objective evidence of plasma leakage such as a haemoconcentration (haematocrit elevated by 20 per cent), and thrombocytopenia with a platelet count of 100 000/mm ^{3} or less. Liver enzymes in serum may be elevated. The duration of shock is usually short. The mortality rate in aggressively treated patients is 1 per cent or less.

Differential diagnosis and diagnosis

The differential diagnosis during the acute phase of illness includes influenza, measles, rubella, typhoid, leptospirosis, rickettsia, malaria, and other arboviral infections with rash. Other viral haemorrhagic fevers and meningococcaemia should be considered in patients with haemorrhagic manifestations.

A definitive diagnosis depends on isolating the virus, detecting viral antigen or RNA in serum or tissues, or a rising titre of specific antibodies. The MAC-ELISA is the most widely used serological test for dengue diagnosis. Because antidengue IgM antibodies persist for several months, and because not all patients have detectable IgM antibodies 6 to 10 days after onset, diagnosis based on a single IgM antibody MAC-ELISA result should be considered provisional.

Prevention and control

Patients should be protected from mosquitoes and people should avoid mosquito bites in areas infested with *Ae. aegypti.* There are currently no licensed vaccines. Prevention and control can only be achieved by controlling *Ae. aegypti* in the large urban centres of the tropics. The most effective way to achieve this is via larval mosquito control by elimination of breeding sites in open stagnant water around communities where transmission is endemic/ epidemic.

Treatment

Supportive care includes intensive monitoring of vital signs and haematocrit. If signs of shock appear, prompt replacement of plasma volume and correction of metabolic acidosis, electrolyte imbalance, and hypoglycaemia are essential. After 1 or 2 days, the capillary leakage ceases and resorption of extravasated fluid begins. Care must then be taken not to induce pulmonary oedema by excessive intravenous fluids. Treatment with corticosteroids does not reduce mortality in children with dengue shock syndrome. Aspirin (salicylic acid) should be avoided.

Japanese encephalitis

Aetiology and epidemiology

Japanese encephalitis virus is the type species of the Japanese encephalitis serocomplex which includes several antigenically related viruses, including St Louis encephalitis, Rocio, West Nile, Koutango, Usuto, Murray Valley encephalitis, Kunjin, Alfuy, Stratford, and Kokobera viruses. Sequence analysis of the structural proteins suggests there are several genotypes of Japanese encephalitis, in distinct geographical areas.

Japanese encephalitis has a widespread distribution throughout Asia which has expanded in the past 20 years, with outbreaks in the Pacific, Australia, Nepal, and

Western India (Fig. 2). It is the most important cause of arboviral encephalitis, with about 45 000 cases reported annually. The highest incidence is in temperate and subtropical regions of China, northern Thailand, Nepal, and India. The virus is maintained in a cycle involving culicine mosquitoes and water birds and is transmitted to humans by *Culex* mosquitoes, primarily species of the *Cx. tritaeniorhynchus* complex, which breed in rice fields. Pigs are the primary amplifying host in the peridomestic environment. Epidemics occur in late summer in temperate regions and throughout the year in some tropical areas of Asia. Children have the highest attack rates, because of cumulative herd immunity with age.

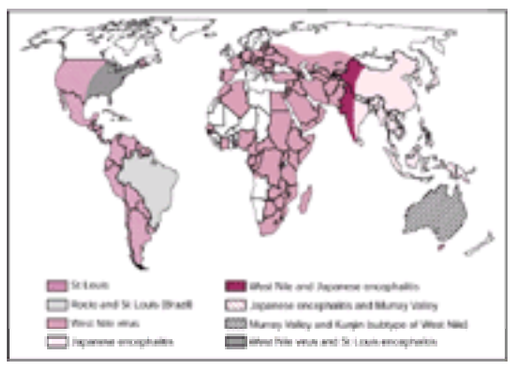

Fig. 2 The geographical distribution of the Japanese encephalitis serocomplex of the family Flaviviridae.

Clinical characteristics (see also Chapter 24.14.2)

Only about one in 250 infections result in symptomatic infection, which ranges from a febrile illness with headache, to aseptic meningitis, to encephalitis, and death. After an incubation period of 6 to 16 days, illness usually begins with a prodrome lasting several days followed by abrupt onset of high fever, change in mental status, nausea and vomiting, headache, and seizures, which occur in more than three-quarters of all paediatric patients. Generalized weakness and changes in tone, especially hypertonia and hyper-reflexia are common, but focal motor deficits, including cranial nerve palsies, paresis, hemiplegia, or tetraplegia, may also occur. Respiratory dysregulation, coma, abnormal plantar reflexes, and prolonged convulsions are associated with a poor prognosis.

Laboratory examination often reveals a moderate, peripheral leucocytosis and mild anaemia. Hyponatraemia, reflecting inappropriate antidiuretic hormone secretion, is common. Cerebrospinal fluid pressure is usually normal, pleocytosis ranges from a few to several hundred cells per mm ^{3}, and cerebrospinal fluid protein is moderately elevated in about half the cases.

Five to 30 per cent of cases are fatal; young children are more likely to die, and if they survive, are more likely to have residual neurological defects. Overall, up to 70 per cent of survivors have residual neurological abnormalities including parkinsonism, paralysis, behavioural changes, and psychological deficits. Evidence suggests that infection fails to clear in some patients, with clinical relapse several months after resolution of the acute illness. The clinical effects of congenital infection are unknown. Spontaneous abortions of women infected in the first and second trimesters have been reported.

Diagnosis

The differential diagnosis includes other viral encephalitides including arboviruses, herpes, and enteroviral infections, cerebral malaria, and bacterial infections. Epidemiological features such as place of residence or travel, season, and occurrence of other cases in the community provide clues to the diagnosis. Patients with encephalitis are rarely viraemic. Specific IgM can be detected in cerebrospinal fluid, serum, or both in nearly all patients by the seventh day after onset. Confirmation can be obtained by demonstrating four-fold or greater changes in specific IgM or neutralizing antibody titre.

Prevention and control

A formalin-inactivated mouse brain vaccine is used widely in Japan, Korea, Taiwan, Thailand, and other countries in Asia for childhood immunization and is licensed in Britain, the United States, and other developed countries to protect travellers. Hypersensitivity reactions to this vaccine, including generalized urticaria and angioedema, have occurred within minutes to as long as 2 weeks following vaccination at a rate of 1 to 104 per 10 000. Tissue culture based-vaccines (inactivated and live-attenuated) have been used in China. The risk to travellers to endemic areas during the transmission season can reach 1 per 5000 per month of exposure; risk for most short-term travellers may be less than 1 per million. In general, vaccine should be offered to people spending a month or more in endemic areas during the transmission season, especially if travel includes rural areas. Water and crop management and animal husbandry have been used to decrease human exposure to mosquito bites in the peridomestic environment.

Treatment

No specific therapy is available, but supportive treatment can reduce morbidity and mortality. One uncontrolled study showed a beneficial effect of a-interferon. Dexamethasone did not prevent death caused by oedema-induced increases in intracranial pressure in patients with severe encephalitis.

St Louis encephalitis

Aetiology and epidemiology

St Louis encephalitis virus is prevalent throughout the western hemisphere from Canada to Argentina (Fig. 1). The natural transmission cycle involves wild birds and *Culex* mosquitoes. Although clinical illness has been sporadically reported throughout much of this region, the highest incidence occurs in North America during epidemics. Fewer than 100 human cases are generally reported annually; epidemics with hundreds of cases have occurred in North America every 10 to 20 years.

Clinical characteristics

The ratio of infection to clinical illness is high, ranging from 800:1 in children under 10 years to 85:1 in persons over 60 years. Illness ranges from fever with headache, to aseptic meningitis, to encephalitis, and death. Advanced age is the strongest risk factor for both symptomatic disease and severity of encephalitis. After an incubation period of 4 to 21 days, the typical presentation of encephalitis is fever, headache, chills, nausea, and dysuria. Within 1 to 4 days, central nervous system signs appear and may include meningism, tremor, abnormal reflexes, ataxia, cranial nerve palsies, convulsions (especially in children), stupor, and coma. Complications include bronchopneumonia, sepsis, stress ulcer, and pulmonary embolism. Recovery is usually complete, except that 10 to 25 per cent of very young infants have residual mental deficits, personality changes, muscle weakness, and paralysis. Underlying diseases such as hypertension, diabetes, and alcoholism affect the outcome. The case fatality rate is about 6 per cent overall, but is only 1 per cent of those under 5 years, as the disease is generally milder in children. Short-lived sequalae of nervousness, memory impairment, and headache occur uncommonly in older children and adults.

The peripheral leucocyte count, serum transaminases, and creatine phosphokinase may be elevated. Hyponatraemia due to the syndrome of inappropropriate antidiuretic hormone secretion may be noted in up to one-third of patients. The cerebrospinal fluid contains fewer than 500 cells/mm ^{3}, principally leucocytes.

Diagnosis

The differential diagnosis includes other viral encephalitides such as arboviruses, herpes, and enterovirus, as well as other bacterial and fungal infections of the central nervous system. Epidemiological features (residence, season of the year, and occurrence of other cases in the community) provide diagnostic clues. Because of serological cross-reactivity with other flaviviruses, positive serum samples should be subjected to cross-neutralization tests. From fatal cases, virus may be isolated

from brain tissue or demonstrated by immunofluorescence. Virus has not been isolated from the blood during the acute phase of illness.

Prevention and control

No vaccine is available. Prevention is aimed at personal protection from mosquito bites and mosquito abatement.

Treatment

Treatment is supportive; no specific therapy is available.

West Nile encephalitis (see also Chapter 24.14.2)

Aetiology and epidemiology

West Nile virus is enzootic in Africa, the Middle East, and western Asia, and has caused periodic outbreaks in humans and horses in southern and central Europe (Fig. 2). In 1999, the virus was first detected in the New World during an outbreak in New York City. By 2001 the virus' distribution expanded to the entire eastern half of the United States and southern Ontario. Continued geographic expansion throughout the Americas is likely.

Phylogenic studies indicate two viral lineages: lineage one includes most strains isolated in recent outbreaks in Europe, the Middle East, and North America; lineage two includes many of the strains enzootic in Africa. Kunjin virus (see below) is a variant of West Nile virus and fits within lineage one. West Nile virus is maintained in a cycle involving culicine mosquitoes and wild birds. Bird migration may be important for transporting the virus geographically, particularly to temperate areas.

From the 1950s to the 1970s, epidemics, rarely associated with severe neurological disease and death, occurred in Israel, France, and Africa. No epidemic activity was then reported until the mid-1990s when epidemics associated with severe neurological disease and death in humans and/or equines were recorded in Algeria, Morocco, Tunisia, Italy, Romania, Israel, southern Russia, France, and the United States. Several of these epidemics have included hundreds of cases. Outbreaks typically occur in late summer and early autumn in temperate regions.

Clinical characteristics

Illness ranges from fever with headache, to aseptic meningitis, to encephalitis, and death; but most infections are asymptomatic. Investigations in Romania and the United States showed that less than one per cent of those infected developed meningitis or encephalitis requiring hospitalization. Approximately 20 per cent of those infected developed a systemic febrile illness. Advanced age was the most important risk factor for developing both encephalitis and death. The incubation period is 3 to 7 days (range 3–15 days). Mild illness presents as a dengue-like illness with fever, headache, backache, myalgia, and anorexia that lasts 3 to 6 days. A roseolar or maculopapular rash occurs in about half the patients and lasts up to a week without scaling. Generalized lymphadenopathy has also been reported as a common finding. In recent outbreaks, however, only about one in five patients had a rash and lymphadenopathy was uncommon. Disorientation, disturbed consciousness, and generalized weakness are predominant signs in persons with encephalitis. Ataxia, extrapyramidal signs, hypotonia, hyper-reflexia, coma, and seizures may be present. Motor weakness may be profound, suggesting Guillain–Barré syndrome. Other serious, non-neurological, rare complications include myocarditis, pancreatitis, and fulminant hepatitis.

Recovery is usually complete, but among those with severe encephalitis, up to half of survivors have residual neurological deficits. Case fatality rates in recent large outbreaks have ranged from 5 to 14 per cent. The peripheral leucocyte count, serum transaminases, and alkaline phosphatase may be elevated. Thrombocytopenia and anaemia may be present. Hyponatraemia can occur in up to three-quarters of patients. The cerebrospinal fluid usually contains up to 2000 cells/mm ^{3}, mostly leucocytes, and moderately elevated protein.

Diagnosis

The differential diagnosis includes other viral encephalitides including arboviruses, herpes, and enterovirus, as well as other bacterial and fungal infections of the central nervous system. Guillain–Barré syndrome should be considered in patients with profound muscle weakness. Epidemiological features (residence, season of the year, and occurrence of other cases in the community) provide diagnostic clues. Because of serological cross-reactivity with other flaviviruses, positive samples should be tested by cross-neutralization. Virus isolation or nucleic acid amplification tests of acute-phase blood, cerebrospinal fluid, or brain biopsy samples may provide a definitive diagnosis, but will not detect virus in all patients.

Prevention and control

No vaccine is available. Prevention is aimed at surveillance, mosquito abatement, and taking personal precautions to avoid mosquito bites.

Treatment

Treatment is supportive; no specific therapy is available.

Yellow fever

Aetiology and epidemiology

Yellow fever was first described in the seventeenth century and was one of the great plagues of mankind for over 400 years. In 1900, mosquito transmission and the viral aetiology were proven. The virus was isolated in 1927 and a vaccine developed in 1937. The virus is present in tropical America and Africa, but does not occur in Asia. Epidemics still occur, especially in West Africa. Between 1986 and 1991, a series of outbreaks in Nigeria caused an estimated 100 000 cases (although only about 5000 were officially reported), with attack rates in affected areas of 30/1000 and case-fatality rates exceeding 20 per cent. In South America, the disease affects up to 300 people annually, principally young men working in forest areas exposed to *Haemagogus* mosquitoes breeding in tree holes (jungle yellow fever). Disease in unvaccinated travellers is rare; however, since 1996 four travellers died in the US and Europe of infection acquired in South America and Africa.

Yellow fever virus has two cycles of transmission: jungle yellow fever and urban yellow fever. The forest or jungle transmission cycle involves canopy-dwelling mosquitoes and monkeys. The urban cycle involves humans as the vertebrate host and *Ae. aegypti* as the principal vector. In the past 30 years, *Ae. aegypti* has reinvaded Central and South America and a small outbreak of urban yellow fever occurred in Bolivia in 1998. The American tropics currently have the highest risk of urban epidemics of yellow fever in over 50 years. Epidemics in Africa often occur in moist savannah regions, involving forest (sylvatic) or peridomestic *Aedes* mosquitoes and humans as viraemic hosts. In dry areas and urban centres, epidemic transmission occurs where water-storage practices breed domestic *Ae. aegypti*. Several hundred thousand people are infected annually; outbreaks are frequent.

Clinical features

Approximately 1 in 20 infections results in clinical disease with jaundice. In its classical form, disease occurs abruptly after an incubation period of 3 to 6 days. The initial phase ('period of infection') is characterized by viraemia, fever, chills, headache, lumbosacral pain, myalgia, nausea, and prostration. On examination, the patient may have a relative bradycardia, and conjunctival injection. Within several days, the patient may recover transiently ('period of remission'), only to relapse ('period of intoxication') with jaundice, albuminuria, oliguria, haemorrhagic manifestations (especially 'black vomit' haematemesis), delirium, stupor, metabolic acidosis, and shock. The prognosis in such cases is poor; 20 to 50 per cent die during the second week of illness.

Clinical laboratory tests reveal leucopenia, thrombocytopenia, hepatic dysfunction, and renal failure. The bleeding diathesis is caused by decreased synthesis of clotting factors and may be complicated by disseminated intravascular coagulation. Pathological findings include midzonal hepatic necrosis and eosinophilic degeneration of hepatocytes (Councilman bodies), possibly representing apoptosis, and acute renal tubular necrosis. Focal myocarditis, and brain swelling and

petechial haemorrhages contribute to pathogenesis. Recovery is complete, without postnecrotic hepatic cirrhosis.

Diagnosis

Exposure and travel history provide important clues to aetiology. The differential diagnosis includes viral hepatitis, leptospirosis, rickettsial infections, dengue haemorrhagic fever, Rift Valley fever, Ebola, and Crimean–Congo haemorrhagic fever. Serological cross reactions with other flaviviruses may complicate serology. Postmortem histopathological examination of the liver is diagnostic, with or without immunocytochemical staining for viral antigen. Liver biopsy should never be performed on living patients, as it may precipitate haemorrhage.

Treatment

Treatment is symptomatic. Intensive care requires prompt awareness and treatment of acidosis, shock, and metabolic imbalance. Patients with renal failure may require dialysis.

Prevention and control

The live, attenuated 17D vaccine, delivered as a single 0.5-ml subcutaneous dose, is highly effective, and has minimal side-effects. Immunity is probably life long, but for travel certification, revaccination is recommended every 10 years. People with documented egg allergy should not be immunized or should be skin tested with the vaccine. The vaccine must not be given to children under 6 months of age, in whom there is a risk of postvaccinal encephalitis, and it is best to delay vaccination until 9 months of age. On theoretical grounds, immunosuppressed patients (including those with clinical AIDS) should not be immunized. The immune response in HIV infected persons is impaired. No evidence of clinical congenital infection has been found. Immunization during pregnancy is contraindicated, but, if inadvertently performed, recipients should be reassured and followed. The immune response in pregnancy was found to be impaired. Fatal infection following vaccination with the 17D strain has been rarely reported. Effective control has been achieved by controlling the principal urban mosquito vector, *Ae. aegypti*. This approach would also prevent epidemic dengue fever/dengue haemorrhagic fever in tropical urban centres.

Other mosquito-borne infections

Kunjin

Genomic sequencing indicates that Kunjin virus is a variant of West Nile virus. It is found over most of tropical Australia and Queensland and has a similar transmission cycle involving birds and *Culex* mosquitoes. Infection is usually asymptomatic, but occasional cases of encephalitis have been reported. Infections are generally milder than with Murray Valley encephalitis and are not life threatening. Kunjin virus infections that are non-encephalopathic usually present with fever, often with polyarthralgia. Cases occur sporadically, with only nine reported from 1990 to 1998. Treatment is supportive; there is no vaccine.

Murray Valley encephalitis

Murray Valley encephalitis is enzootic in New Guinea, in northern Western Australia, and in the Northern Territory, and possibly in northern Queensland (Fig. 1). The virus has a transmission cycle involving birds and *Culex* mosquitoes and is transmitted to man by *Cx. annulirostris* mosquitoes from the end of March to early June. Only one in 1000 to 2000 infections results in clinical illness; of those that have neurological disease, approximately one-third are fatal and a quarter have residual neurological deficits. Clinical illness resembles Japanese encephalitis. Children and the elderly are at the highest risk. In 1974, the largest recorded epidemic involved 58 cases and 10 deaths; since then, sporadic cases have been identified. Serological diagnosis is complicated by the presence of the closely related Kunjin virus, which also causes encephalitis. Treatment is supportive; there is no vaccine.

Rocio encephalitis

Rocio virus is antigenically related to St Louis encephalitis virus and is known only in Brazil. Epidemics in 1975 to 1976 caused 871 cases, principally among young adult, male, agricultural workers and fisherman. Since then, only sporadic illness has been reported. The probable vector is *Aedes scapularis* and wild birds are amplifying hosts. The clinical disease is typical viral encephalitis, with a 4 per cent mortality and 20 per cent of patients have neuropsychiatric sequealae. Virus is not recoverable from blood, but post-mortem diagnosis may be made by virus isolation from brain tissue. Treatment is supportive; there is no vaccine.

Tick-borne infections of the central nervous system

Tick-borne encephalitis

Aetiology and epidemiology

There are two subtypes of tick-borne encephalitis virus, eastern and western, which differ only slightly in viral protein structure. These viruses, along with the louping ill, Powassan, Kyasanur Forest disease, and Omsk haemorrhagic fever viruses, belong to the tick-borne encephalitis antigenic complex. The disease caused by the eastern subtype is also known as Russian spring/summer encephalitis and Russian epidemic encephalitis; and the western subtype as FSME (Fruehsommer-Meningo-Enzephalitis), early-summer encephalitis, and Kumlinge's disease. The geographic distribution of disease is determined by that of their tick vectors: *Ixodes persulcatus* for the eastern subtype causing human disease principally in the Far East, the Urals, and western Siberia; and *Ixodes ricinus* for the western subtype which occurs at highest incidence in eastern and central Europe, Moldavia, the Ukraine, and Byelorus, with smaller numbers of cases from western Europe, the Balkans, and Scandinavia.

Infections occur during the period of tick activity from April to November. Tick-borne encephalitis is largely a rural infection; occupational and vocational pursuits favouring tick exposure are risk factors. Human infection and outbreaks following consumption of raw milk or cheese from asymptomatic goats, or more rarely, sheep or cows, have been described. Hundreds to thousands of cases occur annually, with reported attack rates up to 200/100 000 residents in Latvia, the Urals, and Western Siberia. Aerosolized virus has caused laboratory infections.

Clinical features

Most human infections are subclinical. The illness produced by each subtype is generally similar but that produced by the eastern subtype carries a worse prognosis. The incubation period is 7 to 14 days, with a range of 2 to 28 days. Incubation periods of 3 to 4 days follow milk-borne exposure. The Western subtype typically produces a biphasic illness. The first phase is a non-specific, influenza-like, febrile illness lasting 2 to 7 days followed by an afebrile and relatively asymptomatic period lasting 2 to 10 days. Flushing, conjunctival haemorrhage, nausea, vomiting, dizziness, and myalgia are common findings. Approximately one-third of patients then develop higher fevers with aseptic meningitis or meningoencephalitis. The eastern subtype usually progresses without an asymptomatic phase. Signs and symptoms of meningoencephalitis or meningoencephaloymelitis include somnolence, coma, asymmetrical parasesis of the cranial nerves, tremors of the extremities, nystagmus, severe pain in the extremities, and flaccid paralysis of the neck and upper extremities.

Permanent paralysis develops in 2 to 10 per cent of patients with the western subtype, 10 to 25 per cent with the eastern. Corresponding case fatality rates are 0.5 to 2.0 per cent and 5 to 20 per cent for the western and eastern subtypes, respectively.

Laboratory findings include neutrophilia, although neutropenia, thrombocytopenia, and elevated liver enzyme levels may occur early. The cerebrospinal fluid white blood count is usually below 500/mm^3, primarily of mononuclear cells.

Diagnosis

The differential diagnosis is similar to Japanese encephalitis; the pattern of flaccid paralysis may be confused with poliomyelitis. A history of bite by small ixodid ticks is elicited in fewer than half the cases. Specific diagnosis is made by virus isolation from blood or cerebrospinal fluid during the first week of illness, or by serological

tests, including IgM enzyme immunoassay and neutralization test.

Treatment

Treatment is supportive.

Prevention and control

Effective inactivated vaccines are available in Europe in formulations for adults and children. Mass vaccination in Austria produced a dramatic decline in disease incidence. Vaccines appear to produce equal protection against the eastern and western strains. Use of a vaccine, available in the United Kingdom, should be seriously considered for tourists planning camping or extensive outdoor activities during the tick transmission season in enzootic areas, particularly in Russia and Central Europe. Commercial hyperimmune globulin preparations are available for use after tick exposure or to provide short-term pre-exposure prophylaxis.

Louping ill

This is a disease of veterinary importance, causing neurological illness in sheep and to a lesser extent in cows, horses, farmed deer, sheep-dogs, and pigs. The virus, isolated in 1931, is a member of the tick-borne encephalitis complex, and is transmitted by *Ixodes ricinus*. Louping ill occurs in the hill country along the western coast of Scotland and northern England, Ireland, and Norway. Natural infections resulting in human disease have been rare, but laboratory infections are not uncommon. Ten naturally occurring cases have been documented, including a veterinarian, abattoir workers, and farmers. Some of these cases were attributable to contact with sheep blood. The human disease is typically aseptic meningitis or encephalitis; no fatal infections have occurred. Avoidance of tick bite in enzootic areas is recommended. The licensed tick-borne encephalitis vaccine may be protective.

Powassan encephalitis

The virus was first isolated from the brain of a fatal case in Powassan, Ontario in 1958. Since then, approximately 20 human cases have been recognized in eastern Canada and the eastern United States, primarily in children, with a case-fatality rate of 10 per cent and a high incidence of residual neurological dysfunction. Serological surveys indicate an antibody prevalence of 1 to 4 per cent. The distribution of the virus in North America is considerably wider than indicated by human cases, and the diagnosis should be suspected in any case of summer–autumn encephalitis. The virus is transmitted between *Ixodes scapularis* (ricinus complex) ticks and rodents. The clinical features are those of viral encephalitis, with localizing neurological signs and convulsions. There is no specific treatment or vaccine.

Tick-borne haemorrhagic fever

Kyasunur Forest disease

Aetiology and epidemiology

This virus is a member of the tick-borne encephalitis antigenic complex. The virus has been isolated from humans, monkeys, and ticks since it was first recognized in 1957 during an outbreak of haemorrhagic fever affecting wild monkeys in Karnataka (then Mysore) State, India. Several hundred cases are reported annually, principally among people working in the forest in Karnataka State. In 1983, 1555 cases, including 150 deaths, occurred. The peak seasonal incidence is between February and May. The virus is transmitted between immature ixodid ticks (*Haemaphysalis spinigera*) and small mammals (rodents, porcupines), passes to the adult stage during moulting, and is spread to man and wild monkeys by adult ticks.

In 1995, a subtype of Kyasanur Forest disease virus was isolated from patients in Jeddah, Saudi Arabia, with clinical symptoms ranging from febrile illness to fatal haemorrhagic disease. Human infections were associated with handling meat or drinking unpasturized camel's milk. The virus seems to be associated with sheep and camels, and to be transmitted by ticks.

Clinical characteristics

After an incubation period of 2 to 7 days, there is abrupt onset of fever, chills, headache, myalgia, abdominal pain, nausea, vomiting, and diarrhoea. Physical signs include bradycardia, lymphadenopathy, and haemorrhagic manifestations. Hypotension is frequently noted during the end of the acute stage. Fatal cases develop shock and pulmonary oedema. A biphasic illness is not uncommon, with resolution of the first phase in 5 to 12 days, and return of the fever and signs of meningoencephalitis after an interval of 1 to 3 weeks. Localizing neurological signs are infrequent, and residual defects are rare. Convalescence is prolonged. Laboratory abnormalities include leucopenia, thrombocytopenia, and elevated serum transaminases during the acute phase.

Diagnosis

Diagnosis is by virus isolation from blood collected during the first week after onset or by serological tests. Virus isolation should be conducted under biosafety level four conditions.

Prevention and control

Tick bites should be avoided in endemic areas. Proper care should be taken when handling raw meat, and camel's milk should be pasteurized. A formalin-inactivated virus is available in India.

Treatment

Treatment is supportive; specific therapy is not available.

Omsk haemorrhagic fever

This disease was first recognized in 1945 in western Siberia. Cases were frequent between 1945 and 1949, with morbidity rates of 500 to 1400/100 000, but subsequently have been rare, mainly occurring among residents of rural areas working in the fields. The virus is a member of the tick-borne encephalitis complex. Human infections are acquired by tick bite or contact with infected muskrats. The disease is characterized by abrupt onset of fever, headache, myalgia, facial flushing, conjunctival suffusion, minor haemorrhagic manifestations, and leucopenia. Recovery occurs in the second week, and the case fatality rate is low (0.5–3 per cent). The differential diagnosis includes tularaemia, rickettsial infection, and leptospirosis. Specific diagnosis is made by virus isolation from blood during the acute phase or by serological tests. Only a few laboratories outside Russia with biocontainment level 4 facilities are capable of providing laboratory assistance. Tick-borne encephalitis vaccines may cross-protect against Omsk haemorrhagic fever.

7.10.14 Bunyaviridae

J. W. LeDuc and J. S. Porterfield

The family Bunyaviridae currently contains around 300 viruses, and is divided into five genera (see Table 1). The family name, and that of the genus *Bunyavirus*, is derived from the type species, Bunyamwera virus, which was isolated in Uganda from *Aedes* mosquitoes. The other genera are also named after viruses: the genus *Hantavirus* after Hantaan virus, the causative agent of Korean haemorrhagic fever; the genus *Nairovirus* after Nairobi sheep disease virus; the genus *Phlebovirus* after phlebotomus or sandfly fever virus; and the genus *Tospovirus* after tomato spotted-wilt virus. All members of the family share certain structural, biochemical, and genetic properties, such as a spherical, enveloped virion 80 to 120 nm in diameter (see Fig. 1), and a genome of single-stranded, negative-sense RNA divided into three segments. Members of different genera vary substantially in their biological and biochemical properties and in the details of their mechanisms of replication. Bunyaviruses, nairoviruses, and phleboviruses, which together make up the greater part of the family, are all arthropod-borne animal viruses, or arboviruses; these circulate in nature in a wide variety of different vertebrate hosts and are biologically transmitted between vertebrates and to humans by the bites of blood-sucking arthropods, principally mosquitoes for bunyaviruses, sandflies for phleboviruses, and ticks for nairoviruses. By contrast, hantaviruses are not arboviruses, but are zoonotic agents infecting rodents and other small mammals, which may spread to humans if they are in close contact with their infected excreta, and tospoviruses are arthropod-transmitted plant viruses of no known medical importance.

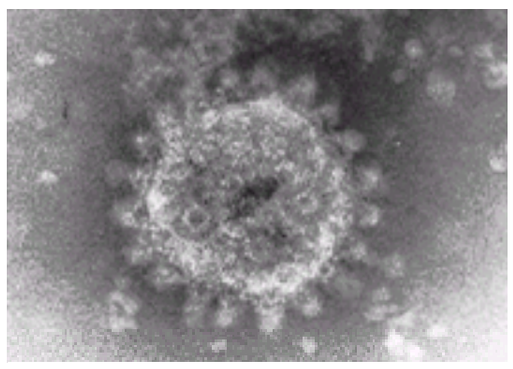

Fig. 1 Electron micrograph of Crimean–Congo haemorrhagic fever virus (× 400 000) (by courtesy of Dr D.S. Ellis).

Viruses within the larger genera are further subdivided into serogroups of more closely related members, there being at least 18 serogroups within the bunyaviruses, and seven within the nairoviruses (see Table 1). Of over 60 Bunyaviridae that are known to infect man, the type species and those that cause major human diseases are shown in bold type in Table 1 and are described in more detail in the following sections. Table 2 lists the continental distribution of the remaining viruses that cause only minor human infections and also indicates the principal arthropod vector of each virus. The habitats in which the different viruses and their vectors occur range from arctic to tropical, with every intermediate form. The enzootic cycles by which arboviruses are maintained in nature are very imperfectly understood; most viruses undergo alternate cycles of replication in vertebrate and invertebrate hosts, but transovarial and trans-stadial transmission within some mosquitoes, ticks, and phlebotomine flies, and venereal transmission from vertically infected male mosquitoes to uninfected females are also known to occur. Most arboviruses have a narrow host range, occur within a limited area, and are transmitted by specific vectors to a limited number of vertebrate hosts, but some viruses infect a wider host range, are transmitted by more than one type of vector, and may occur in more than a single continent. It is of interest that, for different members of the family, tick transmission predominates in Asia, but is unknown in South or Central America, and although some Bunyaviridae have been isolated in Australia, none is known to infect man in that continent. Further epidemiological details can be found in more specialized publications.

Following viral entry, whether through the skin after the bite of an infected arthropod or by another route, virus replicates in draining lymph nodes, which are frequently enlarged, and a viraemia follows. Symptoms develop when virus lodges in other sites and undergoes further replication cycles. Appropriate virucidal agents and methods include bleach, phenolic disinfectants and detergents, autoclaving or boiling, and the use of g-irradiation. Various enzymes such as nucleases will also inactivate these viruses. For human pathogens with the ability to spread by the aerosol route, biosafety level 3 (hantaviruses, Oropouche virus, others) or 4 (Crimean–Congo haemorrhagic fever virus only) is recommended. Added precautions are necessary when handling hantavirus-infected animals and virus concentrates.

Genus *Bunyavirus*

Much of our knowledge about the family as a whole derives from intensive studies on the type species, Bunyamwera virus, and a few other members of this large genus. The three-segmented genome permits reassortment when two closely related viruses infect the same cell, either in nature or under controlled laboratory conditions. Such studies have been used to establish the genomic control of viral proteins, and to analyse the basis of virulence for both vertebrate and invertebrate hosts. Two bunyaviruses, Akabane and Aino viruses in the Simbu serogroup, are notable for their ability to produce congenital deformities in sheep, goats, and cattle in Japan, Australia, Africa, and in the Middle East. However, there is as yet no evidence that any member of the genus or family produces teratogenic effects in man, although there is concern that Oropouche virus, an important Simbu serogroup pathogen of northern South America, may be a threat to pregnant women.

Bunyamwera virus

Symptoms

A mild, febrile illness, usually with headache, joint and back pains, sometimes associated with a rash, and occasionally with mild involvement of the central nervous system. Serological surveys indicated that infection of man is widespread in sub-Saharan Africa but most infections are unrecognized. Laboratory infections have been recorded. Garissa virus, recently isolated from haemorrhagic fever patients during outbreak investigations in Kenya and Somalia, contains L and S genome segments virtually identical to Bunyamwera virus, but with the M segment coming from a virus most closely related to Cache Valley virus. Neither Bunyamwera nor

Cache Valley virus is known to cause haemorrhagic disease in humans.

Treatment and prognosis

No treatment is necessary and the prognosis is excellent.

California encephalitis virus, Inkoo, Jamestown Canyon, La Crosse, Tahyna, and snowshoe hare viruses

The viruses named above, and perhaps others currently unrecognized, are responsible for the clinical condition known as California encephalitis. The viruses are widely distributed in nature throughout many parts of North America, Europe, and Eurasia. Most recognized human infections in the United States are due to La Crosse virus and are reported from Ohio, Wisconsin, Minnesota, and West Virginia; in 1999 a total of 70 cases was reported from nine states. The great majority of these occur in children, more often males than females, although Jamestown Canyon virus is unusual in that more adults are involved. There is nearly always a history of outdoor exposure in areas where woodland mosquitoes are prevalent. The incubation period is 5 to 10 days. Most cases of La Crosse encephalitis are relatively mild with headache, fever, and vomiting, progressing to lethargy, behavioural changes, and occasional brief seizures, followed by improvement. Severe cases (10 to 20 per cent) have an abrupt onset of fever and headache, disorientation, and seizures during the first 24 h of illness, sometimes progressing to coma and requiring intensive supportive care. Overall, symptomatic children suffer seizures in about 50 per cent of cases, status epilepticus in 10 to 15 per cent, and mortality approaches 1 per cent. Residual seizures occur in 6 to 13 per cent, persistent hemiparesis in about 1 per cent, and cognitive dysfunction in a small but poorly defined percentage of cases.

In Europe, Tahyna virus is widely distributed in Austria, the former Czechoslovakia, France, Germany, Italy, Norway, Romania, the former Yugoslavia, and the former USSR. Antibody rates can exceed 95 per cent in certain parts of the former Czechoslovakia, and are around 50 per cent in the Rhone valley in France and the Danube basin near Vienna; however, overt disease is seldom recognized. Inkoo virus is prevalent in Finland and in neighbouring regions of Russia, with the great majority of adult Lapps having antibodies; emerging information suggests that small children may have signs of central nervous involvement during acute infection. Antibodies reactive with California serogroup viruses have also been found in human sera collected in Sri Lanka, China, and in the far northern latitudes of Eurasia where a number of California serogroup viruses have been isolated from mosquitoes, some related to Inkoo and Tahyna viruses, but others to snowshoe hare virus. In another Russian study of some 50 persons, mainly 14 to 30 years of age, with infections caused by California serogroup viruses, about two-thirds had an influenza-like illness without central nervous involvement, while the remaining third had aseptic meningitis.

Control, treatment, and prognosis

Measures to limit mosquito breeding, particularly of *Aedes triseriatus*, are useful in endemic regions. No vaccines are available, and there is no specific treatment, although the fluid and electrolyte balance must be maintained, and anticonvulsive drugs may be required to control seizures. Intravenous ribavirin has been used to treat severe La Crosse encephalitis; however, more comprehensive clinical trials are needed.

Oropouche virus

Symptoms

Prior to 1961, Oropouche virus was known to have caused only a mild fever in a single forest worker in Trinidad, but that year it was responsible for a substantial epidemic in the Belem area of northern Brazil, with some 7000 individuals affected. Over the ensuing 40 years, massive epidemics of febrile illness have been recorded throughout the Amazon Basin, with perhaps as many as 200 000 persons infected. Symptoms include headache, generalized body pains, back pains, prostration, and moderately high fever (40°C). Rash occasionally accompanies infection, as does meningitis or meningismus. Illness lasts from 2 to 5 days, occasionally with protracted convalescence. No fatalities have been reported.

Control, treatment, and prognosis

No vaccine is available. Transmission is probably by the biting midge *Culicoides paraensis* and outbreaks appear to be a long-term consequence of agricultural development of the Amazon Basin. Accumulated organic waste from cacao and banana production provide ideal breeding sites for *Culicoides*, leading to massive populations and subsequent epidemic Oropouche disease. Thus, measures to reduce *Culicoides* breeding may be of benefit. Treatment is supportive, and the prognosis is good, although convalescence may be protracted.

Genus *Hantavirus*

Haemorrhagic fever with renal syndrome

The genus *Hantavirus* takes its name from Hantaan virus, the cause of Korean haemorrhagic fever in Korea. The name Hantaan in turn is from the Hantaan River near the demilitarized zone between North and South Korea, where the virus was first recovered from its rodent host, *Apodemus agrarius*. Hantaan virus was only isolated in 1976, although the clinical diseases it and related hantaviruses cause in the Eurasian continent have been known much longer under many different synonyms: epidemic haemorrhagic fever, Korean haemorrhagic fever, nephropathia epidemica, with haemorrhagic fever with renal syndrome preferred. Four distinct viruses are responsible for most recognized haemorrhagic fever with renal syndrome: Hantaan virus, found primarily in Asia; Dobrava virus, found in an enclave of disease in the Balkan region and sparsely elsewhere in Europe; Puumala virus, found in Scandinavia, western Russia, and much of Europe; and Seoul virus, probably globally distributed wherever *Rattus norvegicus* populations exist uncontrolled. Hantaan and Dobrava viruses cause severe, life-threatening disease with mortality of about 5 per cent, reaching as high as 30 per cent in select populations. Puumala virus infections are less severe, although patients still require admission to hospital, with death in less than 1 per cent of admitted cases. Seoul virus is thought to be the least severe of the pathogenic strains of hantaviruses, although it too has been associated with human deaths.

Each hantavirus is specifically associated with a particular rodent host in nature: Hantaan virus with the striped field mouse, *Apodemus agrarius*; Dobrava virus suspected with the yellow-necked mouse, *Apodemus flavicollis*; Puumala virus with the bank vole, *Clethrionomys glareolus*; and Seoul virus with the Norway rat, *Rattus norvegicus*. Human infection is from aerosols of infectious rodent excreta, or rarely by rodent bite, and is occupationally associated. Most disease is seen among adult men in rural environments. Those with occupations at greatest risk include farmers, woodcutters, shepherds, and especially the military in the field. Most hantavirus disease is markedly seasonal, with peak incidence seen in the late autumn and early winter, although the Balkan form is found most commonly during summer months in Greece and adjacent countries.

Symptoms

Incubation period for hantaviruses is rather variable, and may approach 2 months in some cases, but is generally 12 to 16 days. Severe disease, as typically associated with Hantaan or Dobrava virus infections in Asia or the Balkans, is characterized by five phases:

1. febrile, of 3- to 7-day duration;
2. hypotensive, lasting from a few hours to 3 days;
3. oliguric, from 3 to 7 days;
4. diuretic, from a few days to weeks;
5. a prolonged convalescence.

Characteristic signs and symptoms of the febrile phase include fever, malaise, headache, myalgia, back pain, abdominal pain, nausea and vomiting, facial flushing, petechias, and conjunctival haemorrhage (Fig. 2). The hypotensive phase is characterized by nausea, vomiting, tachycardia, hypotension, blurred vision, haemorrhagic signs, and shock, with approximately one-third of the deaths occurring during this phase. In the oliguric phase, nausea and vomiting may persist, and blood pressure may rise; kidney failure presents, which may include frank anuria; and about one-third of the cases may experience severe haemorrhage as epistaxis, gastrointestinal, cutaneous, or bleeding at other sites. Nearly one-half of deaths occur during the oliguric phase. In the diuretic phase, urine output increases to

several litres per day. Convalescence is protracted and may require months before full strength and function are regained.

Fig. 2 Patient with acute Korean haemorrhagic fever, showing extensive conjunctival haemorrhages (by courtesy of Professor H.W. Lee).

Less severe forms of the disease may skip phases, or spend less time in each phase. The milder forms of haemorrhagic fever with renal syndrome, such as nephropathia epidemica due to Puumala virus, follow a similar, but less severe course, with abrupt onset of fever of 38 to 40 °C, headache, malaise, backache, and generalized abdominal pain. Back or loin pain is especially common. Signs of renal failure are usually not as pronounced, and the need for renal dialysis varies. Transient blurred vision occurs in about 10 per cent of cases. Infection due to Seoul virus follows a similar course, but may present with more evidence of liver involvement. There is no evidence of person-to-person transmission.

Treatment and prognosis

Admission to hospital, avoidance of trauma and unnecessary movement, close observation, and careful supportive care are essential to patient survival. Treatment is phase specific, with special attention to fluid balance and volume, and control of hypotension and shock. Dialysis may be required in cases of acute renal failure. Specific antiviral therapy using ribavirin has been shown to be efficacious if started early in disease. Recovery is protracted, but until now considered complete and without permanent complications. Recent evidence, however, suggests that persons previously infected with Seoul virus may be at increased risk of chronic renal disease, hypertension, or stroke.

Hantavirus pulmonary syndrome

Recently, a new hantavirus disease, Hantavirus pulmonary syndrome, was reported from the United States and soon recognized in several South American countries as well. More than half the originally identified cases died in 1993, but mortality rates have declined to 20 to 40 per cent as clinical experience is gained. Cases were reported predominantly from the western United States and Canada, and more recently from Argentina, Chile, Brazil, and other South American countries. Sin Nombre virus was first associated with hantavirus pulmonary syndrome, but many additional hantaviruses have now been recognized as likely causes of this syndrome (Table 1). As Old World hantaviruses are generally associated with specific microtine rodents, so each American hantavirus appears to be associated with a specific sigmodontine host. A chain of apparent human-to-human transmission of Andes virus occurred during an outbreak in southern Argentina, including transmission to medical staff, suggesting that application of universal precautions when treating suspected cases of Hantavirus pulmonary syndrome may be warranted.

Symptoms

Hantavirus pulmonary syndrome is unusual in that symptoms are primarily those of acute unexplained adult respiratory distress syndrome, rather than renal disease. A nondescript prodrome of fever, myalgia, and malaise may last 4 to 6 days, with nausea, vomiting, and abdominal pain, often accompanied by dizziness. On admission, physical examination of patients with confirmed cases reveals fever (> 38 °C), tachycardia (> 100/min), tachypnoea (> 20/min), and often hypotension (systolic < 100 mmHg), and rales. Laboratory findings include hypoxia, leucocytosis, haemoconcentration, thrombocytopenia, atypical lymphocytosis, elevated serum lactate dehydrogenase and glutamic pyruvic transaminase, and prolonged prothrombin time (> 14 s). Chest radiography is helpful in diagnosis, noting progression from subtle interstitial findings to frank bilateral alveolar oedema; pleural effusions are usually present (Fig. 3). Thrombocytopenia and haemoconcentration are independent statistical predictors of Hantavirus pulmonary syndrome, although not present in every patient. Disease progresses rapidly once the lungs begin to fill, with death commonly seen in 24 to 48 h after admission, or sooner, due to hypoxia and/or circulatory failure. Hypotension and shock may occur independently in patients whose hypoxaemia is medically controlled.

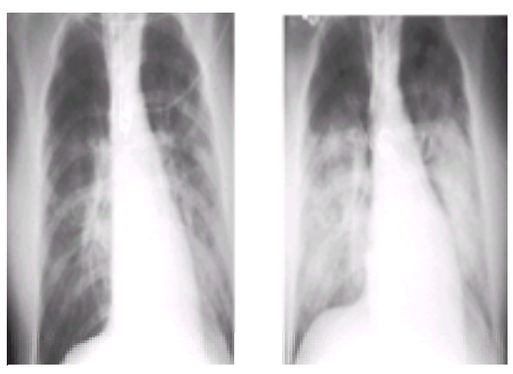

Fig. 3 Chest radiograph of patient with early Hantavirus pulmonary syndrome (L), and same patient 24 h later (R) showing development of bilateral perihilar alveolar oedema (by courtesy of Dr Loren Ketai).

Treatment and prognosis

Treatment is supportive, with careful management of hypoxia, fluid balance, and shock. About two-thirds of patients will require intubation and mechanical ventilation. Fluid loss into the lungs leads to haemoconcentration, but infusion of fluids exacerbates pulmonary oedema; consequently fluids should be administered with caution and careful monitoring. Limited experience in open label trials suggests that intravenous ribavirin does not have a marked effect on the course of Hantavirus pulmonary syndrome, perhaps because of the speed with which the disease progresses.

Control

Prevention involves avoidance of infected rodents, either through efficient rodent control programmes in urban settings for Seoul virus, or maintenance of clean campsites so that waste food is not allowed to accumulate and attract rodents. Vaccine development is under way, and nationally approved inactivated vaccines reported to be safe and efficacious against Hantaviruses are available for use in Asia.

Genus *Nairovirus*

The genus *Nairovirus* is named after Nairobi sheep disease, an acute, haemorrhagic gastroenteritis affecting sheep and goats in East Africa, with transmission by the

sheep tick, *Rhipicephalus appendiculatus*. In addition to the type species, which has caused laboratory infections, the genus also includes several other viruses known to infect man, of which the most important is Crimean-Congo haemorrhagic fever virus. Other nairoviruses causing less important human infections are Ganjam virus, almost indistinguishable from Nairobi sheep disease virus but first isolated in India from *Haemaphysalis intermedia* ticks collected from healthy goats; Hazara virus, recovered from *Ixodes redkorzevi* ticks collected from the vole *Alticola roylei*, in a subarctic habitat at an altitude of 3660 m in the Khaghan valley of Hazara district, Pakistan; Dugbe virus, isolated in Nigeria from *Amblyomma variegatum* ticks collected from healthy cattle; and Soldado virus, repeatedly isolated from a variety of bird ticks but recently linked to a mild illness in man.

Crimean–Congo haemorrhagic fever virus

Crimean haemorrhagic fever was first recognized as a cause of an acute, febrile, haemorrhagic disease affecting man in the Crimean region of the former USSR, transmitted by ticks and carrying a mortality of 15 to 30 per cent. In Africa, Congo virus was first isolated in the then Belgian Congo (now Democratic Republic of the Congo) from the blood of a local 13-year-old boy, and it caused a moderately severe laboratory infection; related viruses were isolated in Uganda, where more laboratory infections occurred, one of which ended fatally after a severe haematemesis. In Asia, a virus indistinguishable from Congo virus was isolated from pools of ticks collected from a variety of wild and domestic animals in Western Pakistan. It was later demonstrated that Crimean haemorrhagic fever virus was serologically indistinguishable from Congo virus, hence the use of the term Crimean–Congo haemorrhagic fever virus. Different strains of this virus have been associated with outbreaks of severe and sometimes fatal disease in the Crimea, Rostov, and Astrakhan regions of the former USSR, in Albania, Bulgaria, and Yugoslavia, in East, West, and South Africa, in Iran, Iraq, and in Western Pakistan, and in China. Most infections are acquired by tick bites, but infections have occurred in both hospital and laboratory environments. In South Africa an association with wild birds has been reported.

The incubation period is about 1 week. The onset of fever is usually sudden, and fever is usually continuous, although occasionally remittent or biphasic. Signs and symptoms include fever, headache, nausea, vomiting, joint pains, backache, photophobia, together with circulatory disorders, thrombocytopenia, and leucopenia. Haemorrhagic manifestations are common, with bleeding from nasal, gastric, intestinal, uterine, and renal membranes (Fig. 4). Patients may present with acute abdominal pain, mimicking an acute surgical emergency, and operating-theatre staff have become infected and have died through contact with infected blood or secretions exposed at operation. The mortality is about 15 to 30 per cent, but may be as high as 40 to 80 per cent in hospital or nosocomial outbreaks. Transient hair loss has been reported.

Fig. 4 Patient with Crimean–Congo haemorrhagic fever showing extensive ecchymoses on the arms and thorax (by courtesy of Professor D.I.H. Simpson).

Control, treatment, and prognosis

No vaccine is available. Avoidance of tick bites may reduce the risk of infection. In hospital outbreaks, meticulous attention to the containment of infected secretions is essential and barrier nursing should be used. There may be neurological involvement, which usually indicates a poor prognosis. Those patients who recover may be left with a polyneuritis that persists for months, but eventual recovery is to be expected.

Genus *Phlebovirus*

At least nine different phleboviruses are known to infect man (see Table 1). Pappataci fever, sandfly fever, or Phlebotomus fever was recognized as a clinical entity in the Mediterranean area during the nineteenth century, and the association with *Phlebotomus papatasi* sandflies was clearly demonstrated by showing that filtrates of human blood would reproduce the disease in human volunteers. For many years it was thought that man was the only vertebrate host, but antibody studies indicate that gerbils, cattle, and sheep may also be infected. Naples virus was isolated by American investigators from human serum collected during an outbreak of sandfly fever in Naples, and the Sicilian virus was isolated by the same workers from American troops with a similar fever in Palermo, Sicily. The two viruses have many common properties, but they are serologically quite distinct. Sandfly fever is widespread throughout the Mediterranean area, and also occurs in Egypt, Greece, Iran, Turkey, the former Yugoslavia, Bangladesh, India, Pakistan, and the southern states of the former USSR. Toscana virus, serologically related to the Naples virus, is found in countries bordering the Mediterranean; it is notable for its ability to infect the central nervous system, especially in central Italy where it is thought to be responsible for at least 80 per cent of acute summertime infections of the central nervous system in children. The viruses that cause classic sandfly fever do not occur in the New World, but in South and Central America a similar clinical condition follows infection with Alenquer, Candiru, Chagres, and Punta Toro viruses.

Rift Valley fever has long been known as a disease of domestic animals, mainly sheep, in East Africa, which occasionally spreads to farm workers and others handling infected animals. The infection is endemic, but seldom recognized, in many wild game animals in Africa. Molecular studies have established that Rift Valley fever virus is very similar to sandfly fever viruses and Punta Toro virus in having an ambisense replication mechanism; this property distinguishes the genus *Phlebovirus* from other genera within the family. In its biological properties, Rift Valley fever virus differs from the sandfly fever viruses, Punta Toro viruses, and most other members of the genus, in being normally transmitted by mosquitoes rather than sandflies. When it was recognized that the tick-transmitted Uukuniemi and Zaliv-Terpeniya viruses also shared an ambisense replication strategy, these viruses were removed from their earlier classification in the genus Uukuvirus and were redesignated to the genus *Phlebovirus*. The only evidence that Uukuniemi virus can infect man is the finding of specific antibodies in some human sera collected in Estonia and in the former Czechoslovakia. Zaliv-Terpeniya virus was isolated from bird ticks collected on an island in the Sea of Okhotsk, Sakhalin region, and there is some evidence that it may be pathogenic to man.

Sandfly fever, Naples, and Sicilian viruses

Symptoms

After an incubation period of 2 to 6 days, there is an abrupt onset of fever, chills, nausea and vomiting, epigastric pain, and often severe, generalized headache leading to incapacitating prostration. Fever of 38 to 40 °C usually resolves after 2 to 3 days, but may be biphasic and persist for a week. There is no rash, but small haemorrhages into the skin and mucous membranes may be seen. Photophobia and eye pain are not uncommon, lymphadenopathy is often seen, and the liver may be tender, although jaundice is rare. The disease is self-limiting, with complete recovery. No deaths have been attributed to either sandfly fever, Naples, or Sicilian viruses.

Rift Valley fever virus

Following its initial isolation in 1930 as the agent of enzootic hepatitis of domestic animals in Kenya, Rift Valley fever virus was recognized as the cause of sporadic human infections in East, Central, and West Africa, with a particular capacity to infect those handling the virus in the laboratory. In East and Central Africa the virus has been isolated from a variety of mosquito species and recent studies have shown that the virus is capable of persisting in mosquito eggs during the dry season, emerging when larvae hatch in the rainy season. From 1951 to 1956 there were severe epizootics in lambs in southern Africa, and many human cases occurred. Further human cases with several deaths were seen in South Africa in 1975, and a major outbreak occurred in East Africa following El Niño flooding in 1997 to 1998, apparently seeding a 'virgin soil' outbreak in Saudi Arabia and Yemen in 2000.

.In the Central African Republic in 1969 a virus isolated from *Mansonia africana* mosquitoes and named Zinga virus was associated with several cases of haemorrhagic fever; Zinga virus was later shown to be a strain of Rift Valley fever virus. In West Africa, Rift Valley fever virus was isolated from mosquitoes in Nigeria and from bats in Guinea, but despite the presence of antibodies in human sera collected in Nigeria and Senegal, human disease was unrecognized until 1987 when a substantial epidemic occurred in Mauritania, with further epidemics in following years. In 1977 the virus spread, apparently for the first time, into Egypt, producing a major epizootic in domestic animals, principally sheep and goats, but also cattle, and causing some 600 human deaths within a period of 3 months. The virus has been detected periodically since then in Egypt, and the principal vector seems to be the mosquito, *Culex pipiens*. It is of interest that both the Egyptian and the Mauritanian epidemics appear to be linked to major ecological changes following the construction of the Aswan Dam on the Nile and dams on the Senegal River.

Symptoms

After an incubation period of 3 to 6 days there is an abrupt onset of fever, shivering, nausea and vomiting, epigastric pain, and often severe, generalized headache. The fever may be biphasic, with temperatures between 38 and 40 °C, and may remain elevated for at least a week. There is no rash, but small haemorrhages into the skin and mucous membranes may be seen. Photophobia and eye pains are not uncommon; there may be conjunctival inflammation, and a central serous retinitis, leading to central scotoma and sometimes to retinal detachment. The fundus may show macular exudates that are slow to disappear. There is often a lymphadenopathy, and although the liver is frequently involved and may be tender, jaundice is rare, but appears to have been more common during the recent outbreaks in Mauritania. Convalescence may be protracted, but is usually uncomplicated; however, a small percentage of patients may suffer severe complications such as haemorrhagic fever, encephalitis, or eye lesions. Haemorrhagic disease presents as above, but progresses with petechial, mucous membrane, and gastrointestinal haemorrhagic, jaundice with severe liver and renal dysfunction often progressing to disseminated intravascular coagulation, hepatorenal syndrome, and may end in death. Patients with encephalitis typically recover from acute febrile disease only to present within a few days to 2 weeks later with headache, meningismus, confusion, and fever, often leading to residua or ending in death. Ocular complications are characterized by rapid onset of decreased visual acuity due to retinal haemorrhage, exudates, and macular oedema. These are also seen after apparent recovery from the initial disease. About half of these patients suffer some degree of permanent vision loss. Deaths from Rift Valley fever were rare before the 1977 outbreak in Egypt, but the Mauritanian epidemics in which at least 25 persons died with jaundice and haemorrhagic manifestations, and the recent East African and Arabian Peninsula outbreaks with several hundred suspect fatalities clearly establishes it as a life-threatening infection.

Control, treatment, and prognosis

Veterinary vaccines have been used for a number of years, and formalin-inactivated vaccines have also had limited use for the prevention of disease in laboratory workers and others exposed to high risk of infection. Improved vaccines based on molecular techniques are under development. Although there are no reports of nosocomial transmission, barrier nursing would be a sensible precaution.

Unassigned viruses and viruses causing only minor disease in man

The great majority of the viruses listed in Table 2 cause only a mild, febrile illness, but the following show certain additional features.

Bhanja virus (unassigned)

This virus was first isolated from *Haemaphysalis intermedia* ticks collected from healthy goats in India, but has since been isolated in Sri Lanka, in Africa, and in Europe. Infection of goats is widespread in Italy and in the former Yugoslavia, where there have been several reported human cases, including some with severe neurological disease, and at least two deaths. Laboratory infections have also occurred.

Bwamba virus (*Bunyavirus*)

This was first isolated in Uganda in 1941 and is very widespread throughout sub-Saharan Africa. More than 75 per cent of adult human sera collected in Nigeria and over 95 per cent of human sera collected in Uganda and Tanzania have antibodies against Bwamba virus. The original cases showed fever, headache, generalized body pains, and conjunctivitis, but no rash, although a rash has been described in the Central African Republic. No fatalities have been reported.

Nyando virus (*Bunyavirus*)

This virus was first isolated from mosquitoes in Kenya; it has since been isolated from man in the Central African Republic, where it caused fever, myalgia, and encephalitis.

Tataguine virus (unassigned)

This causes fever, rash, and joint pains in at least five African countries (Cameroon, Central African Republic, Ethiopia, Nigeria, and Senegal).

Wanowrie virus (unassigned)

This virus was first isolated in India from *Hyalomma marginatum* ticks collected from sheep. It has also been isolated in Egypt and Iran, and in Sri Lanka, where it was recovered from the brain of a 17-year-old girl who died following a 2-day fever with abdominal pain and vomiting.

7.10.15

Arenaviruses

Susan Fisher-Hoch and Joseph McCormick

General considerations

Ecology and epidemiology

Arenaviruses infect rodents in the New and Old Worlds. There are at least 15 arenaviruses but only five produce significant human disease (Fig. 1); Lassa, Junin, Machupo, Guanarito, Sabia and lymphocytic choriomeningitis virus (LCMV). Arenaviruses have coevolved over very long periods of time with their natural rodent host so that the distribution of a given virus is restricted to its host range. Further, division into Old World (LCMV, Lassa) and New World (Tacaribe complex) viruses based on geographic distribution and antigenic typing is endorsed by nucleocapsid sequencing data.

Fig. 1 World map showing the approximate distribution of arenaviruses.

Rodents normally experience silent, lifelong infection, with perinatal transmission. Lifelong viruria is the primary source of contamination of the environment. Human infection results from intrusion into the rodents' ecological niche or infestation of poor housing. The virus infects through skin lesions and possibly mucosae or rodent-urine-contaminated dust aerosol. Human-to-human spread is common for Lassa fever both in community and hospital settings, but is apparently rare with the other pathogenic arenaviruses. Disease may be severe and haemorrhagic and all the pathogenic arenaviruses require Biosafety Level 4 (BSL4), except LCMV (BSL3).

Virology

By electron microscopy, host-cell ribosomes included in the virion resemble grains of sand ('arena' = sand in Latin) (Fig. 2). They are enveloped, pleomorphic, membrane viruses 50 to 300 nm (mean 110–130 nm) in diameter with a virion density in sucrose of 1.17 g/cm^3. They contain two segments of single-stranded RNA, tightly associated with a nucleocapsid protein of 65 000 to 72 000 molecular weight. The large strand of ambisense RNA, of molecular weight 2.0 to 3.2 × 10 ^{6}, codes for the viral polymerase and a zinc finger protein. The small single strand of ambisense RNA, molecular weight about 1.1 to 1.6 × 10 ^{6}, encodes the glycoprotein precursor and the nucleoprotein. The genome is enclosed in a membrane bearing two glycosylated proteins of molecular weights 34 000 to 44 000 (G1) and 54 000 to 72 000 (G2), derived from glycoprotein precursor by post-translational cleavage. Antigenic cross-reactivity is conserved at least at one epitope across all known arenaviruses.

Old World arenaviruses

Lassa fever

Epidemiology

Distribution and ecology

Lassa fever was first described in West Africa in the 1950s, but not isolated until 1969. It occurs from Northern Nigeria to Guinea, an area with a population of perhaps 180 million. Its only known reservoir is *Mastomys natalensis*, one of Africa's commonest rodents. In southern Africa, a related *Mastomys* carries the closely related Mopeia virus which can infect humans but is unable to cause significant clinical disease. *Mastomys* are highly commensal with man. In some areas, 50 per

cent of domestic rodents may be *Mastomys*, averaging 2.4 animals per house, but they have limited movement within a village. Prevalence of Lassa virus infection is variable in *Mastomys* and tends to cluster in houses, so that infection is endemic but focal.

Lassa fever is the haemorrhagic fever most likely to occur in travellers returning to developed countries. In the year 2000, at least four cases were imported into Europe. Cases in foreigners in 2000 have been seen during peacekeeping efforts in Sierra Leone. The rebels' stronghold is at the centre of the Lassa fever endemic area.

Epidemiology

Lassa fever is the arenavirus which affects the largest number of humans. Over 200 000 infections occur annually, and several thousand deaths. All age groups and sexes are affected. Antibody prevalence increases with age suggesting that most virus transmission to humans takes place in and around the home. Antibody prevalence ranges from 4 to 6 per cent in Guinea, 15 to 20 per cent in Nigeria, and up to 60 per cent in some villages in Sierra Leone. Seroconversion to Lassa virus positive ranged from 5 to 22 per cent/year among seronegative Sierra Leonean villagers. Disease to infection ratios range from 9 to 26 per cent in Sierra Leone, and the proportion of febrile illness associated with seroconversion to Lassa virus from 5 to 14 per cent. Five to 8 per cent of infected people may be hospitalized, of whom 17 per cent may die if untreated. However, the case fatality for all Lassa virus infections (hospitalized and non-hospitalized, symptomatic and asymptomatic) may be as low as 2 per cent. In endemic areas, Lassa fever may account for 10 to 16 per cent of all adult medical admissions and about 30 per cent of adult deaths among medical admissions.

Transmission

Direct contact between virus contaminated articles and surfaces and cuts and scratches on bare hands and feet may be the most important and consistent mode of transmission in endemic areas. The sporadic pattern of human infection in the community does not suggest aerosol transmission. Nosocomial spread in hospitals is associated with inadequate disinfection and direct contact with infected blood and contaminated needles. Increasing and indiscriminate use of routine intravenous therapy in West African hospitals, along with inadequate needle and syringe care, led to large-scale epidemics. A prospective study in a hospital in an endemic area showed that simple but rigorous barrier nursing techniques can reduce the frequency of infection in hospital personnel handling Lassa fever patients. In London, none of 159 unprotected hospital contacts of a severely ill Lassa fever patient was infected. In developed countries, (United Kingdom and United States) in 1990, there were no secondary infections among 907 documented hospital contacts of infected patients (188 classified as high risk).

Risk factors

Rodent-to-human infection is strongly associated with indiscriminate food storage, and practices such as catching, cooking, and eating rodents. Person-to-person spread is common in households. Risk of infection in villages is associated with direct contact, nursing care, or sexual contact with someone during the incubation, acute, or convalescent phases of illness.

Clinical features

Incubation period and prodrome

Following an incubation period of 7 to 18 days, symptoms begin insidiously with fever, weakness, malaise, severe, usually frontal, headache, and a painful sore throat (Fig. 3). More than 50 per cent of patients then develop joint and lumbar pain and 60 per cent or more develop a non-productive cough. Severe retrosternal chest pain, nausea with vomiting or diarrhoea, and abdominal pain are also common.

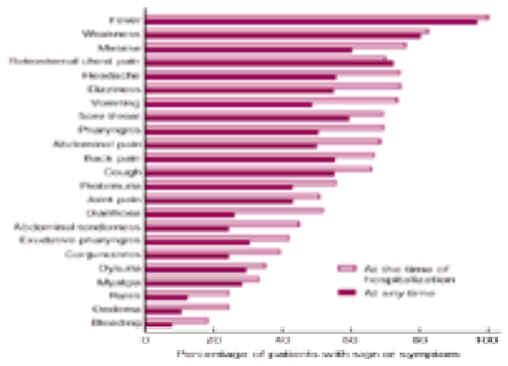

Fig. 3 Frequency of signs and symptoms of Lassa fever.

Respiratory and pulse rate and temperature are elevated and blood pressure may be low. There is no characteristic rash; petechiae and ecchymoses are not seen. About a third of patients will have conjunctivitis. More than two-thirds have pharyngitis, half with exudates, diffusely inflamed and swollen posterior pharynx and tonsils, but few ulcers or petechiae. The abdomen is tender in 50 per cent of patients. Neurological signs in the early stages are limited to a fine tremor, most marked in the lips and tongue.

Severe disease

Up to a third of hospitalized patients progress to a prostrating illness 6 to 8 days after onset of fever, usually with persistent vomiting and diarrhoea. Patients are often dehydrated with elevated haematocrit. Proteinuria occurs in two-thirds of patients, with moderately elevated blood urea nitrogen. About half of Lassa fever patients have diffuse abdominal tenderness without localizing signs or loss of bowel sounds. The severe retrosternal or epigastric pain seen in many patients may be due to pleural or pericardial involvement. Bleeding is seen in only 15 to 20 per cent of patients, restricted to mucosal surfaces, conjunctivitis, gastrointestinal, or genital tracts. Severe pulmonary oedema and adult respiratory distress syndrome is common in fatal cases with gross head and neck oedema, stridor, and hypovolaemic shock (Fig. 4).

Fig. 4 Acute Lassa fever in a patient showing facial oedema, decerebrate posturing, and respiratory distress. This patient survived.

Over 70 per cent of patients have abnormal electrocardiograms (non-specific ST-segment and T-wave abnormalities, ST-segment elevation, generalized low voltage complexes, and changes reflecting electrolyte disturbance), but none correlates with clinical or other measures of disease severity or outcome. There is no clinical evidence of myocarditis. Neurological signs are infrequent, but carry a poor prognosis, progressing from confusion to severe encephalopathy with or without general seizures, but without focal signs. Cerebrospinal fluid is usually normal, apart from a few lymphocytes, and low titres of virus relative to serum. Pneumonitis and pleural and pericardial rubs develop in early convalescence in about 20 per cent of hospitalized patients, sometimes associated with congestive cardiac failure.

Laboratory measurements

A normal mean white blood cell count on admission to hospital ($6 \times 10^9/1$) may mask early lymphopenia with relative or absolute neutrophilia, as high as $30 \times 10^9/l$. Thrombocytopenia is moderate, even in severely ill patients, but platelet function is markedly depressed. Serum aspartate aminotransferase levels greater than 150 U/l are associated with a case fatality of 50 per cent (Fig. 5). The ratio of aspartate aminotransferase to alanine aminotransferase is as high as 11:1. Prothrombin times, glucose, and bilirubin levels are nearly normal, excluding biochemical hepatic failure.

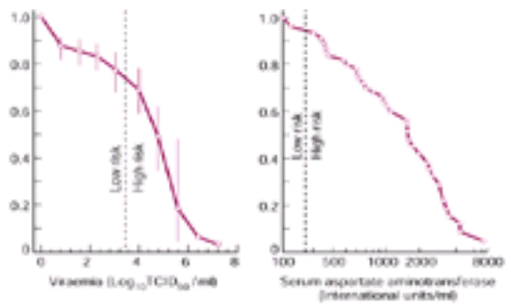

Fig. 5 Cumulative survival in Lassa fever related to serum viraemia and aspartate aminotransferase (AST) levels.

Viraemia of greater than 3 $\log_{10}$ $TCID_{50}$/ml is associated with increasing case fatality (Fig. 5). High virus titres occur in liver, ovary, pancreas, uterus, and placenta, but there is no histological evidence of organ failure. High viraemia and aspartate aminotransferase together carry a risk of death of nearly 80 per cent.

Mortality

The overall death rate for all infections may be as low as 2 per cent, but is about 16 per cent in hospitalized patients. In Nigeria, much higher death rates have been observed. The case fatality may be over 30 per cent in the third trimester of pregnancy, and 50 per cent in patients with haemorrhage.

Complications and sequelae

Nearly 30 per cent of patients develop uni- or bilateral-deafness beginning during convalescence. About half show a near or complete recovery after 3 to 4 months, but the other half remain permanently deaf. Many patients also exhibit transient cerebellar signs during convalescence, particularly tremors and ataxia. Infrequent complications are uveitis, pericarditis, orchitis, pleural effusion, ascites, and acute adrenal insufficiency. Renal and hepatic failure are not seen.

Lassa fever in pregnancy

Lassa fever is a common cause of maternal mortality in parts of West Africa. In the third trimester there is a two to three-fold risk of maternal death from infection. Very high levels of virus replication have been found in placental tissue. Mortality was reduced four-fold in women spontaneously or therapeutically aborted (OR for fatality with pregnancy intact 5.5). Fetal loss is as much as 87 per cent, and does not seem to vary by trimester. Lassa virus is present in the breast milk of infected mothers, and neonates are therefore at risk of congenital, intrapartum, and puerperal infection.

Lassa fever in children

Lassa fever is common in children, but may be difficult to diagnose. In very young babies marked oedema has been reported. In older children the disease may manifest as diarrhoea, pneumonia, or an unexplained prolonged fever. In a hospital in Sierra Leone, 21 per cent of paediatric admissions had Lassa fever, with 12 per cent fatality. An outpatient study found 24/435 children (6 per cent) with evidence of previous Lassa infection and 68 who seroconverted (16 per cent).

Differential diagnosis

The diagnosis of Lassa fever must be considered if there is a history of potential exposure to rodents or patients in or from West Africa. Cerebral malaria or septicaemia must be excluded but double infections can occur, particularly with malaria. In West Africa, fever with pharyngitis, proteinuria, and retrosternal chest pain had a predictive value for Lassa fever of 81 per cent and a specificity of 89 per cent. Likewise a triad of pharyngitis, retrosternal chest pain, and proteinuria (in a febrile patient) correctly predicted Lassa fever 80 per cent of the time (sensitivity 50 per cent). Bleeding and sore throat had specificity for fatal outcome of 90 per cent (sensitivity only 36 per cent). In contrast, vomiting and sore throat had a specificity of only 47 per cent for fatal disease (sensitivity 89 per cent).

Pathogenic processes

Pathogenesis

Arenaviruses invade through broken skin to lymph nodes, progressing to generalized multiorgan infection, affecting especially the reticuloendothelial system. In Lassa fever, severe disease manifestations are intractable hypovolaemic shock, and/or severe central nervous system involvement, bleeding, and oedema of the face. There is endothelial and platelet dysfunction, despite adequate numbers of circulating platelets.

Pathology

There is focal necrosis of the liver, but damage is insufficient to cause fatal hepatic failure. A substantial macrophage response is seen with little, if any, lymphocytic inflammatory response. Moderate splenic necrosis primarily involves the marginal zone of the periarteriolar lymphocytic sheath. Diffuse focal adrenocortical cellular necrosis has been less frequently observed.

Immunology

The immunological response is complex. While neutralizing antibodies are associated with clearance of viraemia due to the South American arenaviruses, Lassa and lymphocytic choriomeningitis viruses appear to depend primarily on cytotoxic T-cell responses. There appears to be a brisk B-cell response with a classic primary IgG and IgM antibody response to Lassa virus early in the illness. By the sixth day of illness IgG antibodies are found in 46 per cent of patients and IgM antibody in 59 per cent. By the sixteenth day of illness both are found in 100 per cent of patients, but this does not coincide with virus clearance. A high viraemia and high IgG and IgM titres often coexist in both humans and primates, and virus may persist in the serum and urine of humans for several months after infection, and probably in occult sites, such as renal tissue, for years.

In a minority of patients, some low titre serum neutralizing activity may be observed several months after resolution of the disease. Controlled clinical trials with human

convalescent plasma containing high titred antibodies have shown no protective effect. Thus the clearance of Lassa virus appears to be independent of antibody formation. In non-human primates, killed vaccine and vaccinia-vectored vaccines expressing the nucleoprotein elicited high level antibodies to Lassa virus but no protection, while vaccinia-vectored glycoprotein vaccine elicited little antibody, but nevertheless provided protection. Reinfection following natural Lassa infection may occur in humans, apparently without clinical disease.

Laboratory procedures

Diagnosis

Laboratory diagnosis is by isolation of virus from serum, demonstration of a four-fold rise in antibody titre, or high-titre IgG antibody with virus-specific IgM antibody in association with compatible clinical disease, or more recently by detection of viral sequences by reverse transcriptase polymerase chain reaction (RT-PCR), or by detection of viral proteins using an ELISA system.

Virus isolation may be accomplished easily from serum or tissues in cell cultures, but should be performed in BSL4 laboratory facilities. Specimens should be drawn into a vacuum tube to minimize risk of infection. Virus has also been isolated from breast milk, spinal fluid, pleural and pericardial transudate, and from autopsy material. Virus excretion in urine is intermittent but may persist. Antigen detection in conjunctival scrapings, buffy coat preparations, cells from pharyngeal aspirates, and urinary sediment have not been successful. ELISA tests have been notoriously difficult to calibrate in the field, particularly in West Africa. Newer serological tests include recombinant immunoblot techniques. Because of its superior sensitivity and specificity, where possible the ELISA should be used. Specific IgM, if detected early in disease, indicates acute infection. Antigen detection by ELISA and ELISA for IgM have recently been shown to have a specificity of 90 per cent and a sensitivity of 88 per cent compared with RT-PCR, but IgG was only detected in 16 per cent of the cases. A rising titre, with or without IgM, can be very useful in acute diagnosis. The RT-PCR or hybridization is much more rapid, and is as sensitive as virus isolation, and more sensitive than antigen detection by ELISA, and is the assay of choice for reference laboratories when a rapid diagnosis is needed. No commercial diagnostic reagents are currently available. BSL4 reference laboratories do not produce non-infectious reagents for use by other laboratories.

Containment and disinfection

Lassa virus is robust, and withstands drying. Blood from severely ill patients may contain 10^9 infectious units per ml, and rodent urine may contain 10^4 infectious units/ml. However, it can be inactivated by heat, detergents, chlorine, formalin, and UV radiation (including sunshine). Antigenic properties are best conserved by inactivation with gamma irradiation. Disinfection by washing with 0.5 per cent phenol in detergent (for example Lysol), 0.5 per cent hypochlorite solution, formaldehyde, or paracetic acid is recommended.

Patient management

Supportive care

Fluid, electrolyte, respiratory, and osmotic imbalances should be corrected, and full intensive care support, including mechanical ventilation offered if required. However, even vigorous support may be insufficient to prevent fatal progression of advanced disease. Pregnant patients often present with absent fetal movements, and survival may depend on aggressive obstetric intervention.

Antiviral therapy

Ribavirin (tribavarin) is effective but must be given early in disease. Ribavirin is given by intravenous infusion as a 2-g loading dose followed by 1 g every 6 h for 4 days then 0.5 g every 8 h for 6 more days. Toxicity is confined to mild reversible anaemia. A five to ten-fold decrease in the case–fatality ratio was demonstrated in patients treated with ribavirin compared with untreated patients when therapy was given within the first 6 days of illness. Patients with high aspartate aminotransferase and viraemia, risk factors for unfavourable outcome (Fig. 5), who were treated within the first 6 days of illness suffered a 5 to 9 per cent case fatality. Those with the same risk factors receiving treatment more than 6 days after the onset of illness had a 26 to 47 per cent fatality, compared with 52 to 78 per cent untreated. Ribavirin is contraindicated in early pregnancy because of potential terato-genicity, but the fetus rarely survives the infection. It has been used in late pregnancy (>24 weeks) but its efficacy has not yet been determined.

Prevention

Hospital containment

The key to prevention of human-to-human transmission is isolation of febrile patients and rigorous use of gloves and disinfection. Complete support, including intensive care, or surgery, should be provided. Patient isolators should not be used since they induce loss of manual dexterity and inhibit intensive care and communication. Recommendations issued for patient management and handling of clinical specimens from AIDS patients are adequate for containment of Lassa fever.

Contacts

High risk is associated with percutaneous or mucosal contact with blood or body fluids. Medium risk contacts (unprotected contact with blood or body fluids) may safely be observed for development of persistent high fever for 3 weeks from the last date of contact by daily temperature measurement and telephone reporting. The practice of following up airline passengers and other low risk contacts (no unprotected physical contact with patient or body fluids) is unnecessary.

Prophylaxis

Oral ribavirin should be offered to high-risk contacts as soon as possible after exposure to Lassa virus (600 mg orally, four times a day for 10 days).

Vaccine

A vaccinia virus recombinant expressing Lassa glycoprotein (G) protected primates from infection, but a nucleoprotein expressing recombinant did not. Immunization of primates with inactivated (gamma irradiated) whole Lassa virus resulted in brisk antibody responses to both proteins, but all animals died with serum virus titres equal to unvaccinated controls. In humans, the presence of antibody to neither glycoprotein nor nucleoprotein at the time of hospital admission was associated with survival, or even severity of disease.

Following Lassa virus challenge, high survival rates are seen after vaccination with vaccines expressing G, despite low or undetectable antibody levels preinfection. The duration of the interval between vaccination and challenge, and the challenge dose, affected the efficacy of vaccines. Almost all surviving, asymptomatic animals experienced viraemia, even those vaccinated with Mopeia virus (essentially a live, attenuated Lassa virus), consistent with the hypothesis that virus replication is controlled by CTL responses and not antibody responses. These data show that the G gene is necessary and sufficient to protect primates against a large parenteral challenge dose (Table 1).

Persistence

Lassa virus may persist at low titre for a limited time in primates, but virus is sequestered, and transmission is unlikely. Viraemia in patients is quickly controlled. However, virus may be detected intermittently in human urine for up to 60 days.

Control

Control of rodents would prevent Lassa fever in West Africa. Improvement of housing and food storage might reduce the domestic rodent population, but such

changes are not easily made without massive improvement in the local economy.

Lymphocytic choriomeningitis virus

Epidemiology

Distribution and ecology

Lymphocytic choriomeningitis (LCMV) virus was isolated in 1933 from the cerebrospinal fluid of a patient with suspected St Louis encephalitis. It is widely distributed in its natural host, *Mus musculus*. Transmission from feral rodents to humans rarely results in clusters of disease, and person-to-person spread has not been demonstrated. The virus has acquired scientific importance in laboratory studies of immunological tolerance and virus-induced immunopathological disease.

Epidemiology

The prevalence of antibody to LCMV virus in the general population is between 1 and 5 per cent. Sporadic disease in rural areas occurs during the colder months but in urban areas with large rodent populations the epidemiology may be different. In Baltimore, 4.7 per cent of those attending a sexually transmitted disease clinic had antibodies to LCMV.

Risk factors and transmission

Although feral mice cause sporadic infection, the most common sources of human infection are pet or laboratory rodents particularly hamsters, white mice, or nude mice. Laboratory outbreaks of human disease have followed contact with infected animals or virus, and aerosol transmission may have occurred.

Clinical features

Incubation period and disease

The incubation period is about 1 to 3 weeks. About 35 per cent of infections are asymptomatic, and a further 50 per cent have a febrile illnesses without significant central nervous system manifestations. About 15 per cent have lymphocytic choriomeningitis (disease to infection ratio 1:3). Illness begins with fever, malaise, weakness, myalgia, and headache, often severe, retro-orbital, and associated with photophobia. Anorexia, nausea, dizziness, and myalgia are common. Only two deaths have been reported, but there is prolonged convalescence.

Laboratory findings

Leucopenia and mild thrombocytopenia are common, and cerebrospinal fluid from patients with meningeal signs contains several hundred white cells, predominantly lymphocytes (>80 per cent), with slightly increased protein and occasionally low sugar levels. Virus is found in spinal fluid during acute disease.

Complications and sequelae

About one-third of patients with central nervous system manifestations will develop encephalopathy while the rest exhibit aseptic meningitis. An interstitial pneumonia, alopecia, orchitis, and transient arthritis of the hands have been described. Convalescence is prolonged with persistent fatigue, somnolence, and dizziness, and deafness. Neurological sequelae are unusual.

Differential diagnosis

LCMV should be considered in patients with fever with persistent meningeal signs, particularly if a history of rodent contact is elicited.

Pathogenic processes

Pathology

There are no published descriptions of the pathology of LCMV infection in humans. In one report of a fatal case there was perivascular macrophage infiltration in multiple areas of the brain. Antigen was observed in the meninges and cortical cells by IFA. In animal studies, the leptomeninges show dense infiltration with lymphocytic cells, with little involvement of the brain parenchyma.

Immunology

Antibody to LCMV appears in the first week of illness, with titres peaking at 40 to 60 days. In the natural host, the mouse, the immunology of natural and experimental infection has been extensively studied, but extrapolation to human disease needs to be made with caution.

Laboratory diagnosis

Virus may be cultured from cerebrospinal fluid or detected using RT-PCR during the acute phase of disease. IgG and IgM antibody may be detected in serum.

Patient management

There is no standard treatment for LCMV infection. Ribavirin is effective *in vitro*, but penetration into the cerebrospinal fluid is poor, however as the disease is severely debilitating its use should be considered.

Prevention

Laboratory outbreaks continue to occur, particularly through handling of persistently infected mice. The virus is a major laboratory hazard, and care must be taken to avoid infection. Exposure is too infrequent for there to be a market for a vaccine.

New World arenaviruses

The New World arenaviruses causing human disease are Junin (Argentine haemorrhagic fever), Machupo (Bolivian haemorrhagic fever), Guanarito (Venezuelan haemorrhagic fever), and Sabia (Brazilian haemorrhagic fever). The most important rodent hosts are the South American genera *Calomys*, *Sigmodon*, and *Oryzomys*. Together these are known as the South American haemorrhagic fevers. All are endemic in geographically limited areas, but new, related viruses are emerging in other yet unaffected areas. Between June 1999 and May 2000 three patients, two from southern California and a third from the San Francisco Bay area, died of an acute febrile illness with lymphopenia, thrombocytopenia, and acute respiratory distress syndrome. Two had liver failure and haemorrhagic manifestations. RNA fragments detected by PCR from all three patients shared 87 per cent identity with a recently described arenavirus from New Mexico, Whitewater Arroyo virus.

Argentine haemorrhagic fever

Epidemiology

Distribution and ecology

Argentine haemorrhagic fever was first recognized in the 1950s in the fertile farmland of north-western Buenos Aires Province in Argentina, and Junin virus was first isolated in 1958. The major rodent hosts are *Calomys musculinus* and *Calomys laucha* which, unlike *Mastomys* or *Mus*, are affected by the virus, with up to 50 per cent fatality in infected suckling animals, and stunted growth in many others. These are agrarian rodents, and most human cases are male agricultural workers, particularly harvesters of sugar cane.

Virology

Monoclonal antibody studies show Junin to be most closely related to Machupo and Tacaribe viruses, otherwise cross-reactivity with other New World arenaviruses is restricted to the nucleoprotein. Junin viruses comprise three clades depending on geographical origin, with the live attenuated Argentine haemorrhagic fever vaccine strain, Candid 1, a fourth, separate clade. No particular viral epitopes have been associated with varying severity or clinical forms of the human disease.

Epidemiology

About 21 000 cases have been reported since the early 1960s, averaging about 360 a year with wide annual fluctuations. Peak incidence is during summer and early autumn. The disease appeared to spread to new areas as incidence in the earlier affected areas decreased, possibly because of the virus' effect on rodent populations. Overall human antibody prevalence is about 12 per cent, with predominance in male agriculture workers, and about 30 per cent had no history of typical illness, (disease to infection ratio 2:3). The recent introduction of a live attenuated vaccine has dramatically reduced the incidence.

Transmission

The major routes of virus transmission to humans is probably through virus-infected dust, and mechanical harvesters are traditionally cited. Whether infection is through contamination of cuts and abrasions or mucosae or by aerosol is unclear. There is no recorded person-to-person spread. Recent studies have shown that the major host species, *Calomys musculinus*, is most frequently captured from roadsides and fence lines.

Clinical features

Incubation period and prodrome

After an incubation period of about 12 days, there is insidious onset of malaise, high fever, severe myalgia, anorexia, lumbar pain, epigastric pain and abdominal tenderness, conjunctivitis and retro-orbital pain, often with photophobia, and constipation. Nausea and vomiting frequently occur after 2 or 3 days of illness. There is no lymphadenopathy or splenomegaly, sore throat or cough, but there is high fever, marked erythema of the face, neck, and thorax, and conjunctivitis. Respiratory symptoms are uncommon. Petechiae appear by the forth or fifth days of the illness. There may be a pharyngeal enanthem, but pharyngitis is uncommon.

Severe disease

The infection either resolves after about 6 days or progresses to severe disease. In contrast to Lassa fever, South American haemorrhagic fevers are associated with haemorrhagic manifestations in nearly half of the patients (gingival haemorrhages, epistaxis, metrorrhagia, petechiae, ecchymoses, purpura, melaena, and haematuria). Severe cases have nausea, vomiting, intense proteinuria, microscopic haematuria, oliguria, and uraemia. Fatal cases develop hypotensive shock, hypothermia, and pulmonary oedema. Renal failure has been reported but glomerular filtration rates, renal plasma flow, and creatinine clearance are usually normal. There is some electrocardiographic evidence of myocarditis. Fifty per cent of Argentine haemorrhagic fever and Bolivian haemorrhagic fever patients also have neurological symptoms during the second stage of illness, such as tremors of the hands and tongue, progressing in some patients to delirium, oculogyrus, and strabismus. Meningeal signs and cerebrospinal fluid abnormalities are rare.

Laboratory findings

A low white blood cell count and a platelet count are invariable. Bleeding and clot retraction times are concomitantly prolonged. Though reductions of levels of Factors II, V, VII, VIII, and X and of fibrinogen are observed, alterations in clotting functions are usually minor. Disseminated intravascular coagulation is not a significant feature, despite some reports of the presence of fibrinogen degradation products and absence of fibrinolysis. Proteinuria is common and microscopic haematuria also occurs. Liver and renal function tests are only mildly abnormal. Virus titres in serum are not as high as in Lassa fever, but the infection is also apparently pantropic.

In a febrile patient, the combination of a platelet count of less than 100 000/mm ^{2} and a white blood cell count of less than 2500/mm ^{2} has a sensitivity and specificity of 87 per cent and 88 per cent respectively. The combination of a platelet count of less than 100 000/mm ^{2} and a white cell count of less than 4000/mm^2 has a sensitivity of 100 per cent and a specificity of 71 per cent. These criteria are now recommended for use in screening patients for potential therapy with immune plasma or ribavirin.

Mortality

Mortality is about 16 per cent in laboratory-confirmed, hospitalized patients with untreated Argentine haemorrhagic fever. There are no estimates of overall mortality in populations.

Complications and sequelae

A late neurological syndrome in about 10 per cent of cases, consisting mainly of cerebellar signs, is associated with treatment using high titre antiserum. It begins between 4 and 6 weeks after onset of acute illness and lasts less than a week. It is characterized by fever, headache, ataxia, and intention tremors, and a mild cerebrospinal fluid pleocytosis with anti-Junin virus antibody in the cerebrospinal fluid. Most patients recover within 3 months. Mild permanent damage to acoustic centres has been detected in a small group of patients. Argentine haemorrhagic fever is reported to be severe in pregnancy.

Pathogenic processes

Pathogenesis

Despite the different degrees of bleeding, there are sufficient similarities between the course of disease in Argentine haemorrhagic fever, Bolivian haemorrhagic fever, and Lassa fever to speculate that they share pathophysiological pathways. Organ function, other than the endothelial system, appears to remain intact, and the critical period of shock is brief, lasting only 24 to 48 h. Hepatitis is mild and renal function is well maintained. Bleeding is more pronounced but is not the cause of shock and death. Capillary leakage is significant, but the dramatic head and neck oedema characteristic of severe Lassa fever is absent. Proteinuria is significant, and dehydration important. Though petechiae suggest endothelial damage, no clear evidence of virus replication in endothelium has been demonstrated. Persistent hypovolaemic shock despite intravascular volume expanders suggest that this is due to leakage of fluid into extravascular spaces. Adult respiratory distress syndrome is not described, but tissue oedema is frequent and pulmonary oedema may follow vigorous intravenous fluid replacement.

Other observations include high levels of interferon in severely ill patients, and a decrease in complement. More recently, proinflammatory cytokines, namely interferon-a and tumour necrosis factor-a (TNF-a) and interleukins, IL6, IL8, and IL10, have been variably reported. A platelet inhibitor, which may be interferon-a, similar to that described in Lassa fever, has inhibitory effects on thrombin-induced aggregation and ^{14}C serotonin release. Raised G-CSF levels correlated with TNF-a and disease severity.

Pathology

There are large areas of intra-alveolar or bronchial haemorrhage, petechiae on organ surfaces, and ulcerations of the digestive tract, although bleeding is not

massive. Large areas of intra-alveolar or bronchial haemorrhage are often seen with no evidence of inflammatory process. Pneumonia with necrotizing bronchitis or pulmonary emboli is observed in half of the cases. Haemorrhage and a lymphocytic infiltrate have been observed in the pericardium, occasionally with interstitial myocarditis. Lymph nodes are enlarged and congested with reticular cell hyperplasia. Splenic haemorrhage is common, and medullary congestion with pericapsular and pelvic haemorrhages are frequently seen. Adrenal necrosis has not been reported. Renal damage occurs in about half of the fatal cases, and consists of severe structural damage in the distal tubular cells and collecting ducts with relative sparing of the glomeruli and proximal tubules. There is no evidence of direct viral central nervous system infection. Microscopically, there is mild oedema of the vascular walls, with capillary swelling and perivascular haemorrhage associated with viral antigen but no immunoglobulins. Electronmicroscopy shows intracytoplasmic and intranuclear inclusions and marked, non-specific cellular damage in all organs examined.

Immunology

In striking contrast to Lassa fever, the antibody response to Junin virus is effective in clearing virus during acute disease, and may also be sufficient to protect against infection. Neutralizing antibody may be detectable at the time the patient begins to recover from the acute illness, and the therapeutic efficacy of immune plasma in patients with Junin infection is directly associated with the titre of neutralizing antibody in the plasma given. This neutralizing antibody is directed towards the surface glycoproteins. Nevertheless, like Lassa, Junin virus may persist. In vaccine studies in Argentina, some people do not produce measurable neutralizing antibodies but do mount a Junin-virus-specific lymphocytic proliferative response. It is probable that both humoral and cellular immunity are important in limiting virus replication and thus in recovery and protection.

Differential diagnosis

Argentine haemorrhagic fever should be considered in patients in the endemic area, particularly male agricultural workers, who present with fever of unknown origin and a bleeding diathesis. No cases have been reported outside Argentina.

Laboratory diagnosis

Antibodies measured by IFA may be positive by the end of the second week of illness. Neutralizing and complement fixing antibody to Junin are usually detectable 3 to 4 weeks after onset. ELISA systems for antibody and antigen are described with sensitivity and specificity of 99.2 per cent and 98.8 per cent, respectively, but reagents are not generally available. Virus may also be cultured from serum, but this must be performed in BSL4 conditions. For acute diagnosis, RT-PCR on whole blood samples is now the method of choice with sensitivity of 98 per cent and specificity 76 per cent.

Patient management

Specific treatment

In contrast to Lassa fever, convalescent-phase plasma has been shown to be highly successful in Argentine haemorrhagic fever, reducing the mortality from 16 per cent to 1 per cent in patients treated in the first 8 days of illness. Viraemia is reduced within 24 h of treatment, and clinical symptoms and haematological alterations are less severe than in control cases receiving non-immune plasma. Efficacy is directly related to the concentration of neutralizing antibodies. Delayed treatment is less successful. Availability of appropriately screened plasma may be a problem. Ribavirin is effective in experimentally infected primates, and its therapeutic use late in disease is being explored. The late neurological syndrome of Argentine haemorrhagic fever may be associated with therapy, particularly very high titre immune plasma.

Prevention

The human–rodent encounter resulting in Argentine haemorrhagic fever occurs during crop harvests, and there are no means of controlling feral rodents. A successful live attenuated vaccine, Candid 1, for Argentine haemorrhagic fever has now undergone Phase III studies, and is in use in the endemic area of Argentina, where is has almost eliminated the disease. The vaccine has proved safe in large-scale trials, and has a protective efficacy of 84 per cent.

Bolivian haemorrhagic fever

Epidemiology

Bolivian haemorrhagic fever is caused by Machupo virus, first isolated in 1965, and is limited to a portion of the department of Beni in Bolivia. The only known reservoir is *Callomys callosus*, found in the highest density at the borders of tropical grassland and forest, in the eastern Bolivian plains, northern Paraguay, and adjacent areas of western Brazil. Infected rodents develop haemolytic anaemia and splenomegaly, with up to 50 per cent fatality among infected suckling animals, and stunted growth in many others. The virus renders *Calomys callosus* essentially sterile with the young dying *in utero*. Transmission from rodent to rodent is horizontal, not vertical, and is believed to occur through contaminated saliva and urine.

By 1962, more than 1000 cases had been identified in a confined area of two provinces. The largest known epidemic of Bolivian haemorrhagic fever, involving several hundred cases, followed a marked and unusual increase in the *Calomys* population in homes in the town of San Joaquin in 1963 and 1964. This seems to have been a unique event, and there have been virtually no cases until 1994, when there was an outbreak in north-eastern Bolivia. Since all ages and both sexes are affected, it can be assumed that most patients were infected in their homes. Person-to-person spread is rarely reported.

Virology

The sequence of the nucleocapsid protein of Machupo virus shows close relatedness to Junin and Tacaribe viruses. This, together with previous demonstrations of antigenic similarity and cross-protection, suggest that vaccines developed against Argentine haemorrhagic fever might also be effective against the Bolivian disease.

Clinical features

The incubation period, clinical disease, and pathology of Bolivian haemorrhagic fever closely resemble Argentine haemorrhagic fever. Initial symptoms include headache, fever, arthralgia, and myalgia. In the later stages of this illness, patients may develop haemorrhagic manifestations including subconjunctival haemorrhage, epistaxis, haematemesis, melena, and haematuria, as well as neurological signs including tremor, seizures, and coma. Case fatality in the 1960s was 22 per cent. Neurological sequelae are observed in experimentally infected primates. Diagnosis is made in the same way as for Argentine haemorrhagic fever. Machupo virus also induces a humoral immune response, which may include neutralizing antibody.

Treatment

During the 1960s, convalescent-phase immune plasma from survivors of Bolivian haemorrhagic fever was used. However, there is now a paucity of survivors of Bolivian haemorrhagic fever who can donate immune plasma, and there is no active program for collection and storage of Bolivian haemorrhagic fever immune plasma. In 1994, intravenous ribavirin was offered to two patients who both recovered without sequelae, but Machupo virus infection was only confirmed in one.

Prevention

The ideal method of prevention for these rodent-borne diseases is to prevent contact between rodents and humans. The effectiveness of this was admirably shown in the outbreaks of Bolivian haemorrhagic fever in the 1960s when rodent control programmes in the villages were highly successful in eliminating the epidemic situation. The Candid 1 vaccine used in Argentina has been proposed for use against infection with this virus.

Venezuelan haemorrhagic fever

Epidemiology

Guanarito virus, the aetiological agent of Venezuelan haemorrhagic fever, was first isolated in 1991. Person-to-person transmission is not reported, and is unlikely since there is low frequency of infection in family contacts and none in exposed hospital workers. That all ages and sexes are infected suggests transmission occurs in and around houses. Disease is endemic, without seasonal variation. There are no data on prevalence and risk factors for infection have not been identified. The cotton rat, *Sigmodon alstoni*, is now thought to be the principal rodent reservoir of Guanarito virus. Despite intensive surveillance, Venezuelan haemorrhagic fever has been detected in only the small region of western Venezuela where the first outbreak was seen.

Virology

Morphology and antigenic properties of Guanarito show it to be a new member of the Tacaribe complex with which it cross reacts broadly. Phylogenetic analysis of the nucleocapsid gene open reading frame showed that Guanarito virus is a genetically distinct arenavirus, with 32 per cent nucleotide sequence divergence ranging from 30 per cent (Junin) to 45 per cent (LCMV). This sequence region is a probable antigenic domain (amino acids 55–63) shared among all arenaviruses. Phylogenetic trees of rodent isolates delineate nine distinct Guanarito genotypes, most of which are restricted to discrete geographical regions. Human disease is not associated with a particular genotype or host rodent.

Clinical features

Little information is available but hospitalized patients with severe disease are described as febrile with prostration, headache, arthralgia, cough, sore throat, nausea/vomiting, and diarrhoea. Haemorrhage is manifest as epistaxis, bleeding gums, menorrhagia, and melaena. On physical examination, patients are toxic and usually dehydrated, with pharyngitis, conjunctivitis, cervical lymphadenopathy, facial oedema, or petechiae. Thrombocytopenia and neutropenia are common. The case fatality in 15 patients was over 60 per cent, but surveys suggest that overall mortality to infection ratio is much lower. Post mortem pathology included: pulmonary oedema with diffuse haemorrhages in the parenchyma and sub pleura; focal hepatic haemorrhages; cardiomegaly epicardial haemorrhages, splenic and renal swelling; and widespread bleeding into cavities. Like Argentine haemorrhagic fever and Bolivian haemorrhagic fever, antibodies to Guanarito virus appear later in the illness. The infection is likely to respond to ribavirin therapy, although no data are available.

Sabia virus

Sabia virus emerged in 1990 when it was isolated from a fatal case in São Paulo, Brazil. Subsequently, it caused two laboratory-acquired infections. Its natural distribution and host are still unknown. One incident involving a human exposure occurred in the Yale Arbovirus Research Unit on August 8, 1994 when a senior scientist was exposed to Sabia virus while purifying the virus from a large volume of tissue culture fluid. The patient treated himself immediately with ribavirin, and made a rapid and full recovery.

Molecular studies confirm that Sabia virus is distinct from all other members of the arenaviridae and shares a progenitor with Junin, Machupo, Tacaribe, and Guanarito viruses. It has a unique, predicted, three stem–loop structure in the S RNA intergenic region.

7.10.16 Filoviruses

Susan Fisher-Hoch and Joseph McCormick

Primary human infections with filoviruses are exceedingly rare. The first appearance of these viruses was in Marburg in 1967 when laboratory, medical, and animal care personnel exposed to tissues and blood from African Green monkeys were infected. A unique virus isolated from these patients had a strange, looped and branched filamentous form, hence filovirus. In 1976 and 1979, epidemics of a haemorrhagic disease with very high mortality in northern Zaire and in southern Sudan were found to be due to two strains of a related, yet distinct filovirus, named Ebola virus. Over the next 10 years rare, sporadic cases of filovirus infections in Africa were the only continuing evidence of the existence of these viruses. Their natural host and ecology remained elusive. In 1989, a filovirus was isolated near Washington, DC, from dying cynomolgus monkeys shipped to the United States from the Philippines. Since 1990, both Ebola and Marburg viruses have re-emerged in Central Africa causing several devastating epidemics.

Virology

Nucleotide sequence analyses now places the filovirus family in the order Mononegavirales. Filoviruses are among the largest known viruses, with highly variable length (up to 14 000 nm). They undergo rapid, lytic replication in the cytoplasm of a wide range of host cells. The virions are of uniform 80-nm diameter, with a helical nucleocapsid, consisting of a central axis, 20 to 30 nm in diameter, surrounded by a helical capsid, 40 to 50 nm in diameter, with 5-nm cross-striations. A host-cell membrane-derived layer with 10-nm projections in regular array surrounds the nucleocapsid.

The virions contain a single negative-strand RNA genome ranging from 4 to 4.5 $\times 10^{6}$ daltons. The RNA is a template for at least seven polypeptides, a nucleoprotein (N), a glycoprotein (G), a polymerase (L), and four other undesignated proteins (VP40, VP35, VP30, and VP24), two of which are associated with the nucleocapsid. The surface glycoprotein is heavily glycosylated. An abundant, but poorly glycosylated protein, VP40, and the nucleoprotein (N) are associated with the nucleocapsid. There is apparently close identity at the glycoprotein level among Asian filoviruses, but not African filoviruses.

Epidemiology

In 1967, epidemiological investigations revealed that 20/29 persons with blood contact with Marburg infected monkeys became infected, and four of 13 exposed to tissue culture. Five of the secondary cases resulted from person-to-person contact at home or in hospital. About 400 to 600 animals originating from four shipments reached Europe from Uganda over a 3-week period. Data on concurrent Belgrade enzootics showed an unusually high mortality characterized by ongoing transmission during 6 weeks quarantine; 46/99 animals died from a first shipment, and 20 and 30 from another two. No evidence could be found of epizootics in Uganda, but later some indirect, controversial information emerged that there had at that time of the outbreak been excess deaths in monkey colonies in islands near Lake Kyoga, north of Lake Victoria. Since then there were three isolated, primary human Marburg infections and two secondary cases in tourists or expatriate residents; one a traveller in Zimbabwe and two others from the Mount Elgon region of western Kenya, not far from the shores of Lake Victoria. Extensive epidemiological investigations in Zimbabwe and on Mount Elgon revealed no clues of the origin of these infections. In May 1999, an outbreak of Marburg virus disease occurred in Watsa and Durba in eastern Democratic Republic of Congo. There were an estimated 76 cases with 52 deaths in miners and their families. The common risk factor in miners was illegally entering and working in an officially closed gold mine in an area with major rebel fighting and in which investigations proved difficult and dangerous. Since then, sporadic reports suggest that the suspect outbreak may be ongoing.

Nearly a decade after the Marburg outbreak, simultaneous outbreaks of another lethal haemorrhagic fever struck in northern Zaire (Republic of Congo) and Sudan in 1976. Two more filoviruses were isolated, Ebola (Zaire) and Ebola (Sudan); 280 deaths among 318 probable or confirmed cases were identified in Zaire (case fatality 88 per cent). The index case may have been a recent traveller in the northern Equateur region of Zaire who visited the clinic of a mission hospital in Yambuku. The subsequent nine cases, however, had all received treatment for other diseases at the hospital. The major risk factor was receiving an injection at this hospital. Eleven of the 17 staff members of the hospital died, and the outbreak only terminated when the hospital was closed. There was subsequent dissemination in surrounding villages to people caring for sick relatives, attending childbirth, or through sexual intercourse. The following year, 1977, a single fatal case was identified in Tandala, also in northern Zaire. Also in 1976, an outbreak of a similar disease occurred in southern Sudan, with the index case in a single cotton weaving factory. There were 151 deaths among 284 cases identified (case fatality about 53 per cent). The focus of the infection was in the town of Nzara where the factory was located, and spread was to close relatives. The epidemic was augmented by high levels of transmission at nearby Maridi hospital following transfer of one of the Nzara patients, and further cases transferred to Juba and Khartoum. There were 203 cases in Maridi, 93 of which were probably infected in the hospital and 105 in the community. Forty one staff members died, and at the height of the epidemic all wards contained patients with overt haemorrhage. In 1979, there was a similar outbreak in Sudan when 22 of 34 infections (65 per cent) were fatal. Though closely related, the viruses from Zaire and Sudan were found to be distinct. The two virus strains isolated in Sudan in 1976 and 1979, however, are identical.

A large outbreak of Ebola virus disease caused by the Zaire strain occurred in 1995 in Kikwit, Democratic Republic of Congo, resulting in 315 cases with 81 per cent case fatality. Eighty cases (25 per cent) occurred among health-care workers, and the epidemic centred again around the hospital with secondary spread in the community. The outbreak was terminated by the initiation of barrier-nursing techniques, health education efforts, and rapid identification of cases

In 1994 and 1995, 49 patients with haemorrhagic symptoms were hospitalized in north-eastern Gabon. Two other epidemics (spring and fall 1996) occurred in the same province, one of which was the result of contact of a number of young people with the carcass of a dead chimpanzee. This chimpanzee was later cooked and eaten. Infection was associated with handling the carcass or meat of the dead animal, but was not associated with eating cooked meat. A single case, infected with a closely related strain, occurred in a veterinarian working in Côte d'Ivoire. In 2001 further outbreaks occurred in Gabon.

Sudan virus Ebola haemorrhagic fever re-emerged in Uganda in August 2000 in a widespread epidemic which only terminated in January 2001; 425 presumptive cases were recorded from three districts in an estimated population of 1.8 million. The first cases came apparently from rebel areas, and no information is available on the source of this outbreak. There were 224 deaths (case fatality 53 per cent); 29 health-care workers were infected. Infection of 14/22 health-care workers after establishing isolation wards required reinforcement of infection control measures. Two distant focal outbreaks in Uganda were initiated by movement of infected contacts.

In 1989 and early 1990, a filovirus closely related to Ebola virus was isolated from cynomolgus monkeys recently imported from the Philippines (in quarantine facilities in Reston, Virginia, in Texas and in Pennsylvania) into the United States. No link with Africa or African animals could be identified and this must be considered at present an Asian filovirus. Pathogenicity for cynomolgus monkeys was uncertain because of a high rate of concurrent infection with Simian haemorrhagic fever virus (SHFV), a DNA virus which is a known, severe simian pathogen unrelated to the Filoviridae. Evidence for ongoing epizootics and transmission was found in the Philippine export facilities which had provided the monkeys. Further importations of infected monkeys into Italy and the United States have occurred since 1990.

In the Philippines, there was no illness in any individuals associated with infected monkeys, and no association between seropositivity and other risk factors, such as bites, scratches, or eating monkey meat. In the facility at Reston, Virginia, five animal handlers had a high level of daily exposure to infected and dying animals, and four of these developed antibodies. One cut his finger while performing a necropsy on an infected animal. Daily monitoring of this individual revealed transient

viraemia and seroconversion, but neither he nor his colleagues had any illness attributable to filovirus infection.

Ecology

Transmission from the unknown natural reservoir to humans is rare. Searches for evidence of virus infection in many species of animals captured in central African countries have failed to provide any clues. Bats remain highly suspect, since they were indirectly implicated in the Kitum cave cases of Marburg disease and were also present in the sugar cane-processing factory where the index cases of both 1970s Sudan outbreaks worked.

Transmission and risk factors

Person-to-person spread has been the major mode of transmission in epidemics, with contact with patients ill with Ebola is the most important factor. Other risk factors are contaminated needles, blood or secretions, preparation of a body for burial, or, occasionally, sexual contact. Epidemiological studies do not suggest spread through casual contact or by aerosol transmission. The mode of acquisition of primary infection is totally unknown.

The most significant risk factor for the monkeys infected in the epizootic in the Philippines was being an occupant of a gang cage (six-fold increase of risk, $p < 0.001$, OR 5.96, 95 per cent CI 2.87–12.38). Ebola (Reston) has been identified at high titre in respiratory secretions in monkeys, and respiratory transmission at close quarters may be a factor in epizootics with this virus.

Laboratory infections and bioterrorism

The outbreak of Marburg virus in 1967 was in individuals handling fresh monkey tissues or contaminated equipment without gloves or other protective clothing. Otherwise there has only been one reported laboratory-acquired infection (needlestick) with Ebola virus in 1976. Because of its lethal potential, Ebola has been a candidate for biological warfare. Little information is available, but it has been handled extensively in biological research, and further accidental infections are said to have occurred with the death of one scientist in a laboratory in the former Soviet bloc. The key to safe laboratory handling of this virus is extreme care in avoiding accidental inoculation. Ebola has been named as a candidate for biowarfare or bioterrorism, but without extensive biological modification it is unsuitable for dissemination in this way.

Disease

Marburg and Ebola diseases are clinically indistinguishable. The incubation period is 3 to 10 days, shorter with needle transmission. The illness-to-infection ratio is high, though it is clear that asymptomatic infections occur. In contrast Ebola (Reston) virus is uniformly asymptomatic.

Onset is abrupt with fever, severe headache, myalgia, arthragia, conjunctivitis, and extreme malaise. Sore throat is often associated with severe swelling and dysphagia, but no exudative pharyngitis. A papular, eventually desquamating rash may occur. In non-human primates, petechiae are striking. Abdominal pain and cramping followed by diarrhoea and vomiting develop on the second or third day of illness. Jaundice is not a feature. There is invariably biochemical evidence of hepatic disease with elevated aspartate transaminase (AST) levels maximal by day seven of illness. Bilirubin is not elevated, and alanine transaminase (ALT) is disproportionately low. Bleeding begins about the fifth day of illness, most commonly from the mucous membranes. Death is associated with hypovolaemic shock and severe bleeding. Infection in pregnancy results in high maternal fatality and virtually 100 per cent fetal death. Central nervous system involvement has led to hemiplegia and disorientation, and sometimes frank psychosis. Even in convalescence, patients show prolonged weakness, severe weight loss, and in a few survivors serious but reversible personality changes are recorded, namely confusion, anxiety, and aggressive behaviour. Blindness has been recorded as a sequel.

Ten of the 29 known primary Marburg infections died (35 per cent). No fatalities occurred among the 10 secondary cases, overall mortality was 10/39 (25.6 per cent). The mortality ratios during the two epidemics of Ebola disease in Sudan were 55 and 65 per cent, while that during the Zaire epidemic in 1976 was 88 per cent. In the Kikwit epidemic of 1995, mortality was 81 per cent, and in Uganda in 2000, 53 per cent, though it was much higher in children (80 per cent).

Animal models

The monkey has been the most successful animal used for the study of Marburg and Ebola viruses, and has been used extensively for the study of pathogenesis of filovirus infection.. The ability of any of the viruses to kill guinea pigs is variable. Ebola (Zaire) kills guinea pigs consistently after several adaptive passages, the Sudan variant and Marburg virus do not. Only the Zaire virus is lethal for suckling mice.

Pathogenesis and immunopathogenesis

High titres of virus are found in serum and tissues taken at autopsy, and particles may be seen in large numbers with some obvious tropism for reticuloendotheial cells. The most profound physiological alteration, invariably associated with death, is hypotensive shock. Fatal infection is marked by absent specific IgG and barely detectable IgM, whereas in survivors early and increasing levels of Ebola-specific IgG against viral nucleoprotein (NP) and 40-kDa viral protein (VP40) is followed by activation of cytotoxic T cells. In fatal cases, DNA fragmentation in blood leucocytes and levels of 41/7 nuclear matrix protein in plasma indicate that massive intravascular apoptosis proceeds during the 5 last days of life. In survivors, upregulation of FasL, perforin, CD28, and IFNg messenger (m)RNA in peripheral blood mononuclear cells coincide with clearance of circulating viral antigen. In survivors there is also early activation of T cells, evidenced by mRNA patterns in peripheral blood mononuclear cells and marked release of IFNg in plasma. It is clear that events very early in Ebola virus infection determine control of viral replication, apoptosis of immune cells and possibly other cells, and recovery or death.

Bleeding is prominent, manifest as petechiae, uncontrolled bleeding from venepuncture sites and haemorrhagic effusions. Thrombocytopenia is invariable but bleeding is not usually of sufficient volume to account for the shock, nor is it associated with solid evidence of disseminated intravascular coagulation (DIC) in the small number of animals or humans studied so far, although much has been written about DIC in Ebola and Marburg disease. As in Lassa fever, platelet dysfunction has been described in experimentally infected primates, in which there is a decline in *in vitro* platelet aggregation beginning 1 to 3 days prior to the onset of bleeding and shock and progressing to virtually no aggregation at death. Liver enzymes (AST and ALT) are raised, but the rise in AST is disproportionately higher than ALT, as was described in the early Marburg cases.

At autopsy both Marburg and Ebola infected humans and primates show widespread haemorrhagic diathesis into skin, membranes, and soft tissue. There is focal necrosis in liver, lymph nodes, ovaries, and testis. Most prominent are eosinophilic inclusion bodies in hepatocytes (Councilman-like), without significant inflammatory response.

Several individuals in direct contact with blood or infectious secretions during two outbreaks in Gabon did not develop symptoms, but seroconverted with IgM and IgG between 2 and 4 weeks following exposure. Acute Ebola infection was confirmed by detection of viral genomic (negative-stranded) RNA in peripheral blood mononuclear cells for 2 weeks after exposure, together with positive-stranded viral RNA, indicating viral replication. These individuals mounted an early, strong inflammatory response, with high levels of IL-1a, IL-6, TNFa, MCP-1, and MIP-1a/b, but without evidence of an immediate T-cell response. This unexpected observation suggests that the early inflammatory response is able, in some individuals, to control viral replication and disease.

Diagnosis

Care should be taken in both drawing and handling blood specimens since virus titre may be extremely high, and the virus is stable for long periods even at room temperature. Sera may be safely handled for immunological tests by inactivating with gamma irradiation, or, if this is unavailable, heating for 60°C for 30 min. High or rising titre filovirus-specific IgG is diagnostic as is the presence of IgM by IFA. An antigen detection ELISA system has been found to be of considerable use in monitoring epidemics and epizootics. Virus may be isolated and identified within 2 to 3 days if suitable containment facilities are available. Polymerase chain reaction (PCR) assays are available for acute diagnosis.

Immunofluorescent antibody tests (IFA) used for serological studies is unreliable at low-titre or in the absence of a history of clinical disease. Antibody, sometimes with high prevalence, has been reported in monkeys and humans from many geographic locations, including unlikely populations such as Cona Indians from Central

America and Alaskans. Newer generation tests using recombinant antigens appear to have reduced the number of non-specific reactions whilst retaining sensitivity.

Patient management

Fluid, electrolyte, respiratory and osmotic imbalances should be managed carefully. Patients may require full intensive care support, including mechanical ventilation, along with blood, plasma, or platelet replacement. The maintenance of intravascular volume is a particular challenge but every effort is justified since the crisis is short lived, and complete recovery can be expected in survivors. There is no specific therapy, and the value of immune plasma is unproven.

Control

Since the reservoir(s) of the viruses are not known, no specific precautions can be identified which would avoid infections from the natural source of the viruses. Interruption of person-to-person spread of the virus is essential to control. Early institution of safe and orderly care of the ill should be set up with effective surveillance of high-risk contacts and prompt isolation of further cases.

Vaccine

Recent vaccine candidates have been described in animal studies, including a DNA vaccine which protected guinea pigs and monkeys. Human vaccines are not available at the time of writing, but may become so shortly.

Papovaviruses

K. V. Shah

General description

Papovaviruses are small, spherical, non-enveloped, doubled-stranded DNA viruses that multiply in the nucleus. Viruses of the papovavirus family infect a wide variety of species including man and are largely host specific. They fall naturally into two subfamilies, papillomaviruses (wart viruses) and polyomaviruses. Papillomaviruses and polyomaviruses differ in many significant ways. The genetic information of papillomaviruses is carried on only one DNA strand but that of polyomaviruses is distributed over both strands. Papillomaviruses infect surface epithelia and produce disease at these sites. Polyomaviruses are carried by viraemia, after initial multiplication at the site of entry, to affect internal organs such as the kidney and the brain. Viruses of both subfamilies produce experimental tumours in laboratory animals but only papillomaviruses are related to naturally occurring cancers. Within each subfamily the viruses are immunologically related and share nucleotide sequences but the two subfamilies are distinct.

More than 100 human papillomaviruses have been recognized, 35 types infecting mucous membranes (genital and respiratory tracts, and the oral cavity). Human papillomaviruses are the aetiological agents of skin warts, genital warts, respiratory papillomatosis, and papillomas at other mucosal sites (e.g. mouth, eye). Infection with some genital tract human papillomaviruses causes cervical cancer, one of the most common female malignancies in the world. Human papillomaviruses contribute to cancers at other sites.

Two polyomaviruses, BK virus and JC virus, infect man. JC virus is the aetiological agent of progressive multifocal leucoencephalopathy, a fatal demyelinating disease of immunodeficient people. Because of the emergence of AIDS, it is now more frequent and is found in younger people. BK virus is associated with haemorrhagic cystitis in bone marrow transplant recipients, and with renal failure in renal transplant recipients.

Human papillomaviruses (HPVs)

Human papillomaviruses cannot be propagated in tissue culture and require nucleic acid hybridization assays for their identification. Their double-stranded circular genome contains about 8000 base pairs, divided into an early region, necessary for transformation, a late region, encoding for capsid proteins, and a regulatory region, containing control elements (Fig. 1). Open reading frames of the viral genome are located on one strand: E1 to E8 in the early region and L1 and L2 in the late region. The functions assigned to the different open reading frames are listed in Table 1.

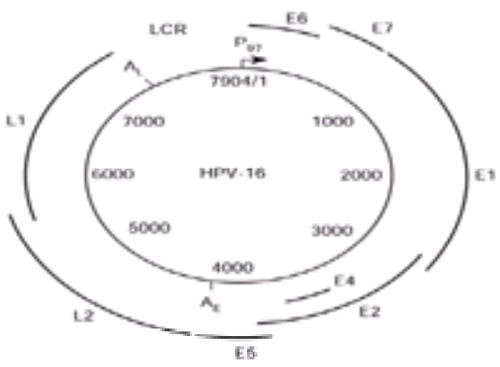

Fig. 1 Genomic map of HPV-16. On the inner circle, P97 represents the transcriptional promoter and A_E and A_L designate early and late polyadenylation sites. The location of the early-region open reading frames (E1–E8), the late-region open reading frames (L1, L2), and of the long control or regulatory region (LCR) are shown. (Reproduced from Shah and Howley (1990), with permission.)

Human papillomaviruses only infect humans. They show a marked degree of cellular tropism. Mucosal human papillomaviruses do not readily infect cutaneous epithelia and cutaneous human papillomaviruses are rarely present on mucous membranes. Infection is initiated when, after minor trauma (e.g. during sexual intercourse or after minor skin abrasions), the basal cells of the epithelium come in contact with infectious virus particles. The virus stimulates the proliferation of basal cells. The early-region open reading frames are expressed in all layers of the infected epithelium, but expression of the late-region open reading frames and synthesis of viral particles occur only in the upper differentiating and keratinizing layers.

Important disease associations and characteristics of mucosal HPVs are listed in Table 2; the genital tract is the reservoir for all but a few mucosal human papillomaviruses and genital human papillomavirus infections constitute the most common viral sexually transmitted disease. Genital human papillomaviruses may sometimes infect non-genital mucosal sites, for example, the respiratory tract, the mouth, and the conjunctiva. Transmission of genital tract HPV types 6 and 11 from an infected mother to the baby at birth results in juvenile onset recurrent respiratory papillomatosis. Infection with two types, HPV-13 and HPV-32, appears to be confined to the mouth.

Table 3 lists disease associations of cutaneous HPVs, transmitted by direct contact with infected tissue or by contact with a contaminated object.

Anogenital warts*

Anogenital warts (condylomas) are the most commonly recognized clinical manifestations of genital HPV infections. More than 90 per cent of condlyomas result from infections with HPV-6 and HPV-11. It is estimated that in the United States there are more than a million annual consultations with private physicians for anogenital warts.

Epidemiology

Genital and anal warts are most common between the ages of 16 and 24 years. They are transmitted by direct sexual contact to 60 per cent of sexual partners of

people with genital warts. Rarely, genital lesions are secondary to common warts on non-genital areas. Both anogenital warts and laryngeal papillomatosis may occur in children whose mothers had vulval warts at the time of delivery. Anogenital warts in children can also be due to close but non-sexual contact within a family or can be secondary to common skin warts, but in many cases sexual abuse by an infected adult is responsible.

Clinical features

The incubation period is between 3 weeks and 8 months (mean 2.8 months). In men, condylomata acuminata (exophytic condylomas) most often appear on areas exposed to coital trauma—the glans penis, coronal sulcus, prepuce, and terminal urethra. The soft fleshy vascular tumours are usually multiple and may coalesce into large masses (Fig. 2). Sessile or papular warts are more likely to occur on dry areas such as the shaft of the penis (Fig. 3). The raised pink or grey lesions, 0.5 to 3 mm in diameter, may occur alone or with exophytic condylomas. Subclinical HPV lesions (flat condylomas) are identiified by examining the genitalia with magnification after the application of 5 per cent aqueous acetic acid solution. The affected areas are slightly raised and shiny white (acetowhite), with a rough surface (Fig. 4). Flat condylomas affect the same areas as exophytic condylomas.

Fig. 2 Condylomata acuminata (exophtic condylomas) of the penis.

Fig. 3 Sessile (papular) warts of the penis.

Fig. 4 Subclinical HPV lesions (flat condylomas) of the penis after application of 5 per cent aqueous acetic acid.

Perianal warts are usually exophytic and in moist conditions around the anus may reach a large size. In 50 per cent of cases, condylomas also appear in the anal canal (Fig. 5). Areas of acetowhite epithelium indicative of subclinical HPV infection may be associated with perianal warts or occur alone.

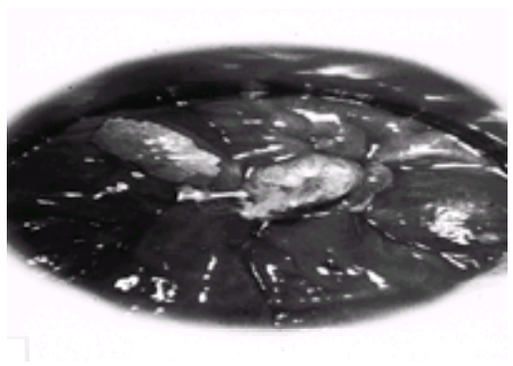

Fig. 5 Condylomata acynubate of the anal canal in an anoreceptive homosexual man.

In women, exophytic condylomas are the most common HPV lesions (Fig. 6). They appear at the fourchette and adjacent areas, and may spread to the rest of the vulva, the perineum, anus, vagina, and cervix. Multiple sessile warts may affect the labia and perineum. Subclinical HPV infection presents as slightly raised acetowhite lesions: the fissuring of these may cause dyspareunia. About 15 per cent of women with vulval warts have exophytic condylomas on the cervix. Subclinial infection is more common, and consists of acetowhite lesions with punctation due to capillary loops, which can be identified by colposcopy (Fig. 7). Large, exophytic vulval condylomas may develop during pregnancy and may become so large that they compromise delivery. Most regress postpartum.

Fig. 6 Condylomata acuminata of the vulva.

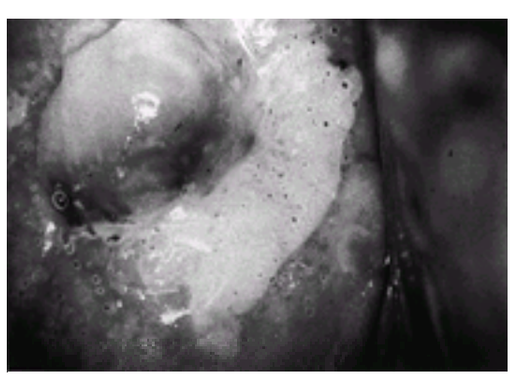

Fig. 7 Subclinical HPV infection of the cervix.

Intraepithelial neoplasia comprises Bowen's disease, bowenoid papulois, and carcinoma *in situ*. They may be associated with genital warts but contain sequences of HPV-16 or HPV-18 and may become malignant.

Diagnosis and management

Genital warts must be distinguished from Fordyce's spots, fibroepithelial polyps, molluscum contagiosum, and the papillar lesions of secondary syphilis. Intraepithelial neoplasia may be difficult to distinguish; lesions that appear atypical or respond poorly to treatment must be biopsied early.

Associated sexually transmitted diseases must be excluded. Sexual partners should be examined. Intraepithelial neoplasia must be excluded. Cervical cytological examination should always be done on women with vulval warts and on female partners of men with penile warts.

No specific antiviral treatment is available. The application of podophyllin or other cytotoxic agents, such as 5-fluorouracil and tricloracetic acid, is often unsuccessful. Warts may be destroyed with cryotherapy by liquid nitrogen or a nitrous oxide cryoprobe, electrocautery, electrodessication, and scissor excision. Interferons have been used in the treatment of persistent anogenital warts. A topical cream, which can be self-administered and is immunomodulatory, has become available recently for the treatment of genital warts.

Cervical cancer (see Chapter 21.5)

Human papillomavirus DNAs are recovered from more than 90 per cent of cases of invasive cervical cancer and squamous intraepithelial lesions of the cervix, which precede invasive cancer. The viral genome is present in the tumour cells of primary as well as metastatic cervical cancer. The progression from low-grade squamous intraepithelial lesions to invasive cancer may take more than 10 years; human papillomaviruses are found throughout this disease process. The viruses are recovered much less frequently from cytologically normal women of comparable age. In prospective studies of women with normal cervical cytology, the presence of HPV is a strong risk factor for the subsequent development of squamous intraepithelial lesions.

Certain HPV types are preferentially associated with invasive cancers. From their distribution in normal individuals and in preinvasive and invasive cervical disease, genital tract HPVs have been categorized as 'high-risk', 'intermediate-risk', and 'low-risk' types (Fig. 8; Table 2). HPV-16 and HPV-18 are the predominant viruses in invasive cancers and account for 40 to 60 per cent and 5 to 20 per cent, respectively, of HPV-positive cancers in different studies. About a dozen additional types of HPV are found in small proportions of invasive cancers. The 'low-risk' HPVs are almost never detected in invasive cervical cancers.

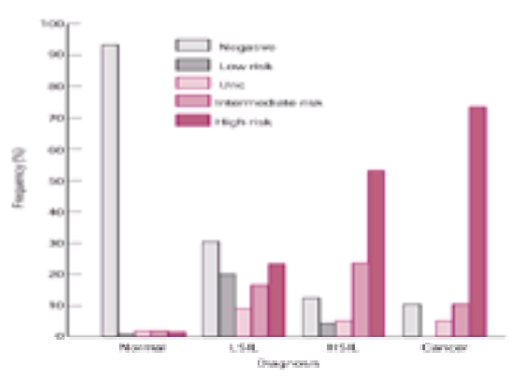

Fig. 8 Distribution of HPV types in normal women and in preinvasive (low-grade and high-grade squamous intraepithelial lesions (SILs)) and invasive cancer. In each diagnostic category, specimens are grouped as containing high-risk, intermediate-risk, and low-risk HPV types (see Fig. 8; Table 2), or as containing unclassified HPVs (Unc), or as negative (Neg). (Modified and reproduced from Lörincz *et al.* (1992), with permission.)

Comparisons of different HPV types for their ability to transform human keratinocytes *in vitro* show that HPV-16 and HPV-18, those most clearly associated with naturally occurring cervical cancers, also have the greatest oncogenic potential in laboratory studies. The transforming functions of HPVs are localized to open reading frames E6 and E7; these are the frames consistently expressed in naturally occurring HPV-positive cancers. The viral genome is integrated into the cellular DNA in most cervical cancers. The break in the circular viral genome that is required for integration occurs most frequently in the E1/E2 region and results in an enhanced expression of the transforming E6 and E7 open reading frames. The transforming HPV proteins E6 and E7 interact with cellular tumour-suppressor proteins p53 and Rb, respectively. It is likely that the oncogenic effect of HPVs is mediated partly by their ability to inactivate the tumour-suppressor proteins which normally regulate the cell cycle.

Epidemiology

Human papillomavirus infections of the genital tract are extremely common in sexually active populations. In young sexually active women, prevalence of HPV

infection as measured by the detection of HPV DNA in genital tract specimens by the sensitive polymerase chain reaction may be greater than 40 per cent. The prevalence decreases with increasing age. Most of these infections are found in women with normal cervical cytology and undoubtedly resolve without leaving a trace. Only a small proportion of infections progress to squamous intraepithelial lesions and then to invasive cancer. The cofactors that might be required for this progression are not conclusively identified, but smoking, use of oral contraceptives, parity, presence of other sexually transmitted diseases, and diet are incriminated to some degree, in some studies. Human immunodeficiency virus infection, and associated immunosuppression, leads to a much higher prevalence, and longer persistence, of HPV infections and to greater incidence of squamous intraepithelial lesions.

Prevention and control of cervical cancer

Screening for cervical cytological abnormalities by Pap smear and treatment of preinvasive and invasive cancers identified by screening have been credited with the decrease in incidence of cervical cancer and mortality due to the disease that has been observed in many developed countries over the last 40 to 50 years. The recognition that HPVs are linked aetiologically to cervical cancers has led to the exploration of HPV-based strategies for prevention and control of cervical cancer.

Clinical management

Women who have cytological abnormalities which are low grade or of uncertain significance may benefit from an HPV diagnosis. The presence of cancer-associated HPVs (high risk plus intermediate risk) would indicate a need for closer monitoring and colposcopy; HPV-negative women would be monitored routinely.

Prophylactic vaccines

Tests in rabbits, cattle, and dogs show that immunization of these animals with conformationally correct L1 capsid protein of their respective papillomaviruses protects them against papillomavirus-induced disease. Vaccines based on HPV L1 proteins have been formulated and tested in human volunteers to evaluate their safety. It is anticipated that the efficacy of these vaccines will soon be tested in clinical trials.

Therapeutic vaccines

Human papillomavirus-associated cancers express HPV E6 and E7 proteins in their tumour cells. Candidate therapeutic vaccines targeted to these proteins are being developed for the treatment of high-grade squamous intraepithelial lesions and invasive cancer.

Cancers at other lower anogenital tract sites

Human papillomavirus infections are very common on the vulva, vagina, penis, perineum, and anus. Synchronous neoplasia at multiple sites in the female lower genital tract is almost always associated with HPVs, especially HPV-16. Carcinoma of the vulva is aetiologically heterogeneous. Vulval cancers occurring in younger women are associated with HPVs but the typical squamous cell carcinoma of the vulva in older women is not. Neoplasia of the anal canal, seen frequently in HIV-seropositive homosexual men, is strongly associated with HPVs.

Cancer of the oropharynx

Some pharyngeal cancers, especially tonsillar cancers, appear to be associated with high-risk HPVs, most often HPV-16. The HPV-positive cancers are characterized by more frequent basaloid pathology, less frequent p53 mutations, and better prognosis, than HPV-negative cancers.

Respiratory papillomatosis

This rare disease is most common in children under the age of 5 years. It may become life threatening if it obstructs the airways. Papillomatosis usually involves the vocal cords and presents with hoarseness or voice change. Papillomas may recur after surgical removal.

HPV-6 and HPV-11, genital tract HPVs that are responsible for most of the exophytic genital warts also cause respiratory papillomatosis. Infants are infected during passage through the birth canal. In adults, transmission may occur by sexual contact. Respiratory papillomas very rarely progress to invasive cancer. Irradiation of papillomas with X-rays (a practice now discontinued) increases the risk of malignancy.

Caesarean delivery for mothers who are found to have genital warts or are infected with HPV-6 or HPV-11 would reduce the risk of juvenile onset respiratory papillomatosis, but it is not generally recommended because of the small risk of disease following perinatal infection. Interferon therapy is not very effective in the treatment of respiratory papillomas.

Human papillomaviruses in the oral cavity

The genital tract HPVs, especially HPV-6 and HPV-11, may infect the oral cavity (Table 2) and are readily recovered from oral lesions diagnosed histologically as condylomas or warty lesions. Focal epithelial hyperplasia of the mouth is distributed worldwide but is highly prevalent in indigenous populations of Central and South America and of Alaska and Greenland; it is aetiologically associated with HPV-13 and HPV-32. These two types are found exclusively in the oral cavity.

Skin warts (see Chapter 23.1)

Skin warts and verrucas may occur anywhere on the skin and are morphologically diverse. They are most common in older children and young adults. Except in the rare condition known as epidermodysplasia verruciformis (see below), they almost never become malignant. Most regress within 2 years. Specific HPV types are strongly associated with specific types of warts (Table 3).

Epidermodysplasia verruciformis

This is a rare, lifelong disease in which a patient has extensive warty involvement of the skin that cannot be resolved. It generally begins in infancy or childhood with multiple, disseminated, polymorphic wart-like lesions on the face, trunk and extremities that tend to become confluent. The warts are either flat or reddish-brown macular plaques that resemble pityriasis versicolor. In about a third of the cases, foci of malignant transformation occur in macular plaques in areas of the skin exposed to sunlight. The tumours are slow growing and rarely metastasize.

Epidermodysplasia verruciformis is often familial. Patients sometimes have a history of parental consanguinity. The pattern of inheritance is suggestive of an X-linked recessive disease resulting in an immunological inability to resolve the infection. The flat warts yield the same HPV types as those of normal individuals but a very large number of HPVs that are seldom encountered in normal individuals are recovered from the macular plaques (Table 3). It is unclear how patients with epidermodysplasia verruciformis become infected with these particular papillomaviruses. The factors that contribute to the occurrence of carcinoma in these patients therefore include a genetic defect, infection with specific HPVs, for example, HPV-5 and HPV-8, and exposure of the affected area to sunlight.

Non-melanoma skin cancers

HPV sequences have been recovered frequently from normal skin, from psoriatic lesions, and from non-melanoma skin cancers of normal and immunosuppressed populations. The sequences represent cutaneous HPV types, epidermodysplasia verruciformis (EV)-associated HPVs and many novel HPV sequences. It appears that the normal skin is seeded with many HPV types but it is not clear to what extent they contribute to the development of non-melanoma skin cancers.

Human polyomaviruses

In 1971 BK virus was isolated from the urine of a renal transplant recipient and JC virus was recovered from the brain of a patient with progressive multifocal leucoencephalopathy. The viruses have a double-stranded DNA genome of about 5000 base pairs, which is divided into an early region encoding viral T proteins, a

late region encoding viral capsid proteins, and a non-coding regulatory region. The early and late regions are transcribed from different strands of the viral DNA. Although BK and JC viruses are homologous for 75 per cent of their nucleotide sequence, the infections are readily distinguishable by conventional tests.

Infection occurs in childhood and is largely subclinical. Most children acquire antibodies to BK virus by the age of 10; infection with JC virus occurs at a later age. Early acquisition of antibodies suggests that infection occurs by the respiratory route. Both viruses establish latent, often lifelong, infection in the kidney and are occasionally excreted in the urine of normal people. Reactivation in immunodeficient people is responsible for most associated illnesses. The viruses are reactivated in pregnancy but without any apparent harm to the mother or the newborn.

BK virus-associated illnesses

Reactivation of BK virus in renal transplant recipients may cause ureteric obstruction, a late and uncommon complication of transplantation. Reactivated BK virus infection in patients with renal transplants has recently been linked and renal dysfunction and graft rejection. In bone-marrow transplant recipients receiving allogeneic marrow, late onset haemorrhagic cystitis and BK viruria are strongly correlated. Primary BK virus infection may be responsible for an occasional case of cystitis in normal children. A case of fatal tubulointerstitial nephritis in an immunodeficient child was ascribed to primary BK virus infection. Reports of the virus in pancreatic islet cell tumours and in brain tumours are unconfirmed.

Progressive multifocal leucoencephalopathy (see also Chapter 24.14.2)

JC virus causes progressive multifocal leucoencephalopathy, a subacute demyelinating disease of the central nervous system occurring in individuals with impaired cell-mediated immunity. Until recently, it was a rare disease found mainly in older patients with lymphoproliferative disorders or chronic diseases. In the past decade, it has been seen much more frequently and the majority of cases are in younger patients, as a complication in 1 to 2 per cent of AIDS cases. It has also been recognized in children who have inherited immunodeficiency diseases or have AIDS.

The key pathogenetic event in the leucoencephalopathy is the cytocidal JC virus infection of oligodendrocytes, which are responsible for the production and maintenance of myelin. This leads to foci of demyelination that tend to coalesce and eventually involve large areas of the brain. Infected oligodendrocytes, containing large inclusion-bearing nuclei filled with abundant virus particles, surround the foci of demyelination (Fig. 9). Enlarged astrocytes often show bizarre nuclear changes but are mostly virus negative. They are found within the foci of demyelination. JC virus is disseminated haematogenously to the central nervous system, probably through virus-infected B lymphocytes. The brain may be seeded with JC virus either at the time of primary infection or when the virus is reactivated in times of immunological impairment.

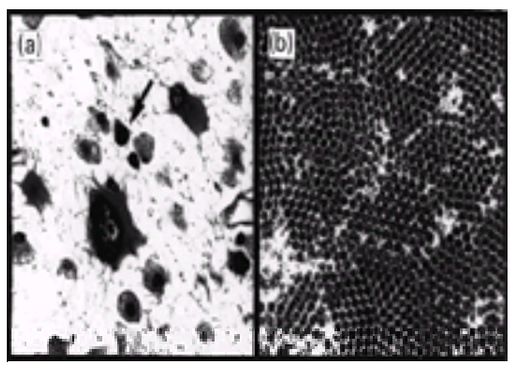

Fig. 9 A lesion of progressive multifocal leucoencephalopathy showing oligodendrocytes with enlarged, deeply staining nuclei (arrow) and giant astrocytes (left). A crystalloid array of JC virus particles in an infected oligodendrocyte nucleus (right). (Reproduced from Shah (1992), with permission.)

Progressive multifocal leucoencephalopathy starts insidiously. Early signs and symptoms indicate the presence of multifocal asymmetrical lesions in the brain and involve impairment of vision and speech, and mental deterioration. The disease is usually relentlessly progressive and fatal within 3 to 6 months but rarely it can become stabilized with survival for many years. Computed tomography and magnetic resonance imaging have been successfully used for diagnosis. Treatment with cytosine arabinoside and the presence of an inflammatory response in the brain have been associated with the few relatively successful outcomes.

7.10.18 Parvovirus b19

*B. J. Cohen**

Viruses of the subfamily Parvovirinae infect vertebrates

Introduction

Parvoviruses (family *Parvoviridae*) are widespread in nature causing disease in many animal species. They are small (23 nm), icosahederal, non-enveloped viruses (Fig. 1) containing a single-stranded DNA genome. The *erythrovirus* genus, which replicates only in nucleated red blood cell precursors includes human parvovirus B19 (B19 virus), the only member of the family *Parvoviridae* known to cause disease in humans. B19 virus was discovered in 1975 by chance as an asymptomatic infection in blood donors being screened for hepatitis B antigen.

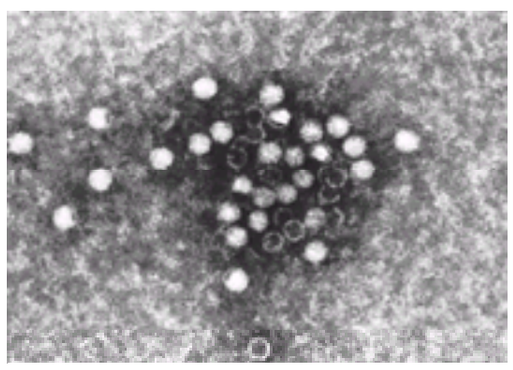

Fig. 1 Immune electron micrograph of parvovirus particles in serum from a case of aplastic crisis. Some particles are penetrated by the negative stain and appear 'empty'; other particles resist the stain and appear 'full'.

Epidemiology

B19 infection is usually spread by respiratory droplets. Contamination of hands and surfaces may also contribute. More rarely, it is bloodborne, either across the placenta or by transfusion of contaminated blood components. Infection is most common in children between 6 and 10 years. By 20 years of age, 60 to 70 per cent of the population have been infected. Susceptible adults remain at risk of infection, often following exposure to B19 virus in their own children. Epidemics occur every 4 or 5 years with peaks of infection in winter and spring.

Clinical features of parvovirus B19 infection

At least a third of B19 infections in children and adults are asymptomatic or present as non-specific febrile illness.

Erythema infectiosum

The most common specific clinical manifestation is erythema infectiosum, an erythematous rash illness (fifth disease) of childhood. The rash has an incubation period of 17 to 22 days (Fig. 2 and Plate 1) and classically the illness begins with mild fever and lassitude followed by the facial erythema referred to as 'slapped cheek disease' (Fig. 3). Subsequently the rash spreads to the trunk and limbs where it has a lacy or reticular appearance and tends to fade and recrudesce for a week or so after its initial appearance. School outbreaks are common during epidemic periods. Sporadic cases in children and adults may be misdiagnosed as rubella, streptococcal infection, or allergy. Occasionally, B19 infection presents as a purpuric rash.

Fig. 2 Slapped cheek' rash of erythema infectiosum: note circumoral pallor. (By courtesy of Dr Ken Mutton.) (See also Plate 1.)

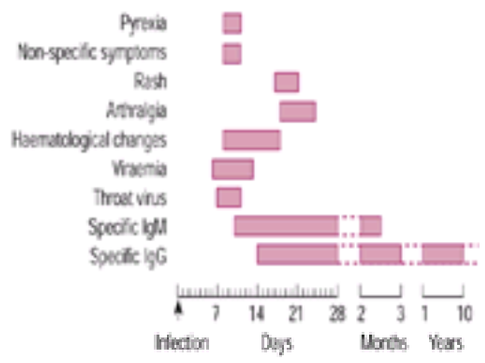

Fig. 3 Sequence of events following intranasal inoculation of volunteers with parvovirus B19.

Acute arthropathy

More than 80 per cent of adults with B19 infection (especially women) present with painful or swollen joints. An acute-onset, symmetrical polyarthritis specifically affects the small joints of the hands and feet. It usually resolves within a few weeks. In about 20 per cent of adult females with B19 infection, joint symptoms persist for more than 2 months and may resemble rheumatoid arthritis. Rheumatoid factor is usually absent and there is no erosive joint disease. No association with rheumatoid arthritis has been confirmed.

Infection in pregnant women

About 10 per cent of B19 infections in the first 20 weeks of gestation end in spontaneous abortion, a rate of fetal loss about 10 times greater than that in unaffected pregnancies. Embryopathy usually presents as hydrops fetalis 4 to 6 weeks after a maternal infection, which may be symptomatic or clinically silent. In epidemic years, 10 to 20 per cent of cases of non-immunological hydrops fetalis are associated with B19 infection. Fetal anaemia due to B19 infection may be treated with *in utero* blood transfusions. Surviving infants have no evidence of congenital disease or malformation.

Transient aplastic crisis

Interruption of erythropoiesis caused by B19 is transient and insufficient to cause clinically significant anaemia in individuals with normal red cell lifespan and function. In those with a shortened red cell lifespan, such as patients with sickle cell anaemia, B19 infection can rapidly lead to a more profound anaemia termed an aplastic crisis. In the acute phase there is erythroid aplasia and the absence of reticulocytes in peripheral blood and, in recovery, reticulocytosis and the appearance of giant pronormoblasts in the bone marrow. B19-induced aplastic crisis has also been recorded in patients with hereditary spherocytosis, b-thalassaemia intermedia, pyruvate kinase deficiency, and other red cell disorders.

Chronic anaemia in immunocompromised patients

Patients with congenital immunodeficiency, HIV infection, acute lymphatic leukaemia, or immunocompromise following organ transplantation fail to produce neutralizing antibody to B19 virus and infection becomes chronic. This results in persistent anaemia and patients may become transfusion dependent.

Prevention and therapy

A recombinant DNA-derived vaccine is being developed. To minimize spread by infected blood components, blood donor screening has been proposed, but its cost-effectiveness is unknown. The testing of plasma pools, however, is likely to become mandatory and should result in the reduction of viral load, if not the complete removal, of B19 virus from blood products. Early recognition of B19 infection in hospital patients is important for prevention of nosocomial transmission. Severe infections in immunocompromised patients are treated with high-dose intravenous normal immunoglobulin (400 mg/kg body weight for 5 or 10 days).

Laboratory diagnosis

Detection of B19 virus, by polymerase chain reaction (PCR) for example, is important for diagnosis in patients presenting in the viraemic phase of infection, including those with aplastic crisis, immunocompromise, and fetal infection. In most cases, however, the presenting symptoms of rash and arthropathy are postviraemic phenomena (Fig. 3) and the diagnosis is most commonly confirmed by detecting B19-specific IgM. The IgM response persists for 2 to 3 months after acute infection. Thereafter, B19-specific IgG remains as the sole marker of infection in the past and indicates immunity. Reinfection occurs only in the immunocompromised patient.

---

7.10.19 Hepatitis viruses (including ttv)

N. V. Naoumov

Viral hepatitis is an ancient disease which remains an important health problem worldwide. The archetypal viral hepatitis, yellow fever (Chapter 7.10.13), is not included within this group. Over the last 30 years five major hepatitis viruses have been identified—A, B, C, D, and E (Table 1). These unrelated human viruses, different in their genome organization, biology, and epidemiology, are similar in their hepatotropism. Ten to fifteen per cent of cases of viral hepatitis are considered as non-A to E hepatitis: their aetiology remains unknown. The search for new hepatitis agents led to the identification of hepatitis G virus (HGV or GB virus-C) and TT virus. Both have been detected in a high proportion of the general population, but their pathogenic role is uncertain. The search for new agents responsible for the small proportion of patients with cryptogenic hepatitis continues. Details of symptomatology, management, and prevention of viral hepatitis are given in Section 14.20.

Hepatitis A virus (HAV)

HAV particles were detected by immune electron microscopy in 1973 in stool samples of patients with hepatitis A. The virus is classified in the genus *Hepatovirus* within the Picornaviridae family. The genome of HAV is a single-stranded, linear RNA of approximately 7500 nucleotides (Table 1). This includes a 5' non-translated region (**5'NTR**) of approximately 740 nucleotides, followed by a single long open reading frame (**ORF**) encoding a polyprotein of 2200 amino acids and a short 3' non-translated segment. After translation, the HAV polyprotein undergoes multiple cleavages by a virally encoded enzyme—3C protease. The polyprotein is considered to contain three functionally separate domains. At the aminoterminal end is domain P1 that includes the major structural polypeptides of HAV in the following sequence—VP2, VP3, and VP1. A fourth very small polypeptide, VP4, presumed to be involved in the HAV capsid formation, is located at the extreme aminoterminal end of the polyprotein. These four structural polypeptides assemble into a viral capsid containing 60 copies of each. How the viral RNA is incorporated into the virion is unknown, but both empty and RNA-containing capsids have been observed in most virus preparations. The other P2 and P3 domains of the viral polyprotein include at least six separate proteins involved in viral replication. These include 2B and 2C helicase, 3A and 3B proteins, 3C (the viral protease), and 3D (an RNA-dependent RNA polymerase).

Hepatocytes are the predominant site of HAV replication *in vivo*. Recent data indicate that HAV may also replicate within the epithelial cells of the gastrointestinal tract. However, the mechanism by which HAV reaches the liver remains unknown. Maximal HAV replication in hepatocytes occurs before serum aminotransferases increase. The virus is excreted via the biliary system into the faeces where it can be found in high concentrations around 1 to 2 weeks before the start of clinical symptoms. Viraemia is present from the earliest phase of infection. It results from HAV replication within hepatocytes. HAV differs from other picornaviruses in its non-cytolytic replication. Liver injury is immune mediated by natural killer cells, virus-specific CD8+ cytotoxic T lymphocytes, and non-specific inflammatory cells recruited to the liver. When clinical symptoms appear there is a humoral immune response and antibodies to structural HAV proteins (anti-HAV) are detectable in the serum. Initially these are mainly IgM antibodies (IgM anti-HAV) that usually persist for approximately 6 months. During convalescence, anti-HAV of IgG class become the predominant antibodies. They remain detectable indefinitely, representing protective immunity to HAV.

Hepatitis B virus (HBV)

In 1965, Blumberg and colleagues identified the surface antigen (**HBsAg**) of HBV, initially termed 'Australia antigen', and in 1970 the complete virion (a 42 nm particle) was detected by Dane and colleagues, using electron microscopy. The genome of HBV, the smallest DNA virus, contains only 3200 nucleotides (Table 1). One of the DNA strands, the 'minus' strand, is an almost complete circle containing four overlapping reading frames: precore/core, polymerase, envelope, and X genes (Fig. 1). The other ('plus') strand is shorter and varies in length. HBV belongs to the hepadnavirus family that includes similar hepatotropic DNA viruses specific for woodchucks, ground squirrels, and Pekin ducks.

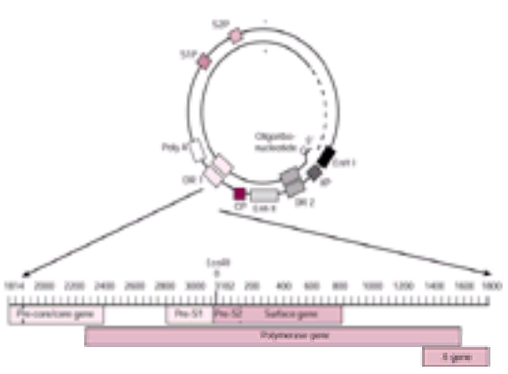

Fig. 1 Schematic representation of hepatitis B virus genome. CP, core promoter; S1P, preS1 promoter; S2P, pre-S2 promoter; XP, X gene promoter; EnhI, enhancer I; Enh II, enhancer II; DR1 and DR2, direct repeat 1 and 2; EcoRI, restriction site for EcoRI enzyme used as a starting point for numbering.

Genome organization

The envelope ORF contains three start codons separating the pre-S1, pre-S2, and S sequences. The surface gene encodes the major envelope protein (HBsAg) of 226 amino acids. The translation product of the pre-S2 and S gene is the middle envelope protein and the product of pre-S1, pre-S2, and S gene is the large envelope protein. In addition to the complete virion, many more non-infectious, 22 nm, spherical and filamentous subviral particles are produced in infected hepatocytes. HBsAg and the middle envelope protein are present in all viral and subviral particles, while the large protein is present in the virions and in some subviral filaments. The domain which binds to a specific HBV receptor (still not defined) on the plasma membrane of hepatocytes resides within the pre-S1 region.

The precore/core ORF has two start codons encoding two closely related proteins. Translation from the preC-start codon produces a precursor molecule, designated precore protein. In the endoplasmic reticulum, this protein undergoes two proteolytic steps at the amino- and carboxy-terminal ends. The resultant polypeptide is secreted from hepatocytes as hepatitis B e antigen (**HBeAg**). This is a non-structural protein, which is not essential for viral replication. However, detection of HBeAg in serum is a good marker of HBV replication. Translation from the C-start codon yields the nucleocapsid protein (**HBcAg**) of 183 amino acids. In the cytoplasm of hepatocytes HBcAg assembles spontaneously into nucleocapsid particles. HBeAg and HBcAg share about 90 per cent of the amino acids but differ substantially in their conformation. The polymerase ORF encodes the HBV polymerase protein with 832 amino acids. It has three functional domains—terminal protein, reverse

transcriptase, and RNAase H activity. The X ORF encodes a protein with 154 amino acids. The X protein is not essential for the replication of hepadnaviruses, but is believed to contribute to HBV-related hepatocarcinogenesis. It functions as a transactivator of cellular and other viral genes.

Seven different genotypes of HBV (A, B, C, D, E, F, and G) have been determined. The variations involve approximately 10 per cent of the genome. Genotype A is predominant in Central and Northern Europe, genotype D in the Mediterannean basin, genotypes B and C in Asia, and genotype E in Africa.

Viral replication

Following HBV entry into hepatocytes, the nucleocapsid is transported to the nucleus (Fig. 2). Cellular enzymes repair the open circular HBV DNA into covalently closed circular DNA (**cccDNA**), which serves as a template for synthesis of pregenomic and messenger RNAs. Viral DNA does not integrate into the host genome as part of the normal replication cycle. The pregenomic RNA is transported to the cytoplasm and serves as mRNA for translation of new core and polymerase proteins. When these three components (pregenomic RNA, core and polymerase proteins) reach sufficient quantities, they assemble into nucleocapsid particles. The polymerase protein is directly involved in the pregenomic RNA encapsidation. Inside the particles the pregenomic RNA is reverse transcribed into DNA 'minus' strand, while the RNA template is simultaneously degraded by RNAaseH. Finally, the 'plus' strand is produced, which completes a new partially double-stranded HBV DNA. Some of the newly synthesized nucleocapsids with HBV DNA are transported back to the nucleus, which maintains a stable pool of cccDNA. Others are enveloped and leave the cell as new virions. Hepadnavirus replication differs from that of retroviruses. Integration into the host genome is not obligatory during replication and functional mRNAs are produced from several internal promoters of the circular DNA genome.

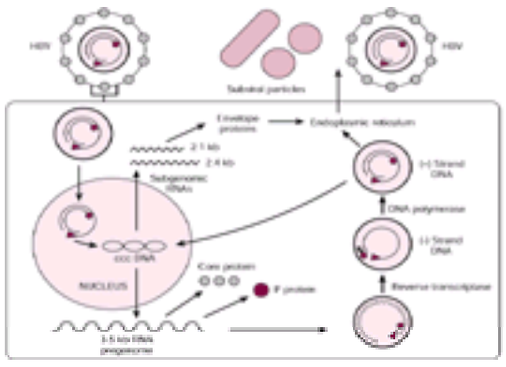

Fig. 2 Replicative cycle of hepatitis B virus.

Host immune response and pathogenesis

HBV is a non-cytopathic virus. The virus-specific cellular immune response is the main determinant of the outcome of infection. Both HLA class I- and class II-restricted T-cell responses are strong, polyclonal, and directed to multiple viral antigens in patients with acute self-limiting hepatitis B. Despite clearance of serum HBsAg, HBV DNA remains detectable by polymerase chain reaction (**PCR**) in most cases, and HBV-specific CD4+ and CD8+ T-cell reactivity has been demonstrated 10 to 20 years after acute infection. Cytokines released from these cells, especially interferon-g, exert non-cytolytic control on HBV replication without causing cell death. Thus, eradication of HBV may be rare, but the effective immune response controls HBV DNA expression and there is no liver disease. Patients with chronic HBV infection (seropositive for HBsAg) show weak virus-specific T-cell reactivity, which is the dominant cause for HBV persistence. This ineffective response, together with antigen non-specific inflammatory cells, recruited at the site of inflammation, results in progressive liver damage. During the course of chronic HBV infection, spontaneous reactivation of hepatitis may occur, associated with enhanced immune reactivity.

The humoral immune response involves antibodies directed to different HBV antigens (Table 1). It is clinically significant for: (i) diagnosis—the antibody profile in the serum, together with the result of HBsAg and HBeAg, is used to define the phase of HBV infection; (ii) prophylaxis—the development and the level of the protective antibody (anti-HBs) is used to monitor the response to vaccination; (iii) pathogenesis—the humoral immune response contributes to viral elimination from the circulation by forming immune complexes. In some cases, tissue deposition of antigen–antibody complexes is responsible for extrahepatic pathology such as glomerulonephritis, polyarteritis nodosa, arthritis, and skin changes.

Evolution of chronic HBV infection

The changes in HBV–host interactions over time and associated liver disease define three consecutive phases, particularly after vertical transmission of HBV. The early 'immunotolerant' phase is characterized by high levels of virus replication. HBeAg and HBV DNA are readily detectable in serum, while there is minimal liver inflammation. Over the years this is followed by a phase with enhanced immune reactivity to the virus, as reflected by hepatic inflammation and elevated serum aminotransferases. Serum HBeAg is still positive and serum HBV DNA level is usually lower. Some patients will progress spontaneously to the next 'non-replicative' phase, manifested by seroconversion to anti-HBe, undetectable HBV DNA (by conventional techniques), and resolution of hepatic inflammation. Persistent virus replication leads to the emergence of mutations in the HBV genome. Three groups of HBV mutants have direct clinical significance. First, surface escape HBV mutants can emerge in recipients of active and passive immunization. They contain mutations within the immunodominant 'a' determinant of the HBsAg, which abrogate the neutralizing effect of anti-HBs. The second group includes HBV mutants with impaired translation of HBeAg—HBe minus mutants. The most frequent is a G to A mutation at position 1896, which results in a precore stop codon. The third group includes mutations in the polymerase gene that may emerge during treatment with nucleoside analogues, such as lamivudine or famciclovir. The most typical is a lamivudine-associated mutation in the conserved YMDD (tyrosine–methionine–aspartate–aspartate) region of the polymerase, leading to substition of methionine with valine or isoleucine.

Hepatitis C virus (HCV, see also Chapter 7.10.20)

HCV was identified in 1989 and was shown to be the main aetiological agent of parenterally transmitted non-A, non-B hepatitis. For the first time a virus was discovered and characterized by molecular techniques without being seen or grown in culture. The virus has been placed in a separate genus of the Flaviviridae family (Table 1). The lack of an *in vitro* system supporting HCV replication has been a major limitation to the understanding of its biology and the development of antiviral compounds. Synthesis of a full-length cDNA clone, capable of generating infectious RNA transcripts, is an important step to establish a tissue culture system.

Genome organization

The HCV genome is a single-stranded RNA containing a single ORF encoding a polyprotein of 3010 to 3033 amino acids (Fig. 3). Both at the 5' and the 3' ends, it has a non-translated region (NTR). The 5'NTR consists of 341 nucleotides and is the most conserved region of the genome. It forms multiple stem–loop structures, important for ribosome entry and presumably for viral RNA replication. The 3'NTR comprises several regions, including a highly conserved sequence of 98 nucleotides at the 3' terminus, thought to be required for initiation of replication. Because HCV RNA does not replicate via a DNA intermediate, it does not integrate into the host genome. The HCV polyprotein undergoes proteolytic processing in the cytoplasm of infected cells resulting in 10 mature proteins from core to NS5B (Fig. 3). The putative nucleocapsid or core protein is conserved and highly immunogenic, containing several B- and T-cell epitopes. The envelope glycoproteins (E1 and E2) are believed to form the outer spikes of the viral envelope. The HCV E2 protein binds to the major extracellular loop of human CD81 molecule. CD81 is a cell surface protein, expressed on various cells including hepatocytes. It may act as a receptor for HCV. The first 27 amino acids at the N-terminus of the E2 region (between amino acids 384 and 410 of the polyprotein), which show a very high degree of variation, is termed hypervariable region I (**HVRI**). E2 is part of the virus envelope; it contains neutralizing epitopes, one of which appears to be in the HVRI; the immune pressure on this protein leads the selection of escape mutants. The NS3 serine protease domain and the NS4A protein form a complex that is essential for efficient polyprotein cleavage. Specific inhibition of the proteolytic activities of virally encoded proteases is regarded as a promising strategy for inhibiting HCV replication. The non-structural protein NS5B possesses RNA polymerase activity. This enzyme is also essential for HCV replication and is another important target for antiviral drug development.

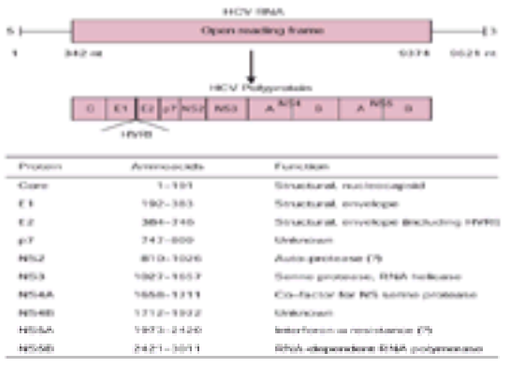

Fig. 3 Hepatitis C virus genome and proteins.

Genome variation and quasispecies

HCV is exceptionally heterogeneous. The NS5B replicase is an error-prone enzyme with no proof-reading activity. During HCV replication this generates many mutant strains which are selected on the basis of their fitness. Based on a phylogenetic analysis of the HCV core, E1, and NS5 regions, six major HCV genotypes (from 1 to 6) have been defined, with a further division into subtypes (1a, 1b, 2a, 2b, etc.). Isolates of type 1 are widely present throughout the world. Genotype 1a and 1b are predominant in North and South America and Europe. Genotypes 2 and 3 are widely distributed in many countries, but are rare in Africa. Genotype 4 is predominant in north and central Africa, especially Egypt, while genotype 5 is most frequent in southern Africa. Genotype 6 is responsible for many HCV infections in Hong Kong and Vietnam. HCV genotypes 7, 8, and 9 have been identified only in Vietnam where they represent almost 20 per cent of all HCV infections. Despite the substantial genomic variations between different HCV genotypes, both clinical and virological data show no significant phenotypic differences in the severity of liver damage or the potential to cause hepatocellular carcinoma. Genotype 1b responds less well than genotypes 2 or 3 to antiviral treatment.

In an individual host, the HCV population is a mixture of closely related, but heterogeneous, RNA sequences centred around one dominant viral sequence. The heterogeneous isolates in a single patient are termed 'quasispecies'. This is commonly based on the genomic variability within the HVRI region. Viral diversity increases during chronic HCV infection as a result of immune escape from antibodies directed to this hypervariable region.

Host immune response and pathogenesis

Clinical evidence suggests that HCV is not cytopathic for infected cells. A most striking feature of HCV is the high rate of chronic infection. The immune response is believed to play a central role in viral clearance and pathogenesis. Neutralizing antibodies are produced during HCV infection. However, they are isolate specific and are usually effective only against HCV strains present before the appearance of the corresponding antibodies. Although antibodies to core and non-structural proteins are detectable in the serum, no specific antibody profile has been established as a predictor of outcome. The titre of antibodies to E1 and E2 proteins correlate with viraemia. The presence of strong and multispecific T-helper cell responses to HCV results in viral clearance. In patients with chronic HCV infection both the CD4+ T-helper cell and the cytotoxic T-lymphocyte responses are much weaker than during acute, resolving infection. Although HCV-specific cytotoxic T lymphocytes have been detected in peripheral and intrahepatic lympocytes, they seem functionally impaired as they are unable to clear the virus. HCV may escape immune elimination through peripheral tolerance, exhaustion of T-cell response by a high viral load, viral inhibition of antigen presentation, and viral mutations abrogating or antagonizing antigen recognition by virus-specific T cells. Further studies are needed to clarify these possibilities and to provide a scientific basis for new therapeutic concepts and the development of effective vaccine.

Hepatitis D virus (HDV)

HDV is a defective virus that causes acute and chronic liver disease only in association with hepatitis B virus. This unique pathogen was discovered in 1977 by M. Rizzetto in liver biopsies from patients with hepatitis B. HDV particles contain the viral RNA nucleocapsid, which is hepatitis †-antigen (**HDAg**) and an outer envelope (HBsAg) provided by the helper virus HBV. The HDV genome is a single-stranded, circular RNA (Table 1). It is the smallest known animal virus genome. Because of a high degree of internal complementarity, 70 per cent of the nucleotides are base-paired. This gives it an unusual, rod-like structure. HDV RNA replicates via RNA-directed RNA synthesis by transcription of genomic RNA to a complementary antigenomic †-RNA that serves as a template for subsequent genomic RNA synthesis. HDV produces a single protein, HDAg, which is encoded by the antigenomic RNA. RNA editing of the antigenomic RNA allows the virus to make two forms of HDAg—'small (S)' (195 amino acids) and 'large (L)' (214 amino acids). Both forms are present in the virions and have different functions in the HDV replicative cycle. HDAg-S facilitates HDV RNA replication, while HDAg-L inhibits replication and is required for assembly of the virion. Although the formation of †-virions requires the helper fuction of HBV, the replication of HDV RNA within the cell can occur without HBV.

Three distinct HDV genotypes have been recognized. Genotype I, the most widespread, has been identified in North America, Europe, Africa, and Asia. It is associated with a broad spectrum of chronic liver disease. Genotype II is found only in east Asia and seems to cause mild hepatitis-†. Genotype III is found exclusively in northern parts of South America and is associated with particularly severe hepatitis.

Host immune response and pathogenesis

HDV can infect either simultaneously with HBV (coinfection) or as a superinfection of a chronic carrier of HBsAg. Because HDV requires the helper function of HBV, the duration of †-infection is determined by the duration of HBsAg positivity. Like antibodies to HBV nucleocapsid (anti-HBc), antibodies to HDAg are not protective. Chronic HDV infection is accompanied by high titres of IgG anti-HD. High serum levels of IgM anti-HD indicate acute †-infection or exacerbation of chronic hepatitis D. The roles of cellular immune responses to HDAg, HBV antigens, or both in the immunopathogenesis of hepatitis D is uncertain. The lack of liver pathology in transgenic mice expressing HDV and data from experimental infections suggest that HDV is not cytopathic. This is supported by the experience with patients undergoing liver transplantation for HDV cirrhosis. Although HDV always recurs in the graft, necroinflammation is absent unless HBV recurs as well. The presence of microvesicular steatosis in severe hepatitis D indicates a possible direct cytopathic effect in some circumstances.

Hepatitis E virus (HEV)

HEV was first identified in 1983 by immune electron microscopy of the faeces of patients and is now recognized as the agent responsible for enterically transmitted non-A, non-B hepatitis. The virus is classified in the Caliciviridae family. Without a cell culture system, studies on HEV have required experimental transmission to susceptible non-human primates, such as cynomolgous macaques. The HEV genome is a single-stranded, polyadenylated RNA of approximately 7500 nucleotides containing three open reading frames (Table 1). ORF1 encodes non-structural proteins involved in virus replication—helicase and RNA-dependent RNA polymerase. ORF2, comprising approximately 2000 nucleotides, codes for the major structural proteins. ORF3 has 328 nucleotides and also appears to code for a structural protein. The genomic organization of HEV is different from HAV and HCV because the structural and non-structural proteins are coded by discontinuous, partially overlapping ORFs. Non-structural proteins are encoded at the 5' rather than at the 3' end of the genome. Unlike HAV, HEV infection may be zoonotic. HEV RNA has been found in the faeces of wild pigs. Serological evidence of infection has been found in pigs, cattle, and sheep in endemic regions. Sequence analyses have identified two major genotypes of HEV (isolates from Burma and Mexico), which show 25 per cent nucleotide variability. The amino acid variability ranges from 1 to 5 per cent among different HEV isolates from Asia to 14 per cent between the Mexican and Asian isolates. A new genotype was recently isolated from a patient in the United States.

The primary site of HEV replication is not fully understood. Following intravenous HEV inoculation in experimental models, the elevation of serum aminotransferases occurs after 24 to 38 days. Expression of HEV antigens has been detected in the cytoplasm of hepatocytes as early as 7 to 10 days after inoculation. Experimental data indicate that during an initial phase with high HEV replication, the virus may be released from hepatocytes into bile before serum 'liver' enzymes increase and there are morphological changes in the liver. Virus shedding ceases when serum aminotransferases return to normal. HEV RNA is detectable by reverse transcriptase polymerase chain reaction (**RT-PCR**) in the serum of virtually all patients within 2 weeks of the start of hepatitis. Prolonged viraemia (4 to 16 weeks) has also been reported. Detection of anti-HEV by enzyme immunoassay involving recombinant HEV antigens or synthetic peptides is the most frequently used method for diagnosis

and for epidemiological studies.

The humoral immune response develops gradually in parallel with the rise in serum alanine aminotransferase. The serum level of anti-HEV IgM peaks around the time of peak enzyme levels and is detectable for 5 to 6 months. Although the IgG anti-HEV response persists for several years after the acute hepatitis, the natural history of protective immunity to HEV is not fully established. In contrast to HAV, hepatitis E shows an unusually high attack rate among adults, suggesting that immunity to HEV, if acquired in childhood, may wane.

GB virus-C (GBV-C) or hepatitis G virus (HGV)

The genome of GBV-C was identified in 1995 by molecular hybridization in the serum of a patient with the initials GB. Separately, another group of investigators identified the genome of a new RNA virus, named hepatitis G virus. The comparison of HGV and GBV-C genomes revealed high homology, both at nucleotide (86 per cent) and amino acid level (100 per cent). In is now accepted that they represent two isolates of the same virus. GBV-C/HGV is an RNA virus with a single ORF encoding a polyprotein of approximately 3000 amino acids (Table 1). Together with another two RNA viruses, GBV-A and GBV-B, it belongs to the Flaviviridae family. These three viruses show various similarities with HCV. Specific features of the GBV-C/HGV genome include absence of core gene (nucleocapsid); long 5'- and 3'NTR and lack of poly(A) tail. Unlike HCV, this virus has a very conserved E2 region. Longitudinal studies have shown that GBV-C/HGV can establish chronic infection with RNA persistence in serum for up to 15 years. Some patients clear the virus spontaneously and develop anti-E2 reactivity, which is used as a marker of past infection. Anti-E2 also seems to confer protective immunity. A large body of evidence suggests that GBV-C/HGV does not cause liver disease.

TT virus (TTV)

TTV was identified in 1997 by investigators in Japan. By applying the methodology used for the identification of GBV-C, they detected the genome of a new DNA virus in the serum of a patient with cryptogenic post-transfusion hepatitis. The patient's initials (TT) prompted the name of this new virus and a causative role for acute and chronic hepatitis was suggested. Subsequent studies revealed that the TTV genome is circular, single-stranded DNA of approximately 3850 nucleotides (Table 1). Two partial ORFs have been predicted, but TTV proteins have not been expressed so far. It is suggested that TTV belongs to a new family—Circinoviridae. TTV DNA has been detected in non-human primates and farm animals. The primary site of TTV replication is unknown. TTV DNA is present in the liver and in all fractions of peripheral blood mononuclear cells, although TTV RNA transcripts are detectable only in liver tissue. Unlike other DNA viruses, TTV shows remarkable genomic variability. The phylogenetic analysis demonstrates the presence of many genotypes although there is no internationally agreed classification yet. The TTV population in one patient could comprise several genotypes.

TTV infection is highly prevalent worldwide (for instance up to 92 per cent of healthy subjects in Japan). Initially, the virus was thought to be transmitted parenterally, although its prevalence in the general population indicates the importance of non-parenteral routes as well. Prevalence increases with age in paediatric and adult age groups.

It is uncertain whether TTV is pathogenic. Analysis of liver histology in patients with TTV infection and longitudinal studies, as well as experimental TTV inoculation in chimpanzees, demonstrate that this virus does not cause hepatitis. So far, TTV is an example of a human virus with no clear disease association.

7.10.20 Hepatitis C virus

D. L. Thomas

Introduction

By the mid 1970s, it was apparent that both acute and chronic hepatitis could be caused by something other than hepatitis A virus (**HAV**) or hepatitis B virus (**HBV**). This condition, called non-A, non-B hepatitis, was assumed to be a viral infection since it was reproduced in chimpanzees inoculated with blood from affected persons, even after passage through 90 nm filters. However, hepatitis C virus (**HCV**) was not discovered until the late 1980s when a portion of viral RNA was cloned, and the resulting antigen shown to react with sera from persons with non-A, non-B hepatitis. It is now clear that HCV causes most cases of bloodborne non-A, non-B hepatitis.

Aetiology (see Chapter 7.10.19)

Epidemiology

Prevalence of infection

An estimated 170 million people are infected with HCV worldwide. In economically developed nations, HCV infection is found typically in 1 to 2 per cent of the general population. A 10-fold higher HCV prevalence has been found in Egypt and in some regions of Japan, Taiwan, and Italy. In these highly-endemic regions a sharp decrease in prevalence is often found in those less than 30 to 40 years of age, a cohort effect that probably reflects discontinuation of a practice that once contributed to widespread infection. HCV infection occurs in 50 to 90 per cent of persons injecting illicit drugs, more than 90 per cent of patients with haemophilia transfused with clotting factors before they were inactivated, 10 to 50 per cent of patients on haemodialysis, 5 to 20 per cent of patients attending sexually transmitted disease clinics, and 1 to 3 per cent of health care workers. HCV infection is common in people with other bloodborne infections, such as HBV and HIV.

Transmission

Biological basis

Studies with molecular clones demonstrate that infection will occur if sufficient numbers of complete HCV RNA transcripts reach the liver. HCV RNA has been detected in blood, saliva, seminal fluid, and tears, and intravenously injected blood is clearly infectious. In addition, in one instance, a chimpanzee was infected by intravenous injection of saliva. It is not known if other body fluids contain enough intact virions to be infectious when administered percutaneously or if infection can be sustained when virions contact cells present in mucous membranes.

Percutaneous transmission

Nosocomial transmission

The principal route of HCV transmission worldwide is percutaneous exposure to HCV-containing blood. Transfusion of contaminated blood once accounted for 20 per cent of HCV infection in the United States. HCV has also been transmitted by intravenous administration of contaminated immunoglobulin and clotting factors, including several well publicized outbreaks in the United States and Europe. However, the incidence of HCV transmission through administration of blood and blood components has decreased dramatically in regions of the world where donors are screened for HCV antibody and viral deactivation procedures are now used for immunoglobulin and clotting factor products.

Although the incidence in economically developed nations is now very low, patient-to-patient HCV transmission has been documented following percutaneous medical procedures such as colonoscopy with biopsy and use of intravenous infusion devices. In such instances, a common source of transmission can be detected by higher than expected identity in RNA sequences from various persons, as has repeatedly been shown in haemodialysis centres. Nosocomial HCV transmission probably requires a breach in infection control policies, although this may be difficult to recognize retrospectively.

In economically developing nations, most HCV transmission occurs through medical treatments, both by modern and folk practices. In Egypt, where 50 per cent of persons more than 40 years of age are infected, HCV was transmitted through a widespread national campaign of injections to eradicate schistosomiasis. When this practice was discontinued, there was a sharp decrease in HCV prevalence in persons born thereafter. Elsewhere in the world, HCV transmission occurs where education and resources are insufficient to ensure sterilization of devices used for medical injections, scarification rituals, and other percutaneous practices. Misperceptions regarding the benefit of injections appear to be especially important.

Drug use

In some regions of the world, percutaneous exposure to contaminated needles and other drug-use implements is the dominant mode of HCV transmission. HCV infection, which often occurs within months of starting to abuse drugs by injection, is found in 50 to 90 per cent of people admitting drug use worldwide. There are conflicting data as to whether HCV can be transmitted by intranasal use of cocaine.

Sexual transmission

Transmission of HCV by intercourse has not been proven, but some data suggest that it occurs, albeit uncommonly. In some HCV-infected individuals, the only potential exposure that can be detected is sex with another infected person, and HCV infection occurs more often than expected in persons with multiple sexual partners. In the families of HCV-infected people, sexual partners are the only members whose risk of infection is increased. The viral nucleotide sequences often suggest a common source. However, most long-term sexual partners of people with hepatitis C are not infected, and in those who are infected, it is impossible to exclude exposures other than intercourse. In the few studies in which direct comparisons are possible, the prevalences of HBV and HIV in sexual partners are 5- to 10-fold higher than for HCV.

Most authorities do not recommend that people in monogamous relationships use condoms to prevent HCV transmission. However, many encourage HCV-infected people to discuss the risk of transmission with their sexual partners and encourage them to be screened.

Mother-to-infant transmission

HCV infection occurs in 2 to 8 per cent of infants born to HIV-infected mothers. This risk increases if the mother is also HIV infected or if the maternal level of HCV RNA is high. Because of passive transfer of maternal antibodies, the diagnosis of HCV infection in the child must be based on detection of HCV RNA or persistence of antibodies 18 months or more after birth. There is no conclusive evidence that HCV is transmitted by breast feeding, and only a single study that suggests the risk of perinatal infection is reduced by elective caesarian delivery.

Natural history and pathogenesis

Viral persistence

HCV RNA can be detected in blood within weeks of exposure and, for approximately 85 per cent of individuals, remains detectable indefinitely (Fig. 1). Most persistently-infected people have intermittent elevations in serum liver enzymes such as alanine aminotransferase (**ALT**) and after 10 to 20 years, 2 to 20 per cent develop cirrhosis. Within 5 years, approximately 20 per cent of those who develop cirrhosis will have a life-threatening complication, such as ascites, variceal bleeding, hepatic encephalopathy, or hepatocellular carcinoma.

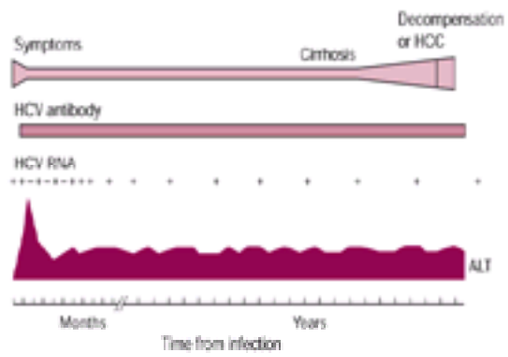

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

Fig. 1 Natural history of HCV infection.

The incidence of cirrhosis is higher in persons infected at older ages and those who ingest alcohol, especially more than 50 g/day (or the equivalent of three alcoholic drinks). The effect of smaller amounts of alcohol is not known. HIV and HBV infections also appear to increase the incidence of HCV-related cirrhosis. Neither HCV genotype nor HCB RNA level are strong determinants of disease progression.

The pathogenesis of cirrhosis is poorly understood. A few HLA alleles have been associated with cirrhosis and more vigorous cytotoxic T-lymphocyte responses have been associated with severe liver disease. Conversely, immunosuppression from sources as diverse as HIV infection, agammaglobulinaemia, and steroid use appears to increase the incidence of cirrhosis.

Viral clearance

In approximately 15 per cent of people, HCV RNA can no longer be detected in blood one or more years after exposure, although HCV antibody and T-lymphocyte responses may remain. Long-term sequelae like cirrhosis and hepatocellular cancer do not appear to occur in those with viral clearance.

The mechanisms of viral clearance are not known. Both humoral and cellular immune responses are detectable to multiple HCV antigens within months of exposure, but occur even in those with persistent infection. Over time, individual variants may be eliminated from the HCV quasispecies only to be replaced by others that are sufficiently different to escape immune effectors. Those who clear HCV infection also tend to have strong T-cell proliferation responses to HCV antigens and a T_{H1} cytokine phenotype. The importance of these findings in viral clearance remains to be shown.

Clinical features

Acute infection

Acute HCV infection is indistinguishable from other forms of acute viral hepatitis, causing malaise, nausea, and right upper quadrant pain, followed by dark urine and jaundice. These symptoms occur in approximately 20 per cent of acutely infected adults, less frequently and typically with less severity than for hepatitis A or hepatitis B. Fulminant hepatic failure is rare.

HCV RNA is detectable before symptoms occur, but the level of viraemia varies in the first 6 months and can be transiently undetectable even in those who ultimately have persistent infection. Serum levels of liver enzymes such as ALT rise more than 10 times normal, then decline and, for those with persistent HCV infection, fluctuate indefinitely. The serum bilirubin may also be elevated for weeks after symptoms are first noted, but ultimately returns to a normal level. HCV antibody can usually be detected within a month of symptoms and within 8 weeks of exposure.

Chronic infection

The 85 per cent of people who develop persistent infection can be differentiated from those with viral clearance by repeated testing for HCV RNA in blood for 12 or more months. Other tests, such as serum ALT levels and the quantity of serum HCV RNA, do not reliably predict the outcome.

Fatigue and malaise may herald the onset of cirrhosis, which is suggested by thrombocytopenia, neutropenia, hypoprothrombinaemia, and hypoalbuminaemia. These haematological indicators of cirrhosis develop as late findings and imply a bad prognosis. Liver enzymes fluctuate throughout the course of HCV infection with little correlation to symptoms or the long-term outcome. Cirrhosis can occur even in the 20 to 40 per cent of patients who have repeatedly normal ALT levels. The levels of HCV RNA and HCV genotype likewise are poor predictors of disease. Probably the only reliable marker of disease progression is the liver biopsy (see below).

Extrahepatic manifestations

These include mixed cryoglobulinaemic vasculitis and membranoproliferative glomerulonephritis (see Chapter 20.7.8). Diagnosis of cryoglobulin-related vasculitis is based on the clinical syndrome as HCV-infected people commonly have cryoglobulins detectable in their serum. HCV infection is commonly associated with sporadic

porphyria cutanea tarda, and less commonly, with Sjögren's syndrome, lichen planus, idiopathic pulmonary fibrosis, and Mooren's corneal ulcers.

Pathology

The histopathological features of acute HCV infection are less severe than with the other hepatitis viruses. Mononuclear (mostly lymphocytic) inflammation is present throughout the lobule. Sinusoidal lining cells are activated and fat can be seen. Over time, the level of inflammation varies and fibrosis can occur, beginning in the portal areas and, in some cases, extending as septae beteween portal zones. Fibrous bands that bridge portal triads and formation of nodules denotes cirrhosis. The Knodell system quantifies the degree of periportal necrosis (0 to 10), intralobular necrosis (0 to 4), and portal inflammation (0 to 4) along with the stage of disease or fibrosis score (0 to 4). Although the histological findings fluctuate, this information remains the most important predictor of disease outcome and is often used to ascertain which individuals would benefit from treatment.

Liver cancer

Each year, an estimated 1 to 4 per cent of people with HCV-associated cirrhosis will develop hepatocellular cancer. The pathogenesis is unknown. The highest incidences are reported in Japan and Italy. In China and Korea, HBV infection is a more common cause of hepatocellular carcinoma. Serum a-fetoprotein levels and hepatic ultrasound are used for screening in persons with cirrhosis.

Diagnosis

Serological testing

HCV infection is usually diagnosed by testing for HCV antibodies in serum with an enzyme immunoassay that includes recombinant HCV proteins. Second and later generations of these antibody assays are highly sensitive screening tools (Table 1). Problems arise in acute infection as antibody development can be delayed for several months after exposure and in those with compromised antibody production (e.g. haemodialysis and agammaglobulinaemia). Uncommonly, false-negative enzyme results have been reported in persons on haemodialysis and, less commonly, HIV-positive people.

A positive HCV antibody test needs further evaluation. In low-risk screening (e.g. volunteer blood donation) an immunoblot assay can be used to detect antibodies to a variety of recombinant antigens. Reactions to more than one antigen strongly suggests infection. Where HCV infection is expected, HCV RNA testing is a more expedient confirmation approach, providing both an independent assessment of infection and indication of whether the infection has cleared or is ongoing.

HCV RNA testing

HCV RNA can be detected and quantified by a number of amplification techniques including reverse transcription polymerase chain reaction (**RT-PCR**). The reliability of HCV RNA assays has been questioned and the values of different quantitative tests are difficult to compare, although an international standard has been advanced. HCV genotype can be assessed by phylogenetic analysis of nucleotide sequences or detection of subtype-specific point mutations in RT-PCR amplified RNA.

Treatment

Interferon-a

Interferon-a induces expression of multiple genes that have antiviral and antiproliferative activity including those encoding RNAase L, 2'-5' oligo-adenylate synthase, M protein, and protein kinase R.

Almost half of the patients receiving interferon-a-2b (3 million units subcutaneously three times a week for 6 months) have a normal serum ALT and undetectable HCV RNA by the end of treatment (end of treatment response). However, many relapse and 6 months after completion of therapy, fewer than 20 per cent still have a normal ALT level and undetectable HCV RNA (sustained response). Longer treatment reduces the number of relapses, but overall sustained (6 months after treatment) response rates remain low. Higher interferon doses and daily administration accelerate the pace of viral clearance but do not consistently improve sustained virological response rates.

Interferon-a therapy causes a number of adverse reactions. Flu-like symptoms occur within 6 h of the first dose but generally diminish in 1 to 2 weeks. Fatigue, depression, and other mood disturbances may be severe, especially if there is a history of such problems in the past. Hair thinning and thyroid abnormalities may occur. Bone marrow suppression is common including neutropenia, thrombocytopenia, and anaemia. Interferon-a cannot be used safely in pregnancy.

Interferon-a therapy has been associated with improvements in quality-of-life indices and reductions in the incidence of hepatocellular cancer and cirrhosis. Although uncommon, sustained virological responses are durable; 5 years later more than 90 per cent of sustained responders still have normal serum ALT levels and no HCV RNA in blood or liver.

Other interferon formulations, including a recombinant consensus interferon, interferon-a-2a, and interferon-a-2b-n $_1$ (lymphoblastoid interferon) have similar efficacy and adverse effects. Interferon-a has been covalently linked to polyethylene glycol (pegylated interferon), resulting in a longer half-life (weekly dosing), higher sustained serum levels, and improved HCV clearance.

Interferon and ribavirin

Ribavirin is a guanosine analogue that has broad antiviral activity but may affect HCV by inducing a shift toward a T $_{H1}$ immune response. Used orally alone, ribavirin returns the level of serum ALT to normal in some individuals but does not substantially change HCV RNA levels. However, in combination with interferon-a-2b, 1000 to 1200 mg of oral ribavirin daily improves the sustained virological response rates both for people who have never been treated and those who initially responded to interferon but then relapsed (but not those who never responded). As initial treatment, approximately one-third of patients treated with interferon and ribavirin have a sustained virological response. Responses to interferon-a and ribavirin vary according to pretreatment characteristics, especially HCV genotype (Fig. 2). It is likely that pegylated interferon-a and ribavirin will be the most effective therapy available in 2001.

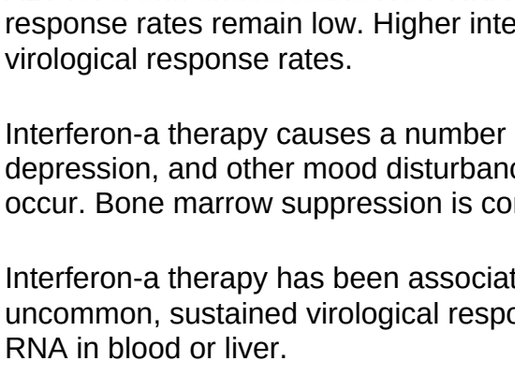

Fig. 2 Sustained virological response rates according to regimen and pretreatment factors.

Adverse reactions to ribavirin and interferon-a are similar to those with interferon-a alone, but ribavirin causes haemolytic anaemia in many patients. Ribavirin is

teratogenic; pregnancy must be prevented during and for up to 1 year after administration, whichever sex is being treated.

Other therapies

Oral amantadine and herbal products such as milk thistle have been used to treat HCV infection. New drugs are expected that interfere with the viral protease, helicase, or replicase, or with viral translation.

Prevention

Primary prevention

HCV transmission is preventable by reducing percutaneous exposures, while ensuring the safety of those that are medically or culturally necessary. HCV-infected people should not allow others to come into contact with their blood, especially by sharing razors or dental devices. HCV is not transmitted by typical household exposures (hugging, kissing, sharing eating utensils or food). Counselling may be needed to prevent unwarranted ostracism.

No vaccination has been licensed to prevent HCV transmission. Since HCV reinfection has been demonstrated even with an autologous inoculum, it is difficult to induce immunity that protects against infection. However, it may be possible to reduce viral persistence by vaccination.

Secondary prevention

Once infection occurs, the incidence of cirrhosis and hepatocellular cancer can be reduced by medical treatment and elimination (or reduction) of alcohol ingestion. Because of drug toxicity and expense, interferon-a use is rare except among selected residents of economically developed nations. More accessible treatments are needed to prevent development of disease worldwide.

Postexposure prevention

Although administration of HCV antibody-containing immunoglobulin may increase the time to development of infection, infection is not usually prevented, and immunoglobulin preparations available in many countries no longer contain HCV antibodies. Therefore, most authorities recommend that persons exposed to HCV do not receive immunoglobulin. Exposed persons should be monitored (for example, at 2 and 6 months) for development of HCV antibodies and possibly HCV RNA, since treatment may be more effective if provided within the first year of infection. There are no interventions available to prevent HCV transmission from a mother to her infant; in particular, current medical treatments (interferon and ribavirin) are contraindicated in pregnancy, immunoglobulin administration is not advised, caesarian section is not routinely indicated, and breast feeding should not be discouraged.

7.10.21 HIV and AIDS

G. A. Luzzi, T. E. A. Peto, R. A. Weiss, and C. P. Conlon

Introduction

The acquired immunodeficiency syndrome (**AIDS**) was first recognized in 1981 in the United States, when several cases of *Pneumocystis carinii* pneumonia and Kaposi's sarcoma were reported in homosexual men in New York and California. The variety of unusual infections and other conditions declared a new form of cellular immunodeficiency. Soon after, the syndrome was reported in injecting drug users, haemophiliacs, and recipients of blood transfusions. Early epidemiological data suggested that the cause was a sexually transmissible bloodborne infective agent. During 1983, in France, a new retrovirus was isolated from a patient with persistent generalized lymphadenopathy. Initially referred to as 'lymphadenopathy-associated virus' (**LAV**) or 'human T-lymphotropic virus III' (**HTLV-III**), it was renamed 'human immunodeficiency virus' (**HIV**) in 1986.

At the time of its discovery, HIV was already widespread, the earliest infections probably having occurred before the 1950s. The recognition of heterosexual intercourse as the most common means of HIV transmission worldwide followed the investigation of epidemics in Africa and the Caribbean. Infected mothers could pass the virus on to their fetus or neonate, establishing vertical transmission as another important route of HIV infection.

In 1986 a second retrovirus causing AIDS, HIV-2, was identified in West Africa. It is largely confined to this region, while HIV-1 is the cause of the world pandemic of AIDS. Over the past 5 years there have been advances in the understanding of the pathogenesis of HIV, in clinical monitoring, and in therapy. Table 1 lists the milestones in the history of HIV and AIDS (acquired immunodeficiency syndrome).

Epidemiology

The global HIV-1 pandemic has affected developing countries in particular. Despite under-reporting, the World Health Organization (**WHO**) estimated that by the end of 1998 over 10 million people had died of HIV, and over 30 million people were alive and infected worldwide, of whom 90 per cent were living in sub-Saharan Africa, South and South-East Asia, and Central and South America (Fig. 1).

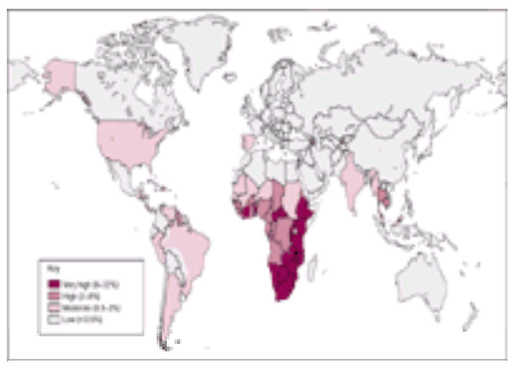

Fig. 1 World distribution of HIV (UNAIDS/WHO, 1998). (Reproduced from *Report on the global HIV/AIDS epidemic*, June 1998. (1998). UNAIDS/WHO, with permission.)

The numbers of people infected with HIV must be distinguished from cases of AIDS, which follows an asymptomatic period of about 10 years and may be influenced by interventions such as antiretroviral therapy. Worldwide, the WHO estimated a 9 per cent increase in new infections in 1997 compared with 1996.

In North America, western Europe, and Australasia the epidemic began in the late 1970s and early 1980s among homosexual men and injecting drug users. However, in these regions the proportion attributable to heterosexual transmission has increased. The estimated incidence of AIDS in western Europe rose every year between 1985 and 1994, stabilized in 1995, and fell by 10 per cent in 1996 and by over 20 per cent in 1997. A similar trend has been observed in North America. Cases attributed to injecting drug use form the largest proportion of diagnosed cases of AIDS in Europe. Large epidemics of HIV have been reported in injecting drug users in several countries of the former Soviet Union.

Some two-thirds of all cases are found in sub-Saharan Africa, where HIV transmission is predominantly heterosexual and perinatal. The estimated overall prevalence there is 7 to 8 per cent, rising to 20 to 30 per cent in some countries such as Zambia and Zimbabwe, where AIDS has curtailed population growth. Because of the predominant heterosexual transmission, the overall male-to-female ratio in Africa is approximately 1:1 compared with 9:1 in North America and western Europe.

In Africa, predicted rates of AIDS and new HIV infection were expected to plateau by 2000 and then to fall gradually, whereas trends suggest a continuing rise in South and South-East Asia, where the emergence of epidemic HIV occurred later. A rapid rise in incidence occurred in Thailand and India in the late 1980s, initially among intravenous drug users and prostitutes and then through heterosexual spread; the WHO estimates that 3 to 5 million people have been infected in India alone. Rapid spread and major epidemics of HIV have also been reported in China, Cambodia, Burma (Myanmar), and Vietnam.

High rates of transmission of HIV continue in developing countries because of the lack of awareness, poverty, high rates of other sexually transmitted infections, and higher risk behaviour such as the use of prostitutes and injecting drug use.

HIV-2 is endemic in parts of West Africa and is increasingly prevalent in Angola, Mozambique, France, and Portugal. In other parts of the world the prevalence is very low, although it is present in India. The clinical features of HIV-2 are similar to those of HIV-1, but some patients with HIV-2, for unknown reasons, appear to progress much more slowly.

HIVs may be regarded as zoonoses: HIV-1 is derived from a simian immunodeficiency virus in the chimpanzee (*Pan troglodytes troglodytes*), and the animal reservoir for HIV-2 is the sooty mangabey monkey (*Cercocebus atys*). Variation of HIV-1 RNA sequences has been identified, leading to a classification of 11 sequence subtypes (or clades), A to K, of the main group M, and N (new) and O (outlier) as two quite distinct groups in west central Africa. The subtypes have varying geographical distributions. For instance, subtypes A and D are found in central Africa, B in North America and Europe, and E in Thailand. Study of the genetic and geographical divergence of subtypes has shed light on the emergence and global spread of HIV.

Cellular biology of HIV

The viral replication cycle

HIV-1 (Fig. 2) and HIV-2 belong to the lentivirus subfamily of retroviruses. Retrovirus implies a 'backwards' step in biological information during viral replication attributable to its enzyme, reverse transcriptase. As with all retroviruses, the viral genes in infectious particles are carried as RNA, but upon infection of the host cell, reverse transcriptase catalyses the synthesis of a double-stranded DNA viral genome (Fig. 3). Insertion of the DNA genome into the chromosomal DNA of the infected cell is effected by viral integrase. The integrated provirus may remain latent, particularly in resting lymphocytes. In actively infected cells, however, RNA transcripts and proteins are synthesized, leading to the formation of new virus particles.

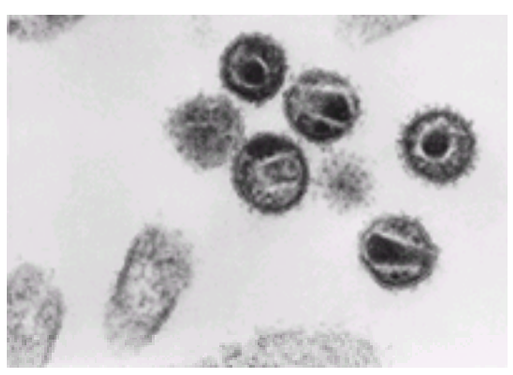

Fig. 2 Electron micrograph of HIV-1. (Reproduced by courtesy of H. Gelderblom.)

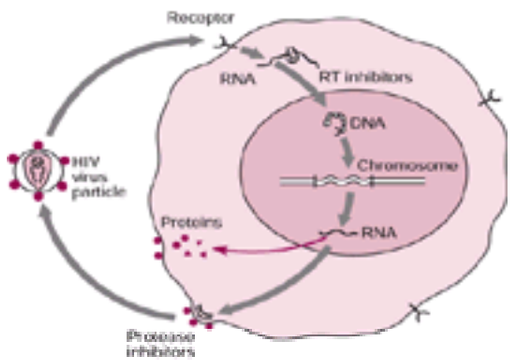

Fig. 3 Replicative cycle of HIV.

The core proteins derived from the *gag* and *pol* genes are made as large polypeptides that are then cleaved into smaller components representing the enzymes and building blocks of the virus. This cleavage is achieved by the viral protease. The unique reverse transcriptase and protease are targets of antiretroviral therapy (see Antiretroviral therapy below). Reverse transcriptase inhibitors such as zidovudine and lamivudine affect an early step in HIV replication, whereas the protease inhibitors, such as saquinavir or indinavir, block a late stage of virus assembly (Fig. 3). Compounds that inhibit any stage of HIV replication, without being too toxic to the infected person, are potential antiviral drugs. Agents have been developed to block viral entry (fusion inhibitors); in future, the integrase and viral RNA processing may become therapeutic targets.

HIV genes and proteins

Although regarded as a complex retrovirus, HIV has only nine genes (Fig. 4). The three structural genes are *gag*, *pol*, and *env*, encoding the core proteins p19, p24, and p17, the enzymes (protease, reverse transcriptase, and integrase), and the envelope glycoproteins (gp120 and gp41), respectively. The major regulatory genes *tat* and *rev* encode proteins that are not assembled into the virus but are essential for replication in the cell. The Tat protein acts in positive feedback to enhance transcription of viral RNA from the DNA provirus, while the Rev protein helps the efficient transport of viral RNA from the nucleus to the cytoplasm. Either of these proteins could be a suitable target for antiviral therapy, particularly Tat, because the synthesis of all the other viral proteins depends on its activity.

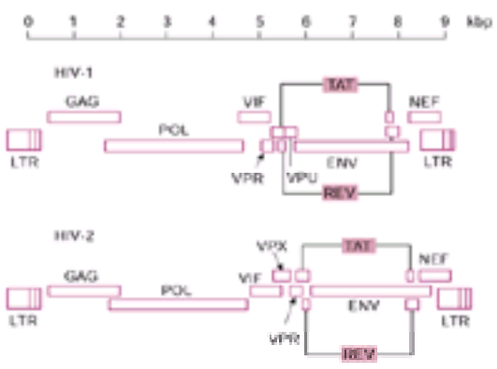

Fig. 4 HIV genome map.

The functions of the four accessory genes of HIV are less well understood. *Vif* encodes a protein assembled in virus particles that appears necessary for the infectivity at a stage soon after entry, possibly by facilitating disassembly of the virion to allow reverse transcription. Nef also effects an early postentry function; it is not needed by laboratory-adapted HIV strains or if virus enters via endosomal vesicles rather than fusing with the outer cell membrane. It also downregulates surface expression of the primary cell-surface receptor for HIV, the CD4 antigen, by drawing CD4 into clathrin-coated pits. Vpu similarly interacts with CD4, promoting its degradation by directing it to the ubiquitin–proteasome pathway. Vpr has dual functions; first, it directs the preintegration complex of the virus, containing the newly synthesized DNA, into the nucleus so that it can integrate into chromosomal DNA; second, it blocks cell proliferation in the G2 phase of the cell cycle, thereby enhancing the amount of viral progeny released per cell.

Unlike HIV-1, HIV-2 and the simian immunodeficiency virus (**SIV**) lack *vpu*, but have an alternative gene, *vpx*. HIV-2 Vpr leads the viral genome into the cell nucleus but does not arrest the cell cycle. These proteins presumably recognize cellular proteins and some of these interactions are species-specific. Thus the Vpr and Vif proteins in SIV of African green monkeys do not function in human cells, while the equivalent proteins of SIV from sooty mangabey monkeys work well in human cells. This could explain why sooty mangabey SIV was able to infect humans and become HIV-2, whereas the more widespread African green monkey SIV has not led to a zoonosis. Another difference is that HIV-1 incorporates the cellular protein cyclophylin A (the target of the drug ciclosporin A) into virus particles, where it may co-operate with Vif and is required for steps early in the infection. In contrast, HIV-2 does not contain cyclophylin A and replicates well without it.

HIV receptors and cellular tropism

CD4 is the cell-surface receptor for HIV; it is expressed on T-helper lymphocytes, the cells that become depleted in AIDS. CD4 is also expressed (to a lesser extent but sufficient to permit infection) on macrophages, Langerhans dendritic cells in mucous membranes, and brain microglial cells. These are the other target cells for HIV infection. CD4 is necessary to initiate HIV infection but is not sufficient to allow the virus to fuse with host-cell membranes: another cellular component or co-receptor is required.

Different substrains of HIV, even those isolated from the same patient, exhibit specific tropisms for different cell types in culture. All isolates can infect primary CD4 lymphocytes, but only some infect macrophages while others can infect cell lines established from CD4+ leukaemic cells. Macrophage-tropic strains predominate early in the course of HIV infection, and may be more transmissible from person to person. They do not cause CD4 lymphocytes to fuse together in culture and hence are referred to as non-syncytium inducing (**NSI**) strains. In contrast, many HIV isolates established from late-stage infection rapidly adapt in culture to infect T-cell lines and are syncytium-inducing (**SI**). Approximately 50 per cent of patients with AIDS develop SI strains in addition to NSI strains. The differences in cellular tropism and SI/NSI phenotype occur in all HIV subtypes or clades, which appear to reflect geographical variation of HIV rather than specific biological properties of the virus.

The complex cellular tropism of HIV has been explained by the discovery that different members of the chemokine receptor family act as co-receptors to CD4 for HIV entry into cells. Chemokines are chemoattractant, locally acting hormones or cytokines that bind to one or more receptors which are structurally related to olfactory and neurotransmitter receptors. Following binding to the CD4 receptor, primary NSI strains use CCR5, the chemokine receptor for macrophage-inhibitory proteins (**MIP-1a**, **MIP-1b**) and RANTES. In contrast, the SI strains of HIV use the CXCR4 co-receptor, the receptor for another chemokine, stromal-derived factor-1 (**SDF-1**). Other receptors such as CCR3 (the receptor of eotaxin) can be used by some NSI strains.

High levels of MIP-1a or -b in the blood correlate with relative resistance to HIV infection. Some exposed yet uninfected individuals are homozygous for an inherited defect of the CCR5 receptor involving a 32 base-pair deletion in the *CCR5* gene. This mutation has a high frequency in Caucasian people but is not found in African and Asian populations. Individuals who are homozygous for the deletion are healthy, indicating that the CCR5 receptor is not essential for the development of immune competence, probably because MIP-1 and RANTES can also bind to alternative receptors. However, homozygotes are genetically resistant to infection by NSI strains of HIV and the few homozygotes with A32 deletions who are HIV-positive appear to have been infected with SI strains that utilize CXCR4 instead. Other, more subtle, mutations in the promoter region of the *CCR5* gene allowing only low levels of co-receptor expression may confer relative resistance to HIV infection and also, if infection occurs, slower progression to AIDS.

The outer envelope glycoprotein, gp120, is the molecule on HIV that binds to CD4 and subsequently to the co-receptor. Gp120 is anchored to the viral envelope via gp41, the viral protein that is thought to effect membrane fusion. The gp120–gp41 is present in the viral envelope as a trimeric complex. SI strains have a gp120–gp41 structure that is less stable than NSI strains, readily undergoing conformational change on binding to CD4. This property makes SI strains more sensitive to neutralization by gp120 antibodies and also to inactivation by soluble forms of recombinant CD4, which were once seen as promising therapeutic agents. NSI strains, however, are more resistant. Mutations in the V3 loop of gp120 can convert NSI strains to SI strains. These mutations arise naturally during progression to AIDS and may allow HIV to switch to infect different cell types via new co-receptors.

The natural chemokines act as competitive inhibitors of HIV entry; certain chemically modified chemokines and chemical analogues act as strong HIV inhibitors without triggering the downstream signalling of the receptor. This has led to a new class of potential anti-HIV drugs, called 'co-receptor inhibitors'.

Diagnosis of HIV infection

Acute infection is accompanied by the development of serum antibodies to the core and surface proteins of the virus, usually within 2 to 6 weeks. Most seroconversions occur within 3 months of infection, and very rarely up to 6 months. Routine diagnostic tests, if negative, should be repeated 3 months after any possible exposure. Where there has been a high risk of transmission, additional tests that detect HIV directly (detection of viral RNA or DNA by polymerase chain

reaction, **PCR**) should be used, and may confirm HIV infection before antibodies become detectable.

Following seroconversion, antibody to envelope protein persists indefinitely in the serum and forms a highly specific test for HIV infection. In general, one or more sensitive enzyme immunoassay tests that detect HIV-1 and HIV-2 antibodies are used as the initial screening tests. Positive screening tests are confirmed by additional tests to confirm the presence of HIV antibodies.

Pretest discussion and counselling

Where possible, patients should understand the implications of being tested for HIV and should give informed consent before the test is done. This is especially important for asymptomatic people. Awareness of being HIV-positive allows the use of effective prophylaxis against the major opportunistic infections, and highly active antiretroviral drugs. It should also encourage behavioural change to reduce the risk of transmission to sexual partners, and may benefit children exposed to perinatal infection. However, early diagnosis may cause distress and disruption of domestic, social, and professional lives, although the infected person may be free from symptoms for many years. HIV-positive people may find it difficult to obtain life or medical insurance, obtain work, buy a house, and travel abroad.

Where HIV is relevant to the investigation of a patient's symptoms, it is in their interest to be tested so that appropriate treatment for an opportunistic condition, antiretroviral therapy, and prophylaxis can be provided. Where the patient is too ill to give consent, testing may be justifiable on these grounds. A high level of confidentiality must be maintained; disclosure of HIV-positive status should generally be allowed only in the medical interests of the patient and with their knowledge and consent.

Clinical presentation and features

Acute HIV syndrome

Between 2 and 6 weeks after exposure to HIV, 50 to 70 per cent of those infected develop a transient, often mild, non-specific illness (sometimes called primary infection or seroconversion illness) similar to infectious mononucleosis, with fever, malaise, myalgia, lymphadenopathy, and pharyngitis. However, unlike infectious mononucleosis over 50 per cent of people develop a rash, typically erythematous, maculopapular, and affecting the face and trunk. Other rashes and patterns of distribution, and oral and genital ulcers have also been reported. The illness begins abruptly and usually lasts for 1 to 2 weeks, but may be more protracted. Neurological complications include acute encephalitis, lymphocytic meningitis, and peripheral neuropathy. Severe or long-lasting illness and neurological involvement are associated with accelerated progression to AIDS and a bad prognosis, which may be influenced by early antiretroviral therapy.

Diagnosis requires a high index of suspicion. Acute HIV infection is a time of high viraemia (typically 10^5 to 10^6 viral particles/ml) during which antibodies to HIV may initially be absent (Fig. 5). Serological tests often need to be repeated at intervals to establish the diagnosis. Rapid diagnosis during the early stages of acute infection may be provided by detecting HIV viraemia using tests for HIV RNA or proviral cDNA (by PCR). A transient decrease in CD4 lymphocytes is usual during primary illness. Occasionally this may be substantial and associated with opportunistic infections such as oral or oesophageal candidiasis, and rarely pneumocystis pneumonia.

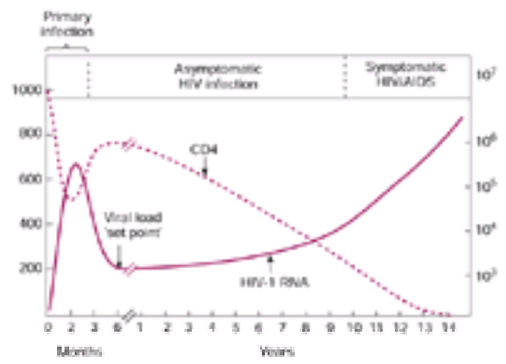

Fig. 5 Schematic representation of typical changes in CD4 lymphocyte count (left axis, per mm^3) and plasma HIV-1 RNA (right axis, copies/ml) with time, during the natural history of HIV infection.

Aggressive therapy of acute HIV infection with antiretroviral drugs does not eradicate the infection but, on theoretical grounds, may alter the natural history. After acute infection, the viral load becomes relatively stable after 6 to 9 months (Fig. 5). The plasma HIV RNA level at this virological steady state or 'set point' is of prognostic importance; therefore, treatment of the initial viraemic illness may lower the risk of progression. A placebo-controlled trial of zidovudine monotherapy during acute HIV infection showed a short-term benefit, but whether long-term outcomes are better compared with deferred treatment is not known. There are also concerns about the long-term toxicity of antiretroviral drugs. Current guidelines generally recommend considering treatment with highly active antiretroviral therapy, ideally within a clinical trial. The optimal duration of therapy for acute HIV infection is unknown.

Early HIV infection

Following the acute syndrome or subclinical seroconversion, there usually follows an asymptomatic period lasting an average of 10 years without antiretroviral therapy. Although a time of clinical latency, there is intense viral turnover: 10^9 to 10^{10} viral particles are replaced daily and the half-life of circulating CD4 lymphocytes is substantially reduced.

During the asymptomatic period, physical examination may be normal, but about one-third of patients have persistent generalized lymphadenopathy. The enlarged nodes, caused by a non-specific follicular hyperplasia, are usually symmetrical, mobile, and non-tender. The cervical and axillary nodes are most commonly affected. Nodes that are markedly asymmetrical, painful, or rapidly enlarging should be biopsied to exclude tumours such as lymphoma and opportunistic infections such as tuberculosis.

Symptoms of progressive HIV infection can be prevented by highly active antiretroviral treatment (see Management of HIV and prevention of complications, below). In the absence of treatment, patients often develop minor opportunistic conditions affecting the skin and mucous membranes. These are also common throughout the later stages of HIV disease. They include a range of infections: fungal (e.g. tinea, *Pityrosporum*), viral (e.g. warts, molluscum contagiosum, herpes simplex, herpes zoster), and bacterial (e.g. folliculitis, impetigo); and also eczema, seborrhoeic dermatitis, and psoriasis.

Drug rashes may occur at all stages of HIV, and particularly in late disease. Reactions to co-trimoxazole occur in up to 30 per cent of patients. They are most common when high doses are used in the treatment of pneumocystis pneumonia. Dapsone, clindamycin, b-lactam antibiotics, pentamidine, and nevirapine are commonly associated with drug rash.

Oral hairy leucoplakia usually appears as corrugated greyish-white lesions on the lateral borders of the tongue in homosexual men (Fig. 6). The condition is symptomless and non-progressive, but acts as a useful clue to HIV seropositivity. Epstein–Barr virus DNA has been demonstrated in these lesions.

Fig. 6 Oral hairy leucoplakia.

One of the characteristic clinical presentations of HIV disease is a sore mouth and throat due to oropharyngeal candidiasis (oral thrush) (Fig. 7). This sign of worsening immunodeficiency may be recurrent. Topical antifungals (amphotericin lozenges or nystatin suspension) are usually effective in the early stages, but later oral azole antifungals (ketoconazole, fluconazole, or itraconazole) are needed. *Candida albicans* is usually responsible, but other species (e.g. *C. glabrata*) may be implicated.

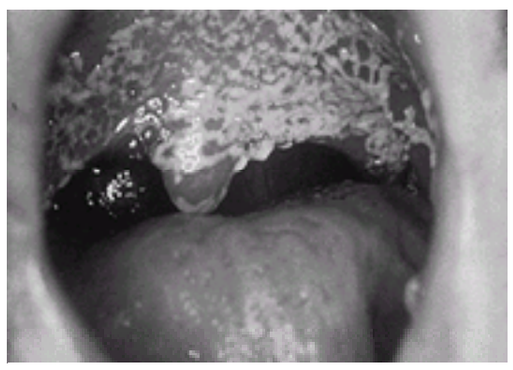

Fig. 7 Oral candidiasis.

There is an increased incidence of periodontal disease in those with HIV. Necrotizing (ulcerative) gingivitis and periodontitis may require extensive debridement and antimicrobials. Recurrent oropharyngeal aphthous ulceration is common and may be painful. Recurrent ulcers may occur in the oesophagus and other parts of the gastrointestinal tract. They usually respond to local or systemic corticosteroid therapy. Resistant cases may respond to thalidomide.

Later in the course of infection, intermittent or persistent non-specific constitutional symptoms may develop, which include lethargy, anorexia, diarrhoea, weight loss, fever, and night sweats. These symptoms may presage severe opportunistic infections or tumours.

Progression to AIDS

Various staging systems for HIV infection and case definitions of AIDS have been used since 1982 and modified by increased understanding of the pathogenesis and natural history. The 1987 Centers for Disease Control (**CDC**) definition listed a range of specific diseases indicative of AIDS. In 1993, an expanded definition was introduced in the United States that included additional AIDS indicator diseases, people with proven HIV infection, and a CD4 lymphocyte count of less than 200/mm ^{3} (0.2×10^{9}/l), irrespective of clinical manifestations. This last criterion has not been adopted in Europe.

The value of making a distinction between AIDS (as defined) and HIV infection at other stages is questionable, especially in industrialized countries. AIDS-defining illnesses were essential for surveillance when HIV status was frequently unknown, the natural history of HIV infection was poorly understood (the proportion developing opportunistic complications was uncertain), and disease-modifying drugs were not available. However, effective prevention of many of the opportunistic infections has led to an increase in the proportion of symptomatic patients who do not fulfil the criteria for AIDS. Highly active antiretroviral therapy often improves the clinical condition and survival even when started after progression to AIDS. These factors have undermined the epidemiological value and prognostic importance of a strict AIDS case definition. It is probably more useful to consider progressive HIV disease as a continuous spectrum.

However, clinical criteria to identify symptomatic HIV disease and AIDS are needed in developing countries, where laboratory confirmation of HIV seropositivity and AIDS-defining diseases is not possible. The WHO has, therefore, adopted clinical case definitions for AIDS surveillance in resource-poor countries, based on clinical manifestations with or without laboratory confirmation of HIV infection.

Non-progression

While the average time between infection with HIV and the development of AIDS is about 10 years, approximately 20 per cent of patients progress rapidly to AIDS within 5 years and 10 to 15 per cent remain clinically well for 15 to 20 years. Long-term healthy survivors are often called non-progressors, and to an extent this subgroup represents simply the tail end of a normal distribution of progression rates. Cohort studies have demonstrated that most apparent non-progressors are slow progressors, in whom a gradual decline in the CD4 lymphocyte count and increments in HIV viral load can be demonstrated. Although several investigators have reported virological, genetic, and cellular and humoral immunological factors that may be associated with non-progression, limitations in study design have made it difficult to identify what was responsible. A mutation in the gene for the macrophage chemokine receptor CCR5 is associated with non-progression in the heterozygous state; homozygotes have high-level resistance to HIV infection (see Cellular biology, above).

Management of HIV and prevention of complications

Impact of highly active antiretroviral therapy

Although a decline in the number of cases of AIDS and mortality from HIV was reported from the United States and Europe before the advent of protease inhibitors in 1996, the subsequent marked reductions in morbidity and mortality are mostly attributable to antiretroviral regimens that include the newer potent agents (protease inhibitors or non-nucleoside reverse transcriptase inhibitors) in combination with nucleoside drugs. Among 1255 HIV-positive patients attending HIV clinics in eight cities in the United States, mortality declined from 29.4 per 100 person-years in 1995 to 8.8 per 100 person-years in the second quarter of 1997. The incidence of pneumocystis pneumonia, disseminated *M. avium* complex (**MAC**) infection, and cytomegalovirus (**CMV**) retinitis declined dramatically. The mortality of patients with CD4 counts below 100/mm^{3} fell for the first time in 1996, at a time when protease inhibitors were increasingly being included in treatment regimens. A decline in the incidence of opportunistic infections, notably oral candidiasis, toxoplasmosis, cryptosporidiosis, and cryptococcal meningitis, was reported from the United States and Europe.

In Europe, the expected survival 10 to 15 years after seroconversion was shown to have risen substantially after the introduction of highly active antiretroviral treatment (Fig. 8). For instance, in the 35 to 44 years' age group, survival 10 years after acquiring HIV in the era of highly active antiretroviral treatment (1997–98) was estimated to be 83 per cent, compared with 43 per cent for those infected between 1986 and 1996.

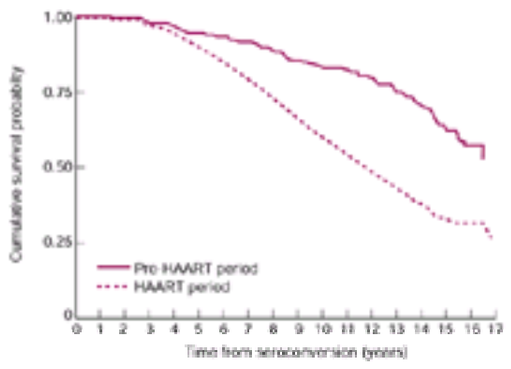

Fig. 8 Estimated proportions of individuals surviving from HIV-1 seroconversion in 1986–96 (pre-HAART* period) and 1997-98 (HAART* period). *HAART, highly active antiretroviral therapy. (CASCADE collaboration, *Lancet* (2000), **355**, 1158.)

Whether antiretroviral drugs will ever eradicate HIV and bring about a 'cure' is regarded as unlikely. Although HIV may be undetectable in plasma for many months, a long-lived reservoir of infectious virus can be recovered from latently infected (resting) memory CD4 lymphocytes. Since the half-life of this cell population is about 6 months, many years of effective antiretroviral treatment would be needed to clear virus from this reservoir. Other compartments exist that are relatively inaccessible to drugs—for instance, in the central nervous system, retina and testes—and unless viral replication can be successfully prevented at such sites there is also the risk of reinfection of compartments previously cleared by therapy.

General management

Ideally, HIV infection should be identified at the asymptomatic stage. Clinical and laboratory monitoring can detect waning immunity and the risk of disease progression, prompting antiretroviral therapy and prophylaxis against infections such as pneumocystis pneumonia. Serological screening detects past or current infections such as toxoplasma, CMV, hepatitis B and C, and syphilis, which may be reactivated or progress during immunosuppression. Clinic visits provide an opportunity for discussion of such issues as safer sex. Many problems can be managed by a primary care physician. Routine dental care is needed. Clinical and laboratory monitoring, the management of late complications, and the prescription and monitoring of antiretroviral drugs require specialist supervision.

Monitoring

Monitoring involves regular clinical assessment and prognostic laboratory tests. Oral candidiasis, or physical signs such as asymptomatic cutaneous Kaposi's sarcoma are of prognostic importance. CD4 lymphocyte count and quantitative estimation of HIV RNA in the blood plasma (viral load) are the two laboratory markers that have the best prognostic value.

The CD4 lymphocyte (T-helper cell) count is a reliable indicator of HIV-related immune impairment. CD4 counts, normal at or above 600/mm ^{3}, vary considerably, even in the absence of HIV infection. A fall in the CD4 lymphocyte count to below 200/mm ^{3} is associated with a risk of opportunistic infections of about 80 per cent over 3 years without antiretroviral treatment. However, progression is variable and a minority remain well for several years with stable low CD4 counts. This variability is explained partly by differences in HIV viral load. The level of CD4 lymphopenia generally determines the spectrum potential of infections (Table 2). For instance, whereas oral and oesophageal candidiasis and pneumocystis pneumonia are frequent at CD4 counts of 100 to 200/mm ^{3}, disseminated MAC infection and CMV retinitis are rarely seen until the CD4 count is below 50/mm ^{3}.

The prognostic value of measuring HIV RNA in plasma was reported from the United States in 1996. In HIV-positive men in a subgroup of the Multicenter AIDS Cohort Study, only 8 per cent with less than 5000 copies of HIV RNA/ml progressed to AIDS over 5 years, whereas 62 per cent with viral loads above 35 000 developed AIDS. For a given level of CD4 lymphocytes, variations in viral load predict the risk of progression. The most useful prognostic information is therefore derived from the CD4 count and viral load taken together (Fig. 9).

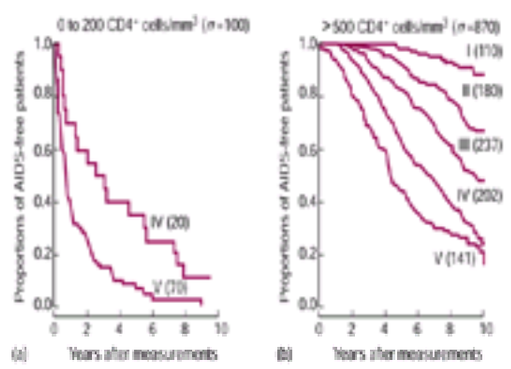

Fig. 9 Curves showing AIDS-free survival with time among groups with different baseline CD4 lymphocyte counts, according to HIV-1 RNA category. The five categories were (copies/ml): I, 500 or less; II, 501 to 3000; III, 3001 to 10 000; IV, 10 001 to 30 000; and V, above 30 000. (Sample sizes are shown in brackets).

In industrialized countries, HIV viral load measurements have become widely available. Techniques include reverse transcription followed by amplification by the polymerase chain reaction (**RT-PCR**), branched DNA (**bDNA**) signal amplification, and nucleic acid sequence-based amplification (**NASBA**). Highly sensitive tests with very low detection limits (about 20 copies/ml) are increasingly used.

Antiretroviral therapy

Nucleoside analogues

Knowledge of the viral lifecycle (Fig. 3) led to the development of a number of antiretroviral compounds with clinically useful activity against HIV (Table 3). The forerunner of these was zidovudine (AZT or ZDV), first shown to be active against HIV *in vitro* in 1985. Zidovudine, a nucleoside analogue that inhibits HIV reverse transcriptase, slowed down the rate of disease progression over a 12-month period in patients with AIDS and improved short-term survival, well being, body weight, and neurological features. However, clinical progression associated with viral resistance to the drug was observed after a year or two of therapy. When early treatment with zidovudine was compared to deferred zidovudine, there was no difference in survival or disease progression after 3 years.

The clinical failure of monotherapy prompted combination therapy in an attempt to reduce the development of drug resistance. Double nucleoside combinations proved superior to zidovudine monotherapy, especially in patients without prior exposure to zidovudine. Treatment with at least three drugs is more effective and has become the standard of care. In general, two nucleoside drugs are used with either a non-nucleoside reverse transcriptase inhibitor or a protease inhibitor. A combination of three nucleoside analogues (zidovudine, lamivudine, and abacavir) can also be used, and is available as a single tablet taken twice daily (Table 4).

Non-nucleoside reverse transcriptase inhibitors

The prototype of the class is nevirapine, a potent and selective inhibitor of HIV reverse transcriptase. When nevirapine is given alone, resistance develops rapidly and

this drug is of limited effectiveness in double therapy or when added to failing regimens. However, in antiretroviral-naive patients without AIDS (CD4 200 to 600/mm ^{3}), over a half of patients treated with nevirapine plus two nucleosides (zidovudine and didanosine) had undetectable plasma HIV RNA after 1 year of therapy, compared with 12 per cent for zidovudine/didanosine only. Efavirenz and delavirdine (which is not licensed for use in the United Kingdom) are other non-nucleoside reverse transcriptase inhibitors with similar properties to nevirapine.

Protease inhibitors

The HIV-encoded protease (or proteinase) is required for the production of mature infectious viral particles. This enzyme cleaves a number of structural proteins and enzymes from the polyprotein precursors produced by translation of the *gag* and *gag–pol* genes. Inhibitors of HIV protease act synergistically with nucleoside drugs and are potent inhibitors of HIV replication.

Protease inhibitors have a greater effect on HIV viral load and CD4 counts than nucleoside reverse transcriptase inhibitors, especially when used in triple therapy.

Indinavir, in combination with two nucleoside analogues (zidovudine/lamivudine or stavudine/lamivudine) produced good results in a large controlled trial with clinical endpoints (ACTG 320). Compared to double therapy (two nucleosides), the triple combination reduced the proportion of patients who progressed to AIDS or death from 11 to 6 per cent over about 38 weeks. The responses of CD4 cells and plasma HIV RNA paralleled the clinical results. Similar results were reported for combinations that involved other protease inhibitors, saquinavir, ritonavir, and nelfinavir. Ritonavir, in low dosage, may be included to boost blood levels of other protease inhibitors (especially saquinavir, indinavir, and a newer drug, lopinavir) by competitive inhibition of their hepatic metabolism. Combinations of non-nucleoside drugs and protease inhibitors are also being evaluated.

Other drugs

Fusion inhibitors, such as T-20, stop the HIV glycoprotein gp41 from effecting fusion of the viral and cellular membranes, and thereby prevent HIV entry into host cells. Compounds that inhibit HIV integrase and prevent proviral DNA integration into the host cell genome are also being identified. Hydroxyurea, not in itself an antiviral compound, is sometimes used in combination with nucleoside reverse transcriptase inhibitors; *in vitro* studies suggest that it acts synergistically by reducing the intracellular substrate for making DNA and thereby increasing the efficiency of chain termination. Another adjunctive agent under investigation is interleukin-2 (given subcutaneously), which raises CD4 lymphocyte counts substantially when used in combination with antiretrovirals. Influenza-like side-effects are prominent and therapy is very expensive. Its long-term efficacy is currently unknown and being studied in a large trial (ESPRIT).

General points on HIV therapy

There is a plethora of results from clinical trials of antiretroviral drugs, but several large, randomized controlled trials have made the greatest impact. Comparison between trials may be difficult because of differences in the clinical stage of HIV disease in those enrolled, CD4 counts at entry, previous antiretroviral experience, duration of treatment, and in the drug regimens used. Many trials measure surrogate endpoints, especially HIV viral load reduction and changes in CD4 lymphocyte count. It is assumed that these reflect clinical effectiveness. However, trials conducted over periods of less than 1 year may not predict longer term results. The value of such short-term studies based on surrogate markers is to identify treatments that should be evaluated in large, well-designed controlled trials that measure clinical endpoints (progression of HIV disease or death) ideally over several years. HIV trials may be stopped prematurely when significant differences in clinical outcomes are demonstrable between study arms, but before longer term benefits can be assessed. In fact, the long-term efficacy of currently recommended anti-HIV treatment regimens remains unknown.

When to start treatment

The optimum time to start antiretroviral therapy is not known, and no trials have adequately addressed this question. Data from several clinical cohorts suggest that patients who start treatment when the CD4 count is below 200/mm^3 have an increased mortality when compared with those starting at higher CD4 levels. Currently, there is no clear evidence for an advantage in starting treatment at any given range of CD4 count above 200/mm ^{3}. Therefore, recent guidelines generally recommend starting before the CD4 count drops to below 200/mm^3, or if the patient develops symptomatic HIV disease. Asymptomatic patients with CD4 counts in the range of 200 to 350/mm^3 whose CD4 counts are falling rapidly or who have a high viral load should be monitored more intensively, and earlier intervention may be considered.

What to start with

Highly active antiretroviral regimens consist of at least three drugs, usually a backbone of two nucleosides with either a non-nucleoside reverse transcriptase inhibitor or a protease inhibitor (see Table 4). As discussed above, for pharmacokinetic reasons, two protease inhibitors (one of which is low-dose ritonavir) may be used, and a triple nucleoside regimen is also available. The best starting regimen(s), and how treatment should subsequently be sequenced, have not been determined. No regimen or sequencing strategy has been shown to be clinically superior in controlled trials. Several factors should be taken into consideration when selecting initial therapy, including potential drug interactions, toxicity, and the likelihood of adherence. HIV viral load and CD4 count should be checked after 2 to 3 months. The aim of initial treatment is to achieve a reduction in viral load to undetectable levels (ideally <50 copies/ml) within 6 to 9 months of starting treatment. Whether initial regimens that include more than three drugs are clinically superior in the longer term is being studied in ongoing trials such as Initio.

Changing therapy

Recommendations for changing the treatment regimen are based on theoretical considerations. The principal reasons are treatment failure, toxicity, and poor adherence. There is no agreed definition for treatment failure. Patients whose viraemia was initially suppressed, and whose viral load subsequently rises, should be considered for changing to a completely new regimen of at least three drugs. This may be guided by a resistance test (see Drug resistance, below). However the optimal point at which the switch should be made remains to be defined. Poor absorption of protease inhibitors may sometimes cause treatment failure related to low blood levels, without development of resistance; measurement of blood levels may be useful in selected cases. In cases of drug toxicity (for instance, a severe rash), if the responsible agent is identified then a single drug substitution can be made. If adherence is poor or likely to be the cause of treatment failure, changing to a combination that is simpler to take should be considered, for instance based on once or twice daily dosage and low pill burden (see Patient adherence, below).

'Salvage' therapy

Salvage therapy is generally defined as treatment following exposure to multiple antiretroviral drugs. In this situation, numerous drug-resistance mutations are usually present and the likelihood of achieving sustained viral suppression below the detection level is much lower than for patients who have limited or no previous antiretroviral exposure. This is especially true if drugs from all three major classes have previously been used. Studies using clinical endpoints suggest that declines in viral load correlate with improvements in clinical outcome, even if suppression to below the detection limit is not achieved. Several factors may be considered when selecting a treatment regimen in these circumstances, including drugs or drug classes to which the patient has not been exposed, drugs with a lower likelihood of resistance that can be recycled, inclusion of new drugs or a new class of drug such as nucleotides, and results of tests for viral resistance. Whether 'mega' antiretroviral treatment using five or more drugs for salvage is superior to standard triple therapy is being examined in the OPTIMA trial in the United Kingdom, the United States, and Canada.

Patient adherence

A substantial proportion of HIV patients do not follow treatment recommendations. Reasons for non-adherence include poor communication, the complexity of drug regimens and number of tablets, disruption of life (including timing and food restrictions), side-effects, concerns about long-term effects, and lack of confidence in non-curative treatments of indefinite duration. Adherence to treatment requires a high level of understanding and motivation in the patient. This is of particular concern in HIV therapy because of the risk of developing drug-resistance mutations during suboptimal therapy. The recent development of simplified regimens (for example, once or twice daily dosage; reduced pill burden) has helped.

Drug resistance

Viral resistance is a major factor in treatment failure. There is evidence that resistant mutants arise spontaneously even in the absence of antiretroviral therapy. This

tendency is greatest when HIV viraemia is high, and lowest when HIV replication is completely suppressed by a potent drug combination.

Extensive genotypic variation of HIV occurs because of very high viral turnover and transcription errors by the reverse transcriptase enzyme, so that all possible single-point mutations are likely to occur frequently. While mutations causing resistance to single agents may be present before antiretroviral treatment, on statistical grounds it is unlikely that specific combinations of multiple mutations will be present. However, multiple mutations do develop during antiretroviral therapy with more than one drug when viral replication is at a high level. Therefore, controlling viral replication with a highly potent treatment regimen limits the appearance of resistant HIV mutants.

Genotypic and phenotypic assays have been developed to test for drug resistance in HIV isolates. Genotypic assays that identify codon mutations correlating with *in vivo* resistance to antiretrovirals are relatively easy to perform and inexpensive. Phenotypic assays that measure the ability of the virus to grow in increasing concentrations of drugs are time consuming and expensive, but provide more direct evidence of resistance to a particular drug. The clinical and prognostic value of resistance assays is being evaluated, and, increasingly, they are used in the selection of drug regimens and investigation of treatment failure. Interpretation of resistance patterns is increasingly difficult as the number of drugs and mutations involved increases.

Resistance mutations to antiretroviral agents are identifiable in up to 15 per cent of recent seroconverters in the United States, and transmitted drug resistance is increasing in Europe. Resistance mutations may be lost in the absence of therapy, so the clinical significance of the transmission of a virus carrying resistance mutations to one or multiple drugs is currently uncertain.

Drug toxicity and interactions

Adverse reactions to antiretroviral agents are relatively common; treatment may have to be stopped. Minor gastrointestinal disturbances (nausea, vomiting, diarrhoea), rashes, and headache are common, but some adverse reactions are serious. Drug interactions must be considered when prescribing antiretroviral drugs, especially in late HIV disease. Antiretroviral agents may interact with each other and with other drugs. Ritonavir, a potent inhibitor of cytochrome P-450, is especially prone to raising blood levels of other drugs and should not be given with most antiarrhythmics, anxiolytics, and antihistamines. Caution is required with several analgesics, anticonvulsants, and other categories of medication.

Metabolic complications, especially mitochondrial toxicity and disturbances of lipid and glucose metabolism, have emerged as important adverse effects of antiretroviral therapy. Mitochondrial toxicity is especially associated with nucleoside drugs (such as didanosine and stavudine) and may result in neuropathy, myopathy, pancreatitis, hepatic steatosis, and lactic acidaemia. Mild degrees of lactic acidaemia cause non-specific symptoms including malaise and gastrointestinal disturbance of gradual onset; progression can lead to fatal lactic acidosis. Nucleoside drugs are thought to cause mitochondrial dysfunction by inhibiting mitochondrial DNA polymerase-g.

A syndrome of lipodystrophy (loss of fat from face and limbs), truncal fat accumulation, hyperlipidaemia, and insulin resistance has been associated with protease inhibitors but has also been described with other antiretroviral drugs, and may not respond to changing the drug regimen. Whether the effects on lipid metabolism increase the risk of ischaemic vascular diseases is currently uncertain.

Considerable immune restoration seems to occur after treatment with potent antiretroviral regimens in patients with low CD4 lymphocyte counts. New disease manifestations have been reported. Disseminated MAC may cause widespread lymphadenopathy when antiretroviral therapy is started. Several new manifestations of CMV ocular disease have been reported, including vitritis, cystoid macular oedema (previously seen in HIV-negative patients following withdrawal of iatrogenic immunosuppression), and epiretinal membrane formation. These new disease manifestations are likely to be immune recovery phenomena.

Treatment interruptions

In general, once treatment is started it is continued indefinitely. There has been recent interest in whether interrupting treatment (in supervised or structured treatment interruptions) can be beneficial. In theory, such interruptions might enhance immune responses, reduce long-term toxicity, or reduce resistant virus by allowing repopulation with wild-type virus. The effect of treatment interruptions on clinical outcomes is being studied in clinical trials.

Late complications and their management

Pneumocystis carinii pneumonia

P. carinii pneumonia, one of the hallmarks of AIDS, is now less common because of primary prophylaxis and antiretroviral therapy. Some 85 per cent of cases occur in patients with CD4 lymphocyte counts below 200/mm^3, and mostly at counts below 100/mm^3. Symptoms—typically: increasing shortness of breath, dry cough, and fever—usually develop subacutely over a few weeks. Malaise, fatigue, weight loss, and chest pains or tightness may occur. Chest signs are usually minor (crackles) or absent. The characteristic chest radiograph shows bilateral perihilar interstitial shadowing (Fig. 10), but may be normal. Other appearances include localized infiltrates or consolidation, upper lobe shadows resembling tuberculosis, nodular lesions, and pneumothorax; effusions are very rare. The arterial oxygen saturation is less than 95 per cent at rest or falls after exercise.

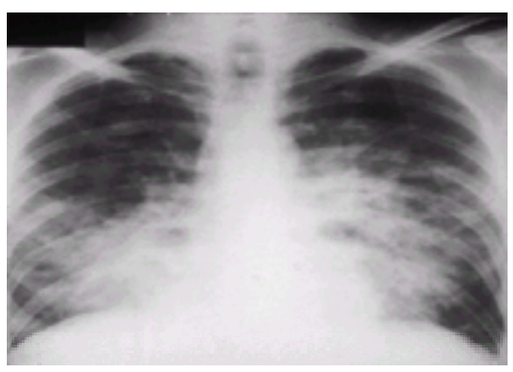

Fig. 10 Chest radiograph: *Pneumocystis carinii* pneumonia.

A foamy intra-alveolar exudate containing abundant *P. carinii* develops, which is associated with an interstitial inflammatory infiltrate and progressive impairment of lung function. The diagnosis can sometimes be confirmed by microscopy of sputum, which is induced by nebulized saline in isolated, properly ventilated rooms to reduce the risk of tuberculosis transmission (see Multidrug-resistant tuberculosis, below). *P. carinii* cysts and trophozoites are visualized by the use of special stains. If the result is negative, fibreoptic bronchoscopy with bronchial lavage may be indicated (Fig. 11); other causes of lung disease or coexistent infection may also be diagnosed by this technique, including tuberculosis, fungal infections, and Kaposi's sarcoma. Immunofluorescence using monoclonal antibodies, or DNA amplification by PCR, may improve diagnostic sensitivity when compared with conventional staining techniques, but these methods are not yet used routinely. In a minority of patients with *P. carinii* pneumonia the diagnosis is not confirmed.

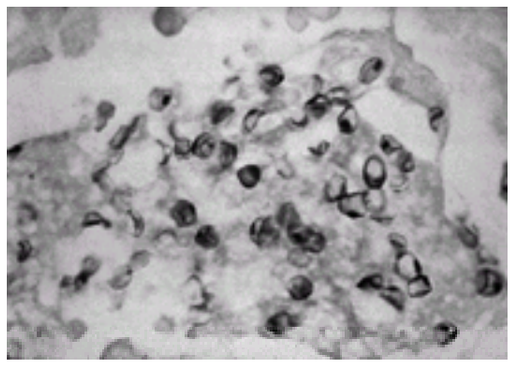

Fig. 11 *Pneumocystis carinii* cysts in bronchoalveolar lavage aspirate.

High-dose co-trimoxazole (120 mg/kg daily in divided doses) for 3 weeks is the first-line treatment for pneumocystis pneumonia. Oral therapy is often adequate, but in moderate and severe cases the drug should be given intravenously. The drug can be given orally if fever, symptoms, and oxygenation have improved after 10 days. Adverse reactions to co-trimoxazole—especially neutropenia, anaemia, rash, and fever—occur in up to 40 per cent of patients, usually after 6 to 14 days. Intravenous pentamidine (4 mg/kg per day) is the second-line choice for patients who do not tolerate co-trimoxazole.

Patients intolerant of co-trimoxazole and pentamidine may be treated with clindamycin plus primaquine or dapsone plus trimethoprim. These regimens have only been evaluated in patients with mild to moderate pneumocystis pneumonia, as has atovaquone, an antiprotozoal drug that is active against *P. carinii.* Although slightly less effective than co-trimoxazole, atovaquone causes fewer adverse effects.

In patients with moderate or severe pneumocystis pneumonia, high-dose corticosteroids reduce morbidity and mortality. If the arterial oxygen tension (PaO_2) is less than 9.3 kPa or the alveolar–arterial oxygen gradient is greater than 4.7 kPa, oxygen and intravenous methylprednisolone or oral prednisolone should be given for 5 to 10 days. Patients who develop respiratory failure may require ventilatory support. After treatment for pneumocystis pneumonia has been completed, secondary prophylaxis should be given to prevent recurrence. This can be discontinued if there is a good response to antiretroviral treatment, with a rise in the CD4 count sustained above 200/mm^3.

Bacterial pneumonia

The risk of bacterial pneumonia is increased in HIV, especially if the CD4 lymphocyte count is below 200/mm^3. The most common cause is *Streptococcus pneumoniae*; *Haemophilus influenzae* and *Moraxella catarrhalis* are relatively common, and *Staphylococcus aureus*, *Klebsiella* spp., and other Gram-negative rods are important causes in advanced HIV disease. Rarer causes include *Nocardia* spp. and *Rhodococcus equi.* The presentation may be atypical, and radiological appearances frequently include diffuse infiltrates that resemble pneumocystis pneumonia, as well as more typical segmental or lobar patterns. Cavitation with abscess formation, pleural effusion, and empyema may occur. HIV predisposes to recurrent invasive pneumococcal infections with bacteraemia; recurrent bacterial pneumonia in a 12-month period is an AIDS-defining condition. Chronic lung damage with bronchiectasis and colonization by *Pseudomonas aeruginosa* have been reported.

Other pulmonary complications

Disseminated fungal infections, including *Cryptococcus* spp., may involve the lungs. In endemic areas histoplasmosis, coccidioidomycosis, and disseminated *Penicillium marneffei* infection need to be considered (see Other disseminated infections, below). Invasive *Aspergillus fumigatus* infections may occur in patients with advanced HIV disease who have additional risk factors such as severe neutropenia. Patients usually have severe systemic illness. The radiographic appearances in all these fungal infections are usually non-specific. Bronchoalveolar lavage may be needed for diagnosis. HIV-associated lymphocytic interstitial pneumonitis causes diffuse abnormalities, usually in children but occasionally in adults. Bronchiolitis obliterans-organizing pneumonia is a steroid-responsive cause of lung infiltrates, probably a tissue response to various underlying conditions, which has also been reported in HIV and may be confused with pneumocystis pneumonia.

Tuberculosis

The interaction between HIV and tuberculosis was recognized early in the HIV epidemic. Studies in Central Africa in the mid-1980s showed that more than 60 per cent of newly diagnosed tuberculosis patients were HIV-positive at a time when the background seroprevalence of HIV in the population was much lower. Intravenous drug users were shown to have an increased risk of developing active tuberculosis if they were HIV-positive. After decades of progressive decline in the incidence of tuberculosis in the United States, notifications increased during the mid-1980s, soon after the emergence of the HIV epidemic. A similar trend was subsequently observed in western Europe. Globally, tuberculosis remains the most frequent life-threatening opportunistic infection in AIDS.

Most cases of tuberculosis in HIV-positive individuals represent reactivation of dormant bacilli. However, molecular typing of isolates of *Mycobacterium tuberculosis* by restriction fragment length polymorphism (**RFLP**) analysis suggests that up to 40 per cent are new infections. The WHO estimates that one-third of the world's HIV-positive population is co-infected with tuberculosis. In communities where *M. tuberculosis* is a common endemic organism, those who are immunosuppressed by HIV have an increased risk of relapsing or contracting new infections. Where the background prevalence of tuberculosis is low, the disease is uncommon in HIV-positive patients unless they become exposed, for instance through travel. Testing for HIV should be considered in patients presenting with active tuberculosis, and tuberculosis should be considered as a cause of unexplained symptoms in patients with HIV.

Active tuberculosis may occur at any time during the course of HIV infection. In early-stage HIV, it is more likely to present with the typical clinical features: subacute history of cough, fever, and weight loss, upper lobe cavitary disease and/or pleural disease on chest radiographs, and a positive skin test to tuberculin. In late-stage HIV, infected patients are more likely to present atypically with unusual chest findings, extrapulmonary involvement, and cutaneous anergy. The chest radiograph may be normal in up to 40 per cent of cases. Sputum smears should be examined for acid-fast bacilli. Blood cultures may be positive for *M. tuberculosis*.

Studies in Zambia have shown that, compared with HIV-negative patients, HIV-positive individuals with tuberculosis are less likely to be sputum-positive on microscopy, show less cavitation and more involvement of the lower lobes, and are more likely to relapse after completion of therapy and to die prematurely. Patients with advanced HIV infection are more likely to develop extrapulmonary tuberculosis involving lymph nodes, pericardium, liver, bone marrow, or meninges.

The standard 6-month regimen of three or four antituberculosis drugs (isoniazid, rifampicin, pyrazinamide, and ethambutol) is generally effective in patients with HIV, unless there is resistance to one or more of these first-line drugs. The drug regimen may need to be adjusted when *in vitro* sensitivity results are known. For fully sensitive organisms, after 2 months on three or four drugs, isoniazid and rifampicin should be continued for a further 4 months. Patients with pulmonary tuberculosis should be isolated initially. Contact tracing is important; HIV-positive contacts are at particular risk. Tuberculin testing is used to determine whether contacts should take isoniazid chemoprophylaxis.

Up to 20 per cent of patients with HIV experience adverse reactions to antituberculosis drugs. In HIV-positive patients with tuberculosis in Africa, the sulpha-based drug thiacetazone has been associated with serious skin reactions, including toxic epidermal necrolysis and fatal cases of Stevens–Johnson syndrome. Whereas response rates for conventional short-course tuberculosis treatment in industrialized countries are similar to those achieved in HIV-negative patients, in resource-poor countries and where compliance is less easily achieved, cure rates are lower and there is a risk that resistance will develop. Several countries have adopted 'directly observed therapy' to address this problem.

Multidrug-resistant tuberculosis

Over 15 outbreaks of multidrug-resistant tuberculosis (**MDRTB**) have been reported since the late 1980s. MDRTB isolates are resistant to at least two first-line antituberculosis drugs, most commonly isoniazid and rifampicin, and are often resistant to several agents. Most have occurred in HIV units in hospitals, but there have been outbreaks in prisons, drug treatment centres, and nursing homes. Most documented outbreaks have been in the United States. Elsewhere, over 200 people were involved in Buenos Aires, Argentina, and another outbreak affected over 100 people in Lisbon, Portugal. In MDRTB outbreaks, healthcare workers may become

infected. Initially, the mortality among HIV-positive patients was very high (up to 93 per cent), but more recently the outcome has improved because of more rapid diagnosis and treatment with at least four drugs to which the *M. tuberculosis* isolate is sensitive *in vitro*. To prevent outbreaks of MDRTB, special precautions are required when HIV-positive patients with possible tuberculosis are admitted to hospitals. Diagnosis must not be delayed, appropriate treatment must be started without delay, and drug resistance identified. Precautions include the isolation of patients in negative-pressure rooms, use of respiratory protection for staff, and special care during certain procedures such as bronchoscopy or nebulized pentamidine administration. With effective treatment, patients rapidly become non-infectious, but precautions need to be continued until the sputum is repeatedly smear-negative.

Mycobacterium avium complex

Patients with advanced HIV infection and CD4 lymphocyte counts below 50/mm^3 are at high risk of disseminated *M. avium* complex (**MAC**) infection, particularly in industrialized countries where it is reported to develop in up to 40 per cent of patients with AIDS. *M. avium* is a ubiquitous environmental organism of low pathogenicity that can be isolated from domestic water supplies. Infection is likely to be through the gastrointestinal tract. MAC infection becomes widely disseminated in those with advanced HIV and causes fever, night sweats, weight loss, diarrhoea, abdominal pain, anaemia, disturbed liver function, and reduced overall survival. The organism can usually be cultured from blood or bone marrow, or may be recognized as acid-fast bacilli in tissue biopsies (for example from lymph node, small bowel, or liver). It is unclear why the diagnosis is uncommon in underdeveloped countries; high mortality from other opportunistic infections at earlier stages of immunosuppression may be partly responsible.

MAC infection is intrinsically resistant to most first-line antituberculosis drugs. The optimal regimen has not been determined, and although clinical benefit and microbiological response is often achieved, survival benefit has been difficult to prove. Comparative trials suggest that initial therapy should be with two or three drugs: clarithromycin or azithromycin and ethambutol should be used, and additional rifabutin or a quinolone (e.g. ciprofloxacin) considered. In severely ill patients intravenous amikacin may be useful as the third agent. Lifelong treatment may be required to prevent relapse; but if immunity is restored by highly active antiretroviral therapy it may prove possible to cure MAC infection.

Other non-tuberculosis mycobacteria

Other mycobacteria, notably *M. kansasii*, *M. genavense*, and *M. celatum*, may cause opportunistic infections in those with HIV. *M. genavense*, which colonizes pet birds, was discovered in European patients with HIV and causes fever, diarrhoea, and severe weight loss. HIV does not seem to affect the incidence or natural history of leprosy (*M. leprae*).

Oesophageal candidiasis

Oesophagitis presents with retrosternal pain on swallowing, and in patients with HIV is most commonly caused by *Candida albicans.* Oesophageal candidiasis indicates advanced immunosuppression and is an AIDS-defining condition. The diagnosis should be suspected in a patient with oral candida and dysphagia, and may be supported by barium swallow or confirmed by endoscopy and biopsy. Treatment is with oral azole antifungal agents. Fluconazole may be more effective than ketoconazole. It may recur and in patients with severe immunosuppression, candida may become resistant to prolonged azole treatment. Resistance tends to develop gradually and can be monitored by *in vitro* testing. Such patients require treatment or continuous suppression with high doses of fluconazole (which is better tolerated than high doses of ketoconazole or itraconazole) or intermittent treatment with intravenous amphotericin. Azole-resistant oro-oesophageal candidiasis has become much less common since the advent of highly active antiretroviral therapy.

The differential diagnosis of oesophageal candidiasis includes oesophagitis caused by cytomegalovirus (**CMV**) or herpes simplex virus (**HSV**), which require specific antiviral therapy, and aphthous ulceration, which may respond to oral prednisolone or thalidomide.

HIV and the nervous system

The nervous system is a major site of involvement for direct and indirect complications of HIV at all stages of infection. All parts of the nervous system may be affected. In advanced HIV, opportunistic infections and tumours (lymphoma), and tissue damage caused by HIV replication in the brain and spinal cord, are important and relatively common during progressive HIV disease.

Cerebral toxoplasmosis

Cerebral infection with the intracellular protozoan *Toxoplasma gondii* is the most frequent infection of the central nervous system in AIDS when the CD4 lymphocyte count is below 200/mm^3. It usually results from reactivation of toxoplasma cysts in the brain, leading to the formation of focal lesions that are typically multiple but may be single. Symptoms develop subacutely and include focal neurological disturbance, headache, confusion, fever, and convulsions. On CT scanning the lesions appear as ring-enhancing masses with surrounding oedema (Fig. 12). Magnetic resonance imaging (**MRI**) is more sensitive and frequently detects lesions not visible on the computed tomography (**CT**) scan. Serum antibodies to *Toxoplasma* spp. are usually detectable; their absence makes the diagnosis unlikely but does not exclude it. Detection of toxoplasma DNA in cerebrospinal fluid by PCR is being evaluated as a diagnostic test. The principal differential diagnosis is cerebral lymphoma; other causes of focal brain lesions in AIDS include cryptococcoma, cerebral abscess (including infection with *Nocardia* spp.), tuberculoma, progressive multifocal leucoencephalopathy, and neurosyphilis. Brain biopsy is required for a definitive diagnosis, but is rarely performed. As toxoplasmosis is by far the most common treatable cause of focal cerebral lesions in HIV, it is standard practice to treat for this and only consider biopsy if there is no clinical improvement in 7 to 10 days.

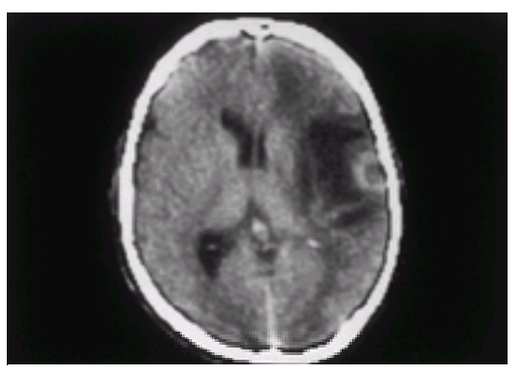

Fig. 12 Cerebral toxoplasmosis: ring enhancement and surrounding cerebral oedema (CT scan with contrast).

The condition responds well if treatment is started early; a combination of sulfadiazine at 4 to 6 g/day and pyrimethamine at 50 to 75 mg/day is the treatment of choice. More than 40 per cent of patients experience adverse effects, especially rash and nephrotoxicity caused by sulfadiazine. The haematological toxicity of pyrimethamine may be reduced by adding folinic acid (10 mg/day). If sulpha drugs are not tolerated, clindamycin with pyrimethamine is an effective alternative. Highly active retroviral treatment should also be started. Corticosteroids may be used to reduce cerebral oedema in patients with large lesions and serious mass effects, but this is controversial.

Treatment is usually given for 3 to 6 weeks, and in the absence of effective antiretroviral treatment relapse is common after stopping. In these circumstances, lifelong maintenance treatment is usually required using pyrimethamine (25–50 mg/day) with a sulpha drug or clindamycin. However, these can be discontinued if antiretroviral treatment leads to sustained immunological recovery.

Cryptococcal meningitis

Although infection of the central nervous system with *Cryptococcus neoformans* can occur in the absence of immunodeficiency, it most commonly arises in association with HIV infection. Before the widespread use of azole antifungals for mucosal candidiasis it accounted for 5 to 10 per cent of opportunistic infections in patients with AIDS. The presentation is usually subacute and may be subtle and non-specific with headache, vomiting, and mild fever, and few neurological signs. Less frequently, psychiatric disturbance, convulsions, cranial nerve palsies, truncal ataxia, or focal intracerebral lesions may occur. Neck stiffness is unusual. The diagnosis is made by identifying cryptococci in the cerebrospinal fluid by India ink staining, detection of cryptococcal antigen in the cerebrospinal fluid (uniformly positive), and culture. Cryptococcal antigen is also usually detectable in serum. *C. neoformans* in patients with AIDS causes minimal inflammation so the white cell count of the cerebrospinal fluid is often only mildly raised and the protein and glucose levels of the cerebrospinal fluid may be normal.

A randomized, controlled trial showed that the combination of amphotericin B and 5-flucytosine was superior to amphotericin B alone or fluconazole alone for the treatment of cryptococcal meningitis. Amphotericin B and 5-flucytosine together lead to more rapid sterilization of the cerebrospinal fluid but are not as well tolerated as fluconazole. Most patients should be given the combination, but milder cases may be treated with fluconazole alone. Resistance of cryptococcus to fluconazole is very rare. Itraconazole can be effective, but is not generally recommended. Adverse reactions to amphotericin are frequent, especially fever, myalgia, renal impairment, and electrolyte disturbances. Close monitoring is required. Lipid formulations of amphotericin are reserved for patients intolerant of conventional formulation. Raised intracranial pressure is associated with clinical deterioration and the risk of blindness: repeated lumbar punctures, ventricular shunting, or acetazolamide therapy may be required.

Without secondary prophylaxis, cryptococcal meningitis relapses in 50 to 80 per cent of patients with HIV in the absence of antiretroviral treatment. Oral fluconazole (200 mg/day) is effective for lifelong maintenance. This can be discontinued if antiretroviral treatment leads to sustained immunological recovery.

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy is a progressive demyelinating condition of advanced HIV disease caused by JC virus, a polyomavirus cytopathic for oligodendroglia. It presents with focal neurological deficits, personality changes, or ataxia; headache and mass effects are absent. Brain MRI, the investigation of choice, usually shows multiple white-matter lesions. JC virus is detectable in cerebrospinal fluid by PCR, but this is not usually necessary for diagnosis. There is no specific treatment. Survival of less than 6 months is usual, but progression may sometimes be halted or reversed by highly active antiretroviral therapy. Cidofovir is active against JC virus and is being evaluated in patients. The other human polyomavirus, BK virus, is a very rare cause of encephalitis and interstitial nephropathy in AIDS.

HIV encephalopathy

HIV can infect the nervous system directly, leading to a variety of clinical problems. Most patients dying of AIDS show histological evidence of brain involvement including neurone loss. A smaller number (up to 10 per cent) develop the cognitive, behavioural, and motor abnormalities of dementia. In the early stages, there is impairment of concentration and memory and mood changes mimicking depression; gradual progression leads to intellectual incapacity and motor disability so that patients cannot care for themselves. Neurological signs include slow movement, incoordination, motor weakness, hyperreflexia, and extensor plantar responses; brain imaging shows reduced grey matter volume in the cortex and basal ganglia. Ultimately, a nearly vegetative condition develops with virtual mutism, inability to walk, and incontinence. These patients die within 2 years. Antiretroviral treatment can prevent, and in the earlier stages reverse, AIDS dementia.

Other psychological/psychiatric problems include anxiety, panic attacks, and depression. Psychotherapy may be helpful. Antidepressants may be needed in severe cases. Acute psychosis is rare. Dystonic reactions to various drugs, such as metoclopramide, are more common in patients with HIV.

In the late stages of HIV disease, the differential diagnosis of HIV dementia includes cytomegalovirus (CMV) encephalitis. This usually presents with rapidly progressive confusion and dementia, impaired consciousness, fever, cranial nerve lesions, and convulsions. MRI shows necrotizing periventriculitis; protein levels in cerebrospinal fluid may be elevated and CMV DNA is detectable in the cerebrospinal fluid by PCR. Ganciclovir and other anti-CMV agents may reduce progression.

Peripheral neuropathy and myelopathy

Peripheral neuropathy can occur at any stage of HIV infection, even at seroconversion, but is most common in advanced disease, when 10 to 15 per cent of patients have a distal symmetrical sensorimotor neuropathy of axonal type causing pain and paraesthesias that may limit walking and, less often, distal weakness and atrophy. Mononeuritis multiplex and acute inflammatory demyelinating polyneuropathy resembling the Guillain–Barré syndrome are also described, generally at an earlier stage. Drugs used in patients with HIV, including stavudine, didanosine, and vincristine, may cause or exacerbate peripheral neuropathy. HIV-related autonomic neuropathy may cause postural hypotension, diarrhoea, impotence, impaired sweating, and bladder symptoms. CMV infection in patients with AIDS presents with a lumbosacral polyradiculopathy causing sacral paraesthesias and numbness, lower limb weakness, and urinary retention that may progress to flaccid paraparesis if untreated.

HIV may involve the spinal cord directly causing a vacuolar myelopathy. This usually presents with bilateral leg weakness and sensory symptoms, usually paraesthesias, and may progress to spastic paraparesis, ataxia, and incontinence.

Ocular disease

Cytomegalovirus retinitis (see also Section 25)

Without antiretroviral therapy, up to 30 per cent of patients with AIDS (and CD4 lymphocyte count below 50/mm ^{3}) develop reactivation of CMV in the form of a destructive and blinding retinitis. This is rare in other types of immunosuppression. It usually presents with blurring of vision, scotomas, floaters, or flashing lights. The characteristic retinal changes are patches of irregular retinal pallor, caused by oedema and necrosis, and haemorrhages in a perivascular distribution (Fig. 13). The retinitis usually starts peripherally and progresses rapidly to involve the macula and whole retina, leading to blindness. Complications include retinal detachment, branch retinal artery occlusion, persistent iritis, and cataract. CMV retinitis should not be confused with cotton-wool spots (HIV retinopathy)—small, pale retinal lesions without haemorrhages that commonly occur in patients with HIV. These are benign and often come and go.

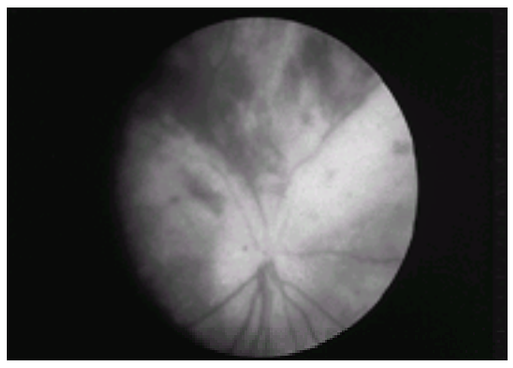

Fig. 13 Cytomegalovirus retinitis.

The diagnosis of CMV retinitis is clinical, based on the characteristic retinal appearance (see Section 25). CMV viraemia may be detectable by PCR and high or rising CMV viral load is associated with an increased risk of developing retinitis and other CMV disease. Anti-CMV drugs (ganciclovir, foscarnet, cidofovir) are virustatic; before the availability of highly active antiretroviral drug combinations, the aim of treatment was to stop progression rather than to cure disease. First-line treatment is with intravenous ganciclovir, which may cause severe neutropenia and thrombocytopenia that are dose-limiting in about 10 per cent of patients. Foscarnet

(phosphonoformate) is a relatively toxic second-line agent that causes dose-limiting reversible renal impairment and symptoms of hypocalcaemia in about 20 per cent of patients. Ganciclovir can also be given as a slow-release intraocular implant, but this may allow CMV to develop at other sites including the other eye.

For maintenance therapy, oral ganciclovir may be adequate, convenient, and well tolerated, although there is a greater risk of disease progression than with daily intravenous infusions of ganciclovir or foscarnet, and the eyes must be examined frequently. Cidofovir is more active against CMV than the other anti-CMV drugs. It can be given by intermittent intravenous infusion, initially weekly and then every 2 weeks. Whereas ganciclovir and foscarnet require a central venous catheter, cidofovir may be given in short infusions through a peripheral vein because of its prolonged antiviral effect. However, cidofovir is relatively toxic, causing irreversible nephrotoxicity, neutropenia, and peripheral neuropathy in over one-third of patients.

With the advent of highly active antiretroviral therapy, CMV retinitis is much less common in developed countries. Sustained suppression of HIV viral load and improvement in immune status can allow discontinuation of maintenance treatment. New manifestations of ocular CMV, such as vitritis, have been reported in patients treated with highly active antiretroviral therapy (see Impact of highly active antiretroviral therapy, below).

Other ocular syndromes

Acute retinal necrosis is a rare condition originally reported in reactivation of varicella zoster virus in otherwise healthy adults. In patients with advanced HIV infection it is usually preceded by dermatomal herpes zoster and typically presents with blurring of vision and pain in the affected eye. Progressive necrotizing retinitis leads to visual deterioration that may be associated with uveitis. An outer retinal necrosis syndrome with little ocular inflammation also occurs in patients with AIDS. There is a high risk of visual loss and retinal detachment. Both eyes may be affected. Suspected acute retinal necrosis should be treated with intravenous aciclovir.

Acute toxoplasma choroidoretinitis may resemble CMV retinitis, but the retinal scarring that follows treatment is distinctive. The disease is more common in countries such as Brazil and France where the background prevalence of toxoplasmosis is much higher than in the United Kingdom. Choroidoretinitis is also a rare complication of histoplasmosis and cryptococcosis.

HIV-related tumours

Kaposi's sarcoma

Kaposi's sarcoma characteristically presents as multiple, purplish nodular skin lesions (Fig. 14). Lesions start as small, pink, deep purple, or brown macules, and develop into nodules or plaques that may ulcerate. They also occur on mucosal surfaces, most commonly on the hard palate. Local or regional oedema and lymph node enlargement may occur. Mucocutaneous lesions are cosmetically and psychologically important but are rarely of clinical importance (Fig. 15). However, visceral disease, which most commonly affects the lungs and gastrointestinal tract, is an important cause of morbidity and even mortality. Lung lesions cause dyspnoea, cough, or haemoptysis, and gut involvement may cause abdominal pain, bleeding, or a rare protein-losing enteropathy. Extensive visceral involvement can cause constitutional symptoms such as fevers, night sweats, and weight loss. Kaposi's sarcoma rarely affects the central nervous system.

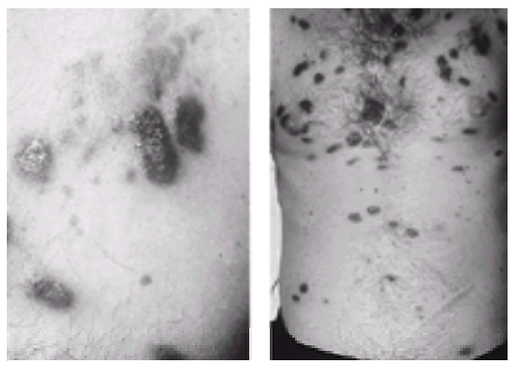

Fig. 14 Cutaneous Kaposi's sarcoma.

Fig. 15 Kaposi's sarcoma of the palate in a patient with HIV infection (copyright D. A. Warrell).

In industrialized countries, Kaposi's sarcoma is over 2000 times more common in HIV-infected individuals than in the general population. Classic Kaposi's sarcoma in HIV-negative individuals occurs in middle-aged and elderly men of Eastern European or Mediterranean origin. Endemic Kaposi's sarcoma in Africa has been known for decades. It is predominantly a disease of older men that has a fairly indolent course. HIV-related Kaposi's sarcoma, on the other hand, is a more aggressive disease and occurs mostly in those people who have acquired HIV via a sexual route, namely homosexual and bisexual men and in younger African men and women. The epidemic of Kaposi's sarcoma in Central and East Africa exactly mirrors the HIV epidemic in these regions. Kaposi's sarcoma is rare in intravenous drug users and very rare in recipients of blood products, including those with haemophilia. These epidemiological features suggested a sexually transmissible aetiological agent.

In 1994, a new herpesvirus, human herpesvirus-8 (**HHV-8**), was found in HIV-related Kaposi's sarcoma and was soon detected in the lesions of all forms of Kaposi's sarcoma. Seroepidemiological studies show that HHV-8 is common only in certain geographical regions, corresponding to where Kaposi's sarcoma was endemic before the era of HIV. HHV-8 is detectable in saliva but less often in semen. This may explain why both sexual and other routes of transmission occur. For instance in Africa, where HHV-8 infection is common, it is transmitted perinatally from mother to child.

Kaposi's sarcoma lesions are characterized by proliferating spindle cells, possibly of endothelial origin, thin-walled slit-like vascular spaces, infiltration by lymphocytes and plasma cells, and extravasated red cells. Multiple lesions appear synchronously in widely dispersed areas. Recent work has suggested a monoclonal origin for Kaposi's sarcoma lesions, but they may be reactive proliferative rather than truly cancerous. HHV-8 is detectable in spindle cells and flat endothelial cells lining the vascular spaces of Kaposi's sarcoma lesions. It is likely that the virus triggers the release of cellular and virus-encoded cytokines that promote the proliferation of spindle cells.

Highly active antiretroviral therapy has led to a dramatic reduction in the frequency and mortality of Kaposi's sarcoma in developed countries. In early Kaposi's sarcoma the progression is often halted or reversed by starting antiretroviral treatment alone. Otherwise, cutaneous lesions may be left untreated or treated with local radiotherapy, cryotherapy, or intralesional vinblastine. Widespread skin or visceral disease is usually treated by systemic chemotherapy, with single or multiple-agent regimens of vincristine, vinblastine, bleomycin, etoposide, and anthracyclines. The combination of vincristine and bleomycin is effective in 50 per cent of patients and well tolerated, but responses are usually short-lived. Liposomal preparations of anthracyclines (such as daunorubicin) are more effective and better tolerated, and are

now the treatment of choice. Treatment of disseminated Kaposi's sarcoma has not been considered to be curative, but remissions may be induced by a combination of highly active antiretroviral treatment and systemic chemotherapy.

Non-Hodgkin's lymphoma

Non-Hodgkin's lymphoma develops in 3 to 10 per cent of HIV-positive patients, an incidence 60 to 100 times higher than in the general population. Most tumours are extranodal and, histologically, 60 per cent are large-cell B-cell lymphomas; 30 per cent are Burkitt's type and the rest are of T-cell or non-B-, non-T-cell origin. Some 50 per cent are associated with Epstein–Barr virus (**EBV**) infection and are more aggressive with a shorter survival. A minority of HIV-related lymphomas are associated with HHV-8. They present as body-cavity lymphomas, causing pleural or peritoneal effusions (primary effusion lymphoma). Patients on highly active antiretroviral therapy have a reduced risk of developing Non-Hodgkin's lymphoma, and consequently the incidence of HIV-related lymphomas in developed countries has declined in recent years.

HIV-associated lymphoma outside the central nervous system may respond well to standard lymphoma chemotherapy regimens, in addition to highly active antiretroviral treatment. Response is better in those who are less immunosuppressed (CD4 above 200/mm ^{3} and no previous AIDS diagnosis). Opportunistic infections cause many deaths during chemotherapy. Lower dose or less toxic chemotherapy protocols are sometimes advocated for patients with more advanced HIV disease.

The central nervous system is a common site of HIV-associated non-Hodgkin's lymphoma, which is nearly always associated with EBV and sometimes with HHV-8 as well. Patients usually present with the symptoms and signs of a space-occupying cerebral tumour. Detection of EBV DNA in the cerebrospinal fluid may help to distinguish these lymphomas from cerebral toxoplasmosis. In the absence of antiretroviral therapy, neither chemotherapy nor radiotherapy have much impact, and the median survival after diagnosis is very poor, at about 3 months. However, this may be substantially prolonged in patients on highly active antiretroviral treatment.

Other tumours in AIDS

Some studies have reported an increased frequency of Hodgkin's disease in patients with HIV, particularly of the mixed cellularity type. Disseminated disease with a poor prognosis seems to be more frequent than for HIV-negative Hodgkin's disease. Castleman's disease (angiofollicular lymph node hyperplasia) is a lymphoproliferative condition that may be HHV-8 related and, in the multicentric form, is also associated with HIV. There is an increased incidence of squamous-cell carcinoma of the conjunctiva in patients with HIV infection, especially in Africa. HIV-infected women suffer a higher incidence of cervical intraepithelial neoplasia (**CIN**) and predisposition to cervical carcinoma; cervical cancer has been designated an AIDS-defining condition. The incidence of vulval intraepithelial neoplasia (**VIN**) is also increased by HIV infection. The incidence of squamous-cell anal carcinoma is increased in homosexual men, but the risk does not seem to be greatly magnified by HIV while the risk of anal intraepithelial neoplasia (**AIN**), a precursor of anal carcinoma, is significantly increased. The development of CIN, VIN and AIN may be related to co-infection with oncogenic types of human papillomavirus, especially type 16.

Common syndromes

Fever of unknown cause

Fever is rarely attributable to HIV infection *per se,* and patients should be fully investigated for other causes. There is increased susceptibility to pyogenic infections as well as opportunistic infections and tumours. Unlike fever of unknown origin (FUO) in other patients, however, most cases of FUO in HIV-positive patients are caused by an infection. Cultures of blood, urine, and faeces should be obtained, and chest radiography done. If sputum is available it should be stained and cultured for tuberculosis. In patients with intravenous lines and devices, catheter-related bacteraemia is an important cause. Occult infections (including sinusitis and dental sepsis) and drug-related fever should always be considered. Rarely, infection with *Pneumocystis* spp. and *Cryptococcus* spp. can present as fever without their typical focal signs, and dissemination to other sites (such as skin, fundi) may occur. Disseminated leishmaniasis is an important cause in those who have visited an endemic area (see Other disseminated infections, below).

In advanced disease, the most common causes of persistent high-swinging fevers are disseminated MAC infection (see *Mycobacterium avium* complex, above) and non-Hodgkin's lymphoma (see Non-Hodgkin's lymphoma, above). Imaging techniques, in particular CT scanning of the abdomen, are essential to find a suitable site for biopsy to diagnose lymphoma.

In some cases, the cause of fever is not found; in early disease the fever may resolve spontaneously. In advanced disease, fever and sweats may continue intermittently for many months. Symptomatic treatment includes non-steroidal anti-inflammatory drugs and low-dose prednisolone; therapeutic trials of anti-MAC treatment may be justified.

Breathlessness

Appropriate management of breathlessness is important because the most common cause, pneumocystis pneumonia, can be rapidly progressive. The differential diagnosis is broad, and includes bacterial pneumonia, pneumothorax, pulmonary Kaposi's sarcoma, other tumours, fungal infections, asthma, and heart failure. Routine investigations should include chest radiography, blood oxygen saturation, and peak flow measurement. Blood from febrile patients should be sent for culture. Sputum should be obtained, if necessary by induction with nebulized saline, and stained for the presence of *Pneumocystis* spp., mycobacteria, and fungi. Bronchoalveolar lavage should be considered early as patients sometimes progress quickly and become too ill for bronchoscopy without the support of mechanical ventilation.

Empirical treatment should cover *Pneumocystis* spp., *S. pneumoniae*, and *H. influenzae* by combining high-dose co-trimoxazole with a suitable broad-spectrum antimicrobial such as cefotaxime. A macrolide such as erythromycin or clarithromycin may be added if atypical pneumonia (such as mycoplasma) is suspected. If the clinical suspicion of pneumocystis is high, corticosteroids should be included if the patient is hypoxaemic (see *Pneumocystis carinii* pneumonia, above). Continuous positive airway pressure (**CPAP**) or mechanical ventilation may be needed in severe cases to allow diagnosis and time for patients to respond to treatment. If the chest radiograph shows diffuse bilateral infiltration and bronchoalveolar lavage fails to reveal any pathogen, presumptive treatment for pneumocystis pneumonia should be continued. If no diagnosis is made and deterioration occurs despite empirical treatment, open-lung biopsy should be considered to establish the diagnosis, but the prognosis is generally poor.

Diarrhoea

Chronic diarrhoea is a common problem in patients with advanced HIV infection, particularly in the tropics, and may be associated with weight loss and malabsorption. No cause other than HIV can be identified in at least half of cases; an HIV enteropathy characterized by partial villous atrophy has been described. The most common opportunistic cause is infection by the protozoan *Cryptosporidium parvum*, which causes a self-limiting gastroenteritis in those who are non-immunosuppressed. In HIV-positive patients diarrhoea may be protracted and severe, with marked fluid and electrolyte losses. The diagnosis is made by finding cryptosporidial oocysts in the stool using a modified acid-fast stain. Symptoms of cryptosporidiosis are often intermittent, as is excretion of the oocysts, so multiple stool specimens may need to be examined. Therapy with highly active antiretroviral drugs is the most important step in treatment. Symptomatic treatment with antidiarrhoeal drugs (such as loperamide), fluid and electrolyte replacement, and nutritional support are required. Octreotide may be useful in the most severe cases.

The coccidian protozoa *Isospora belli* and *Cyclospora cayetanensis* are important but less common causes of HIV-related chronic diarrhoea, diagnosed by the presence of sporocysts in the stool. Isosporiasis may respond to treatment with co-trimoxazole but the relapse rate after stopping treatment is 50 per cent, and similar experience is reported for cyclosporiasis. Microsporidia such as *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are intracellular pathogens that may cause diarrhoea in advanced HIV disease. Special diagnostic staining methods applied to stool samples or electron microscopy of a rectal biopsy are needed to make the diagnosis. Albendazole may be effective, and treatment with highly active antiretroviral therapy may induce remission of intestinal microsporidiosis.

Giardia duodenalis and *Entamoeba histolytica* cysts are more commonly found in the faeces of homosexual men than heterosexual men, but these protozoa usually do not cause special problems in those with HIV. Bacterial infections with enteric pathogens such as salmonella, shigella, campylobacter, and *Clostridium difficile* do not lead to chronic diarrhoea but may take longer to clear. Salmonella infections may cause disseminated infection with recurrent bacteraemia that recurs even after prolonged antimicrobial therapy.

With advanced disease, MAC infection may cause diarrhoea among other symptoms. CMV causes a colitis that typically presents with abdominal pain and

tenderness, fever, and bloody diarrhoea. Rectal or colonic biopsy may confirm the diagnosis by identifying the characteristic nuclear inclusion bodies. HIV-related autonomic neuropathy is a rare cause of diarrhoea that is often most troublesome at night; anticholinergic drugs may help in addition to antidiarrhoeal agents. Diarrhoea in HIV-positive patients is a frequent side-effect of medications such as antibiotics and antiretroviral drugs.

HIV wasting syndrome

Weight loss is one of the most distressing features of progressive HIV infection. Its course fluctuates even in advanced disease; frequently it is attributable to specific complications such as diarrhoeal diseases, lymphoma, or disseminated MAC infection. It may also progress with no cause identified other than advanced HIV infection. In developing countries, such as those in sub-Saharan Africa, the wasting syndrome is characteristic evidence of AIDS and has been called 'slim disease'. Despite severe weight loss, patients may remain well for many months or even years. Numerous therapeutic approaches have been tried, mostly with disappointing results, including oral nutritional support, enteral feeding, total parenteral nutrition, and trials of growth hormone and thalidomide. Anabolic steroids such as nandrolone and stanozolol may reverse HIV-related wasting, but they may cause serious side-effects and their use has not been widely adopted. Highly active antiretroviral therapy is important in the prevention and reversal of HIV-related weight loss, but the fat redistribution associated with some antiretroviral agents may cause face and limb wasting (see Drug toxicity and interactions, below).

Miscellaneous conditions

Bacillary angiomatosis

Disseminated infection with *Bartonella henselae*, the principal agent of cat-scratch disease, is the cause of bacillary angiomatosis, an HIV-associated condition that typically causes multiple subcutaneous vascular lesions, fever, liver lesions (bacillary peliosis hepatis), and osteolytic bone lesions. The skin lesions are usually purplish nodules that may be mistaken for Kaposi's sarcoma, but the histology is distinct, acute neutrophilic inflammation and capillary proliferation, and clusters of bacilli revealed by modified silver staining. The organism may be cultured from blood. A similar syndrome in HIV-positive patients can be caused by the agent of trench fever, *Bartonella quintana.* Bacillary angiomatosis usually responds to treatment with a macrolide antibiotic. Cats and cat fleas form a reservoir for *B. henselae*, and patients who develop bacillary angiomatosis frequently have a history of contact with cats.

Other disseminated infections

In regions where invasive fungal infections are endemic (such as *Histoplasma capsulatum* in the Mississippi river region, *Coccidioides immitis* in the southern United States, and *Penicillium marneffei* in South-East Asia) or where there is a relevant travel history, disseminated fungal infection should be considered in HIV-positive patients presenting with fever, weight loss, anaemia, pulmonary infiltrates, lymphadenopathy, and hepatosplenomegaly. Papular skin lesions may be seen in disseminated histoplasmosis and *P. marneffei* infection. Similar lesions resembling giant molluscum (see Skin conditions in advanced HIV, below) may occur with disseminated cryptococcosis. Blood or bone marrow cultures or direct identification by the use of special stains on tissue obtained from skin lesions, bone marrow, or liver are required for diagnosis. Initial therapy is generally with intravenous amphotericin; itraconazole (for histoplasmosis and *P. marneffei*) or fluconazole (for coccidioidomycosis) may be adequate for subsequent maintenance treatment.

HIV-associated disseminated leishmaniasis is mostly reported from the Mediterranean littoral, South America, and Africa. It is caused by dissemination of *Leishmania* spp., protozoan parasites transmitted by sandflies. A high index of clinical suspicion is required because although the classic features are fever, weight loss, anaemia, and hepatosplenomegaly, a high proportion of patients have fever alone. Most cases can be diagnosed by bone marrow examination. Treatment is usually with the organic antimonial compound sodium stibogluconate, given parenterally.

Other visceral disease

Cryptosporidium (see Diarrhoea, above) and CMV may cause a sclerosing cholangitis-like syndrome with irregular dilatations and stenoses of the biliary tree (demonstrable by endoscopic retrograde cholangiography), abnormal liver blood tests, and occasionally jaundice. CMV is frequently identified histologically in the pancreas at autopsy, but its role in the development of clinical pancreatitis is unproved. A characteristic nephropathy (HIV-related glomerulosclerosis), primary pulmonary hypertension, and cardiomyopathy (see Section 15.16) are well described in patients with AIDS.

Haematological conditions

Thrombocytopenia is relatively common (5 to 15 per cent) in HIV infection and is associated with antiplatelet antibodies; symptomatic thrombocytopenia is uncommon but more likely in the later stages of HIV infection. Life-threatening bleeding is rare. Thrombocytopenia is not a marker for HIV progression and spontaneous remissions are frequent. When treatment is required, the principles and response are similar to those that apply in the treatment of HIV-negative immune thrombocytopenia, and include the use of prednisolone, intravenous immunoglobulin, and splenectomy. Thrombocytopenia also frequently responds to antiretroviral therapy using combinations that include zidovudine, which improves platelet production.

Anaemia is common in patients with advanced HIV infection, and is frequently related to medications (such as zidovudine). Human (B19) parvovirus infection is an important reversible cause of chronic anaemia in HIV infection. Bone marrow biopsy typically shows an absence of erythroid development with occasional giant pronormoblasts, and B19 parvovirus is detected by PCR. The anaemia may respond to treatment with intravenous immunoglobulin.

Mild neutropenia is common in HIV-positive patients at all stages of infection, and may be partly responsible for the increased risk of pyogenic bacterial infections; however, profound neutropenia (below 0.5×10^9/l) is rare. Antineutrophil antibodies may be present. Drugs (such as co-trimoxazole, ganciclovir, antiretrovirals) may increase the incidence and severity of neutropenia. In selected HIV-positive patients with refractory or life-threatening bacterial or fungal infection and severe neutropenia, the addition of recombinant human granulocyte colony-stimulating factor to the treatment regimen may improve the outcome.

Skin conditions in advanced HIV

In the later stages of HIV infection a number of infections have atypical cutaneous manifestations. These include giant molluscum contagiosum, characterized by large flesh-coloured non-tender umbilicated lesions often affecting the face in homosexual men. In advanced HIV disease, genital herpes simplex infection may cause painful chronic genital or anal ulcers that can become resistant to aciclovir and related compounds; intravenous foscarnet or cidofovir are effective. Aciclovir-resistant varicella zoster virus also occurs in AIDS; and reactivation of varicella zoster virus can take an unusual form, with a subacute course and dissemination causing scattered vesicular lesions in the absence of dermatomal zoster. CMV is a cause of chronic perianal ulceration that can be treated with ganciclovir. Atypical cutaneous presentations of syphilis may occur at any stage of HIV infection. In Asia, the varied skin manifestations of *P. marneffei* infection are familiar.

Children and HIV

Most paediatric infections result from the vertical transmission of HIV, although some children may be infected by blood products. The risk of vertical transmission is increased during advanced maternal HIV disease, if delivery is by the vaginal route, and if the baby is breast fed (see Vertical transmission, below). Diagnosis is important during the first year of life because about 20 per cent of HIV-infected children progress rapidly to AIDS during that time; however, a special diagnostic approach is needed before 18 months of age, because over this period uninfected children may have maternal HIV antibody. Techniques for virus detection (for example, HIV DNA by PCR) allow confirmation of HIV infection in 95 per cent of infected infants by 1 month of age. The sensitivity of these virological assays increases over the first few months, so if negative at 3 to 6 weeks, the tests should be repeated at 3 to 6 months; if HIV is not detected at this time, loss of HIV antibody should be confirmed at 15 to 18 months before the child is assumed to be HIV-negative.

HIV-infected children should be managed by paediatricians with experience in HIV care, usually in specialized units. About 10 per cent die in infancy, and progression to AIDS subsequently occurs at the rate of about 5 per cent per year. In recent European series, 40 per cent of children had developed AIDS before the age of 5 years and 25 per cent had died. The commonest AIDS diagnosis in infancy is pneumocystis pneumonia. The CD4 lymphocyte count is less valuable for monitoring than in adults, particularly in very young children; consequently prophylaxis against *Pneumocystis* spp. is usually given regardless of the CD4 count during the first year. In older children, the principles of monitoring are similar to those in adults, using clinical status, CD4 counts, and viral load estimation by plasma HIV-1 RNA measurement. The CD4 percentage (percentage of total lymphocytes) and CD4:CD8 cell ratio vary less with age and are more useful than absolute CD4 counts in

children under the age of 5 years.

In children, clinical conditions reasonably predictive of HIV infection include persistent oral candida, parotid swelling, and recurrent or frequent serious bacterial infections including pneumonia. Failure to thrive, diarrhoea, fever, lymphadenopathy, and hepatosplenomegaly are more common in HIV-infected infants but are non-specific and less predictive. HIV dementia, and other neurological and developmental problems are associated with a poor prognosis. HIV-related lymphocytic interstitial pneumonitis (**LIP**) is almost confined to children and characterized by progressive widespread reticulonodular shadowing on chest radiography. LIP develops gradually and may be asymptomatic; cough, breathlessness, clubbing, secondary bacterial infections, and bronchiectasis occur in severe cases and may be treated with oral prednisolone.

Principles of antiretroviral treatment are similar in children and adults. Clinical trials are in progress to determine optimal antiretroviral combinations, when to start treatment, and the tolerability of the newer drugs in all the major categories. Triple-therapy regimens are well tolerated in children and may produce sustained elevations in CD4 lymphocyte counts, but adherence is particularly difficult. As HIV-infected children grow older, the number of adolescents with perinatally acquired HIV is increasing, raising the need for advice on reducing the risk of sexual transmission.

Prevention of opportunistic infections (see Table 5)

The risk of developing an opportunistic infection rises greatly once the peripheral CD4 lymphocyte count falls consistently below 200/mm ^{3}. It is standard practice to introduce low-dose co-trimoxazole prophylaxis for pneumocystis pneumonia at this stage. This also reduces the risk of cerebral toxoplasmosis and may prevent bacterial pneumonia.

The risk of developing active tuberculosis in HIV-positive American intravenous drug users with positive tuberculin skin tests has been shown to be about 8 per cent per year and can be reduced by taking isoniazid for a year. In developing countries, in particular, the risk of active tuberculosis in HIV-positive individuals is high and isoniazid alone or in combination with rifampicin can reduce the risk, but the feasibility and cost-effectiveness of this approach in resource-poor countries require further evaluation. BCG vaccination does not appear to be protective in HIV.

Primary prophylaxis may prevent other conditions, such as CMV retinitis, cryptococcal meningitis, and histoplasmosis, but because of the relatively low incidence and lack of predictors of risk for these conditions, it is not cost-effective. Before the advent of highly active antiretroviral therapy, after treatment of an opportunistic infection the underlying tendency to the infection usually remained. Thus in early studies, following an episode of pneumocystis pneumonia, patients had a 50 per cent chance of a further episode within a year. Secondary prophylaxis with co-trimoxazole proved effective. Secondary prophylaxis for *Pneumocystis* spp. and other opportunistic infections, including MAC and CMV, can now usually be discontinued if there is a good response to antiretroviral treatment, with CD4 counts sustained above 200/mm^3 and low plasma levels of HIV RNA.

Simple measures, other than drugs, may reduce the risk of some infections. Avoiding undercooked eggs and poultry may reduce the risk of disseminated salmonella infection and adequate boiling of drinking water can prevent cryptosporidiosis. Stopping cigarette smoking may reduce the risk of bacterial chest infections

Prevention of HIV transmission

Sexual transmission

Sexual transmission accounts for most new cases of HIV infection. Education to alter behaviour and reduce the risk of HIV infection is an important part of HIV control programmes. The benefits of 'safer sex' should be publicized; condom promotion in Thailand has made an impact on HIV transmission rates. The presence of other sexually transmitted infections, especially those causing genital ulcers, facilitates HIV transmission. Accordingly, studies in Tanzania and elsewhere have demonstrated that programmes to prevent and treat sexually transmitted infections can reduce the incidence of new HIV infections.

Vertical transmission

As the number of women infected with HIV increases, the problem of vertical transmission of the virus assumes greater importance. In developed countries, the risk of transmission of HIV from a seropositive pregnant woman to her child is about 15 per cent, but this figure may be as high as 30 per cent in sub-Saharan Africa and other parts of the tropics. Although infection of the fetus can occur at any time during pregnancy and has been associated with breast feeding, most infections occur during labour. Zidovudine reduced the risk from 25 to 8 per cent, when given to women during late pregnancy and labour and to the neonate for 6 weeks. Simpler, cheaper regimens have been shown to be effective. During vaginal delivery, intrapartum interventions such as fetal blood sampling and use of fetal scalp clips should be avoided. Elective caesarean section further reduces vertical transmission (see British HIV Association quidelines in the Further reading list). Breast feeding should be avoided, if possible, but is still generally recommended in developing countries where the risks of bottle feeding probably outweigh the risks of breast feeding. Increasingly, the routine offer of HIV testing is being incorporated into antenatal care in developed countries where antiretroviral treatment is available.

Blood products

Screening of blood products began as soon as testing for HIV became available, and heat treatment for factor VIII concentrate was also introduced. These measures dramatically reduced the risk of virus transmission by blood and blood products in industrialized countries. However, there may still be a problem in developing countries where screening is not efficient, or where the background seroprevalence of potential donors is so high that HIV-infected blood may be screened as negative when donated by an individual in the 'window period' immediately after initial infection (see Diagnosis of HIV infection, above).

Injecting drug use

Needle-exchange programmes and the prescription of controlled drugs to registered addicts may reduce the incidence of new HIV infections in injecting drug users. Major problems still exist in countries such as India and Russia, where injecting drug use is becoming more common and education about the risk and the availability of clean needles is very limited.

Occupational exposure and postexposure prophylaxis

Based on data from more than 3000 occupational exposures to HIV, the average risk of HIV infection after needlestick injury or other percutaneous exposure was calculated to be 0.3 per cent (about 1 in 325). The risk following mucous membrane exposure has been estimated to be around 0.1 per cent. The risk of transmission is greatest for deep injuries; if there is visible blood on the device; during procedures involving direct cannulation of blood vessels; or if the source patient has advanced HIV disease. A small retrospective case-control study demonstrated an 80 per cent reduction in the likelihood of seroconversion in healthcare workers who took zidovudine soon after percutaneous exposure to HIV. In view of the greater activity of antiretroviral drug combinations but without direct evidence, it is currently recommended that high-risk occupational exposures to HIV are treated as soon as possible with two nucleoside inhibitors and a protease inhibitor (such as zidovudine, lamivudine, and nelfinavir) for 1 month. Nevirapine is not currently recommended in postexposure prophylaxis regimens because of a relatively high rate of adverse reactions. In the management of occupational exposure to HIV, a careful risk assessment should be done and information provided. If the risk of HIV transmission is identified, antiretroviral therapy should be offered and started promptly to maximize the chance of success. There is a theoretical argument for taking antiretroviral drugs after high-risk sexual exposure to HIV; at present there is no consensus on the appropriateness of postexposure treatment in this context, and no clinical or cost-effectiveness data are available.

Vaccine development

The high degree of viral variation and immune escape present difficulties for the development of an effective HIV vaccine. None the less, group-specific neutralizing antibodies and cross-reacting T-cell clones have been identified, and there is evidence from female prostitutes repeatedly exposed to HIV that certain individuals can develop specific T-cell responses without persistent infection. These individuals may be protected from infection when exposed to live virus.

To date, non-infectious killed whole virus or recombinant subunit vaccines have not been successful to date in protecting chimpanzees from HIV infection, or macaques from SIV infection and disease. Certain live attenuated strains of SIV, with deletion mutations in *nef* and other regulatory genes, initially appeared to

protect adult monkeys from challenge with virulent SIV strains, but more recently were reported to cause AIDS.

Human testing of candidate HIV vaccines, including a vaccine made from tiny recombinant fragments of gp120, the surface glycoprotein of HIV that binds to host-cell CD4 receptors, has so far not been successful. Several new approaches are being examined, which may prove more effective in inducing protective humoral and killer T-cell-mediated immunity. These include DNA vaccines, consisting of pieces of HIV DNA incorporated into harmless plasmid DNA from bacteria, and the use of live vectors (for example, poxviruses such as canary pox and modified vaccinia) to deliver portions of the HIV envelope. Researchers in Oxford are investigating a strategy ('prime–boost') using a DNA vaccine followed by boosting with a modified vaccinia vector vaccine. This approach is also being evaluated for therapeutic vaccination in HIV-positive patients with suppressed viraemia who are being treated with antiretroviral agents, to determine if vaccination will allow interruption of treatment without loss of virological control. Effective vaccination is likely to hold the greatest promise for controlling HIV infection in the future.

7.10.22 HIV in the developing world

Charles F. Gilks

Introduction

The first definite evidence of human infection with HIV dates from a blood sample taken from an unidentified African man in Leopoldville (now Kinshasa) in the Congo in 1959. What happened before then is conjecture but it seems clear that HIV was originally an African primate virus, and that by the time it had spread to North America in the mid- to late 1970s the epidemic in sub-Saharan Africa was already well established. Public health surveillance is poor across Africa, and the disease went essentially unrecognized until AIDS had been identified as a new clinical entity in the United States. It is an uncomfortable truth that the main impetus to discover the cause of AIDS and produce reliable diagnostic tests, and the subsequent search for effective therapies and vaccines, has been the size and scale of the HIV epidemic in the West rather than the developing world.

Unfortunately, massive Western involvement with the disease has not always been directly beneficial. It has taken far too long to appreciate that HIV/AIDS is not the same disease in resource-poor countries as it is in rich North American or European cities; and that different clinical interventions and preventive approaches are necessary. Few textbooks deal with HIV/AIDS as anything but a disease of affluent communities which have access to high-technology medicine and expensive, state-of-the-art therapy. Many policy makers view the epidemic, and possible responses, in the impossible-to-replicate context of the costs to an industrialized health service—rather than what is necessary and can be achieved even with limited resources.

Aetiology

HIV has two variants, type 1 and type 2; each has different groups and subtypes or clades. HIV-1 group M is the cause of the pandemic: in industrialized countries subtype B predominates. In Africa two rare groups N and O have recently been identified; and whilst within group M the whole alphabet of subtypes A to J exist, subtype B is uncommon. In other parts of the developing world, because of founder effects, there is less HIV-1 heterogeneity. HIV-2 is largely restricted to West Africa although localized foci exist elsewhere. Dual infection can occur and prior infection with one type does not appear to generate useful protection against the other.

Most commercial diagnostic kits identify all types and variants of HIV. Typing and subtyping requires special resources and is not routinely carried out. HIV-2 appears to have important biological differences from HIV-1: it is less efficiently transmitted both sexually and vertically; disease progression is slower but it results in the same spectrum of related diseases. Less is known about the biological attributes of HIV-1 subtypes, although disease progression may be faster with some types (for instance subtype A compared with D in Uganda). Immune responses to infection may be both type subtype-specific, which has considerably complicated vaccine development. This chapter deals only with HIV-1 infection.

Epidemiology

Distribution

All parts of the world have reported HIV infection (Table 1). Current estimates (end 1999) suggest that 50 million people have been infected, of whom over 16 million have already died. Sub-Saharan Africa has borne the brunt of the epidemic: although constituting about 10 per cent of global population, 70 per cent of people living with HIV and 85 per cent of deaths come from the region. Ominously, the virus is continuing to spread rapidly in highly populous regions of India and South-East Asia. India has recorded 4 million cases, the largest number. In parts of east and central Africa, prevalence is stabilizing, sometimes at rates in excess of 30 per cent, and the 'HIV endemic' is emerging. In Uganda and Thailand, recent declines in HIV prevalence have been ascribed to behavioural change and successful control programmes. However, there is no developing country where the epidemic is in steady state. The burden of HIV/AIDS disease will continue to grow and the full impact of the epidemic on development and civil society will not be felt for many years.

Transmission

In developing countries, HIV is spread predominantly through heterosexual intercourse. Women become infected an average of 5 to 10 years earlier than men and in Africa more women than men are now infected. Several socio-economic and biological cofactors enhance transmission. In many cities there are large pools of migrant labour, women have few marketable skills, and there is often a preponderance of single men—all of which encourages the sex trade. Poor people have limited resources to devote to safer sex. Early sexual debut and frequent partner changes are common in some communities. Sexually transmitted infections facilitate transmission; in resource-poor societies treatment may often be delayed, incorrect, or inadequate.

Mother-to-child transmission is a direct result of the adult heterosexual epidemic. Infants can be infected transplacentally, during the birth process, or through breast feeding. Without intervention, overall risks are about 30 per cent. In high-prevalence regions up to 10 per cent of young children may be HIV infected. Those who escape infection may become orphans. The problem of AIDS orphans, particularly in urban centres, is a growing crisis. No simple solutions are emerging.

Intravenous drug use is widespread in certain areas and can be the vehicle for explosive transmission—as has occurred in Thailand, Vietnam, north-east India, and the Russian Federation. Needles and syringes may be shared by many individuals and tragically the epidemic may only be recognized when HIV is already well-established. Transmission through infected blood is important where transfusion is used indiscriminately, where inadequate provision is made for screening and quality control, where contaminated equipment is reused, and where professional donors and commercial blood banks resist supervision and regulation. China in particular is facing up to the consequence of poorly supervised and regulated blood transfusion practices.

Surveillance and disease burden

Accurate surveillance is essential to monitor the evolution of the HIV epidemic. Surveillance is often inadequate because of budgetary constraints, limited public health capacity, and occasionally lack of political will. Few countries can measure HIV incidence rates reliably. Antenatal clinic attenders have been the main focus for recording prevalence. At-risk or core transmission groups such as attenders of sexually transmitted disease (**STD**) clinics, and prostitutes are also important groups to

monitor. Many countries have only limited and incomplete national prevalence data. The absence of such basic information has hindered the effectiveness of AIDS control programmes across the developing world.

Surveillance for clinical disease has focused on AIDS, using a clinical case definition and monitoring HIV prevalence in patients with tuberculosis. Given the importance of non-AIDS disease and death and very poor AIDS case reporting across the developing world, the continued promotion of AIDS surveillance must be questioned. Assessing HIV prevalence in specific patient groups, such as those admitted to hospital with acute conditions, will generate more accurate and useful information for health planners.

In high-prevalence countries the burden of disease caused by HIV/AIDS is far broader than appreciated—consequences of fear and denial in the community and inadequate disease surveillance (Fig. 1). Failure to recognize the true impact of HIV has led to fragmented care responses, which serve inadequately the needs of communities affected by HIV. Stigmatization is maintained and potential benefits of enhancing prevention, by linking it with effective care packages, are not realized.

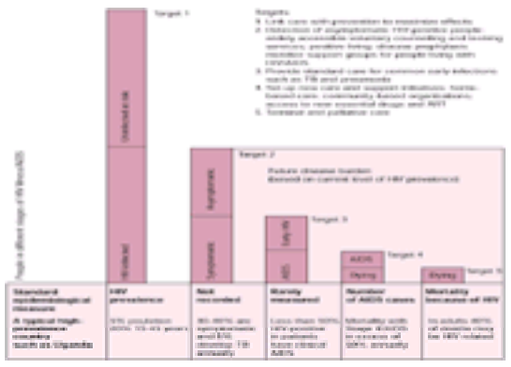

Fig. 1 The HIV/AIDS care burden in a community.

Prevention and control

Control strategies relate to mode of transmission. All require appropriate health information and education, to inform rather than scare and to promote behaviour change. Unfortunately, the background in many developing countries continues to be one of hostility, fear, and denial, in which those infected are discriminated against and stigmatized. Until there is a more rational and accepting attitude to HIV/AIDS, it is difficult to see how interventions can be fully effective. The United Nations Programme on HIV/AIDS (UNAIDS) addresses this by advocating the view that people with HIV/AIDS are not the problem but are part of the solution.

Strategies to reduce sexual transmission concentrate on the universal message of safer sex, condom usage, and improved treatment of sexually transmitted diseases. When properly used, condoms are effective barriers to all sexually transmitted pathogens—not just HIV. Condoms can be distributed free, or sold by local traders who buy at discounted wholesale prices, a process known as social marketing. This encourages the condom market and accepts than clients are more likely to use condoms that have been bought rather than given away. In some countries this has greatly expanded the use of condoms. In other countries, male reluctance is an impediment to widespread usage.

The rationale for improving STD treatment to control HIV is based on the increased risks that any STD, inflammatory or ulcerative, generates for person-to-person transmission of HIV. Initial enthusiasm for this was based on a single, randomized, controlled trial in East Africa (Mwanza, Tanzania) which documented a 42 per cent (95 per cent confidence interval 21–58) reduction in transmission. A larger study in Rakai, Uganda, showed no effect of mass community-wide STD treatment. One further randomized clinical trial is still underway in Uganda. It may be that differences relate to the stage of the epidemic. Improved STD treatment may have most impact where the virus is still epidemic rather than endemic, and where sexual contact with high-risk core transmitter groups is more important that transmission from spouse or regular partner.

In the West, mother-to-child transmission can be virtually eliminated with comprehensive antenatal counselling and HIV testing, antiretroviral therapy, elective caesarian section, and avoidance of breast feeding. In high-prevalence developing countries, where need is greatest, the financial resources and capacity to implement such interventions are woefully lacking. The promise of simple, cheap therapy with nevirapine reduces the cost barrier and has created a wide-ranging international debate with calls for charitable donations or concerted bilateral aid. However, reducing mother-to-child transmission may not be considered a leading public health priority in developing countries, particularly without robust policies addressing the care of AIDS orphans.

With intravenous drug users, education programmes promoting risk reduction, particularly avoiding the sharing of needles or syringes, have been effective in cities such as Bangkok. Implementing needle exchange programmes is usually a political, not public health, issue. Spread through infected blood has been the easiest route to control. Widespread provision of facilities and equipment for screening and, more recently, the advent of rapid single-use HIV tests have minimized the number of infected units transfused. Quality control remains the biggest single issue in maintaining the integrity of the blood supply. Establishing clear and appropriate guidelines for transfusion has reduced dramatically the numbers of units given, especially to anaemic children with malaria.

Clinical features

Natural history

Most people in the developing world who are immunosuppressed through HIV are poor. They are usually forced to live in unhygienic environments with inadequate sewerage and limited clean water, in overcrowded dwellings in close proximity to other sick and healthy people. There is substantial exposure to airborne and water-borne pathogens ensuring that rates of tuberculosis, pneumococcal disease, salmonellosis, and cryptosporidium are higher than in industrialized countries. With intense pathogen exposure, disease early on in the natural history of HIV is far more common (Fig. 2).

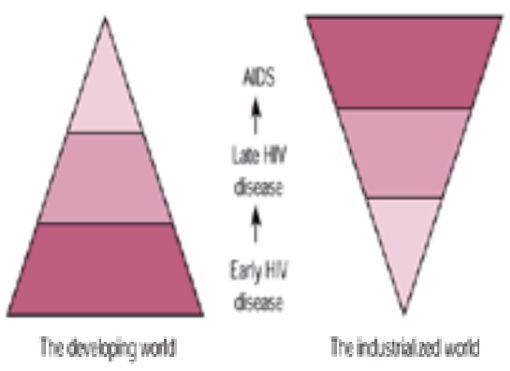

Fig. 2 The burden of disease caused by HIV infection in the developing world and the industralized world.

Poverty also limits the ability to maintain a healthy lifestyle and markedly reduces access to health care. Health-seeking behaviour is delayed and presentation with advanced disease is common. The quality of care available is often substandard. Health centres and hospitals may be rundown, poorly staffed, and lacking in even the most basic of drugs. Diagnostic capacity can be limited with few or no laboratory services provided. It seems obvious that survival will be severely compromised by

such disadvantages.

Surprisingly, despite the scale of the HIV/AIDS epidemic in the tropics, there are few cohort studies in which the natural history of disease has been well characterized. In one seroincident cohort in rural Uganda, initial disease progression was similar to that in Western pretherapy cohorts, and suggested median survival of about 9 years. Several studies document poor survival, a year or less, following the onset of a major AIDS-defining illness. There are no data to suggest that reduced survival with HIV/AIDS in Africa relates overall to more rapid disease progression. Rather, early death from readily preventable or treatable infections shortens survival. Perhaps, once severe intercurrent disease has developed, viral replication may be enhanced causing more rapid disease progression. To date this has not been documented.

Clinical staging

A clinical staging classification has been developed by the World Health Organization for use in clinics without access to CD4 counts or viral load measurement. Patients with asymptomatic disease or minor clinical problems are classified as stage 1 and 2, respectively. The importance of high-grade virulent pathogens early on in the disease process is encompassed; pulmonary tuberculosis (now classified as an AIDS-defining disease in the United States) and severe bacterial infections are stage 3 problems. Opportunistic infections characteristic of AIDS are classified as stage 4 events. The staging system has recently been validated against CD4 counts in Uganda and is useful for predicting survival.

Specific clinical problems

Tuberculosis

HIV-related tuberculosis is of supreme importance. HIV renders the individual highly susceptible to primary infection or reinfection and is a potent reactivator of latent tuberculosis. About 75 per cent of patients have thoracic disease. Classic pulmonary tuberculosis with positive sputum smears is seen in the early stages of HIV, pleural effusions are common, and hilar or paratracheal glands are frequently enlarged. With more advanced immunosuppression, extensive pulmonary disease with negative sputum smears develops. Extrapulmonary disease is common and dissemination with mycobacteraemia is increasingly recognized. Clinical features suggest both acute primary disease and reactivation are occurring.

Diagnosis can be difficult when only radiology and microscopy are available, particularly in smear-negative, disseminated, or extrapulmonary disease. Patients with early HIV disease usually respond well to standard therapy. National treatment guidelines should be followed and all cases notified to the tuberculosis control services. Thiacetazone is associated with high rates of hypersensitivity and should be avoided. In Africa, 25 to 30 per cent of patients may die during or soon after completing appropriate therapy, from community-acquired bacterial infections rather than poor therapeutic response. Treatment failure because of drug resistance is not yet a major problem in Africa but will be elsewhere. Tuberculosis frequently recurs through relapse and reinfection; rifampicin-based therapy may reduce relapse rates.

HIV-associated tuberculosis is preventable. The challenge is how to implement chemoprophylaxis without compromising existing tuberculosis control programmes or promoting drug resistance. One study in Abidjan showed that cotrimoxazole prophylaxis significantly improved survival of patients with tuberculosis/HIV, largely by reducing intercurrent bacterial infections. Studies are underway elsewhere to see how universally valid such an approach may be, given high rates of cotrimoxazole resistance across the developing world.

Pneumococcal infection

Streptococcus pneumoniae infection frequently develops with HIV. Lobar pneumonia accounts for about two-thirds of cases; acute sinusitis, occult bacteraemia, meningitis, pericarditis, skin sepsis, and pyomyositis also occur. Recurrent disease, primarily reinfection, is extremely common with rates of 25 to 30 per cent documented in East Africa.

Most patients with pneumonia are bacteraemic and Gram-positive diplococci are abundant in sputum. Patients respond well to standard penicillin therapy; ampicillin, chloramphenicol, and erythromycin are also effective. Lack of response suggests a second pathogen, often tuberculosis. Mortality rates are consistently higher in seropositive than seronegative patients. In Nairobi, penicillin resistance appears more frequent in pneumococci isolated from HIV-infected patients. Penicillin-resistant pneumococci are widespread; the worry is that HIV will facilitate further spread and evolution.

Polysaccharide pneumococcal vaccine is recommended (without efficacy data) in the United States and Europe. A randomized controlled trial in Uganda showed no efficacy but significantly higher rates of pneumonia in vaccine recipients. It should not be recommended in developing countries. The role of the new conjugate vaccines remains to be established. Studies in Abidjan showed reduced rates of pneumonia as well as other HIV-related problems with cotrimoxazole prophylaxis. Compliance remains a problem with long-term chemoprophylaxis.

Non-typhi salmonellas

Systemic salmonellosis is highly associated with HIV. *S. typhimurium* and *S. enteritidis* are most frequent; other non-typhi salmonellas are less important and HIV does not significantly predispose to *S. typhi* infection. Most patients present with bacteraemia and an enteric fever-like illness clinically indistinguishable from classical typhoid fever. Non-typhi salmonella coinfection also develops in patients with tuberculosis or pneumonia. Diagnosis requires blood culture. With inadequate microbiology facilities, few cases are identified and there is poor recognition of the general importance of non-typhi salmonellas or indeed other Gram-negative bacteraemic infections.

Patients with bacteraemia respond poorly if therapy is delayed, the diagnosis missed, or the organism is resistant. Antimicrobial resistance is common, especially to the widely used broad-spectrum antibiotics. Chloramphenicol, ampicillin and gentamycin, quinolones or third-generation cephalosporins are appropriate; use depends on cost and availability. Most centres treat for 2 to 3 weeks although optimal duration is not established. Relapse and reinfection both occur. Relapse usually develops within 6 to 8 weeks of stopping therapy and close follow-up is indicated. Quinolone maintenance therapy is effective but too costly for most patients. There are many environmental sources and no obvious ways to prevent exposure. Cotrimoxazole prophylaxis may prevent bacteraemia caused by non-typhi salmonellas.

Disseminated fungal infections

Cryptococcus neoformans is the most common disseminated fungal infection associated with HIV. There can be wide regional variations in incidence. In Abidjan evidence of infection was seen in only 2.5 per cent of autopsies. One cohort in Uganda diagnosed cryptococcosis at or around death in 25 per cent of patients. Most patients have subacute or chronic meningitis; some present with fever, non-specific pulmonary symptoms, and fungaemia; and cutaneous nodules occasionally develop. Diagnosis can be made by culture, antigen detection, or cerebrospinal fluid microscopy using Indian ink. Both fluconazole and amphotericin B are effective but lifelong maintenance therapy is required. Antifungal drugs are expensive and not usually considered essential drugs in low-income countries. Most poor families cannot afford therapy. Significant price reductions have recently been announced. Whether fluconazole prophylaxis is effective and implementable remains to be established.

Penicillium marneffei is an important HIV-related systemic mycosis in parts of South-East Asia. *Histoplasma duboisii* has been reported in HIV-positive patients in Central Africa and *H. capsulatum* in Central America and the Caribbean. Coccidioidomycosis and paracoccidioidomycosis have been associated with HIV infection in South America. Several other fungal diseases ecologically or geographically restricted to parts of the tropics may yet emerge as HIV-associated pathogens.

Chronic diarrhoea

Chronic diarrhoea with wasting, called 'slim' across Africa, is the most recognizable and obvious manifestation of AIDS in developing countries. Around 20 per cent of patients in a Ugandan cohort had slim at death. Rates elsewhere are not established.

Many potential pathogens have been associated. Cryptosporidium is probably the most important; prevalence of cyst excretion in African case series ranges from 5 to 48 per cent. In some areas *Isospora belli* is common; with improved diagnosis microsporidia are increasingly recognized. Other protozoan and helminth parasites are

not important. Enteric bacteria can be isolated in perhaps 15 per cent of cases but their pathogenic role is uncertain; enteric viruses are not thought important. Disseminated tuberculosis is probably an agonal endstage infection. As in the West, only about 50 per cent of patients with slim fully investigated will have a putative pathogen identified.

There is no effective therapy for cryptosporidium. Isosporiasis clears with cotrimoxazole but maintenance therapy is necessary. Some microsporidia may respond to albendazole. Imodium or codeine phosphate can initially relieve symptoms; whether benefits are maintained with long-term treatment is not known. Enteric pathogens are ubiquitous and it is difficult to avoid exposure. Hygiene is important but, in practice, is not always easy to implement or affordable. Cryptosporidium cysts can withstand chlorination and it is necessary to bring water to the boil.

The endemic tropical parasitic diseases

For years it has been unclear whether HIV interacts significantly with malaria. As with other intercurrent infections, HIV viral load rises with acute malaria. There is now mounting evidence from pregnant women and adults that HIV-related immunosuppression reduces protective antimalaria responses. The prevalence of placental parasitaemia is twice as high in HIV-positive compared to HIV-negative multigravidas, and this significantly increases the risks of mother-to-child HIV transmission. In endemic malaria areas, adults with HIV infection experience increased rates of clinical malaria with higher parasite densities. Whether severe complicated disease is more common and response to therapy is compromised as malaria-specific immune responses are lost remains to be established. In adults who have no background immunity to malaria, it also appears that HIV is a significant risk factor for severe and complicated disease and death with epidemic *P.falciparum* infection. There are very few data on malaria in HIV-infected children or on the interactions of HIV with *P.vivax*.

Leishmaniasis is well described in patients with AIDS from southern Europe following acute exposure or reactivation of latent infection. There are few case reports from endemic tropical areas. HIV prevalence is low in many remote rural foci, the disease is difficult to diagnose, and patients may die before being immunosuppressed enough to develop disseminated leishmaniasis. Any significant interaction would be of great importance in the kala-azar belt of India.

Unusual manifestations of Chagas' disease have been linked with HIV. There is no clear association with African trypanosomiasis and neither pathogenic amoebas nor giardia are exacerbated by HIV infection. A few cases of *Strongyloides stercoralis* hyperinfection have been described; despite being AIDS defining, it is very uncommon. To date, there are no data suggesting important interactions between HIV and schistosomiasis (except perhaps to reduce egg excretion), other flukes, hookworm, ascaris, filariasis, or any of the cestode/tapeworm infections.

Malignancies

Kaposi's sarcoma and HHV8 are endemic in sub-Saharan Africa. However, Kaposi's sarcoma develops in less than 5 per cent of African patients with AIDS, perhaps related to different patterns of HHV8 exposure. HIV has markedly altered Kaposi's sarcoma epidemiology. Women are more likely to be affected although there is still a male preponderance. Lesions are more extensive, frequently involve the mucosa, and often the viscera. Disease is more aggressive and can progress rapidly. Cytotoxic therapy is expensive and not widely available in developing countries. A relatively cheap regimen using actinomycin D and vincristine has proved effective in Zambia. There are few data on Kaposi's sarcoma and HIV from other regions.

Conjunctival squamous cell carcinoma has been recorderd in East Africa. Lymphomas are uncommon and occur much less frequently than in industrialized countries. No impact on cervical carcinoma has been reported from the tropics.

Opportunistic infections

Many African studies have looked carefully for the classic Western AIDS-defining opportunistic infections. *Pneumocystis carinii* is diagnosed by bronchoscopy or at autopsy in perhaps 2 per cent of patients with chronic lung disease. *Mycobacterium avium* has been isolated from the environment but mycobacteraemic disease is rare; disseminated tuberculosis is far more common. Toxoplasmosis or active cytomegalovirus infections are rarely diagnosed or clinically manifest, although they may be seen at autopsy. The most likely explanation for their rarity is that few poor patients survive long enough to develop profound immunosuppression. In developing countries only the urban elites have such a 'Western' pattern of HIV/AIDS disease.

Future challenges

The critical issue remains to reduce the number of new infections, currently over 16 000 per day. More effective linkage of prevention with care and more attention to adolescent groups are priority areas for action. AIDS orphans are a growing and highly emotive problem. In high-prevalence countries strategies for coping with the profound change in the burden of disease are needed urgently. A growing threat is the increasing toll that HIV/AIDS is having on trained health-care personnel, who themselves are having to cope with the rising tide of HIV/AIDS disease. Continued advances in antiretroviral therapy highlight the inequity in access to care and poor survival in most developing countries. It is difficult to see how any of these challenges can be addressed without substantial increases in health care budgets and commitments from Western industrialized countries to reduce the global inequity in HIV/AIDS care. The new Global Fund may have a huge impact, if health systems are improved along with financing drug purchase..

7.10.23HTLV-I and II and associated diseases

C. R. M. Bangham, M. Osame, and S. Nightingale

HTLV-I

Originally isolated from a patient with a cutaneous lymphoma, the human T-cell lymphotropic virus type I (**HTLV-I**) was the first pathogenic retrovirus to be discovered in humans. In contrast to the human immunodeficiency virus (**HIV**), HTLV-I causes disease in only about 5 per cent of infected people. However, the virus is of special interest and importance because it is associated with two different types of disease: adult T-cell leukaemia/lymphoma (**ATL**) and a range of chronic inflammatory conditions, of which the most commonly diagnosed is HTLV-I-associated myelopathy, also known as tropical spastic paraparesis (**HAM/TSP**). A suggested association with multiple sclerosis has been refuted.

HTLV-I is estimated to infect between 10 and 20 million people worldwide. There are large endemic areas in Central and West Africa, southern Japan, the Caribbean and South America, and smaller foci in the aboriginal populations of Australia, Papua New Guinea, and northern Japan. In Europe and North America the virus is found chiefly in immigrants from these endemic areas and in some communities of intravenous drug users. Within the endemic areas, the distribution of HTLV-I is characteristically uneven; the seroprevalence can vary between 1 and 20 per cent of adults in neighbouring towns.

There are three important modes of transmission: parental and neonatal infection from a seropositive mother, in which breast feeding is a significant factor; sexual transmission, particularly from males to females; and transmission by infected blood, either by transfusion or by sharing of needles among drug users. Transmission of the virus depends on transfer of cells from infected people, because there is little free virus in the serum. Blood for transfusion is now routinely screened for HTLV-I in several countries, including Japan, the United States, and Brazil.

HTLV-I is known as a complex retrovirus: in addition to the three genes present in other typical replication-competent exogenous retroviruses (*gag*, *pol*, and *env*) it encodes at least two further proteins—Tax, which stimulates transcription of the proviral genome, and Rex, which controls the splicing of HTLV-I mRNA. There are closely related leukaemia viruses in monkeys and cattle.

Although it can infect a wide variety of cell types *in vitro*, HTLV-I appears to replicate efficiently only in CD4+ (helper) T cells; these are the cells that are transformed in adult T-cell leukaemia/lymphoma. The cellular receptor for HTLV-I has not been identified, although the gene is known to lie on chromosome 17. Certain cell-surface adhesion molecules (ICAM-1, ICAM-3, and VCAM) also facilitate entry of HTLV-I into the cell.

Antibodies against the Gag protein are the first to appear after infection, and they predominate in the first 2 months. Thereafter, anti-envelope antibodies predominate, and about half of infected individuals subsequently produce antibodies to the Tax protein. Diagnosis of HTLV-I infection depends on the detection of specific antibodies by particle agglutination or enzyme-linked immunosorbent assay (ELISA), and confirmation by polymerase chain reaction (PCR) or western blot assay.

Most people infected with HTLV-I mount a vigorous, chronically activated, cytotoxic T-lymphocyte response to the virus, mostly directed against the viral Tax protein. This cellular response appears to play an important part in reducing the viral burden and the risk of the associated inflammatory diseases such as HAM/TSP.

HTLV-I associated myelopathy (HAM/TSP) and other inflammatory diseases associated with HTLV-I

The association between HTLV-I and HAM/TSP, formerly known as Jamaican neuropathy, was discovered in the Caribbean and in Japan in the mid-1980s. HTLV-I has since shown to be associated with uveitis, and a lymphocytic alveolitis (usually subclinical). There are also less certain associations with chronic infective dermatitis, polymyositis, arthritis, sicca syndrome, and a motor neurone disease-like disorder.

The prevalence of HAM/TSP is between 0.1 and 2 per cent of individuals infected with HTLV-I: about two-thirds of patients are female. Other known risk factors for HAM/TSP include a high proviral load of HTLV-I (Fig. 1) and the *HLA DRB1*0101* gene ('*HLA DR1*'). Possession of the *HLA A*02* gene is associated with a reduced proviral load and a reduced risk of HAM/TSP in Japan.

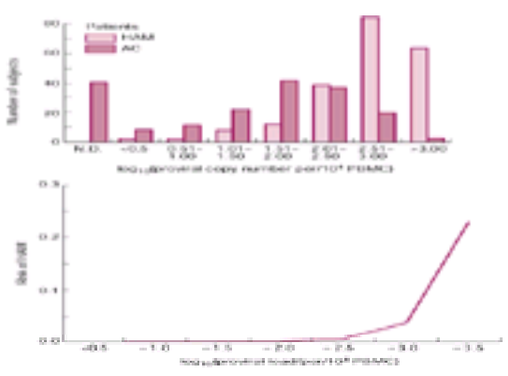

Fig. 1 Upper panel: distribution of HTLV-I provirus load in 202 patients with HAM/TSP (HAM) and 200 asymptomatic HTLV-I carriers (AC) in Japan. The median proviral load in HAM/TSP patients was 16 times greater than asymptomatic carriers. N.D., not detected. Lower panel: the risk of HAM/TSP in people infected with HTLV-I rises rapidly when the proviral load exceeds one copy per 100 peripheral blood mononuclear cells (PBMC). (Adapted from Fig. 2 and Fig. 3 in Bangham *et al*. (1999).)

Clinical features

HAM/TSP is characterized by a spastic paraparesis that is slowly progressive, or in some cases static after initial progression, and anti-HTLV-I antibody positivity in serum and cerebrospinal fluid. Almost all patients show spasticity and/or hyperreflexia of the lower extremities, initially presenting as gait and urinary disturbances. Presentation is commonly with low back pain, weakness of the lower extremities and a poorly defined (mild) sensory affectation, and rarely, with cerebellar ataxia.

Patients with a younger age of onset (less than 15 years) tend to have short stature and slow progression of the disease, while patients with an older age of onset (more than 61 years) show faster progression regardless of the mode of transmission.

Aside from HTLV-I antibody positivity, other essential laboratory findings in the cerebrospinal fluid include lymphocytic pleocytosis and increased neopterin levels. In more than two-thirds of patients, magnetic resonance imaging shows high signals of T_2-weighted spin echo in the white matter of the brain indicating atrophy of the spinal cord.

Autopsy reveals severe involvement of the thoracic spinal cord with mononuclear infiltration, marked myelin and axonal destruction, and astrocytic gliosis.

Several clinical trials have shown transient beneficial effects from corticosteroids, a-interferon, azathioprine, high-dose vitamin C, pentoxifyllene, danazol, and plasmapheresis. The nucleoside analogues zidovudine and lamivudine can reduce the provirus load of HTLV-I, but the clinical benefit is unknown.

Adult T-cell leukaemia/lymphoma (ATL)

HTLV-I infection carries a 5 per cent lifetime risk of ATL; the interval between infection and disease is frequently over 20 years. The disease is slightly commoner in males (1.2:1), and there is evidence of familial clustering of cases. In highly endemic areas it is an important cause of malignant disease: in Kyushu, Japan, ATL accounts for 75 per cent of non-Hodgkin's lymphomas.

The mean age at onset of ATL is about 60 years in Japan, and 40 years in the Caribbean and Brazil; the reason for this difference is not known.

The clinical features of ATL are those of a non-Hodgkin's lymphoma: malaise, fever, lymphadenopathy, hepatosplenomegaly, jaundice, drowsiness, weight loss, and opportunistic infections. Features particularly associated with ATL are skin involvement (nodules, plaques, or a generalized papular rash) and thirst. Laboratory findings include hypercalcaemia and high serum concentrations of lactate dehydrogenase and the soluble interleukin 2 (**IL-2**) receptor. The leukaemic cells are almost invariably CD4+, and are usually CD25+ (IL-2 receptor+). The transformed T cell has a characteristic appearance: the nucleus has several lobules, giving rise to the epithet 'flower cell'. Morphologically similar cells are found in small numbers in the peripheral blood in some asymptomatic carriers of the virus. When the proportion of abnormal cells is high, and there is a lymphocytosis, there is a greatly increased risk of development of ATL. However, in some cases the atypical cells regress spontaneously.

Southern blot analysis indicates the presence of oligoclonal or monoclonal proliferation of CD4+ cells carrying the HTLV-I provirus in their cellular DNA. Typically there is a progression from polyclonal to oligoclonal to monoclonal proliferation in the CD4+ population, accompanied by a progression to increasing IL-2-independence of cellular growth.

ATL is classified into clinical subtypes with different courses and prognoses. Intermediate states between lymphocytosis and frank ATL are called 'smouldering' or 'pre-' ATL. Initially response to standard chemotherapeutic regimes is commonly followed by early relapse with refractoriness to further chemotherapy after 2 to 6 months. Combination of interferon-a and zidovudine can prolong life expectancy by between 6 months and 2 years. The mean survival times (untreated) for acute, lymphomatous, and chronic ('smouldering') ATL in Japan are 6.2, 10.2, and 24.3 months, respectively.

HTLV-II

HTLV-II, a retrovirus closely related to HTLV-I, was first isolated from the tissue of a patient with an atypical form of hairy cell leukaemia. The virus occurs sporadically in West Africa. Among intravenous drug abusers in Europe and North America, infection with HTLV-II is as common as HTLV-I. HTLV-II is common n several native groups throughout the Americas.

HTLV-II is not associated with the typical B-cell form of hairy cell leukaemia, or with other haematological malignancies. A paralytic syndrome similar to HAM/TSP has been reported in individuals seropositive for HTLV-II. Paralysis may be flaccid rather than spastic. However, HTLV-II aetiology is not certain.

7.10.24Viruses and cancer

R. A. Weiss

Introduction

Viruses are important in cancer for three main reasons: first, as a cause for about 15 per cent of the worldwide cancer burden; second, for the discovery and characterization of oncogenes and tumour suppressor genes; and third, as vectors for the delivery of gene therapy and immunotherapy.

Viruses as aetiological agents of cancer

Table 1 lists the viruses implicated in human cancer. In most but not all cases the viral genome is present in the malignant cells; the exceptions appear to be those that promote cancer indirectly, such as human immunodeficiency virus (**HIV**) and hepatitis C virus (**HCV**).

Oncogenic viruses establish persistent, lifelong infections, so that the event of infection may be far removed from the event of malignancy. Moreover, cancer is often a rare outcome of virus infection, and other cofactors play a part in viral carcinogenesis. For example, Epstein–Barr virus (**EBV**) is a ubiquitous infection yet children's Burkitt's lymphoma occurs only in areas of holoendemic malarial infection, whereas undifferentiated nasopharyngeal carcinoma occurs mainly in southern Chinese populations. Aflatoxin may act with hepatitis B virus (**HBV**) to cause liver cancer, and in hereditary epidermodysplasia verruciformis the ultraviolet radiation acts with human papillomavirus (**HPV**) strains to cause skin cancer.

Kaposi's sarcoma is a tumour that occurs much more frequently in immunodeficient patients. Its relative risk in recipients of organ transplants is about 400, and in persons with AIDS about 20 000. HIV probably contributes to Kaposi's sarcoma indirectly through immune suppression, although the Tat protein of HIV may also play a role. The primary cause of all forms of Kaposi's sarcoma is the recently discovered human herpes virus 8 (**HHV-8** or KSHV). This virus is also causally linked to primary effusion lymphoma and plasmablastic multicentric Castleman's disease.

Oncogenic viruses belong to many virus families, which have different routes of transmission. Some, like hepatitis B virus, are frequently acquired perinatally or through subsequent exposure to blood. With human T-cell lymphotropic virus type I (**HTLV-I**) the main route of transmission is vertical through infected cells in breast milk. Sexual transmission is common to HIV, HTLV-I (with a male to female bias), HBV, and HPV. Oncogenic viruses do not appear to be transmitted by the respiratory route, except adenoviruses, or via arthropod vectors, except some veterinary cases, such as bovine leucosis virus. Whereas EBV (transmitted through saliva) occurs worldwide, HBV, HTLV-I, and HHV-8 have a high prevalence mainly in those population groups in which the associated cancers occur.

Certain common human viruses are highly oncogenic in experimental animals but are not linked to human cancer, namely the polyomaviruses BK and JC, and the adenoviruses. Human adenovirus types 2 and 12 readily cause sarcomas and carcinomas in hamsters and other rodents. The viral genomes persist non-productively in the animal tumours and express early genes. It is surprising, then, that there is no epidemiological evidence linking adenovirus or BK infection with human cancer. There is some concern that a simian relative of BK virus, SV40, may be linked with mesothelioma, osteosarcoma, and ependymoma in humans, but these findings remain controversial.

Mechanisms of viral carcinogenesis

Physical and chemical carcinogens are usually mutagens. They cause DNA mutations in specific genes that contribute to the eventual malignant phenotype of the cancer. Oncogenes were first discovered in animal retroviruses, such as the Rous sarcoma virus of chickens, and are now known to originate from cellular genes. Most retroviruses do not carry oncogenes but the DNA provirus integrates into chromosomal DNA and can activate adjacent cellular oncogenes. Oncogene activation by retroviruses is comparable with activation by chromosomal translocation.

The mechanism of cell transformation by HTLV-I is different from that of the majority of animal retroviruses. HTLV-I encodes a viral protein, Tax, which is essential to promote full viral gene transcription. Tax acts as a transcriptional activator by associating with host nuclear proteins which activate expression of the viral genome. However, Tax also up-regulates certain cellular genes such as the interleukin-2 receptor. HTLV-I 'immortalizes' CD4+ T lymphocytes in culture, rather as EBV immortalizes B lymphocytes, but this is only one step in the pathway to malignancy. HTLV-I leukaemia does not become manifest until 40 or more years after infection, and in only 5 per cent of infected people.

Cell transformation by DNA viruses is best understood for polyomaviruses and adenoviruses. The transforming genes of these viruses are expressed early in the infection cycle and prevent tumour suppressor protein function. Adenovirus proteins E1A and E1B and BK T-antigen bind to p53 and Rb and block their normal interaction in the cell cycle. Thus instead of mutating these cellular tumour suppressor genes, the DNA tumour viruses block the normal function of their proteins, which similarly results in unregulated cell proliferation. The HHV-8 genome carries several oncogenes including a homologue of cyclin D2, which inactivates Rb by a different mechanism, phosphorylation.

To cause tumours, most oncogenic viruses persist in the tumour cells, often by integrating into chromosomal DNA. Oncogenic herpesviruses do not integrate but are maintained episomally. EBNA-1 is required for episomal replication of EBV (and LANA for HHV-8), while other nuclear and latent membrane proteins are responsible for the transformed cell phenotype. With HBV, integrated copies are found in many liver carcinoma lines, but a requirement for integration has not been unequivocally shown. HBV expresses transactivating functions from the *X* gene so its transformation may resemble that of HTLV-I. Some viruses might exert an oncogenic effect without persisting in the cells destined to become the malignant clone, by causing mutations in host DNA, thus acting in a 'hit-and-run' manner like other mutagens.

Indirect carcinogenic effects are those in which damage to tissues by viruses may allow clones of premalignant cells to proliferate that would not otherwise do so. HCV and possibly HBV might do this by destroying normal liver cells, resulting in a much greater rate of liver cell regeneration. HIV could be regarded as a special case of indirect viral carcinogenesis, promoting tumour development by destroying helper T-cell immunity to other viruses. The cancers elevated in AIDS are also seen in immunosuppressed transplant recipients, for example non-Hodgkin's lymphoma and Kaposi's sarcoma, and themselves have a viral aetiology.

Treatment and prevention

Oncogenesis is multifactorial, requiring several sequential events before a patient presents with a fully malignant tumour. Yet if a virus plays a crucial role in oncogenesis, its elimination should prevent that type of cancer. Currently, there is no special approach to the treatment of cancers that have a viral aetiology. Among the lymphoid malignancies, some respond well to radiotherapy or chemotherapy, such as Hodgkin's disease, whereas others seldom show remission, such as adult T-cell leukaemia. Cancers that express viral antigens should be responsive to immunotherapy. If immunosuppression promotes their presentation, they should be susceptible to immune attack. For tumours in which viral proteins are required for the maintenance of the malignant state, those proteins are potential molecular targets, as drugs that block them might spare normal cellular functions.

Prevention is preferable to cure and offers the greatest promise of reducing cancer mortality due to viruses. Prevention can be accomplished by three strategies: (i) early screening for tumours, (ii) screening for the virus with prevention of transmission, and (iii) immunization. Early screening is exemplified by cervical smears and, in China, for elevated serum IgA levels to EBV antigens for incipient nasopharyngeal carcinoma. Screening to prevent iatrogenic transmission via blood and blood products is routinely employed in many countries for potentially oncogenic viruses such as HBV, HCV, HIV, and HTLV-I. In Kyushu, Japan, where infection was

endemic, HTLV-I is being steadily eradicated through a policy of antenatal screening to prevent milk transmission.

Prevention of cancer by immunization against oncogenic viruses is likely to have a major impact on world cancer mortality in the twenty-first century. Currently, the only proven, mass-produced vaccine against a human oncogenic virus is the HBV vaccine based on surface antigen. Indeed, it is the first efficacious recombinant subunit vaccine against any virus. Other vaccines under development that are likely to be successful within the next decade are for EBV, HPV, and HTLV-I. Intensive research is also being undertaken on vaccines for HIV and HCV. There are likely to be some obstacles on the route to successful immunization, as HIV is extraordinarily variable, and even the relatively stable HBV shows evidence of immune-escape mutants in the face of vaccination programmes. Nevertheless, immunization against oncogenic viruses is likely to become a most effective cancer prevention strategy.

Viruses as therapeutic agents

Viruses may be put to use in the fight against cancer. First, some cytopathic viruses preferentially replicate in proliferating cells and destroy them, such as parvoviruses and mutant adenoviruses. Second, viruses as foreign antigens may aid the recognition of cancer cells by the host's immune system. Although the mechanism is ill understood, 'xenogenization' of tumour cells by virus infection can, in some cases, enhance immune control of non-infected cells of the same tumour. Third, viruses are favoured vectors for immunization and for gene therapy, by restoring tumour suppressor functions, by enhancing immune responses through the expression of antigens or cytokines, and by locally delivering genes for enzymes that convert inert prodrugs into active, chemotherapeutic agents.

7.10.25 Orf

N. Jones

Aetiology

Orf virus, a member of the *Parapox* genus, normally causes ecthyma contagiosum or 'scabby mouth' (contagious pustular dermatitis) in sheep and goats. Orf virions are ovoid (approximate size, 260 × 160 nm), with tubular threadlike structures criss-crossing the surface of the virions, visible by negatively stained electron microscopy. The orf virus genome is double stranded DNA of 135 kbp. The viral genome encodes a polypeptide homologous to IL-10, inhibitors of interferon, IL-2 and GM-CSF, and a vascular endothelial growth factor. These contribute to the dermal lesions characterized by capillary proliferation and dilatation.

Other Parapox viruses infect cattle, deer, and seals.

Epidemiology

The disease affects mainly young lambs, who contract the infection from one to another, or possibly from persistence of the virus in the pastures (the virus can remain viable for long periods in dried scabs from lesions). Human disease is usually occupational, following contact with infected sheep. It is not uncommon in shepherds, veterinary surgeons, and farmers (Fig. 1). One attack normally confers immunity and human to human spread has not been recorded.

Fig. 1 Orf, typical lesions on a farmer's hand.

Clinical features

In sheep, papules and vesicles appear on the lips (Fig. 2) and gradually heal with no scarring over 4 weeks. In humans, after an incubation period of 5 to 6 days, a small, red, firm papule enlarges to form a flat-topped haemorrhagic pustule or bulla; the centre may be crusted. The lesion is usually 2 to 3 cm in diameter, but may be as large as 5 cm. Lesions are solitary or few in number and commonly occur on the hands and forearms, occasionally the face. Lymphangitis or regional lymphadenopathy are not uncommon. Slight fever and malaise can occur. Recovery is usually complete in 6 weeks and is spontaneous.

Fig. 2 Contagious pustular dermatitis ('orf') in a lamb.

Large fungating granuloma or tumour-like lesions have been reported, especially in association with haematological malignancy.

Erythema multiforme occasionally develops, typically 10 to14 days after the onset of orf (Fig. 3). Rarely, bullous pemphigoid has been reported in association with orf.

Fig. 3 Erythema multiforme complicating orf of the left middle finger in a veterinary student.

Diagnosis

The characteristic lesion in a person exposed to sheep and lambs allows a clinical diagnosis. This can be confirmed in the laboratory by electron microscopy of a biopsy of the orf lesion or by PCR. The virus can also be isolated in cell culture, but this is rarely performed. Histopathological examination of biopsy specimens shows a proliferation of keratinocytes with cellular swelling and balloon degeneration and B type cytoplasmic inclusion bodies.

Treatment

Secondary infection should be treated if it occurs. Large lesions can be removed surgically, but recurrence can occur in the immunocompromised. Cidofovir cream has been used successfuly to treat giant or persistent lesions in immunosuppressed patients.

7.10.26 Molluscum contagiosum

N. Jones

Molluscum contagiosum is a benign skin tumour, caused by a poxvirus, which mostly affects children and young adults. It is exclusively a human disease.

Aetiology

Molluscum contagiosum virus (MCV), a large double-stranded DNA virus, is a member of the Poxviridae, genus *Molluscipox*. MCV has not been transmitted to laboratory animals and there is no *in vitro* cultivation system currently available. Restriction endonuclease analysis of the genome has identified three types, MCV I, MCV II, and MCV III. The majority of infections seem to be due to MCV 1. The virus encodes MC 159L protein which causes abnormal proliferation of epithelium by inhibiting TNF and apoptosis-inducing factors.

Epidemiology

Molluscum contagiosum is common and disease usually follows contact with an infected individual or contaminated object. In tropical countries, the infection tends to occur in younger children (1–4 years) than in temperate climates (10–12 years). Sexual transmission accounts for a second incidence peak in young adults. Unusually widespread lesions have been reported in HIV disease, sarcoidosis, and those taking immunosuppressive therapy.

Clinical features

The incubation varies from 14 days to 6 months. The individual lesion is a shining, pearly, hemispherical, firm, umbilicated papule with a central depression. Lesions can occur singly (Fig. 1) but are commonly multiple (Fig. 2). The lesions gradually grow to a diameter of 5 to 10 mm over 6 to 12 weeks. Occasionally one very large lesion can develop (> 10 mm), or a plaque of very small lesions (agimate form). Most cases persist for 6 to 9 months, occasionally as long as 5 years, following which spontaneous resolution occurs.

Fig. 1 Single lesion on eyelid.

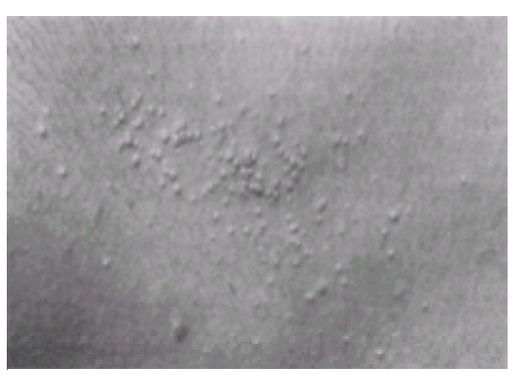

Fig. 2 Molluscum contagiosum: groups of papules characterized by a central punctum.

Lesions are commonly seen on the neck, trunk, or axilla, although any part of the skin can be affected. Lesions are rare on the palms, soles, and mucous membranes. Sexually acquired infections normally result in anogenital lesions. In about 10 per cent of cases, especially where there is a history of atopy, a patchy dermatitis develops around the lesions. In the HIV patient molluscum can be widespread, but particularly involves the face, neck, and around and inside the mouth in male homosexuals. Lesions may become large and atypical, and are mistaken for basal cell carcinomas or other skin tumours. The disease is often unremitting with increasing severity, especially when HIV is advanced.

Diagnosis

The diagnosis is usually clinical, but histological and electron microscopic examination of a curetted lesion establishes the diagnosis. The differential diagnosis can include lepromatous leprosy and, in HIV-seropositive patients, disseminated cutaneous histoplasmosis or cryptococcosis.

Treatment (see also Chapter 23.1)

Advice on prevention of spread of the infection to others should be given, such as avoidance of swimming pools, contact sports, or shared towels, until the lesions have resolved. Treatment may not be necessary, and depends on the site and number of the lesions and the age of the patient.

Cryotherapy (with liquid nitrogen) is effective and should be repeated at 3–4-weekly intervals. Other techniques include diathermy or curettage. In children the application of local anaesthetic cream prior to the procedure may be necessary.

Topical agents such as phenol (10–20 per cent solution), salicylic acid (15–20 per cent), silver nitrate, trichloroacetic acid, lactic acid, tretinoin, and cantharidin are

used. The agent can be delivered to the inside of the lesion using the sharpened end of a wooden applicator stick.

In severe cases associated with HIV, 5 per cent imiquimod cream has proved effective. Recently, the antiviral agent, cidofovir (intravenously or topically), has been successfully used to treat molluscum contagiosum.

7.11.1 Diphtheria

Delia B. Bethell and Tran Tinh Hien

Introduction

Diphtheria is an acute infection of the upper respiratory tract, and occasionally of other mucous membranes or skin, usually caused by *Corynebacterium diphtheriae*. The disease was probably known to the Greeks and Romans. While virtually eliminated from most developed countries by mass immunization, diphtheria remains a threat in poorer countries. In the last decade there has been a resurgence in parts of the former Soviet Union.

Bacteriology

Morphology

C. diphtheriae are pleomorphic, Gram-positive rods or clubs. Adjacent cells lie at different angles to each other—'Chinese letters'. The presence of metachromatic granules, usually two or three per cell, is characteristic but not exclusive; these stain deep blue with Neisser's methylene blue or greyish-black with Albert's stain. Virulent and non-virulent *C. diphtheriae* cannot be distinguished by their morphological appearances.

Culture

C. diphtheriae does not grow well on ordinary agar, but prefers media containing blood or serum. Selective media, such as Loeffler's serum medium and blood tellurite agar, are necessary for its isolation from other respiratory flora, although other corynebacteria can also grow on these media. Biochemical tests are used to identify *C. diphtheriae*. There are three colonial types of *C. diphtheriae*: *gravis*, *intermedius*, and *mitis*. There is no good association between colonial appearance and disease severity.

Toxin production

The clinical manifestations of diphtheria are caused by an exotoxin produced by virulent corynebacteria. The structural gene of the toxin, *tox*, is carried by a lysogenic corynebacteriophage. The phage can pass from toxigenic to non-toxigenic strains; this may be important in outbreaks when harmless strains in carriers' throats may become toxigenic. TOX gene expression is regulated by the *C. diphtheria*-encoded, iron-activated, repressor DtxR; hence iron starvation leads to increased toxin production.

Production of toxin may be assessed using gel precipitation (Elek's test) or guinea-pig inoculation. More recently enzyme immunoassays have been developed.

Pathogenesis

Pseudomembrane formation

This results from an inflammatory reaction to the presence of multiplying toxigenic *C. diphtheriae*. Fluid and leucocytes move from dilated blood vessels to surround necrotic epithelial cells. The fluid clots to enmesh these dead cells, as well as leucocytes, diphtheria bacilli, cellular debris, and occasionally small blood vessels. The latter explains why the pseudomembrane is adherent to underlying tissues and often bleeds when it is pulled away.

Action of toxin

C. diphtheriae does not usually pass beyond the pseudomembrane site; it is the toxin that causes the severe complications of diphtheria. Diphtheria toxin is a 535-residue, 62-kDa exotoxin. It consists of two factors: spreading factor B attaches via its receptor (heparin-binding, epidermal growth factor-like precursor (**HB-EGF-LP**)) to the cell membrane allowing lethal factor A to enter the cell. Factor A catalyses the NAD+-dependent ADP-ribosylation of eukaryotic elongation factor 2, preventing protein synthesis. Locally the toxin causes tissue necrosis, leading to formation of the typical pseudomembrane and, when absorbed into the bloodstream, systemic complications. Diphtheria toxin affects all human cells, but the most profound effects are seen in the myocardium, peripheral nerves, and kidneys. Delivery of a single molecule of factor A to the cytosol of a eukaryotic cell will kill it.

Effects on the heart

Common changes are fatty degeneration of cardiac muscle (myocarditis) and infiltration of the interstitium with leucocytes, which may affect the conduction fibres. Parenchymal necrosis is rare. Generally the heart can recover completely from these effects, although severe fibrosis and scarring may lead to death in late convalescence. Mural endocarditis may cause embolism leading to cerebral infarction and hemiplegia. Valvular endocarditis is extremely uncommon. Neuritic changes may be seen in the nerves to the heart during the late paralytic stage of the disease.

Effects on nerves

Diphtheria toxin causes demyelination and degeneration of both sensory and motor nerves. It affects the nerves to the eye, palate, pharynx, larynx, heart, and limb

muscles. It is unclear whether the toxin can cross the blood–brain barrier and cause central lesions.

Effects on other organs

Non-specific changes in the kidneys, adrenals, liver, and spleen may be seen.

Epidemiology

Man is the only known reservoir for *C. diphtheriae*. Spread is usually via respiratory droplets or direct contact with respiratory secretions or exudate from skin lesions. Cutaneous diphtheria is more contagious than respiratory diphtheria: skin infections are the main reservoir of *C. diphtheriae* in environments of poverty, overcrowding, poor hygiene, frequent and slowly healing traumatization of unprotected skin, and insect bites. Fomites and dust are not important means of transmission, although *C. diphtheriae* may resist drying and has been isolated from dust on the floor of a ward. Diphtheria has been spread by contaminated milk. *C. diphtheriae* is killed y pasteurization and by most common disinfectants. Patients may become carriers of the infection and continue to harbour the organism for weeks or months, or even for a lifetime.

There is no given level of circulating antibody indicating protection or susceptibility to infection. The Schick test is used to assess the antibody response to diphtheria toxin. A measured amount of toxin is injected into the forearm causing a red reaction (positive) unless the patient has a sufficient antibody response to prevent it (negative). A Schick-negative person is very unlikely to have clinically significant diphtheria, while a Schick-positive person may have an attack of any severity. Neonates are very often Schick-negative, protected by maternal antibody, but become Schick-positive around 6 months of age. *C. diphtheriae* tends to die out in a highly immunized population, and children may grow to adult life without encountering the bacillus. In areas of the world that lack an effective immunization programme children generally meet *C. diphtheriae* early, maybe becoming a faucial, nasal, or aural carrier, and young children may suffer severe or fatal attacks of diphtheria.

In the 1990s a diphtheria epidemic gripped parts of the former Soviet Union. Economic hardship, crowding due to large urban migration, low vaccination coverage, and poor primary vaccination practices due to failing health systems have contributed. This has led to large numbers of susceptible children as well as an increase in susceptible adults as immunity was not maintained by periodic boosters. Prior to the vaccine era, most people acquired natural lifelong immunity during childhood through their exposure to *C. diphtheriae.* Serological studies in several countries indicate that 20 to 50 per cent of adults over the age of 20 years are susceptible to diphtheria, with a significant trend of decreasing immunity with increasing age. This potential risk assumes a particular significance in today's international travel.

Clinical features

After an incubation period of 2 to 5 days, diphtheria presents in a variety of forms depending upon the location of the pseudomembrane—anterior nasal, faucial, tracheolaryngeal, malignant, and cutaneous.

Anterior nasal

This is usually unilateral and relatively mild unless it coexists with other forms. It is relatively common in infancy. There is a nasal discharge, initially watery, then purulent and blood-stained. The nostril may be sore or crusted and a thin pseudomembrane can sometimes be seen within the nostril itself.

Faucial

This is the commonest form of diphtheria. Malaise, sore throat, and moderate fever develop gradually. At the onset of symptoms only a small, yellow-grey spot of pseudomembrane may be present on one or both tonsils, easily mistaken for other types of tonsillitis. The surrounding areas are dull and inflamed. Over the next few days the pseudomembrane enlarges and may extend to cover the uvula, soft palate, oropharynx, nasopharynx, or larynx. There is tender cervical lymphadenopathy, nausea, vomiting, and painful dysphagia. The pseudomembrane becomes greenish-black and eventually sloughs off.

Tracheolaryngeal

Some 85 per cent of tracheolaryngeal presentations are secondary to faucial diphtheria, but occasionally there may be no pharyngeal pseudomembrane. Initial symptoms include moderate fever, hoarseness, and a non-productive cough. Over the next day, as the pseudomembrane and associated oedema spread, the child becomes increasingly dyspnoeic with severe chest recession and cyanosis and asphyxiation unless the obstruction is relieved. Tracheostomy brings instant relief if the obstruction is confined to the larynx and upper trachea. In a minority of cases the pseudomembrane also involves the bronchi and bronchioles and tracheostomy has little effect.

Malignant

The onset is rapid, with high fever, tachycardia, hypotension, and cyanosis. Pseudomembrane spreads from the tonsils to cover much of the nasopharynx. It has a thick edge and as this advances the earlier parts become necrotic and foul smelling. There is gross cervical lymphadenopathy. Individual lymph nodes are difficult to feel because of surrounding oedema; this is the characteristic 'bull neck' of malignant diphtheria. The patient may bleed from the mouth, nose, or skin. Cardiac involvement with heart block occurs within a few days. Acute renal failure may ensue. Survival is unlikely.

Cutaneous

In contrast to many faucial infections, cutaneous diphtheria is usually chronic but mild. The morphological features of individual lesions can be extremely variable as *C. diphtheriae* can colonize any pre-existing skin lesion (such as impetigo, scabies, surgical wounds, or insect bites) without altering their picture. However, the ulcerative form is the most frequent and typical. Initially vesicular or pustular, filled with straw-coloured fluid, it soon breaks down to leave a punched-out ulcer several millimetres to a few centimetres across. Common sites are the lower legs, feet, and hands. During the first 1 to 2 weeks it is painful and may be covered with a dark pseudomembrane. After this separates a haemorrhagic base is seen, sometimes with a serous or serosanguinous exudate. The surrounding tissue is oedematous and pink or purple in colour. Spontaneous healing to leave a depressed scar usually takes 2 to 3 months, sometimes much longer.

Systemic complications, such as myocarditis, are rare. Occasionally, the affected limb becomes paralysed.

Other sites

A mild conjunctivitis may accompany faucial diphtheria. Occasionally, pseudomembrane forms in the lower conjunctiva and spreads over the cornea causing considerable damage. Dysphagia may indicate that pseudomembrane has spread from the tonsils to the oesophagus. Other parts of the gastrointestinal tract are not usually affected, but melaena with colicky abdominal pain is described. Diphtheria may spread by fingers from the throat to vulva or penis causing localized sores. *C. diphtheriae* occasionally invades the vagina and cervix, allowing the absorption of toxin. In one patient, pseudomembrane was found on the wall of the bladder at operation; peripheral neuritis and fatal heart failure ensued. Endocarditis is rare, but at least one reported case recovered following antimicrobial treatment.

Other corynebacteria

C. ulcerans produces two toxins, one of which seems to be the same as diphtheria toxin. It may cause membranous tonsillitis but toxic manifestations are rare. However, at least one fatality due to *C. ulcerans* has been reported. *C. ulcerans* has been spread to humans in cows' milk.

C. pseudodiphtheriticum is commonly present in the flora of the upper respiratory tract. It is non-toxigenic, but can cause exudative pharyngitis with a pseudomembrane identical to that produced by *C. diphtheriae*. More commonly it causes endocarditis in patients with anatomical abnormalities or infections of the lungs, trachea, or bronchi in immunosuppressed patients or those with pre-existing respiratory disease.

C. xerosis has been isolated from the blood of patients with endocarditis and from prosthetic valves at operation. *C. haemolyticum* has caused outbreaks of tonsillitis

with or without a maculopapular rash.

Complications

Patients surviving acute diphtheria may develop one or more complication. These result from delayed effects of the toxin following haematogenous spread. The risk and severity of complications correlates directly with the extent of the pseudomembrane and the delay in administration of antitoxin.

Cardiovascular

Approximately 10 per cent of patients with diphtheria will develop myocarditis. Some two-thirds of patients with severe infection will have some evidence of cardiac involvement. The frequency of cardiac involvement in laryngeal and malignant diphtheria is three- to eightfold higher compared with faucial diphtheria, and two- to threefold higher if antitoxin is given more than 48 h after onset of the disease.

Cardiac toxicity usually appears after the first week of illness, but in malignant forms can occur after just a few days. Patients complain of upper abdominal pain and may vomit. They become very lethargic and tired. Examination reveals a rapid thready pulse with hypotension. At this stage profound shock may lead to death. In less severe cases, congestive cardiac failure may develop, with a displaced apex beat, gallop rhythm, and murmurs audible over all areas of the heart. Profound bradycardia may result from heart block. The liver enlarges and oliguria develops. Most deaths from diphtheria occur at this stage. If the patient survives myocarditis, complete recovery is likely.

Electrocardiography (**ECG**) is the best way to demonstrate cardiac involvement. The most common abnormalities are T-wave inversion in one or more chest leads and prolonged QTc intervals. There may be right or left axis deviation, bundle-branch block, or heart block. Very occasionally, atrial fibrillation or tachyarrhythmias are seen. Many more bursts of arrhythmias can be demonstrated if 24-hour ECG monitoring is performed. Numerous ectopic beats have been recorded in patients who lacked other manifestations of cardiac involvement.

Neurological

Neurological complications usually appear weeks after the onset of the disease, when the patient appears to be recovering. Palatal paralysis is common and may be seen from the third week onwards. The patient develops a nasal voice and regurgitates fluids through the nose. This usually resolves within a week or so. A little later there may be blurred vision from paralysis of accommodation, or a transient squint from external rectus paralysis. About the sixth or seventh week more sinister paralyses may develop affecting muscles to the pharynx, larynx, chest and limbs. The nerves to the heart may be affected causing tachycardia and dysrhythmias. Patients may become profoundly hypotonic over a few hours and die from respiratory arrest. However, if intensive-care facilities and skilled staff are available, the patient should be able to make a complete recovery over the following weeks or months.

Diagnosis

In areas where diphtheria is relatively common it should be suspected in any child with exudate in the throat. If the exudate is thick and discoloured the child should be given antitoxin. Clinical diagnosis is much more difficult where diphtheria is rare. The differential diagnosis includes infectious mononucleosis, streptococcal or viral tonsillitis, peritonsillar abscess, oral thrush, and leukaemia and other blood dyscrasias. The bull-neck of malignant diphtheria may be mistaken for mumps. In adults, secondary syphilis can sometimes cause a glairy (resembling egg-white) exudate on the tonsils, and may be accompanied by rash and laryngitis.

Direct smears of infected areas of the throat are often used for diagnostic purposes, but are only of value in experienced hands. Confirmation of the diagnosis depends on culture and identification of *C. diphtheriae* from infected sites. Atypical corynebacteria can be classified only in a reference laboratory.

Treatment

Antitoxin is the mainstay of treatment, but to be effective it must be given before the toxin has reached tissues such as the heart and kidneys, preferably within 48 h of the onset of symptoms. This means that it must be given before bacteriological confirmation. Dosage depends on the site of primary infection, the extent of pseudomembrane, and the delay between the onset of symptoms and antitoxin administration. Between 20 000 and 40 000 units are given for faucial diphtheria of less than 48 h duration or for cutaneous infection; 40 000 to 80 000 units for faucial in excess of 48 h or for laryngeal infection; 80 000 to 100 000 units for malignant diphtheria. For doses over 40 000 units a portion is given intramuscularly followed by the bulk of the dose intravenously after an interval of 30 min to 2 h. Anaphylaxis can occur following antitoxin administration, and adrenaline (epinephrine) should always be available.

Antibiotics are given to eradicate the organism and prevent further toxin production. Benzylpenicillin (penicillin G) 150 000 to 250 000 units/kg per day (90–150 mg/kg/day) is given intravenously in four to six divided doses in children aged 1 month to 12 years. In adults the dose of benzylpenicillin is 12 million to 20 million units/day (7.2–12 g/day) in four to six divided doses. Oral penicillin V is substituted when the patient is able to swallow. Erythromycin may be used for penicillin-sensitive individuals, but a recent study suggests it may not be as effective in eradicating carriage. Antibiotic therapy should continue for 10 to 14 days.

Facilities for urgent tracheostomy should always be available in case of respiratory obstruction. Indications include increasingly laboured breathing and agitation. This procedure will be life-saving in many cases. Most tracheostomies can be closed after just a few days. Steroids may be used in conjunction with tracheostomy to reduce airway swelling, but there have been no controlled trials to support their use. Steroids are of no benefit in preventing myocarditis or neuritis.

Patients with signs or symptoms of cardiac involvement need to be managed in intensive-care units. Oxygen should be given. Temporary cardiac pacing is useful in patients with heart block, but is of doubtful value in cases of malignant diphtheria. An isoprenaline infusion may buy valuable time while the patient is transferred to a centre with facilities for pacing. Digoxin has been used in congestive cardiac failure. It has been suggested that carnitine may prevent some cases of myocarditis.

There is no specific treatment for neuritis. The severest cases will need mechanical ventilation and intragastric or intravenous feeding. With skilled nursing care full recovery can be expected.

Prevention

Diphtheria is a devastating but preventable disease. Its resurgence in Eastern Europe has highlighted the importance of vaccination. Experience to date suggests that a large gap in the immunity of adults poses an outbreak risk, but is probably not sufficient to sustain a large diphtheria epidemic. However, an immunity gap in adults coupled with the presence of large numbers of susceptible children and adolescents creates the potential for an extensive epidemic. Population migration may lead to massive introduction and spread of toxigenic strains of *C. diphtheriae*.

In industrialized countries, infants, children, and adolescents can be effectively immunized using a six-dose schedule: three primary doses of **DTP** (adsorbed diphtheria–tetanus–pertussis) are given in infancy (in the United Kingdom at 2, 3, and 4 months); a first booster dose with DTP vaccine at the end of the second year; a second booster dose with **DT** (adsorbed diphtheria-tetanus) (or DTP) at school entry; and a third booster dose with **Td** (adsorbed tetanus/low-dose diphtheria for adults) at school leaving. Protection against diphtheria may be inadequate if only a single booster of TD or Td vaccine is given at 4 to 10 years of age following the primary doses.

In developing countries, the immunization of infants with a primary series of three doses of DTP was introduced in the late 1970s. By 1995 the coverage of infants was 81 per cent. Where diphtheria is endemic this should be sufficient to prevent an epidemic of diphtheria, as natural mechanisms such as frequent skin infections caused by *C. diphtheriae* probably contribute to maintaining immunity. One or two DT or DTP booster doses may need to be added to the routine schedule in areas at increased risk of diphtheria.

Reduction in the *C. diphtheriae* reservoir due to the large-scale immunization of children means that adults in industrialized countries are no longer immune through natural exposure. Repeated doses of diphtheria toxoid are needed to maintain immunity in the adult population. A lower dose of toxoid is used in older children and adults because of a tendency for more severe adverse effects. Some industrialized countries schedule routine booster doses of Td for every 10 years, but this

strategy is difficult to monitor. Adults in developing countries do not require routine immunization.

Aggressive action is needed in the event of a diphtheria outbreak. Groups at risk should be immunized, there should be prompt diagnosis and management of cases, and identification of close contacts should be made so that the spread of infection can be halted. A single dose of DTP should be used for children under 3 years of age, DT for children aged 3 to 7 years, and Td vaccine for all persons aged over 7 years. Additional doses of vaccine will be needed in non-immunized individuals.

7.11.2 Streptococci and enterococci

S. J. Eykyn

The term *Streptococcus* was first used by Billroth in 1874 to describe chain-forming cocci seen in infected wounds. They were also seen in the blood in puerperal sepsis by Pasteur (1879). In 1884, Rosenbach defined these streptococci as *Streptococcus pyogenes.* This organism remains one of the most important human pathogens. The genus *Streptococcus* contains numerous other species of varying degrees of pathogenicity for humans and animals. *Streptococcus faecalis* and *S. faecium* were split from the genus *Streptococcus* in 1984 and became *Enterococcus* spp. and numerous other species have since been included in this genus. The nutritionally-exacting streptococci *S. adjacens* and *S. defectivus* have also been assigned to a new genus, *Abiotrophia,* to which the newly described species *A. elegans* has been added.

Classification

Traditionally, classification of streptococci has relied on serological reactions, particularly Lancefield grouping based on cell wall carbohydrates, and haemolytic activity on blood agar, which has led to rather unsatisfactory streptococcal taxonomy. Genetic analysis has now enabled the subdivision of the species of *Streptococcus* into six clusters or groups as follows: pyogenic streptococci, milleri or anginosus group, mitis group, salivarius group, mutans group, and bovis group. Since the medically important members of the mitis, salivarius, and mutans groups are all oral streptococci, and of clinical relevance predominantly in endocarditis, they will be considered together.

The pyogenic streptococci

The pyogenic streptococci include the major human pathogen *S. pyogenes* (Lancefield group A), group B streptococci (*S. agalactiae*), and groups C and G streptococci. These organisms are b-haemolytic on blood agar.

Streptococcus pyogenes (b-haemolytic group A)

Since the beginning of the last century, and long before the introduction of antibiotics, infections with *S. pyogenes* declined in incidence and severity until, in the 1980s, highly virulent streptococci appeared causing very severe infections often in otherwise healthy people. Such cases occurred not only in the United Kingdom but in most of the developed world. *S. pyogenes* infection is usually community-acquired but may be acquired in hospital, where the most serious infections are postoperative.

Carriage

Although *S. pyogenes* is an invasive organism, it lives on epithelial surfaces (asymptomatic carriage) usually in the nose and throat; carriage can also be anal, vaginal, and on the scalp. Pharyngeal carriage rates are usually much higher in healthy children (5 to 20 per cent) than in adults (0.5 per cent) and also vary with season, year, and geographical location; they are also higher in crowded living conditions. *S. pyogenes* can persist for months after acute pharyngitis, though in decreased numbers. Survival in the environment is poor and *S. pyogenes* can only survive on skin squames and dust for a limited period and in low numbers.

Pathogenicity, virulence, and typing

S. pyogenes is an extracellular pathogen and produces virulence factors that enable it to avoid host defences and spread in tissues. The main virulence factor is the M protein; streptococci rich in M protein resist phagocytosis by polymorphs. Immunity to *S. pyogenes* infection is associated with the development of opsonic antibodies to antiphagocytic epitopes of M protein; it is usually type specific and lasts for many years, perhaps indefinitely. M protein was first described in the 1920s by Rebecca Lancefield; over 100 M types have now been differentiated. Lancefield also developed the supplementary T typing system which distinguishes 26 serotypes of a trypsin-resistant surface protein (T antigen), most of which can be expressed by several different M types. Certain M types also produce a serum opacity factor (OF+). These typing systems are still widely used in epidemiological studies to distinguish between strains of *S. pyogenes*. Recent studies have shown considerable genetic diversity in *S. pyogenes*, and horizontal transfer and recombination of virulent genes have played a major role. This finding is likely to be relevant to the emergence of new, unusually virulent clones of the organism.

In addition to M protein, lipoteichoic acid, important in the host–bacterial interaction, is expressed on the surface of the organism and is the adhesin that binds the organism to fibronectin on the surface of the oral epithelial cell membranes and initiates the colonization that precedes infection. *S. pyogenes* has a hyaluronate capsule which, like M protein, is also antiphagocytic, and is an additional virulence factor. The extent of encapsulation varies and colonies with prominent capsules are very mucoid on blood agar. Strains of *S. pyogenes* that are both rich in M protein and heavily encapsulated are readily transmitted from person to person, and tend to produce severe infections.

S. pyogenes produces many extracellular substances, several of which are important in the pathogenesis of infection. The most familiar are streptolysin O, deoxyribonuclease (DNAase) B, and hyaluronidase as serum antibodies to these provide retrospective confirmation of recent streptococcal infection. Other extracellular products include DNAases A, C, and D, streptolysin S, proteinase, streptokinase, and the substances previously known as erythrogenic toxins. These toxins have now been designated streptococcal pyrogenic exotoxins (**SPE**) -A, -B, -C, and possibly -D. SPE-A, and possibly others, is coded by a phage gene. These toxins, known as superantigens, have diverse effects on the host. In addition to the rash of scarlet fever, they cause fever, changes in the blood–brain barrier, organ damage, and lethal shock in animals. They have profound effects on the immune system including increasing susceptibility to endotoxic shock, blockade of the reticuloendothelial system, and alterations in T-cell function.

When *S. pyogenes* enters the body, either through the upper respiratory tract mucosa or a break in the skin, a local lesion may occur or there may be spread along tissue planes or lymphatics. The M protein is not toxic in itself but protects the streptococcus from phagocytosis and antibodies to the M protein are opsonic. In some two-thirds of patients with serious invasive disease, who may present with fever, shock, and renal impairment, the portal of entry is the skin, and infection of soft tissue is apparent, but in others the site of infection may not be evident.

Infections caused by *S. pyogenes*

S. pyogenes causes a variety of illnesses ranging from very common, usually mild, conditions such as pharyngitis and impetigo, through common, temporarily disabling cellulitis, to less common, puerperal sepsis and very severe infections such as type II necrotizing fasciitis, bacteraemia, and toxic shock. It is also associated with the non-suppurative sequelae of acute rheumatic fever and acute glomerulonephritis.

Streptococcal pharyngitis

Streptococcal pharyngitis or tonsillitis is one of the commonest bacterial infections in children from 5 to 15 years, but all ages are susceptible. The incubation period, at least in outbreaks, is short (1 to 3 days) and the onset of the infection marked by the abrupt onset of sore throat and pain on swallowing with malaise, fever, and headache. The signs are redness and oedema of the pharynx, enlarged red tonsils with spots of white exudate, and enlarged tender anterior cervical lymph glands. Nausea, vomiting, and abdominal pain are common in children, and in infants and preschool children there may be few definite signs of pharyngitis but fever, nasal discharge, enlarged cervical lymph glands, and otitis media occur.

Suppurative complications

Direct extension of streptococcal pharyngitis can give rise to acute sinusitis or otitis media and other suppurative complications include peritonsillar abscess (quinsy) and retropharyngeal abscess, which often contain oral flora including anaerobes with or without *S. pyogenes*, and suppurative cervical lymphadenitis.

Scarlet fever

Scarlet fever results from infection with a strain of *S. pyogenes* that produces SPE (erythrogenic toxin). It is usually associated with streptococcal pharyngitis but may follow streptococcal infections at other sites and occurs with invasive disease. Scarlet fever rarely follows streptococcal pyoderma. Most cases occur in school-age children and the rash must be distinguished from viral exanthems, Kawasaki disease, and staphylococcal toxic shock syndrome. The rash, which generally appears on the second day of clinical illness, is usually a diffuse erythema, symmetrical, and blanches on pressure. It is seen most often on the neck, chest, folds of the axilla, and groin. Occlusion of sweat glands gives the skin a 'sandpaper' texture, a useful sign in dark-skinned patients. The face appears flushed with circumoral pallor. There are small red haemorrhagic spots on the palate and the tongue is initially covered with a white fur through which red papillas appear ('strawberry tongue') and then, usually after the rash develops, the white fur peels off leaving a raw red papillate surface ('raspberry tongue'). The rash persists for several days and later (up to 3 weeks) peeling may occur, usually on the tips of the fingers, toes, or ears and less often over the trunk and limbs. A similar rash may develop as a reaction to streptokinase thrombolytic therapy.

Streptococcal perianal infection (cellulitis)

This is a superficial, well-demarcated rash spreading out from the anus in young children, usually boys, associated with itching, rectal pain on defaecation, and blood-stained stools. *S. pyogenes* is isolated from perianal cultures and usually also from pretreatment throat swabs.

Streptococcal vulvovaginitis

Vulvovaginitis in prepubertal girls is often caused by *S. pyogenes* and presents with serosanguinous discharge and erythema of the labia and vaginal orifice. As with perianal infections, *S. pyogenes* is usually also found in the throat. In both streptococcal perianal infection and vulvovaginitis, more than one child in the family may be affected and nasopharyngeal carriage is likely in both infected and uninfected children.

Streptococcal skin and soft tissue infections

Pyoderma/impetigo

Almost any purulent lesion of the skin can yield *S. pyogenes*, sometimes with *Staphylococcus aureus.* Such lesions include impetigo, infected cuts and lacerations, insect bites, scabies, intertrigo, and ecthyma. *S. pyogenes* also often causes secondary infection in varicella, occasionally with resultant bacteraemia. The term pyoderma is used synonymously with impetigo for discrete, purulent, apparently primary infections of the skin that are prevalent in many parts of the world, especially in children. These lesions are initially papules, then vesicular with surrounding erythema, and finally pustules with crusting exudate; they may be localized to one part of the body or generalized. Outbreaks of impetigo can occur among adults subject to skin trauma, such as rugby football players (scrumpox), and streptococcal infection of cuts on the hands and forearms are an occupational hazard for workers in the meat trade. Ecthyma is an ulcerated form of impetigo in which ulceration extends into the dermis.

Invasive streptococcal infections of skin and soft tissues

Erysipelas

This is an acute inflammation of the skin with lymphatic involvement. The streptococci are localized in the dermis and hypodermis. It usually affects the face, particularly in the elderly, but may occur elsewhere. It may be bilateral (Plate 1) and is sometimes recurrent. There is usually a history of sore throat, but the mode of spread to the skin is unknown. It is usually accompanied by fever, rigors, and toxicity. The cutaneous lesion begins as a localized area of erythema and swelling and then spreads with rapidly advancing raised red margins that are well demarcated from adjacent normal tissue. Facial erysipelas begins over the bridge of the nose and spreads over the cheeks. Vesicles and bullas appear, which become crusted when they rupture. There is marked oedema and the eyes are often closed. When the infection resolves it is often followed by desquamation. Intense local allergic reactions to topical agents, such as cosmetics, may cause confusion.

Cellulitis (Plate 2)

Cellulitis is commonly caused by streptococci and *Staphylococcus aureus.* This is an acute spreading inflammation of the skin and subcutaneous tissues with local pain swelling and erythema. Fever, rigors, and malaise may precede by a few hours the appearance of the skin lesion and associated lymphangitis and tender lymphodenopathy. Streptococcal cellulitis differs from erysipelas in that the lesion is not raised and the demarcation between affected and unaffected skin is indistinct. It may result from infection of burns, mild trauma, or surgical wounds. When this involves the leg, fungal infection of the feet is often present and predisposes to streptococcal invasion. After the first episode, there is a tendency for recurrence in the same area. Intravenous drug users are also at risk of streptococcal cellulitis associated with skin and tissue infection and septic thrombophlebitis.

(Type II) necrotizing fasciitis (streptococcal gangrene)

This infection, described by Meleney in 1924, involves the deep subcutaneous tissues and fascia (and occasionally muscle as well) with extensive, rapidly spreading necrosis and gangrene of the skin and underlying structures. It is generally community-acquired, usually involving the arm or leg, but may also occur after surgery, even quite minor. Some victims are diabetic, but the majority were previously healthy. Risk factors, providing a portal of entry, include surgery, trauma, childbirth, intravenous drug abuse, and chickenpox. Blunt trauma and muscle strain which may generate a haematoma and use of non-steroidal anti-inflammatory agents are also implicated. The infection begins at the site of trivial or even inapparent trauma with redness, swelling, fever, and rapidly escalating focal pain followed by purple discoloration and the development of bullae, often haemorrhagic. Bacteraemia is often present and within days skin necrosis occurs followed by extensive sloughing. The patient is profoundly ill and the disease has a high case fatality of 30 to 70 per cent. Features of streptococcal toxic shock syndrome are associated in many cases. The United Kingdom media memorably dubbed *S. pyogenes* the 'flesh-eater' in reports of a cluster of cases of necrotizing fasciitis in 1994. Treatment involves early intravenous antibiotics (clindamycin has several theoretical advantages over penicillin), urgent surgical débridement of necrotic tissue, and intensive care to support failing organs and systems (e.g. cardiovascular and renal). Benefits of immunoglobulin are anecdotal.

Streptococcal toxic shock syndrome

This syndrome was described in 1987 in patients with severe *S. pyogenes* infection and clinical features remarkably similar to those of the staphylococcal toxic shock syndrome described a decade earlier. Neither are likely to be new diseases. Definitions of streptococcal toxic shock syndrome vary. Some limit the definition to cases of shock and multiorgan failure where there is a rash or desquamation, whilst others include all cases of shock and its non-specific sequelae such as coagulopathy, uraemia, or jaundice, irrespective of skin lesions. Streptococcal toxic shock syndrome is usually associated with necrotizing fasciitis or myositis. It can occur at all ages and many of those affected are young and previously healthy. Most cases have been community-acquired, though it can be acquired in hospital. M1 has been the predominant serotype in many countries, though others, especially 2, 3, 12, and 28, have also been implicated. Most strains produce SPE-A. Interestingly there is an amino acid homology of 50 per cent and immunological cross-reactivity between SPE-A and staphylococcal enterotoxins B and C, which together with staphylococcal TSS toxin-1 are relevant in non-menstrual staphylococcal toxic shock syndrome.

Streptococcal bacteraemia

In parallel with the increase in serious *S. pyogenes* infections there has been an increase in bacteraemic infections, both community- and hospital-acquired (usually postoperative) (Plate 3). While many patients have an underlying disease, most often malignancy, immunosuppression, or diabetes, others are previously healthy adults between 20 and 50 years old. The portal of entry is usually the skin. The mortality is higher in patients with underlying disease.

Puerperal and neonatal infection

Historically *S. pyogenes* has always been an important cause of puerperal sepsis ('childbed fever'), but in the postantibiotic era it was rarely encountered in obstetric practice until the 1980s when sporadic cases occurred, some with streptococcal toxic shock syndrome, and some women have died. These infections follow abortion or delivery when streptococci (usually colonizing the patient herself) invade the endometrium, lymphatics, and bloodstream. They can be devastatingly severe and present with non-specific signs such as restlessness and gastrointestinal upset that may not immediately suggest sepsis. Fever may be absent resulting in further diagnostic confusion. The streptococcal infection not only involves the uterus and adnexa but sometimes distant sites such as joints as well. It can also affect the baby causing serious neonatal infection including meningitis. Instrumentation in the presence of asymptomatic vaginal or anorectal carriage of *S. pyogenes* can result in severe infection.

Other infections

S. pyogenes can, though rarely does, cause pneumonia (usually associated with viral infection or pulmonary disease), osteomyelitis, septic arthritis, meningitis, pericarditis (Plate 4), endophthalmitis, and endocarditis.

Laboratory diagnosis of *S. pyogenes* infection

S. pyogenes is easy to culture in the laboratory and usually grows on blood agar in 24 hours. Throat swabs must be taken before antibiotics are given or the chance of recovery is slim. Kits for the detection of the group A antigen directly from throat swabs are available and give few false-positive reactions, but they are seldom used in the United Kingdom. Even trivial skin lesions are worth swabbing (if necessary with a moistened swab) and a search for such lesions often pays dividends. Swabs from the surface of cellulitis and erysipelas rarely yield streptococci and although they may be recovered from specimens obtained by aspiration, in practice this is seldom done. Blood cultures should be done in any patient who is ill whether febrile or not. Serological confirmation of infection with *S. pyogenes* when the organism has not been isolated can be obtained by the detection of raised antibodies to its extracellular products. Most laboratories tend to use two or more tests. Interpretation requires knowledge of the level of titres in the community for those without a history of recent streptococcal infection. In the United Kingdom the upper limit of titres in teenagers and young adults without such a history is antistreptolysin O (ASO) 200, antideoxyribonuclease B (ADB) 240, and antihyaluronidase (AHT) 128.

Management and antibiotic treatment of *S. pyogenes* infection

Remarkably, *S. pyogenes* remains exquisitely sensitive to penicillin and this is the antibiotic of choice for treatment, parenterally for severe infections and orally otherwise. Conventionally, 10 days treatment is recommended for pharyngeal infections to eradicate the organism and prevent acute rheumatic fever. In practice, compliance with this regimen is poor as once the symptoms abate there is a natural reluctance to continue the antibiotic. Treatment of patients allergic to penicillin is most often with erythromycin or the newer macrolides (azithromycin and clarithromycin), but some 3 to 5 per cent of strains are erythromycin resistant. *S. pyogenes* is also sensitive to cephalosporins. Topical agents such as mupirocin and fusidic acid are useful in addition to systemic antibiotic treatment in impetigo and other skin lesions. Patients with streptococcal toxic shock syndrome will need intensive care and many require inotropic support, ventilation, and haemodialysis. Urgent surgical intervention is needed for necrotizing fasciitis and myositis. Clindamycin (in addition to penicillin) has been recommended for patients with established invasive streptococcal infections since this drug stops the metabolic activity of the streptococci and thus halts further production of toxin. This is specially relevant in type II necrotizing fasciitis/myositis and streptococcal toxic shock syndrome. Intravenous immunoglobulin has also been used in an attempt to neutralize the streptococcal toxins, but reports of its effects are inconclusive. Prevention of recurrent cellulitis of the lower legs involves meticulous foot hygiene with treatment of 'athlete's foot' fungi and reduction in skin carriage using topical mupirocin. Oedematous limbs can benefit from elastic stockings. Antibiotic prophylaxis may be required in cases of frequent recurrence refractory to these measures. Lastly it should be remembered that *S. pyogenes* is readily transmitted from person to person and thus appropriate infection control precautions should be taken until swabs show the organism has been eradicated.

b-Haemolytic groups C and G streptococci

These streptococci are sometimes referred to as 'large colony-forming group C and G streptococci' to distinguish them from the small colony-forming strains of streptococci with the same Lancefield antigens that belong to the anginosus or milleri group (see below). Groups C and G streptococci are closely related genetically. They are most conveniently regarded as 'pyogenes-like' as the infections they cause are similar to those caused by *S. pyogenes* though these streptococci tend to be less virulent than *S. pyogenes*. Infections with these streptococci are less common than *S. pyogenes* infections. Although post-streptococcal glomerulonephritis has been associated with pharyngitis caused by both groups C and G streptococci, acute rheumatic fever has not. Group C streptococci are less frequently encountered in human infections than group G and most group C infections are caused by *S. equisimilis*; those caused by *S. zooepidemicus* have an animal source. Group G streptococci are frequently isolated from leg ulcers and pressure sores, usually with other bacteria. In such patients cellulitis and systemic upset are rare and the organisms are just colonizing the lesions. They, like *S. pyogenes*, can cause cellulitis in lymphoedematous limbs.

b-Haemolytic group B streptococci (*S. agalactiae*)

The group B streptococcus has been known for over a century as a cause of bovine mastitis and in the 1930s it was recognized as a vaginal commensal, an occasional cause of puerperal fever, and an uncommon cause of invasive disease in adults. Not until the 1960s was it realized that the group B streptococcus was an important neonatal pathogen, and some 20 years later it had replaced *Escherichia coli* as the predominant neonatal pathogen.

Carriage

Group B streptococci can be recovered from various sites in healthy adults but vaginal carriage has been most extensively investigated. Swabs from the lower vagina are more often positive than cervical swabs and carriage rates of 3 to over 40 per cent have been reported. Higher rates have been obtained with selective media and enrichment techniques. Carriage also increases with sexual activity and is highest in women attending genitourinary clinics. The urethra, vagina, perineum, and anorectal region have all been suggested as the prime site of carriage. Some 5 to 10 per cent of normal adults carry group B streptococci in the throat, independent of urogenital and anorectal carriage.

Pathogenicity, virulence, and typing

The chief determinant of virulence appears to be the capsular polysaccharide, and most human strains carry one of six sialic acid-containing polysaccharides that surround the cell wall. In addition, a protein antigen (c, X, or R) may be carried. Certain combinations are common; serotypes III or III/R form one-quarter of all isolates from superficial sites on women, but three-quarters of all group B streptococci causing meningitis in infants. They are also the commonest serotypes found in adult (non-pregnant) infections. The type polysaccharide, like the M protein of *S. pyogenes*, inhibits phagocytosis. Colonization of the mucous membranes of the neonate results from vertical transmission of the organism from the mother either *in utero* by the ascending route or at delivery. The rate of vertical transmission in neonates

born to mothers colonized with group B streptococci is about 50 per cent, but the incidence of symptomatic infection in neonates born to colonized mothers is only about 1 to 2 per cent. It is much higher in preterm infants. Nosocomial colonization of neonates can also occur. In most cases of adult infections (other than in pregnant women) the source of the infection is unknown.

Infections caused by group B streptococci

These are commonly neonatal or puerperal infections, but group B streptococci also cause infection in the non-pregnant adult.

Neonatal infection

The frequency of neonatal infection (bacteraemia, meningitis, or both) has been variously quoted as between 0.3 and 5.4 cases/1000 live births, but these figures have wide confidence limits. Two fairly distinct clinical patterns of disease predominate, but the spectrum is wide and includes impetigo neonatorum, septic arthritis, osteomyelitis, pneumonitis, peritonitis, pyelonephritis, facial cellulitis, conjunctivitis, and endophthalmitis.

Early-onset disease

Symptoms develop within the first 5 days of life with a mean of 20 h, though they can present at birth suggesting an intrauterine onset of infection. Early-onset disease is most often a bacteraemia with no identifiable focus of infection, but can also be pneumonia or, infrequently, meningitis. The presenting signs include lethargy, poor feeding, jaundice, grunting respirations, pallor, and hypotension and they are common to all types of disease. Respiratory symptoms are nearly always present. The only reliable way of detecting meningitis is by lumbar puncture. Mortality rates are high in low birth-weight babies. In addition to positive blood cultures, the infecting strain can be found in the mother's vagina and cultured from 'screening' sites on the baby; these include ear, throat, and nasogastric aspirate.

Late-onset disease

This usually presents between 7 days and 3 months after birth, often in previously healthy babies born after a normal labour who are admitted unwell from home. The pathogenesis is less clear than in cases of early-onset disease and only about half the cases are associated with mucosal colonization during delivery. Most babies have meningitis and concomitant bacteraemia and present with non-specific symptoms such as lethargy, poor feeding, irritability, and fever. Neurological sequelae are common among survivors.

Puerperal infection

Puerperal infection with Group B streptococci usually occurs within 24 to 48 h of delivery or abortion. The source of the organism is always the vagina and infection is more likely when there has been premature rupture of the membranes and chorioamnionitis. Most infections are endometritis with fever and uterine tenderness sometimes associated with retained products of conception, but group B streptococci can also cause wound infection after caesarean section. Bacteraemia is common. Other bacteria, both aerobes and anaerobes, are sometimes isolated from the genital tract and wounds in addition to the group B streptococcus. Very rarely the streptococcus may spread to other sites in puerperal women.

Infection in non-pregnant adults

The prominence given to group B streptococci as neonatal and puerperal pathogens has tended to overshadow their importance in non-pregnant women and men in whom they cause significant morbidity and mortality. Most infections are community-acquired, occur in the middle aged and elderly, and are as common in males as females. Many, though by no means all, patients with group B streptococcal infection have underlying diseases, particularly diabetes and myeloma. Skin and soft tissue infections are especially common in patients with diabetes. Occasional urinary tract infections occur, in men as well as women. Bacteraemic infections serve to emphasize the virulence of group B streptococci, and they have increased in incidence, or perhaps have been increasingly recognized, since the early 1990s. Community-acquired group B streptococcal bacteraemia is similar in many respects to that caused by *Staphylococcus aureus* since common clinical manifestations include endocarditis, vertebral osteomyelitis, septic arthritis, endophthalmitis, and meningitis. As with staphylococcal infections, some bacteraemic patients have more than one metastatic focus of infection, which can lead to diagnostic confusion.

Laboratory diagnosis of group B streptococcal infection

Group B streptococci are readily isolated from any clinical specimen in the laboratory and easily identified by Lancefield grouping. The group B antigen is not shared by any other streptococcus. Importantly the antigen can be reliably detected in fluids such as blood, urine, or cerebrospinal fluid by latex particle agglutination enabling a rapid diagnosis.

Treatment of group B streptococcal infection

Group B streptococci are sensitive to penicillin and this is the antibiotic of choice for treatment. They are rather less sensitive to penicillin than *S. pyogenes* with minimum inhibitory concentrations some four- to 10-fold higher. For this reason penicillin is sometimes combined with gentamicin for meningitis and other serious infections, though this is not of proven benefit. Certainly, the maximum recommended dose of parenteral penicillin should be given whether combined with gentamicin or not. Penicillin allergy is not likely to be an issue in neonates; adults with meningitis can be treated with chloramphenicol. Most group B streptococci are sensitive to erythromycin and they are sensitive to cephalosporins.

Prevention of neonatal infection with group B streptococci

During the 1990s the incidence of disease caused by mother-to-child transmission of group B streptococci in the United States fell by two-thirds as a result of the increased use of intrapartum penicillin in women at high risk of transmitting the infection, an intervention largely brought about by parental pressure. The American authorities recommend either prenatal screening or a risk-based strategy to identify women to receive intrapartum antibiotics. Similar recommendations are to be introduced in the United Kingdom. Any protocol for prophylactic penicillin based on the isolation of group B streptococci in late pregnancy would present difficulties in a busy obstetric unit and culture methods may also fail to detect the organism unless vaginal and rectal swabs are cultured in selective broth media. Maternal colonization with group B streptococci can be identified rapidly and reliably by polymerase chain reaction assay, but this is unlikely to be adopted as a routine round-the-clock service. An effective vaccine is an alternative approach, as yet unavailable.

Streptococci of the anginosus or milleri group

This group of streptococci has been a source of considerable taxonomic confusion, partly the result of a lack of international consensus on nomenclature, but also because of a lack of reliable phenotypic differences between taxa within the group. Most clinicians are familiar with the organism they know as '*Streptococcus milleri*'. There are three species of milleri streptococci, *S. anginosus*, *S. constellatus*, and *S. intermedius*, but despite increasing awareness of the clinical significance of the *milleri* group little is known about the association between individual species and specific sites of isolation and diseases. These streptococci are found in large numbers in the normal flora of the upper respiratory tract, gastrointestinal tract, and genital tract, and are commonly isolated from a range of pyogenic infections, sometimes in pure culture, but often with other organisms, particularly anaerobes. These infections include dental abscesses, intra-abdominal abscesses (especially of the liver), subphrenic abscesses, lung abscesses and empyema, and brain abscesses. Such is the propensity of these organisms to cause deep-seated abscesses that isolation of a milleri streptococcus from a blood culture should prompt investigations to detect such a focus. Milleri streptococci are also commonly isolated from inflamed appendices and postappendicectomy wound infection. Unlike other viridans and non-haemolytic streptococci, milleri streptococci seldom cause endocarditis. They form minute colonies on blood agar and are preferentially anaerobic on primary isolation. They may be a-, b-, or non-haemolytic. Some have the Lancefield antigens A, C, G, or F. All group F streptococci are milleri group whereas not all milleri streptococci are group F. Another useful clue to their identity in the laboratory is the distinct caramel smell of many strains on blood agar, the result of the diacetyl metabolite. Most strains are very sensitive to penicillin.

The mitis, salivarius, and mutans groups of streptococci (oral/viridans streptococci)

This group of usually a-haemolytic (viridans) streptococci includes *S. pneumoniae* and those oral streptococci (*S. mitis*, *S. oralis*, *S. sanguis*, *S. gordonii*, and rarely, *S.*

salivarius) that are the commonest cause of infective endocarditis of oral or dental origin. These streptococci occasionally cause bacteraemia in neutropenic patients who sometimes have detectable mouth lesions and neonatal infection as they are found as part of the normal vaginal flora.

The bovis group of streptococci

Although this group comprises at least three species, *S. bovis* is the main species of medical importance. *S. bovis* is similar to the enterococci in that it bears the Lancefield group D antigen and is a gastrointestinal commensal, but unlike the enterococci, it is sensitive to penicillin. It can be misidentified in the laboratory either as an oral streptococcus or as an enterococcus. Most patients with *S. bovis* bacteraemia will have endocarditis and it is seldom isolated from other sites. It is important to recognize *S. bovis* in a blood culture as the organism is associated with colonic pathology, and patients should be specifically investigated for this.

Nutritionally variant organisms previously classified as streptococci, now *Abiotrophia* spp.

These organisms, which occasionally cause endocarditis, require pyridoxal or thiol group supplementation for growth in the laboratory and tend to form satellite colonies round *Staphylococcus aureus*. Although most blood culture media will support their growth, successful subculture requires supplementation or cross-streaking of the plates with *S. aureus* to provide the necessary growth factors. The *Abiotrophia* include three species, *S. adjacens*, *S. defectivus*, and the recently described *A. elegans*. They are less susceptible to penicillin than other streptococci.

Streptococcus suis

This streptococcus, which can be misidentified in the laboratory as *S. bovis* or an enterococcus as it reacts with group D antiserum, is an important pathogen of young pigs causing meningitis, septicaemia, arthritis, pneumonia, and endocarditis and is also carried in the pharynx of healthy pigs. *S. suis* type II (also referred to as group R streptococci) is not only the most invasive type in pigs, it can cause serious infection—mainly septicaemia and meningitis, but also septic arthritis, pneumonia, and endophthalmitis—in humans, in whom it is an occupational disease of pig farmers, abattoir workers, and factory workers handling pig meat (see Chapter 24.14.1). The streptococcus probably enters the bloodstream via skin abrasions that are common in the above occupations. *S. suis* type II meningitis results in deafness in about half of those affected.

Enterococci

Enterococci are Lancefield group D, Gram-positive cocci that can grow and survive in extreme cultural conditions, and are also more resistant to antibiotics than streptococci. They form part of the normal gut flora of humans and animals. Overall, the commonest clinical isolates of enterococci are *Enterococcus faecalis*, but the more antibiotic-resistant species *E. faecium* is increasingly encountered in hospitals. Nosocomial isolates of enterococci have dramatically increased in the 1990s. Other species, including *E. casseliflavus*, *E. durans*, and *E. avium*, are occasionally isolated. In most cases it is unnecessary to determine the species of enterococci in a clinical laboratory but sometimes differentiation between *E. faecalis* and *E. faecium* is helpful, for instance in epidemiological studies and in endocarditis because of their different antibiotic susceptibilities.

Infections caused by enterococci

Enterococci are an increasingly important cause of nosocomial infection and colonization, possibly the result of the large-scale use of antibiotics such as cephalosporins and quinolones to which they are inherently resistant. They occasionally cause community-acquired urinary tract infections but the most important community-acquired infection is endocarditis, which is increasing in incidence. This infection is almost always caused by *E. faecalis.* Any patient admitted from the community with *E. faecalis* in blood cultures should be assumed to have endocarditis until proved otherwise. Enterococci are predominantly hospital pathogens and cause urinary infection, particularly after instrumentation, intra-abdominal infections, wound infections (usually with other organisms), infections associated with intravascular devices and dialysis, and occasionally endocarditis.

Antibiotic sensitivity and treatment

Enterococci are not only intrinsically resistant to many antibiotics, they show a remarkable ability to acquire new mechanisms of resistance. This allows them to survive in environments in which large amounts of antibiotics are used and also has important therapeutic consequences, particularly for the treatment of endocarditis and other serious infections. Fortunately many patients from whom enterococci are isolated do not require antibiotic treatment. Sensitive enterococci cannot be killed by ampicillin/amoxycillin alone, though combination with an aminoglycoside is bactericidal (synergy); but many strains now exhibit high-level gentamicin resistance and for them the combination is not bactericidal. *E. faecium* is almost always resistant to ampicillin/amoxycillin and *E. faecalis* is occasionally. The first published report of vancomycin-resistant enterococci (**VRE**) was in 1988 from a London hospital outbreak, though such strains had been recognized a year before in Paris. Most strains of VRE in the London outbreak were *E. faecium* and overall most VRE are *E. faecium*. There are four recognized phenotypes of vancomycin resistance; the first isolates of VRE were highly resistant to vancomycin and teicoplanin and exhibit what is known as the VanA resistance phenotype. Since then, levels of resistance to teicoplanin in this phenotype have been more varied. Most VanA enterococci are *E. faecium*, but this phenotype also occurs in *E. faecalis* and occasionally in other species. The VanB phenotype is associated with low-level vancomycin resistance and sensitivity to teicoplanin and is found in both *E. faecalis* and *E. faecium.* Both VanA and VanB are acquired traits. The VanC phenotype is an intrinsic property of *E. casseliflavus* and *E. gallinarum* and these species have low-level resistance to vancomycin but are sensitive to teicoplanin. A fourth phenotype, VanD, has been described in a single strain of *E. faecium*. Vancomycin-resistant *E. faecium*, though not vancomycin-resistant *E. faecalis*, are sensitive to quinupristin/dalfopristin (Synercid) and all VRE are sensitive to the oxazolidinone Linezolid.

The antibiotic susceptibilities of the enterococci outlined above serve to emphasize that these bacteria are the most antibiotic-resistant Gram-positive bacteria now encountered in hospital practice. Fortunately many, perhaps most, of the patients from whom they are isolated do not require antibiotic treatment at all, but for those who do, the effective treatment of serious infection caused by enterococci and particularly antibiotic-resistant strains requires microbiological expertise.

7.11.3Pneumococcal diseases

Keith P. Klugman and Brian M. Greenwood

Streptococcus pneumoniae (the pneumococcus) causes a considerable burden of vaccine-preventable disease. It is a leading cause of bacterial meningitis, pneumonia, otitis media, and sinusitis. The global HIV pandemic has greatly increased the burden of pneumococcal disease in both children and adults and the dissemination of a number of multiresistant pneumococcal clones has complicated the management of this disease. In the first decade of the twenty-first century it is likely that the introduction of pneumococcal conjugate vaccines will reduce the burden of pneumococcal disease in children and may also contribute to interrupting the transmission of antibiotic-resistant strains.

History and biology of the pathogen

Streptococcus pneumoniae is a Gram-positive, lanceolate-shaped diplococcus that was isolated independently by Sternberg and Pasteur in 1881. They had inoculated human sputum into rabbits. The first demonstration of the pathogen as a cause of pneumonia was made by Friedlander in 1883. The sensitivity of the pathogen to ethylhydrocupreine (optochin) was noted in the early 1900s and the use of this agent to treat experimental pneumococcal disease was one of the first examples of antibacterial chemotherapy. The emergence of resistance following treatment was noted in that study in humans and its use was abandoned due to side-effects, including temporary blindness. The multiple serotypes of the pneumococcus are due to 90 distinct capsular polysaccharides. The pneumococcus has played a role in biology beyond that of the description of its virulence factors. The discovery of DNA as the transforming principle was based on the transformation of pneumococcal serotypes.

Adherence and pathogenesis

Newborn infants are free of pneumococcal colonization, and infections follow colonization. Colonization occurs rapidly in developing countries and, in such communities, most infants are nasopharyngeal carriers before the age of 6 months. Early colonization is associated with an increased incidence of otitis media. It is probable that multiple serotypes of pneumococci are carried simultaneously and that current methods of detection fail to identify subdominant strains. The duration of carriage varies by serotype and there is some evidence that the risk of invasive disease is greatest at the time of acquisition of a new serotype.

Pneumococci bind to specific galactose receptors on nasopharyngeal epithelial cells and pneumocytes. The bacteria undergo phase variation into transparent and opaque phenotypes. The transparent phenotype is better able to adhere to epithelial cells in the nasopharynx and adherence is enhanced by interleukin-1 (IL-1) and by tumour necrosis factor-a(TNF-a). The basis for the invasion of colonizing pneumococci is not clearly understood although preceding viral infections, such as influenza or respiratory syncytial virus infection, may be important. Influenza virus enhances the adhesion of pneumococci to respiratory cells and the binding of pneumococci to platelet activating factor is associated with invasion of activated cells. The binding of transparent phenotype pneumococci to the PAF receptor is mediated by a phosphorylcholine ligand. Other surface receptors such as pneumococcal surface adhesin A (PsaA), pneumococcal surface protein C (PspC), and choline-binding protein A (CbpA) also play a role in adhesion.

Once invasion has occurred, other components of the bacterium such as the phosphorylcholine moiety of techoeic acid C polysaccharide in the cell wall contribute to the induction of a marked acute inflammatory response. Cytokines, such as tumour necrosis factor and interleukin 1, play an important part in the pathogenesis of this inflammatory process. Reduction of the inflammatory response of animals with experimentally induced pneumococcal meningitis with drugs such as corticosteroids increases their survival, but it is not known whether this is also the case in humans (see below). Virulence may also be enhanced by pneumococcal surface protein A (PspA), and by the production of bacterial enzymes such as hyaluronidase, neuraminidase, and pneumolysin. The direct neurotoxicity of nitrous oxide may also be important in the neurological damage of pneumococcal meningitis. The pathway of pneumococcal infection is illustrated in Fig. 1 and the pathogenesis of infection is summarized in Fig. 2.

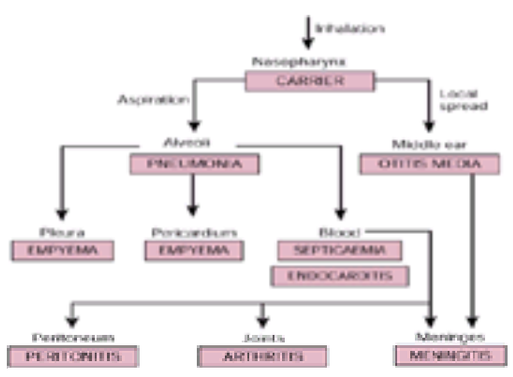

Fig. 1 The pathway of pneumococcal infection.

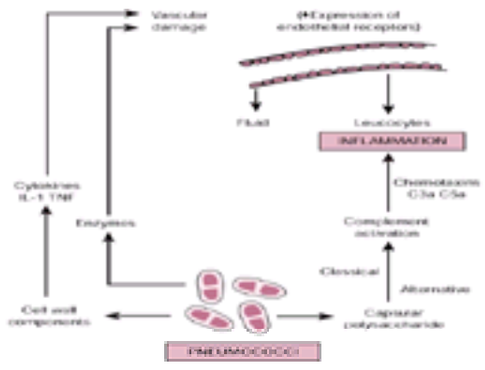

Fig. 2 The pathogenesis of pneumococcal infection.

Antibiotic resistance

There was the emergence of a global pandemic of antibiotic resistance in the pneumococcus during the 1990s. The use of antibiotics selects resistant pneumococci at the national, provincial, hospital, and individual level. The identification of penicillin resistance in the pneumococcus was first made by Hansman and Bullen in 1967, although resistance to macrolides and tetracycline had already been described. Multiresistant pneumococci were found first in South Africa in 1978. These strains were also fully resistant to penicillin (minimum inhibitory concentration greater than 1 µg/ml). The selection of multiresistant strains is complex in that the differential ability of each of the antibiotic classes to select the multiresistant pathogen is not clearly understood. There are data to suggest that trimethoprim sulphamethoxazole may select for multiresistant strains more successfully than b-lactams, and reduction in the use of macrolides and trimethoprim sulphamethoxazole has been associated with a reduction in the prevalence of multiresistant pneumococci.

The nasopharyngeal carriage rate of antibiotic-resistant strains has been shown to predict closely the susceptibility of strains isolated from blood and cerebrospinal fluid. Pneumococcal nasopharyngeal carriage is seasonal with increased rates in winter. There is evidence that HIV infection increases the carriage rate of pneumococci in adults. Carriage can be reduced by the administration of conjugate pneumococcal vaccine. There is some evidence that the same total dose of antibiotic given in low daily doses for a longer period of time may increase the risk of selection of resistant strains, compared to a shorter course in a higher dose.

While b-lactam and multiple resistance in the pneumococcus now have a global distribution, recent emerging problems include very high levels of macrolide resistance in China and fluoroquinolone resistance in Canada and Hong Kong.

Mechanisms of antibiotic resistance

The molecular basis of penicillin resistance in the pneumococcus is the creation of mosaic genes of the penicillin-binding proteins (PBPs) 2X, 2B, and 1A by the transformation and horizontal transfer of DNA from related streptococcal species. The interaction of these altered gene products in the construction of the pneumococcal cell wall is not yet understood but resistant pneumococci make altered cell walls. In certain genetic backgrounds, alterations in the MurM protein may contribute to very high penicillin MICs of 8 to 16 µg/ml.Tetracycline resistance is caused by the acquisition of the tetracycline resistance determinant *tet*M or rarely *tet*O. Macrolide resistance is due to the acquisition of the methylating enzyme encoded by *erm*AM, by the acquisition of an efflux mechanism encoded by the *mef*E gene, by mutations in 23S RNA, or by mutations in the L4 riboprotein. Chloramphenicol resistance is due to the acquisition of the *cat* gene encoding chloramphenicol acetyltranferase. The acquisition of this gene has been shown to be associated with the integration and linearization of a plasmid into the pneumococcal genome. Rifampicin resistance is due to mutations in the *rpo*B gene, which may occur in one of two domains. Additional mechanisms of rifampicin resistance remain to be described. Trimethoprim resistance is caused by an altered *dhfr* chromosomal gene and is mediated by a single base mutation at position 100. Sulphonamide resistance is due to expansions in a small area of the *dhps* gene. While pneumococcal tolerance to vancomycin and other antibiotics has been described to be due to a deletion in the DNA encoding a two-component signalling system, resistance to vancomycin has not yet been described in this pathogen. Fluoroquinolone resistance is mediated by single base mutations in the *par*C gene and high levels of resistance may be obtained by a combination of mutations in the *par*C and *gyr*A genes. Mutations in the *par*E and *gyr*B genes may also contribute to pneumococcal resistance to the fluoroquinolones. The expression of a multidrug inhibitor protein *pmr*A can also confer low levels of fluoroquinolone resistance in the pneumococcus.

Serotype distribution

The distribution of pneumococcal serotypes causing invasive disease differs between children and adults. The so-called paediatric serotypes are serotypes 6A, 6B, 9V, 14, 19A, 19F, and 23F. All these serotypes commonly colonize young infants and most strains multiresistant to antibiotics belong to these serotypes. Serotypes 1 and 5, which are important invasive serotypes in developing countries, are rarely carried in the nasopharynx and thus are less commonly resistant to antibiotics—it is hypothesized that most selection for antibiotic resistance takes place in the nasopharynx. Serotype 1 is a relatively uncommon cause of invasive disease in adults in the United States but remains important in the adult population in most other parts of the world. The serotype 3 capsule is distinguished by its mucoid appearance and encapsulated type 3 pneumococci can often be distinguished from other pneumococci by visual inspection of an agar plate. There is evidence that the serotype distribution of pneumococci causing invasive disease in HIV-infected adults is different to that in adults with no HIV infection. The paediatric serotypes are more common in HIV-infected adults suggesting that these patients may have lost immunity to paediatric serotypes. Antimicrobial resistance has contributed to an increase in the proportion of paediatric serotypes causing invasive disease in both children and adults.

The capsular type is determined by a set of capsular genes. There are common genes in the regions of DNA flanking the capsular genes allowing homologous recombination to occur, and capsular switching of pneumococcal clones has been documented. In some parts of the world (especially Papua New Guinea) children are colonized at a young age with adult serotypes. The reason for the unusual distribution of serotypes in these children is not known. The distribution of serotypes in pneumococci isolated from the nasopharynx cannot be used to predict accurately the serotypes causing invasive disease because some of the most important invasive strains (notably serotypes 1 and 5) are, as mentioned above, rarely carried.

The global burden of pneumococcal disease

The global burden of pneumococcal disease is not known with certainty. However, the World Health Organization estimates that 1 million of the estimated 5 million deaths from pneumonia that occur in young children each year are caused by the pneumococcus. The incidence of pneumococcal bacteraemia in adults over 65 years of age is about 50/100 000 persons per year. The incidence of invasive pneumococcal disease is greatly increased in both adults and children by HIV infection. In South Africa, the incidence of invasive pneumococcal disease in children under the age of 2 years is 1844/100 000 per year.

Risk factors

Predisposing factors to invasive pneumococcal disease are listed in Table 1.

Diagnosis

The mainstay of the diagnosis of invasive pneumococcal disease is the isolation of the organism from a sterile site. Ten to 30 per cent of patients with pneumococcal pneumonia have a positive blood culture. Patients with suspected pneumococcal pneumonia should have an adequate volume of blood cultured because an association has been found in clinical practice between the isolation rate and the volume of blood cultured. Culture of cerebrospinal fluid remains the gold standard for the identification of *Streptococcus pneumoniae* as a cause of meningitis. Gram stain of cerebrospinal fluid and detection of capsular antigen are both useful diagnostic tests, especially when antibiotics have already been given. The definitive identification of a pneumococcal aetiology of otitis media or sinusitis requires the culture of the organism from the middle ear following tympanocentesis or the sinus following sinus puncture.

While a negative pneumococcal culture from the nasopharynx reduces the likelihood of a pneumococcal aetiology of otitis media, there is little clinical use associated

with a positive nasopharyngeal culture. Nasopharyngeal cultures can be used to predict the susceptibility of invasive isolates, but they are not of much diagnostic use in individual patients. The identification of Gram-positive, lanceolate-shaped diplococci in a sputum sample of good quality remains a useful diagnostic aid for pneumococcal pneumonia. In children the most sensitive method of diagnosing pneumococcal pneumonia is lung puncture. While this procedure carries a minimal morbidity in experienced hands, it is not widely used in clinical practice. Some promising data have recently been reported for the direct urinary detection of pneumococcal capsular polysaccharide antigens in adults. The polymerase chain reaction has not yielded a useful clinical advantage when used on blood, compared with blood culture as the gold standard. However, PCR can be used on cerebrospinal fluid to make a rapid diagnosis and can even be used directly to identify penicillin-resistant pneumococcal meningitis.

The microbiological identification of pneumococci rests on the demonstration of typical draftsman colonies producing an a-haemolytic reaction on blood agar. Pneumococci are generally optochin sensitive and are always bile soluble. Agglutination with polyvalent serum can be used to confirm their identity.

Susceptibility testing

Disc susceptibility to a 1µg oxacillin disc is the best predictor of penicillin susceptibility of the pneumococcus. Pneumococci are defined as susceptible to penicillin when they are inhibited by a minimum inhibitory concentration (**MIC**) of less than 0.1 µg/ml. A MIC of 0.1 to 1 µg/ml defines intermediate susceptibility and greater than 1 µg/ml resistance to penicillin. Resistance to amoxicillin is defined as an MIC greater than 2 µg/ml. Susceptibility to the third-generation cephalosporins, cefotaxime or ceftriaxone is defined by a MIC less than 1 ug/ml. Intermediate susceptibility and resistance to these agents are defined by MICs of 1 µg/ml and more than 1 µg/ml, respectively. The differentiation of fully resistant from intermediately penicillin-resistant pneumococci and the identification of cephalosporin-resistant pneumococci cannot be done by disc testing. The definitive method for susceptibility testing of pneumococci is by an agar dilution or micro-broth dilution method. However, many laboratories use the E test to identify penicillin- and cephalosporin-resistant pneumococci. Susceptibility testing to trimethoprim sulphamethoxazole requires the use of lysed blood. Susceptibility to most other agents is predicted by routine disc methods, although there are currently no phenotypic methods available to detect first-step mutants that lead to fluoroquinolone resistance.

Clinical features

The clinical features of pneumococcal infection are described most conveniently in relation to the main clinical syndromes that can be caused by pneumococci. However, these syndromes are not mutually exclusive and many patients with pneumococcal disease have more than one clinical manifestation of the infection, for example pneumonia and meningitis.

Pneumonia

Pneumonia is one of the most common manifestations of pneumococcal disease.

Symptoms

In a typical case of pneumococcal pneumonia, the onset of illness is sudden, although there may be a history of a recent upper respiratory tract infection. Fever is usually the first symptom and it is frequently accompanied by rigors. The patient feels ill, anorexic, and weak. Headache and myalgia may be severe.

Chest pain usually appears during the course of illness although it may not be present on initial presentation. The pain, which results from involvement of the parietal pleura, is sharp and stabbing and is aggravated by deep inspiration or coughing. The patient may try to obtain relief by splinting the affected side of his chest with his hands or lying on the affected side. If the diaphragmatic pleura is involved, pain may be referred to the shoulder or to the abdomen.

Cough may be absent at the onset of the illness but, in most patients, it becomes a prominent symptom. Cough is initially non-productive and painful. Subsequently it becomes productive of a blood-tinged, 'rusty' sputum. Finally, the sputum becomes frankly purulent.

Among young children and elderly people, pneumococcal pneumonia may present less dramatically. The mothers of young children with pneumonia usually give a history of fever and cough and the mother may have noticed that the child has rapid respiration. Elderly patients and those who are immunocompromised may have little or no fever and few respiratory symptoms. In such patients, general malaise and confusion may be the presenting symptoms. The classic features of pneumococcal pneumonia may also be modified by prior antibiotic treatment.

Physical signs

Adult patients with lobar pneumonia are usually febrile and toxaemic. The rectal temperature may be as high as 40°C. Oral temperature may be lower because of hyperventilation. When the patient is first examined, no abnormal physical signs may be detected in the respiratory system. Later the classic signs of lobar consolidation may appear. The patient's breathing becomes rapid and distressed, and the nostrils may dilate on inspiration. Cyanosis may be present as a result of diminished alveolar ventilation or shunting of desaturated blood through the consolidated lung. Chest movement is diminished on the affected side. A dull note is obtained on percussion over the affected lobe. On auscultation, bronchial breathing is sometimes detected, fine crepitations are frequent, and a pleural rub may be heard.

General examination usually shows tachycardia and an atypical systolic murmur may be detected, as in any patient with a high fever. Examination of the abdomen may show some distension or, when the diaphragmatic pleura has been involved, upper abdominal tenderness and guarding. Jaundice may be present. The patient, especially if elderly, may be confused.

The classic signs of lobar consolidation are found infrequently in infants with pneumococcal pneumonia, although some auscultatory abnormalities, such as crepitations, can usually be detected. In young children, the most prominent features of pneumococcal pneumonia are usually a raised respiratory rate, chest-wall indrawing (Fig. 3), and nasal flaring.

Fig. 3 Severe lower-chest indrawing in a child with pneumococcal pneumonia (by courtesy of Dr Alice Greenwood).

Investigations

A polymorphonuclear neutrophil leucocytosis is usually present; a white-cell count of 15×10^9/l or more is found in about three-quarters of cases and counts as high as 40×10^9/1 may occur. A low white-cell count is associated with a poor prognosis. There may be a reticulocytosis. Both conjugated and unconjugated bilirubin levels are raised in jaundiced patients, and serum transaminases may be elevated. The Po_2 is often diminished, and measurement of the degree of hypoxaemia gives an

important indication of the severity of the infection, but the PCO_2 is normal unless terminal respiratory failure occurs.

The sputum of untreated patients usually shows large numbers of Gram-positive diplococci, together with polymorphonuclear neutrophils, and culture is frequently positive for pneumococci. However, in industrialized countries, where many patients have received partial treatment before presentation at hospital, sputum microscopy is positive in only about one-quarter of patients and culture positive in only about a half. Blood culture is positive in 10 to 30 per cent of patients.

Radiographs of the chest usually show homogeneous opacification of the affected part of the lung, but may appear normal on first presentation. Posteroanterior and lateral views are required to make an accurate diagnosis of the site of the infection. A small pleural effusion can be seen in some patients. Pneumococci can cause either segmental or lobar consolidation, or patchy shadowing. The latter is encountered more frequently in children. The lower lobes are affected more frequently than the upper. In about one-third of patients, more than one lobe is involved.

Differential diagnosis

The initial febrile phase of acute pneumococcal pneumonia cannot be differentiated from that of any other acute febrile illness. Once the characteristic respiratory symptoms and signs have appeared, a diagnosis of acute pneumonia can usually be made on clinical grounds, but chest signs may be absent when the patient is first seen. In developing countries, most cases of pneumococcal pneumonia in young children are diagnosed and treated by paramedical primary health-care workers, who may have only limited diagnostic skills. For this reason the World Health Organization (**WHO**) has devised a simple diagnostic scheme, based predominantly on measurement of the respiratory rate and on observation of lower chest-wall indrawing, to help primary health-care workers determine which children with acute respiratory-tract infections probably have pneumonia and require antibiotic treatment (Table 2). This scheme has played an important part in the rationalization of the management of acute respiratory infections in developing countries, but other severe infections, including malaria, can give rise to cough and a raised respiratory rate in young children, thus fulfilling the diagnostic criteria for pneumonia. For this reason an integrated approach to the management of childhood illness by primary health-care workers is now advocated by WHO and UNICEF. An algorithm has been developed which gives guidance on diagnosis and management; it is now being used in many developing countries.

Two important pulmonary conditions that may be confused with acute bacterial pneumonia in adult patients are infarction and atelectasis. Rigors and a high fever favour a diagnosis of pneumonia as opposed to one of infarction; a very sudden onset of symptoms and frank haemoptysis favour a diagnosis of infarction. Pulmonary atelectasis, resulting from the aspiration of mucus, may give rise to symptoms and signs that are very similar to those of pneumonia. Fever and signs of toxaemia are usually less marked in patients with atelectasis than in those with pneumonia unless the collapsed area of lung has become infected. In elderly patients, heart failure with atypical pulmonary oedema may sometimes mimic pneumococcal pneumonia.

Occasionally, subdiaphragmatic lesions such as cholecystitis, a subphrenic abscess, or an amoebic liver abscess cause a clinical picture that mimics that of lower-lobe pneumonia. Conversely, lower-lobe pneumonia, by producing abdominal pain and guarding, may suggest the diagnosis of an acute abdominal condition such as a perforated peptic ulcer, acute cholecystitis, or appendicitis.

Pneumococcal pneumonia can usually be differentiated from viral pneumonias or pneumonia caused by *Mycoplasma pneumoniae* because of its sudden onset, associated severe toxaemia, and accompanying polymorphonuclear neutrophil leucocytosis, but differentiation from other forms of acute bacterial pneumonia cannot be made without the aid of microbiological investigations. Klebsiella pneumonia, staphylococcal pneumonia, and legionnaires' disease may all produce a similar clinical picture. Confusion, signs of multisystem damage, lymphopenia, or a low serum sodium should raise the possibility of legionnaires' disease. In HIV infected patients the differential diagnosis also includes patients infected with *Pneumocystis carinii* and mycobacterial species.

Course and prognosis

Untreated patients who survive long enough to make specific anticapsular polysaccharide antibody recover spontaneously by crisis, or by a more gradual lysis, 7 to 10 days after the onset of their illness. Without treatment the mortality of acute pneumococcal pneumonia is high, especially when bacteraemia is present. Among patients treated promptly with antibiotics, overall mortality is about 5 per cent, but mortality remains as high as 30 per cent in patients with bacteraemia despite antibiotic treatment. Mortality is highest among the elderly and the very young, and among those with an associated underlying illness, such as cirrhosis, alcoholism, or heart disease. HIV infection probably increases mortality in children but this has not been found in all studies. Infection with certain pneumococcal serotypes, involvement of more than one lobe of the lung, bacteraemia, leucopenia, and jaundice are all bad prognostic signs. Most deaths from treated pneumococcal pneumonia occur within the first few days of admission to hospital. It is often difficult to establish an exact cause of death in such patients —peripheral circulatory collapse, cardiac arrhythmias, and respiratory failure are some of the contributory factors.

Complications of pneumococcal lobar pneumonia result from local or lymphatic spread of bacteria to adjacent pleura or pericardium, producing pleural or pericardial effusions, or from bacteraemic spread to meninges and other distant foci. The likelihood of one of these infective complications developing is reduced, but not completely abolished, by prompt treatment with antibiotics. Pneumococcal pneumonia may precipitate congestive cardiac failure in elderly patients and can precipitate acute dilatation of the stomach or paralytic ileus. Herpes labialis is a common accompaniment of the infection.

Pleural effusion and empyema

A large pleural effusion or an empyema develops during treatment in a small percentage (2 to 5 per cent) of patients with established pneumococcal pneumonia. Other patients present with the clinical features of pleural effusion without any preceding symptoms of pneumonia.

Symptoms

Some patients give a history suggestive of a previous parenchymatous lung infection. A history of days or weeks of fever, malaise, anorexia, and marked weight loss is often obtained. Fever may be hectic and accompanied by rigors and episodes of profuse sweating. Patients with a large pleural effusion are breathless and they may complain of dull pain on the affected side. A productive cough is unusual unless a bronchopleural fistula is present.

Physical signs

General examination shows persistent fever and tachycardia. The patient may look toxaemic and there may be signs of recent weight loss. Examination of the chest usually shows the characteristic signs of a pleural effusion—diminished chest movement, dullness of percussion, and diminished breath sounds over the accumulated fluid. The chest wall overlying an empyema may be tender.

Investigations

A persistent polymorphonuclear neutrophil leucocytosis is nearly always present. Radiographs or ultrasonography may be very helpful in localizing a loculated effusion. On aspiration, turbid fluid or thick pus is obtained, which contains pneumococci and degenerate white cells. If antibiotics have been given it may not be possible to culture pneumococci, but pneumococcal antigen can usually be detected by immunological assays.

Differential diagnosis

Association of persistent pyrexia and leucocytosis with abnormal chest signs indicates a chronic pulmonary infection. Absence of copious, purulent sputum differentiates the condition from a lung abscess. Differentiation from tuberculosis may be difficult on clinical grounds alone. Diagnosis of an empyema is confirmed by the aspiration of pus from the pleural cavity. Repeated needling with a wide-bored needle, preferably under ultrasound control, may be needed to find a loculated empyema. Pleural biopsy may provide diagnostic histology.

Course and prognosis

Untreated, an empyema may rupture through the chest wall (empyema necessitas) or rupture into a bronchus causing a bronchopleural fistula. Even when pus is

aspirated and healing achieved, subsequent fibrosis and calcification may seriously restrict expansion of the underlying lung.

Pericardial effusion and empyema

Pneumococci may spread from an infected lower lobe to produce pericarditis. Pericarditis is clinically silent in some patients; in other patients it is manifest only as a transient pericardial rub or as an abnormal electrocardiogram. However, occasionally pericardial involvement is the dominant feature of a pneumococcal infection. Only a proportion of such patients give a history suggestive of an initial acute respiratory-tract infection.

Symptoms

Patients with a pneumococcal pericardial empyema usually give a history of several days, or even weeks, of persistent fever, malaise, anorexia, and weight loss. They may complain of dull or pleuritic central chest pain and they may have noted swelling of the ankles or of the abdomen.

Physical signs

Many patients with a pneumococcal pericardial empyema are critically ill by the time that they reach hospital. They are febrile and toxaemic. There may be signs of severe pericardial tamponade—a rapid, small-volume pulse, pulsus paradoxus, a low blood pressure, elevation of the jugular venous pressure with a further increase during inspiration, and peripheral oedema and ascites. Percussion of the chest may show some enlargement of the area of cardiac dullness but this is an unreliable clinical sign. The heart sounds are usually faint and, in some patients, a pericardial rub is heard.

Investigations

A peripheral blood polymorphonuclear neutrophil leucocytosis is present and blood culture may be positive for pneumococci. A chest radiograph may show globular enlargement of the heart and there may be radiological evidence of an associated lung infection. An ultrasonographic examination may help to define the best site for drainage. The electrocardiogram shows low-voltage potentials and S-T elevation or depression may be present. On aspiration of the pericardium, turbid fluid or thick pus is obtained from which pneumococci can be isolated or in which pneumococcal antigen can be detected.

Differential diagnosis

Detection of the signs of pericardial tamponade in a patient who is febrile and toxaemic should suggest a diagnosis of pericardial empyema. The condition may be confused with tuberculous constrictive pericarditis, but patients with the latter condition usually have a longer history than patients with a pneumococcal pericardial empyema and are less toxic. Staphylococci and, rarely, other pyogenic bacteria can produce a similar clinical picture to that of pneumococcal pericardial empyema. Diagnosis of a pericardial empyema is confirmed by ultrasound and by pericardial aspiration. A pneumococcal pericardial empyema is a medical emergency and, following ultrasonographic examination if this is available, pericardial aspiration should be undertaken, if necessary at more than one site, as soon as this diagnosis is seriously suspected.

Course and prognosis

Pneumococcal pericardial empyema is a serious condition with a high mortality, even in treated patients. Patients who survive the initial episode may develop constrictive pericarditis within weeks or months of their acute illness.

Otitis media

Otitis media is probably the most common form of pneumococcal infection. The condition is seen most frequently in young children but it may also affect adults.

Symptoms

The onset of an attack of acute otitis media is sudden, although there may be a history of a recent upper respiratory-tract infection. Fever and severe pain in the ear are the usual presenting complaints in adults and older children, and patients may complain of deafness and tinnitus. Fever, crying, and extreme irritability are the usual features of the condition in young children, in whom febrile convulsions may occur.

Physical signs

On examination of the affected ear, the tympanic membrane is seen to be red and swollen, and it may bulge outwards into the external ear. If perforation has occurred, the external ear may be full of pus and a ragged hole may be seen in the tympanic membrane. The affected ear is usually partially deaf. In children, meningism may be present; this must be differentiated from meningitis by lumbar puncture.

Laboratory findings

A polymorphonuclear neutrophil leucocytosis is usually found. If the drum has ruptured, pneumococci may be found in the purulent discharge present in the external ear but contaminants are likely to be present also.

Differential diagnosis

A clinical diagnosis of otitis media is rarely difficult provided that the ears of all febrile and irritable children are examined carefully. A tympanogram usually shows a characteristic pattern. The aetiology of the condition can be established by examination of fluid obtained from the middle ear with a fine needle. This technique, widely practised in some countries but not in others, may become increasingly useful as determination of the antibiotic sensitivity pattern of pneumococci becomes an essential requirement for optimum treatment of pneumococcal infections.

Course and prognosis

Prompt treatment is usually followed by a rapid and complete resolution of the infection. However, some patients, especially those in whom rupture of the drum has occurred, are left with partial conductive deafness. When untreated, pneumococcal otitis media can give rise to a chronic discharging ear requiring prolonged and complicated treatment. Spread of the infection posteriorly may result in acute mastoiditis, and spread of the infection upwards can cause pneumococcal meningitis and/or a cerebral abscess.

Pneumococcal meningitis (see also Chapter 24.14.1)

Pneumococcal meningitis may follow damage to the base of the skull, and it can occur as a complication of pneumococcal otitis media or pneumococcal pneumonia. However, many patients with this condition, the proportion varying from series to series, present with the clinical features of acute pyogenic meningitis and have no features to suggest a primary focus of pneumococcal infection.

Symptoms

Fever and headache are the usual presenting symptoms of pneumococcal meningitis. Headache usually comes on gradually over a few hours; it is generalized and may be very severe. Nausea, backache, and photophobia may develop, and convulsions may occur. Confusion may be the most prominent symptom in elderly patients, and failure to feed the first symptom in infants.

Physical signs

Patients with pneumococcal meningitis are febrile and toxaemic. Neck stiffness and a positive Kernig's sign are usually found in adults and in older children. Impairment of consciousness is often present, which varies in severity from drowsiness and confusion to deep coma. Bradycardia and hypertension may indicate the presence of raised intracranial pressure, but papilloedema is rarely seen. Bulging of the anterior fontanelle may be present in infants. Cranial nerve palsies, most frequently of the VIth or of the IIIrd cranial nerve, may be found on presentation and, occasionally, other peripheral localizing neurological signs are present.

An associated pneumococcal lesion, such as otitis media or pneumonia, may be detected. Petechiae are rarely seen. Herpes labialis may be present.

Laboratory findings

A peripheral blood polymorphonuclear neutrophil leucocytosis is usually found and a positive blood culture may be obtained.

Examination of the cerebrospinal fluid shows a turbid fluid, which usually contains an increased number of cells and many bacteria. Most of the leucocytes are polymorphonuclear neutrophils. Cerebrospinal fluid bacterial counts are often very high in patients with pneumococcal meningitis, on average 10 times higher than in patients with meningococcal meningitis. Leucocytes are present in only small numbers in the cerebrospinal fluid of some patients; in such instances the fluid may still be turbid because of the presence of numerous bacteria. The protein level in cerebrospinal fluid is increased and its glucose level decreased below that of blood. Gram stain and culture are usually positive for pneumococci.

Differential diagnosis

It is not usually difficult to establish a clinical diagnosis of pyogenic meningitis in adults and older children. However, problems may arise in the very young and in the very old; signs of meningeal irritation may be absent in both these groups of patients. Fever and irritability may be the only clinical signs of pneumococcal meningitis in an infant. The appearance of confusion may be the only sign indicating involvement of the meninges in an elderly patient with pneumococcal pneumonia. An adverse change in the psychological or neurological state of an elderly patient with pneumonia is an indication for lumbar puncture.

On clinical grounds, pneumococcal meningitis cannot be differentiated with certainty from other forms of pyogenic meningitis. An associated ear infection or pneumonia favours the diagnosis of pneumococcal infection but is not diagnostic. If petechiae are found, meningococcal meningitis is more likely. Bacteriological diagnosis of pneumococcal meningitis is confirmed by examination of the cerebrospinal fluid.

Course and prognosis

The prognosis of patients with pneumococcal meningitis is poor. Many patients make no response to treatment, their conscious level deteriorates progressively, and they die within the first 24 to 48 h after their admission to hospital. Other patients make some initial response to treatment but then relapse, their conscious level deteriorates, and new neurological signs appear. This deterioration may be due to the collection of pus in the extradural space or brain but, more usually, follows a vascular occlusion. Patients who deteriorate after an initial clinical improvement must be fully investigated to exclude the presence of a space-occupying lesion. The clinical course of survivors of the early phase of pneumococcal meningitis is often stormy, being complicated by conditions such as bedsores, pneumonia, and venous thrombosis. It has been estimated that over one-half of survivors from pneumococcal meninigitis are left with some intellectual impairment or residual neurological disability such as deafness or partial hemiplegia. Small children who survive may develop hydrocephalus. Relapses may occur when treatment is stopped. Mortality figures for pneumococcal meningitis vary from series to series but in industrialized countries the true mortality from pneumococcal meningitis is probably around 30 per cent. In developing countries, mortality figures of around 50 per cent have been found consistently. Impairment of consciousness on admission to hospital, associated pneumonia, a low white-cell count, and a high bacterial count in the cerebrospinal fluid are all poor prognostic features. Death is almost inevitable in patients who are in deep coma at the time they are admitted to hospital.

Why the prognosis of pneumococcal meningitis is so poor is uncertain. Although there is little difference in the clinical features of patients with pneumococcal or meningococcal meningitis on presentation at hospital, death is at least five times more likely in a patient with pneumococcal meningitis than in a patient with meningococcal meningitis regardless of the level of patient care available. Vascular damage, rapid multiplication of bacteria, and defective leucocyte function have all been suggested as possible causes for the poor outcome of patients with pneumococcal meningitis, but the reasons for the very poor prognosis of patients with this condition remain a mystery.

Other clinical syndromes

The pneumococcus is an important cause of bacterial sinusitis. The likelihood of a bacterial aetiology of acute sinusitis is increased if the duration of symptoms exceeds 7 days.

Acute, fulminating septicaemia is a rare form of pneumococcal infection and is encountered most frequently in patients without a spleen or in those who are immunocompromised in some way. A sudden onset of fever, peripheral circulatory collapse, and bleeding (purpura fulminans) are the usual presenting features of this condition, which is indistinguishable from other forms of overwhelming bacterial septicaemia. Leucopenia is usually found. Bleeding is due to disseminated intravascular coagulation. The mortality of this condition is very high, even when treatment is started promptly. A milder form of bacteraemia is sometimes encountered in children who present with fever or febrile convulsions without any obvious focus of pneumococcal infection (occult bacteraemia).

Acute endocarditis may complicate pneumococcal septicaemia but this condition is now encountered only rarely. Healthy heart valves, especially the aortic valve, may be attacked and rupture of the aortic valve may occur, producing severe aortic incompetence. Emboli derived from cardiac vegetations may reach the brain and other organs. Progressions of the cardiac lesions may be very rapid and the prognosis of this condition is poor. Valve replacement may be necessary for patients who survive the initial episode.

During the course of pneumococcal septicaemia, with or without endocarditis, bacteria may reach many sites where they can multiply to produce a purulent lesion. Pneumococcal arthritis, verterbral osteomyelitis, ophthalmitis, and orchitis may be produced in this way. The pneumococcus has been rarely associated with the toxic shock syndrome and with the haemolytic–uraemic syndrome.

Pneumococcal peritonitis is an uncommon condition that is encountered most frequently in patients with the nephrotic syndrome or cirrhosis of the liver, conditions frequently resulting in ascites and generalized impairment in immunity. The condition has been described also in healthy young girls, perhaps as a complication of pelvic infection, and occasionally in neonates. The condition is characterized by a sudden onset of fever, and abdominal pain and tenderness. The ascitic fluid is turbid and contains polymorphonuclear neutrophils and pneumococci. The general features of an acute infection may not be so obvious in patients with cirrhosis, and peritonitis must be considered as a possible diagnosis in any patient with this condition whose clinical state shows a sudden deterioration. The prognosis of pneumococcal peritonitis is poor in patients with a serious underlying illness.

Treatment

In the era of the antibiotic-resistant pneumococcus, the appropriate treatment of pneumococcal disease is determined by pharmocodynamic principles. These suggest that successful b-lactam therapy of invasive pneumococcal disease requires drug levels at the site of infection that exceed the MIC of the organism for at least 50 per cent of the dosing interval. The same principle applies to therapy with macrolides. Fluoroquinolones, azalides, and aminoglycosides exert a concentration-dependent killing effect on pneumococci. The best predictor of an appropriate outcome is a measure that includes both the peak concentration and time above the MIC. This is best described by the area under the drug concentration curve over 24 h (**AUC24**). The ratio of the AUC_{24} to the MIC (AUIC) predicts optimal efficacy at a value of [3]125. The application of these principles probably applies to all invasive diseases caused by pneumococci. Their application to the treatment of otitis media has, however, been best studied to date.

Pneumonia

Clinical studies have shown that the drug level most predictive of outcome in pneumonia is the serum concentration. Measurement of these concentrations suggests that b-lactam therapy of pneumonia will successfully treat penicillin-resistant pneumococcal pneumonia. When the drug is given in high dose intravenously is it likely that pneumonia caused by pneumococci with MICs up to 4 µg/ml will respond. A number of studies in both adults and children have shown that the most important predictors of outcome in the management of pneumococcal pneumonia are severity of disease and the presence of underlying disease. b-Lactam susceptibility does not affect outcome when adequate doses of intravenous b-lactam drugs are used to treat the infection. The optimal drugs for treating pneumococcal pneumonia are penicillin or amoxicillin. When there is a high index of suspicion of a pneumococcal aetiology in a patient with pneumonia, intravenous management with penicillin, ampicillin, or amoxycillin is appropriate (amoxycillin has higher antipneumococcal activity than ampicillin). When the aetiology of pneumonia is unclear, empirical management requires broader-spectrum cephalosporin therapy such as treatment with cefuroxime. Cefotaxime or ceftriaxone are more active against pneumococci and ought to be effective against cephalosporin-resistant pneumococcal pneumonia caused by pneumococci with cephalosporin MICs of 1 to 2 µg/ml. The clinical relevance of macrolide resistance remains unclear, but it is likely that macrolide treatment of pneumonia caused by pneumococci with MICs in a range of 1 to 2 µg/ml (*mef*E-mediated resistance) will respond to intravenous macrolide therapy. Pharmocodynamic principles suggest that higher levels of macrolide resistance are likely to result in clinical failure. Newer fluoroquinolones are under development for the management of pneumococcal pneumonia. This class of agent has, until recently, had marginal activity against the pneumococcus, but newer agents with enhanced antipneumococcal activity may be useful for the management of highly penicillin-resistant pneumococcal pneumonia in adults. There is currently no indication for the addition of vancomycin to the management of patients with pneumococcal pneumonia. There are few data on the appropriate antibiotic for oral management of antibiotic-resistant pneumococcal pneumonia and it is in this situation that very high doses of amoxicillin or the new fluoroquinolones may have their most important role.

Otitis media

While the use of antibiotics for the treatment of otitis media remains controversial, pneumococcal otitis media will resolve in a minority of cases only with appropriate antibiotic therapy. Bacterial eradication from middle ear fluid correlates well with clinical response in the management of otitis media. Oral cephalosporins with poor antipneumococcal activity are inferior to amoxicillin in their ability to eradicate bacteria from the middle ear. The choice of appropriate antibiotic therapy for the management of otitis media requires evaluation of local studies in which initial and follow-up tympanocentesis has been performed. Studies with clinical endpoints lack the ability to differentiate between highly active and poorly active agents. Current guidelines suggest that high doses of amoxicillin (90 mg/kg.day) represent the best available oral therapy for pneumococcal otitis media. Patients in whom this therapy has failed require tympanocentesis to document the cause of the failure. Should a highly penicillin-resistant pneumococcus be isolated, the appropriate therapy is intravenous or intramuscular ceftriaxone for 3 days.

Meningitis

The mainstays of therapy of pneumococcal meningitis in developing countries, namely penicillin and/or chloramphenicol, can no longer be relied upon to treat this disease, given the global epidemic of b-lactam-resistant strains. In a study from South Africa in which the usefulness of this combination was tested against penicillin-resistant, but chloramphenicol-susceptible, strains there was a poorer outcome in patients with penicillin-resistant disease compared with those with penicillin-susceptible pneumococcal meningitis. Pharmocodynamic principles suggest that penicillin and chloramphenicol are an inadequate form of therapy for even intermediately penicillin-resistant pneumococcal meningitis. The drugs of choice for the management of pneumococcal meningitis are thus cefotaxime (300 mg/kg.day divided into 3 or 4 doses) or ceftriaxone (100 mg/kg.day divided into 2 doses). Adults should receive full doses of antibiotic. In communities where, for financial reasons, only limited amounts of cephalosporins are available, patients with pneumococcal meningitis should be given a high priority for treatment with these drugs because of the severity of this condition. In some parts of the world, strains with intermediate or full resistance to cefotaxime or ceftriaxone have emerged. In these countries the appropriate initial empiric management of meningitis includes the addition of vancomycin (60 mg/kg.day divided into 4 doses). Amongst the other available cephalosporins, ceftazidime should not be used for the management of pneumococcal meningitis. Cefepime has activity similar to that of cefotaxime and ceftriaxone, and may be used. Cefpirome has enhanced antipneumococcal activity but there are no clinical studies of the efficacy of this agent in the management of meningitis. Amongst the carbapenems, imipenem when used for meningitis is associated with an increased incidence of seizures. Two studies have demonstrated that patients treated with meropenem were not at increased risk of seizures on therapy compared with patients treated with cefotaxime. While newer fluoroquinolones are under clinical trial for the management of meningitis, there are insufficient data to recommend their use at this time.

The use of dexamethasone immediately prior to or simultaneously with the administration of cefotaxime, or ceftriaxone, appears to improve the outcome of pneumococcal meningitis in children. The use of this agent in adult pneumococcal meningitis is unproven and its use in conjunction with penicillin and/or chloramphenicol is controversial.

Other infections

There is little published information on the clinical impact of antibiotic resistance on the management of pneumococcal infections other than pneumonia, meningitis, and otitis media. The pharmocodynamic principles outlined above may be useful in guiding empiric therapy for these conditions.The principles of treatment for pneumococcal sinusitis are the same as those of otitis media. While pneumococci are intrinsically less susceptible than viridans streptococci to aminoglycosides, the addition of an aminoglycoside may have a synergistic effect on the bacterial killing rate in the treatment of pneumococcal endocarditis.

The minimum duration of therapy for invasive pneumococcal infections is under review, but the current usual duration is shown in Table 3.

Chemoprophylaxis

Children at particularly high risk of pneumococcal disease (such as those with sickle cell disease or nephrotic syndrome, or post-splenectomy) should receive regular oral penicillin prophylaxis for the first 5 years of life. The value of prophylaxis after this age is unproven, but should be considered in those who may not have responded to vaccine (such as patients with recurrent bacteraemia). Vaccination of high-risk children should be given at 2 years of age with the 23 valent vaccine. Conjugate vaccine is recommended in infancy, followed by a booter with the 23 valent vaccine at 2 years of age.

Patients who have undergone splenectomy should be educated about the risks of bacteraemia, and have prompt initiation of antibiotic therapy for febrile episodes.

Immunity and vaccines

The basis of immunity to invasive pneumococcal disease is thought to be the development of serotype-specific capsular antibodies of the IgG_2 subclass. These antibodies stimulate opsonophagocytosis, a process that is facilitated by the binding of complement. Previous studies of specific capsular polysaccharide antibody levels in adults have used a radioimmunoassay which detected both specific antibody and antibody to C polysaccharide. The use of C polysaccharide absorption in ELISA assays has helped to make these antibody assays more specific. The IgG response to capsular polysaccharide is poorly developed in young infants and the affinity and opsononophagocytic activity of these antibodies is reduced in older patients and patients infected with HIV.

The first attempt to develop a multivalent pneumococcal vaccine was made by Sir Spencer Lister at the South African Institute for Medical Research in 1917. Robert Austrian pioneered the development of multivalent capsular polysaccharide vaccines in the 1970s when these vaccines were shown to be effective in reducing the incidence of invasive pneumococcal disease in otherwise healthy adult gold miners. The vaccine also reduced the incidence of lobar pneumonia in miners. There is indirect evidence of the efficacy of pneumococcal polysaccharide vaccine against bacteraemia in high-risk groups of adults who have received this vaccine. The most compelling evidence comes from indirect cohort studies. There is less evidence of the efficacy of the vaccine in immunocompromised patients. Protection against pneumonia in the elderly has not been demonstrated in prospective randomized trials. Current indications for the use of the vaccine in the United States are listed in Table 4. Use of pneumococcal polysaccharide vaccines has generally been low in adults in industrialized countries, although in some there has been a recent improvement. Following the results of a trial in Uganda, which showed an increased incidence of invasive pneumococcal disease in HIV-positive subjects who had received polysaccharide vaccine, no firm recommendation about the use of this vaccine in patients who are not on antiretroviral therapy can be made before further studies are performed.

Protein vaccines are an attractive option for developing vaccines that are not serotype specific. The most promising vaccines are based on PspA and PsaA proteins which are conserved among pneumococci of various serotypes. These vaccines are in early clinical trial in humans.

In contrast to polysaccharide or protein vaccines, pneumococcal conjugate vaccines contain polysaccharide chemically linked to protein. These conjugate vaccines are immunogenic in young infants and induce immunological memory. They also reduce nasopharyngeal carriage of pneumococci of vaccine serotype, although in

some studies this has been accompanied by an increase in the carriage rate of pneumococci of non-vaccine serotype. This replacement may be a function either of exogenous infection with non-vaccine strains or simply the eradication of the dominant strain by the vaccine thus unmasking subdominant strains. Pneumococcal conjugate vaccines have been shown to reduce the carriage of antibiotic-resistant pneumococci.

A number of efficacy trials of these vaccines are under way. Results from a trial conducted in California recently became available; over 90 per cent efficacy against invasive pneumococcal disease was found and significant protection, although less marked, was obtained against radiographic pneumonia and recurrent otitis media. Because of serotype replacement the overall impact on pneumococcal otitis media was reduced further. In another study, undertaken in Finland, a conjugate vaccine reduced by 57 per cent the incidence of serotype-specific otitis media. These vaccines thus have the potential greatly to reduce mortality and morbidity from invasive pneumococcal disease and pneumonia in young infants and their availability in the first decade of the new millennium may be one of the most important public health interventions of this decade.

7.11.4 Staphylococci

S. J. Eykyn

Although both Koch and Pasteur made observations on coccal organisms, the polyglot Scottish surgeon Alexander Ogston first associated cluster-forming cocci with abscesses. He presented his findings in German to the Surgical Congress in Berlin in 1880 and his classic paper *Über Abscesse* was published the same year. The Professor of Greek at Aberdeen University suggested the name 'staphylococcus' for the organism (*staphyle*—bunch of grapes; *kokkos*—berry) to distinguish it from the chain-forming streptococci. Rosenbach divided the genus *Staphylococcus* into *Staphylococcus aureus* and *S. albus*. Ogston's coccus was of course *S. aureus*.

Taxonomy

Staphylococci are Gram-positive cluster-forming cocci. There are some 32 recognized species of the genus *Staphylococcus* but only about half are of human origin (Table 1). Staphylococci are skin commensals of mammals and birds and some species, particularly *S. aureus*, are important human pathogens. In the clinical laboratory *S. aureus* is distinguished from other staphylococci by its ability to coagulate plasma. The slide coagulase test detects cell-associated clumping factor (bound coagulase), which reacts with fibrinogen to cause aggregation of the organisms. Commercial kits are used for this test and some also detect protein A, present in most strains of *S. aureus*. Occasional strains do not produce clumping factor or protein A, and certain other species of staphylococci produce clumping factor, hence the gold standard for the identification of *S. aureus* in the laboratory is the tube coagulase test in which staphylococci are mixed with plasma in a test tube. This detects extracellular coagulase (free coagulase), which activates prothrombin and initiates clot formation. The slide coagulase test is used to screen organisms, whereas the tube test is confirmatory and of more taxonomic significance. Other useful screening tests for *S. aureus* are the detection of DNAase activity and fermentation of mannitol, but neither is as reliable as the tube coagulase test.

Many clinical laboratories report any coagulase-negative staphylococcus other than *S. saprophyticus* as *S. epidermidis* without formal speciation and some still refer to these bacteria as '*Staph. albus*'. Availability of commercial identification kits has enabled speciation of coagulase-negative staphylococci in the routine laboratory though this is seldom undertaken routinely. Most clinical isolates are *S. epidermidis* (*sensu stricto*) or *S. saprophyticus* but several other species such as *S. lugdunensis* can occasionally be important pathogens.

Typing

Epidemiological studies of *S. aureus* infection, and increasingly these concern methicillin-resistant strains (**MRSAs**), require typing methods to distinguish between epidemic and endemic strains. Typing can also confirm the correlation between specific staphylococcal infections and a particular type of the organism. In many countries including the United Kingdom such studies still rely on bacteriophage typing. Phage typing has been organized internationally since 1953. The basic international set of phages consists of 23 phages (Table 2). There are four major phage groups—I, II, III, and V—and staphylococci may be lysed by a single phage from one group, more than one phage from a single group, or by phages from more than one group. The internationally recognized gold standard for discriminating between strains of *S. aureus* is pulse field gel electrophoresis (**PFGE**), a DNA finger printing technique. It is neither necessary nor feasible to use PFGE for typing all strains of *S. aureus* as most can be satisfactorily differentiated by phage typing. Epidemic MRSAs are designated specific numerical types (1 to 17) as well as phage types. Phage typing is much less satisfactory for coagulase-negative staphylococci and has largely been abandoned. Epidemiological studies on these bacteria are seldom required in clinical practice but could be done by PFGE.

Staphylococcus aureus

Pathogenicity

S. aureus produces a remarkable variety of extracellular substances that include: general toxic agents such as catalase, hyaluronidase, lipase, and membrane-damaging toxins that may be involved in the pathogenesis of local or systemic inflammation; and specific toxins such as enterotoxins and epidermolytic toxins that mediate particular non-suppurative diseases.

Membrane-damaging toxins

S. aureus produces five toxins that disrupt cell membranes—a-, b-, g-, and †- toxins and leucocidin. Many of these toxins disrupt red cell membranes producing haemolysis. The most extensively studied is a-toxin, which is formed by most strains and produces impressive biological effects; it is cytotoxic and necrotizing, kills leucocytes, lyses platelets, releases catecholamines, and causes renal cortical necrosis yet remarkably its specific role in staphylococcal infection in humans has yet to be defined.

Enterotoxins

There are now 11 staphylococcal enterotoxins—types A, B, D, E, G, H, I, and J which show major antigenic differences and type C which is subdivided into C1, C2, and C3 on the basis of minor antigenic differences. Enterotoxins G, H, I, and J were only described recently and have not yet been confirmed as emetic in humans. Enterotoxin F is identical to toxic shock syndrome toxin 1 and is now known as TSST-1. About 40 per cent of *S. aureus* produce enterotoxin, sometimes of more than one type. Staphylococcal food poisoning results from the ingestion of foods containing preformed enterotoxin. Most outbreaks in the United Kingdom are caused by enterotoxin A with or without D (see Table 3). Staphylococcal enterotoxins have a range of biological activities in addition to their ability to induce vomiting; they are pyrogenic, mitogenic, and can produce thrombocytopenia and hypotension.

P>**Epidermolytic toxins**

These toxins cause intraepidermal splitting and are responsible for the scalded skin syndrome and the blistering of impetigo. The production of epidermolytic toxin is particularly associated with (though not confined to) *S. aureus* of phage group II. There are two epidermolytic toxins, ETA which is heat stable and under

chromosomal control, and ETB which is heat labile and plasmid-mediated, and most phage group II staphylococci produce ETA or both ETA and ETB.

Toxic shock syndrome toxin (TSST-1)

This toxin is responsible for the toxic shock syndrome (**TSS**). Most cases of menstrually associated TSS are mediated by TSST-1 produced by *S. aureus* of phage group I, usually phage 29 or 52; TSS not associated with menstruation can occur with strains producing TSST-1, but also with phage group V strains that produce enterotoxin B.

Carriage

S. aureus is part of the normal flora in some individuals; about 25 per cent of people 'carry' the organism permanently, a similar proportion never do, and the rest do so intermittently. Common carriage sites are the nose, axilla, perineum, and toe webs. Nasal carriage rates vary from 10 to 40 per cent in normal adults outside hospital, but higher rates are often found in patients in hospital, particularly those who have been in hospital for several weeks. High carriage rates are also found in those with skin diseases such as eczema, those with insulin-dependent diabetes, patients on chronic haemodialysis or chronic ambulatory peritoneal dialysis, intravenous drug users, and HIV-positive patients. Some carriers, designated 'shedders', disperse large numbers of staphylococci into the environment on skin squamas. The carrier state is highly relevant to the epidemiology of *S. aureus* infection as to whether or not this complicates surgery or trauma and the source of the *S. aureus* in most patients who develop staphylococcal infection is endogenous.

Host factors in *S. aureus* infection

Intact skin and mucous membranes are important defences against staphylococcal infection. Wounds, whether traumatic or surgical, frequently become colonized with *S. aureus*, which may result in localized infection or in dissemination via the bloodstream to distant sites. Sometimes trivial, even unrecognized, skin trauma precedes such haematogenous spread. Burns and skin diseases are also important portals of entry for staphylococci. Certain viral infections such as influenza damage the respiratory epithelium and allow secondary staphylococcal invasion. Foreign material including intravascular devices, arteriovenous shunts, and vascular and orthopaedic prostheses is also relevant to the pathogenesis and perpetuation of staphylococcal infection.

Once *S. aureus* gains access to the tissues, polymorphs are the most important line of defence. Phagocytosis involves chemotaxis, opsonization, and intracellular killing. Chemotactic defects occur, for example, in Job syndrome (in which patients with recurrent eczema suffer from repeated skin infections and cold abscesses with *S. aureus*) and also in certain other rare syndromes. Opsonic defects tend to predispose to a variety of pyogenic infections, including, but not specifically, *S. aureus* infection, but *S. aureus* is a major pathogen in chronic granulomatous disease producing local and metastatic abscesses. In this disease, intracellular killing by the polymorphs is defective.

Susceptibility of *S. aureus* to antibiotics and antiseptics

Resistance to antibiotics is not a marker for virulence in *S. aureus* and strains that are sensitive to all antistaphylococcal antibiotics, including penicillin, can cause severe community-acquired infections. However, *S. aureus* has a record of rapid and successful development of resistance to antibiotics. Most isolates, whether acquired in the community or in hospital, produce penicillinase (b-lactamase) and are thus resistant to penicillin itself and related compounds including ampicillin and amoxycillin. Staphylococcal b-lactamase has a negligible effect on methicillin, cloxacillin, and flucloxacillin, which were sequentially introduced specifically for the treatment of staphylococcal infection. Methicillin-resistant strains of *S. aureus* (MRSAs) were detected soon after the introduction of methicillin in 1960, and reports of their isolation increased until 1971 when they accounted for some 5 per cent of strains submitted to the Staphylococcus Reference Laboratory of the Central Public Health Laboratory in the United Kingdom. MRSAs then diminished in frequency in the United Kingdom, possibly as a result of increased prescribing of aminoglycosides, but there was a resurgence in the early 1980s and for some years now virtually all hospitals have patients who are colonized or infected with MRSAs. MRSAs are usually, but not always, resistant to a variety of other antibiotics in addition to methicillin, and are resistant to all cephalosporins. *S. aureus* other than MRSA, whether penicillinase producing or not, are sensitive to many cephalosporins, though the newer third-generation cephalosporins, such as ceftazidime, are much less active than cefuroxime and cefotaxime. The incidence of erythromycin resistance relates to its use and varies from about 5 to 20 per cent. Gentamicin resistance is unusual, except in MRSA. Resistance of *S. aureus* to fusidic acid is uncommon, but most cultures contain a few resistant mutants and a fully resistant population can emerge, particularly after topical use. Since 1996 MRSAs of reduced sensitivity to vancomycin have been reported from Europe, Asia, and the United States. Such strains are referred to by the acronyms 'VISA' (vancomycin-intermediate *S. aureus*) and 'GISA' (glycopeptide-intermediate *S. aureus*); GISA is the more appropriate as these strains are of intermediate resistance to both the glycopeptide drugs vancomycin and teicoplanin, but the term glycopeptide is less familiar to clinicians. The emergence of such resistance is of concern as glycopeptides are extensively used for MRSA infections. However VISA/GISA and other MRSAs are sensitive to quinupristin/dalfopristin (Synercid) and the oxazolidinone Linezolid Rifampicin is highly active against *S. aureus*, but as with fusidic acid, minority populations of resistant cells are found and resistance may emerge during treatment.

The topical antibiotic mupirocin (Bactroban) is active against many *S. aureus* although unfortunately in some hospitals mupirocin resistance is common thus limiting the use of mupirocin to eradicate MRSA from the nose and other superficial sites. Most disinfectants and antiseptics inhibit or kill *S. aureus.* Chlorhexidine, hexachlorophane, triclosan, and iodine-containing compounds such as povidone iodine are all used for skin disinfection and when used correctly are highly effective in removing staphylococci from the skin.

Prevention of spread of *S. aureus*

Although any strain of *S. aureus* can spread between people whether patients or staff, measures to control spread are now largely directed at the nosocomial spread of MRSAs. MRSAs have caused innumerable hospital outbreaks in many countries; sometimes these outbreaks have involved colonization rather than infection, but severe infection is increasingly encountered and the MRSA has become the scourge of elective surgery in some hospitals. Several distinct strains have caused epidemics and the prevalent type varies: in the United Kingdom overall type 15 is most common, but in London the incidence of types 15 and 16 is equal. Epidemic strains not only spread readily but can cause severe invasive infection. Colonization with MRSA is a notoriously recalcitrant problem in hospitals, particularly on elderly care units, and is also an increasing problem in nursing and residential homes. Eradication of MRSA from the nose and from some surface lesions is readily achieved with topical agents such as mupirocin, but it is virtually impossible to eradicate MRSA from the throat, sputum, or from sites associated with a foreign body such as an indwelling catheter or tracheostomy unless these are removed. Repeated careful handwashing by all staff in contact with patients is the single most effective measure in preventing spread of staphylococci.

Clinical manifestations

S. aureus usually causes localized infection, sometimes with local spread, but this may result in bacteraemia and dissemination of the infection. Certain staphylococcal syndromes are produced by extracellular toxins rather than local invasion and will be considered separately.

Localized infections

Infection of the skin and its appendages

These infections often arise in association with hair follicles, and minor trauma, maceration, and skin diseases also predispose to them. Folliculitis is a superficial infection of the hair follicle commonly caused by *S. aureus.* Boils (furuncles) are deep-seated infections around a hair follicle usually on the neck, axilla, buttock, or thigh, often recurrent, and sometimes involving more than one member of a family. When several adjacent hair follicles are involved a carbuncle develops, usually on the back of the neck, with multiple draining sinuses and systemic disturbance. Although boils are very common, carbuncles are now rarely seen. Impetigo is a blistering skin lesion with crusting exudate affecting exposed areas (often the face) usually in children. Epidermolytic toxin is associated with these infections. Most acute paronychias are caused by *S. aureus*. Mastitis and breast abscess in the puerperium are caused by *S. aureus* as are many non-puerperal breast abscesses. Newborn babies commonly suffer from staphylococcal infection, with septic spots, 'sticky umbilicus', 'sticky eye', and occasionally breast abscess, as well as the much rarer toxin-mediated staphylococcal diseases. Styes, purulent infections of the glands of the eyelid, are caused by *S. aureus*.

Wound infection

S. aureus is the commonest cause of wound infection after surgery or trauma that does not involve the mucous membranes with their rich anaerobic commensal flora.

Staphylococcal wound infection varies from minimal erythema and serous discharge, through small abscesses often in relation to sutures, to marked cellulitis, deep pus, and wound dehiscence with pain and systemic disturbance. It is of particular concern after operations involving prosthetic material such as joint or vascular prostheses or heart valves as the infection can extend from the wound to infect the prosthesis with disastrous results.

Ear, nose, and throat infection

Staphylococcal infection of the hair follicles or sebaceous glands in the outer external auditory canal causes acute localized otitis externa with severe pain and itching. Acute otitis media and sinusitis are seldom caused by *S. aureus*. Although *S. aureus* is commonly grown from throat swabs, it behaves as a commensal at this site, and such patients have usually been taking antibiotics.

Pleuropulmonary infection

Staphylococcal pneumonia arises either from aspiration or by haematogenous spread with metastatic seeding of the lung. Aspiration pneumonia generally complicates pre-existing lung disease or viral respiratory disease, usually influenza. In children, other viral infections of the respiratory tract, including severe measles in developing countries, may be followed by secondary bacterial infection with staphylococci. *S. aureus* from carriage sites presumably reaches the damaged lung tissue via the trachea and bronchi. In contrast to aspiration pneumonia, haematogenous staphylococcal pneumonia characteristically affects a previously normal lung. There may sometimes be an identifiable local infection, often of the skin and usually trivial, that has resulted in haematogenous seeding or there may be evidence of release of infected thrombi via the venous system as in tricuspid endocarditis or occasionally when there is an infected intravascular device. Staphylococci can usually be isolated from the blood in haematogenous pneumonia, though seldom in aspiration pneumonia. Whatever its pathogenesis, *S. aureus* pneumonia is a severe disease. When secondary to influenza, it may occur without an obvious influenza-like prodromal illness and with alarming suddenness (Fig. 1(a) and Fig. 1(b)). It is usually complicated by abscess formation, empyema, and in children, by pneumatoceles and pyopneumothorax, but the radiological findings at initial presentation vary from local consolidation, to multiple patchy infiltrates, and abscess formation may or may not be detected.

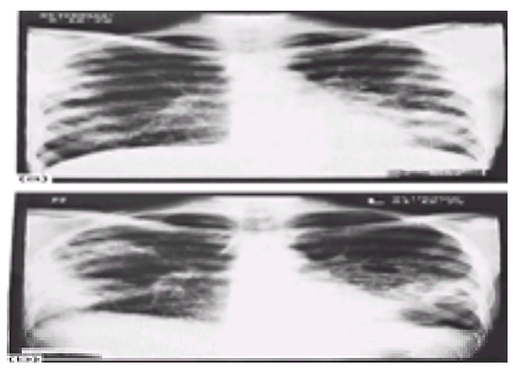

Fig. 1 Chest radiograph of a 24-year-old man with severe staphylococcal pneumonia. (a) on admission and (b) 13 days later. The patient was also suffering from influenza B.

Urinary tract infection

S. aureus urinary tract infection is uncommon and unlikely to occur in patients with a normal urinary tract except in staphylococcal bacteraemia with microabscesses in the kidney as may occur in staphylococcal endocarditis. *S. aureus* urinary infection sometimes occurs in patients with abnormal bladder function but in association with instrumentation or catheterization, presumably from previous urethral colonization with the strain.

Bacteraemia, septicaemia, and metastatic (haematogenous) infection

Bacteraemia in the strict sense means bacteria in the blood, that is, a positive blood culture. This may or may not be symptomatic in the patient. A symptomatic bacteraemia is referred to as a septicaemia. In fact, *S. aureus* in the blood is almost always symptomatic and thus strictly a septicaemia, but the terms tend to be used interchangeably adding to the confusion. Bacteraemia will be used here.

Community-acquired bacteraemia

In most patients who acquire *S. aureus* bacteraemia in the community the staphylococcus has entered the bloodstream from a carrier site or from a trivial unnoticed abrasion and seldom from a defined local lesion. Such bacteraemia then results in serious deep-seated infection. Such bacteraemias have been called 'primary' and are usually much more severe than those secondary to a defined focus of infection. Primary bacteraemia can occur at any age, and often in a previously healthy individual. Such patients may, but often do not, present with initial infection at a specific site. An ill patient with a community-acquired *S. aureus* bacteraemia and no detectable focus of infection will generally have endocarditis (see below).

Hospital-acquired bacteraemia

Nosocomial *S. aureus* bacteraemia usually results from an infected intravascular access site and this is as likely to be a peripheral cannula as a central catheter. There will often be obvious infection at the insertion site, but sometimes only minimal local signs with severe systemic disturbance. Such bacteraemias can result in metastatic infection involving bone, joint, lung, or heart valve. These disastrous iatrogenic sequelae of intravenous access are increasing. Nosocomial bacteraemia also sometimes occurs with severe wound sepsis.

Endocarditis

S. aureus endocarditis is a devastating illness often occurring in a previously healthy individual, but an asymptomatic left-sided valvular abnormality such as a bicuspid aortic valve or mitral leaflet prolapse is sometimes present. The infection typically presents as an influenza-like illness, often with gastrointestinal disturbance. Meningism is seen in about 25 per cent of cases and polymorphs, though seldom organisms, are detected in the cerebrospinal fluid. There may be systemic emboli. Valvular insufficiency can develop within days, sometimes hours, of admission. Staphylococcal endocarditis is a rapidly destructive disease, justifiably called malignant endocarditis by Osler.

The skin manifestations can be mistaken for meningococcal infection (Fig. 2(a) and Fig. 2(b)). Figure 3(a) and Figure 3(b) show another fatal staphylococcal infection in a previously healthy 54-year-old man who was febrile and confused at presentation and hemiplegic within 48 h. Blood and CSF (which contained 5000 polymorphs) grew *S. aureus*.

Fig. 2 Meningococcaemic-like infection in a 22-year-old man who died from an aortic root abscess from *S. aureus* endocarditis on a bicuspid aortic value. A false-positive meningococccaemic latex agglutination test on the cerebrospinal fluid (which contained 1500 polymorphs, but no organisms) taken on admission further increased the clinical confusion.

Fig. 3 Meningococcaemic-like disease. (a) Hand and (b) foot of a man with primary staphylococcal bacteraemia and meningitis who had disseminated intravascular coagulation.

Staphylococcal endocarditis is occasionally complicated by splenic abscess (Fig. 4). Intravenous drug users are at particular risk of staphylococcal endocarditis, but unless the affected individual has a previous valvular abnormality, the infection is likely to involve the tricuspid valve and present with fever, malaise, and respiratory signs that result from septic pulmonary emboli.

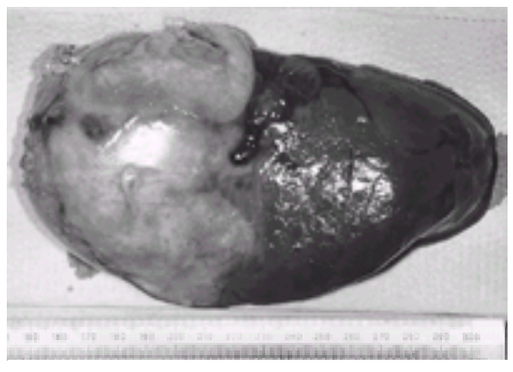

Fig. 4 Splenic abscess complicating staphylococcal endocarditis.

Bone and joint infections

S. aureus is the commonest cause of acute bone and joint infection. These infections can result from a 'primary' bacteraemia, but also from a contiguous focus of infection after trauma or surgery, especially that involving prosthetic implants. The overall incidence of acute haematogenous osteomyelitis has decreased but there has also been a change in its localization. Osteomyelitis of the long bones seen primarily in children, particularly boys, is now uncommon, but vertebral osteomyelitis has increased or is increasingly recognized. Patients with staphylococcal vertebral osteomyelitis are usually middle aged or elderly. This shift in the localization of the infection has not been explained. Vertebral osteomyelitis can be a notoriously difficult diagnosis, repeatedly referred to in the literature as a 'diagnostic pitfall'. Pain, not always localized to the spine is the only consistent feature. Fever is sometimes absent but at least if present should initiate a blood culture, which is likely to be positive whatever the temperature. Any patient with backache, a high C-reactive protein and erythrocyte sedimentation rate, and *S. aureus* in the blood should be assumed to have vertebral infection.

Staphylococcal septic arthritis may occur in previously normal or abnormal joints and at any age. It may involve one or more joints and multiple infection can occur in patients with previous joint pathology such as rheumatoid arthritis, when it may be difficult to diagnose.

Renal cortical abscess (carbuncle) and perinephric abscess

These metastatic staphylococcal infections are rare and usually cause diagnostic confusion. A renal cortical abscess, also known as a carbuncle, is a multilocular abscess involving the renal parenchyma, the result of the coalescence of cortical microabscesses from haematogenous seeding of the kidney from a previous infection, typically a boil, with *S. aureus.* The patient complains of fevers and loin pain but urinary symptoms are usually absent and unless the abscess communicates with the excretory system, the urine contains neither pus cells nor *S. aureus*. Although *S. aureus* is the commonest pathogen in renal carbuncle, perinephric abscesses—those external to the renal capsule but within the perinephric fascia—are more commonly caused by Gram-negative aerobes such as *Escherichia coli* or *Proteus* spp. than staphylococci. A renal carbuncle may rupture into the perinephric space producing a perinephric abscess. Again, urine cultures are unlikely to be positive and the signs are similar to those of a renal carbuncle.

Pyomyositis

See Chapter 24.22.6 for discussion.

Infections mediated by toxins of *S. aureus*

Staphylococcal food poisoning

This syndrome, characterized by vomiting, nausea, abdominal cramps, and diarrhoea, is caused by the ingestion of staphylococcal enterotoxin preformed in the food. The onset occurs within hours of ingestion of food contaminated during its preparation by an individual infected with, or shedding, an enterotoxin-producing staphylococcus. Unrefrigerated protein-rich foods containing meat or milk are likely to support the growth of staphylococci and the subsequent production of heat-stable enterotoxin. Only about 5 per cent of outbreaks of bacterial food poisoning reported to the Communicable Disease Surveillance Centre for which an aetiological agent is identified are caused by *S. aureus*. The diagnosis can be confirmed by culturing incriminated food, any skin lesions, the nose of food handlers, and the stools of the victims. In most outbreaks, both the organism and its toxin can be defined, but occasionally, enterotoxin alone is demonstrated in the food.

Staphylococcal scalded skin syndrome

This rare disease, originally known as Ritter's disease when it was first seen in infants in the late nineteenth century, is more commonly seen in children (Fig. 5) than adults (Fig. 6). It is characterized by the sudden onset of extensive erythema followed by bullous desquamation of large areas of skin. It is caused by the epidermolytic toxins of *S. aureus*. The disease of scalded skin syndrome must be distinguished from a similar clinical entity unassociated with *S. aureus*, that of toxic

epidermal necrolysis (Lyell's syndrome) which occurs in older children and adults and results from drug hypersensitivity. Histologically the two diseases can be readily distinguished as in scalded skin syndrome there is intraepithelial splitting at the level of the stratum granulosum and in toxic epidermal necrolysis there is total epidermal loss with separation at the dermal–epidermal junction.

Fig. 5 Staphylococcal scalded skin syndrome in a child. (Reproduced by courtesy of Professor W.C. Noble.)

Fig. 6 Staphylococcal scalded skin syndrome in an adult.

Staphylococcal toxic shock syndrome (TSS)

This syndrome (Fig. 7) of high fever, mental confusion, erythroderma, diarrhoea, hypotension, and renal failure was first defined in children in 1978, but had been described 50 years earlier and thought to be staphylococcal scarlet fever. In the late 1970s there was an epidemic of toxic shock syndrome in women associated with menstruation and tampon use, initially, and predominantly, in the United States, but later, though in far fewer numbers, in other countries. Toxic shock syndrome has also been described in women who were not menstruating and in men in association with a wide variety of conditions and operations including burns in children. Toxic shock syndrome may be fatal and a mortality rate of around 5 per cent was reported during the 'tampon epidemic'. Since the syndrome is mediated by toxin, the mainstay of treatment is supportive. Antistaphylococcal antibiotics should be given to eradicate *S. aureus* from the local site. Bacteraemia has rarely been reported in toxic shock syndrome. The staphylococci isolated are usually resistant only to penicillin.

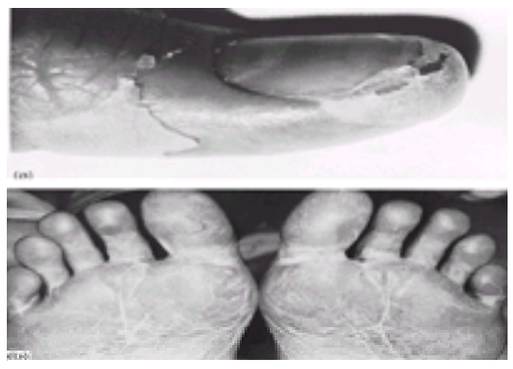

Fig. 7 Toxic shock syndrome. Desquamation of (a) hand and (b) feet in a girl with tampon-associated disease. (Reproduced by courtesy of Dr D.C. Shanson.)

Laboratory diagnosis of *S. aureus* infection

S. aureus is readily isolated in the laboratory. A Gram-stained film may enable a rapid diagnosis of a staphylococcal aetiology; the characteristic clumps of Gram-positive cocci, often intracellular as well as extracellular and sometimes of variable size, are readily identifiable. The diagnosis can be confirmed by culture within 18 to 24 h. Staphylococcal bacteraemia is readily detected by routine blood culture methods. The isolation of *S. aureus* from blood is almost always indicative of a genuine bacteraemia and the organism should only be dismissed as a contaminant if the patient has extensive skin disease such as eczema, rarely otherwise.

Treatment

Drainage of any pus is an essential prerequisite of the management of *S. aureus* infection. This may occur spontaneously or with only minor surgical intervention in most superficial infections such as boils, paronychias, styes, and stitch abscesses. Deep abscesses in wounds or organs and osteomyelitis that has progressed to the point of pus formation require definitive surgical drainage. Infections associated with intravascular devices or other prosthetic material seldom resolve with antibiotics and removal of the foreign material is usually required.

Antibiotics are indicated if the patient is systemically unwell or the infection is spreading and sometimes when given early in the course of a potentially localizing pyogenic infection may arrest its progress. They are of no benefit in staphylococcal food poisoning but should be given in scalded skin syndrome and toxic shock syndrome to eradicate toxin-producing *S. aureus*. The initial choice of agent for staphylococcal infection before sensitivities become available depends on whether the staphylococcus was acquired in the community or in hospital. For community-acquired infections a b-lactamase-resistant penicillin such as flucloxacillin or cephalosporin such as cefuroxime will be appropriate initial treatment and probably also definitive therapy. Penicillin is suitable only if the strain does not produce b-lactamase, and should never be used for the initial 'blind' treatment. Similar constraints apply to ampicillin and amoxicillin. Alternative agents to b-lactams for community-acquired infection when the patient is hypersensitive to penicillin include the macrolides erythromycin, clarithromycin, and azithromycin. Fusidic acid is an excellent antistaphylococcal agent although resistance may arise during treatment, especially when the organism cannot readily be eradicated. When the infection is acquired in hospital and the patient is unwell, in most hospitals it should be assumed to be an MRSA until cultures prove otherwise. The only agents with reliable activity against MRSA are vancomycin, teicoplanin, the combination drug quinupristin/dalfopristin (Synercid), and the oxazolidinone Linezolid. Most staphylococcal infection is satisfactorily treated with a single antibiotic. Combination therapy is often used for serious infections such as endocarditis and bone or joint infection but there is minimal evidence of any advantage over a single agent.

The length of the antibiotic course to treat staphylococcal infection is unknown, but for serious infections such as endocarditis, bone and joint infections, and pneumonia several weeks' treatment may be needed. For most other infections, antibiotics should be given until there is clinical improvement or for about 48 h after fever has resolved. Most patients are treated for too long inviting side-effects. Blood cultures that are persistently positive for *S. aureus* despite appropriate antibiotic therapy are seldom an indication for changing the antibiotics, but rather for an assessment of the need for intervention, for example to remove an infected intravascular device, excise an infected heart valve, or aspirate and wash out an infected joint. Topical antibiotics and antiseptics are useful for the treatment of staphylococcal skin infections.

Coagulase-negative staphylococci

Coagulase-negative staphylococci are the commonest contaminants in the laboratory, particularly, though not exclusively, in blood cultures, but they can also be important pathogens whose incidence continues to increase. The availability of commercial kits for their speciation has served to emphasize that they cannot be regarded as a homogeneous entity; the different species vary not only in their incidence in clinical infections but also in the type and severity of disease produced. Most infections with coagulase-negative staphylococci are hospital acquired, but certain species cause severe community-acquired infection.

Pathogenicity

Coagulase-negative staphylococci (usually *S. epidermidis*) that cause infections associated with prosthetic devices and intravascular catheters produce an exopolysaccharide ('slime') which is important in enabling these organisms to adhere to plastic material and probably also in their resistance to phagocytosis, other host defences, and to antimicrobial action. Coagulase-negative staphylococci from clinical infections produce a variety of potential toxins including haemolysins, cytotoxins, deoxyribonuclease, fibrinolysin, proteinase, and lipase-esterase, similar to those produced by *S. aureus*, and infection caused by some species, especially *S. lugdunensis* and *S. simulans*, mimics that caused by *S. aureus*.

Carriage

Coagulase-negative staphylococci, together with coryneforms, comprise most of the human skin flora. Many different species are found on the skin but the commonest is *S. epidermidis*; *S. hominis* and *S. haemolyticus* are also common. Distribution of species varies on different skin areas: the predominant species on the head and trunk is *S. epidermidis*, on the arms and legs it is *S. hominis*, and as its name suggests *S. capitis* is found mainly on the head. There are also geographical variations.

Host factors in coagulase-negative staphylococcal infection

Most infection with coagulase-negative staphylococci is associated with prosthetic material both in immunocompromised and non-immunocompromised patients. Infection of intravascular catheters arises via the catheter access site or the catheter hub from frequent disconnections. Prosthetic material can also become infected at implantation.

Antibiotic susceptibility

Hospital-acquired coagulase-negative staphylococci, particularly *S. epidermidis* and *S. haemolyticus*, are usually multiply resistant. Most are resistant to methicillin (and thus to cephalosporins), and many to gentamicin and erythromycin. Thus the usual nosocomial strain of coagulase-negative staphylococcus has an antibiotic susceptibility pattern akin to many MRSAs. Rare resistance to vancomycin and teicoplanin has been reported, initially in *S. haemolyticus*. In marked contrast to hospital-acquired infections those acquired in the community are usually caused by very sensitive strains; many are sensitive to penicillin.

Infections caused by coagulase-negative staphylococci

Most infections caused by coagulase-negative staphylococci are acquired in hospital and are increasingly common. They usually arise in association with an intravascular or prosthetic device or implant. Infection with more than one strain may occur in nosocomial infections.

Community-acquired infections though rare are probably increasing or increasingly recognized and are usually severe. In most community-acquired infections, repeated isolation of the same coagulase-negative staphylcoccus from the blood is essential for the diagnosis, and true bacteraemia must be distinguished from contamination.

Intravascular devices

There has been a marked increase in infection of intravascular devices with coagulase-negative staphylococci, particularly in neonates and immunocompromised patients, and they are the commonest bacteria in such infections. The degree of systemic disturbance varies, and this should determine the approach to treatment. In contrast to infections of intravascular devices caused by *S. aureus* for which it is usually necessary to remove the device to control the infection, with those caused by coagulase-negative staphylococci the catheter can often be left *in situ* and the infections controlled with antibiotics. If this fails, the device must be removed. Very occasionally, as with *S. aureus*, persistent bacteraemia can result in metastatic seeding of a heart valve or vertebral body.

Cerebrospinal fluid shunts

Coagulase-negative staphylococci, predominantly *S. epidermidis*, are the commonest cause of infection of cerebrospinal fluid shunts and these infections can present weeks, months, or years after the shunt insertion. They also cause infection of cerebrospinal fluid reservoirs used for chemotherapy. Signs of meningitis may be absent and usual findings include low-grade fever, malaise, and shunt malfunction. Serum antibodies to *S. epidermidis* can be used to monitor treatment and detect relapse. Treatment may require removal of the shunt and antibiotics, usually vancomycin with rifampicin, are best given intraventricularly. Occasionally, glomerulonephritis ('shunt nephritis') occurs in patients with colonized shunts as a result of deposition of immune complexes on the basement membranes of the glomeruli.

Peritonitis associated with continuous ambulatory peritoneal dialysis

Coagulase-negative staphylococci, predominantly *S. epidermidis*, are the commonest cause of peritonitis associated with continuous ambulatory peritoneal dialysis. The bacteria probably gain access to the peritoneum as a result of manipulation of the catheter connections. Patients have abdominal pain, occasionally nausea, diarrhoea, and fever, and abundant polymorphs in the dialysate in which Gram-positive cocci, usually scanty and intracellular, may be detected on a Gram-stained smear. The antibiotic sensitivities of infecting strains vary and since treatment must always be started before this information is available, vancomycin (preferably intraperitoneally) is the drug of choice.

Endocarditis

Coagulase-negative staphylococci can infect native or prosthetic heart valves. Nosocomial native valve infections with coagulase-negative staphylococci (usually *S. epidermidis*) generally result from infected intravascular devices; the affected valve may or may not have been previously abnormal. Nosocomial prosthetic valve endocarditis can be acquired in the theatre at the time of valve replacement surgery or shortly thereafter and presents within weeks or more often months of surgery ('early-onset'). In many series, coagulase-negative staphylococci are the commonest cause of early-onset prosthetic valve endocarditis. Prosthetic infection can also be acquired from an infected intravascular device. Community-acquired coagulase-negative staphylococcal endocarditis, which usually involves native valves, is increasingly recognized and most patients will have a pre-existing cardiac abnormality. The organisms must derive from the patient's skin, but predisposing skin lesions are seldom detected. The infection often mimics *S. aureus* endocarditis with rapidly destructive valvular disease, neurological manifestations, and concomitant vertebral osteomyelitis. The commonest pathogen is *S. epidermidis*, but there are increasing reports of other species, particularly *S. lugdunensis*, which seems to be especially virulent. These community-acquired strains are frequently penicillin sensitive.

Urinary tract infection

Coagulase-negative staphylococci are urinary pathogens both in the community and in hospital but different species are involved. In the community the curiously named *S. saprophyticus* is an important urinary pathogen in sexually active women, second only to *Escherichia coli*. It commonly produces cystitis, but may cause upper urinary tract infection and has been isolated from infected calculi. *S. saprophyticus* is a skin commensal but is not normally found colonizing the urethra, though it has been isolated from the rectal flora of women. Most strains are readily recognized in the laboratory by their resistance to novobiocin. They are sensitive to a wide range of antibiotics. Some nosocomial urinary tract infections are also caused by coagulase-negative staphylococci, predominantly *S. epidermidis*. These infections, usually after urological surgery, are seldom accompanied by pyuria, and may clear spontaneously on removal of the catheter. Nosocomial urinary isolates of coagulase-negative staphylococci are often multiply resistant.

Other infections

Coagulase-negative staphylococci are increasingly isolated from the blood of neonates and immunocompromised, neutropenic patients. Distinguishing true bacteraemia from contamination can be difficult. In many cases bacteraemia is related to the presence of an intravascular catheter (see above). In premature neonates, colonization of the respiratory tract occurs and respiratory infection can result. Infection of prosthetic joints and vascular prostheses is sometimes caused by coagulase-negative staphylococci. The organisms are introduced at the time of the surgery, although the clinical signs of infection may not become evident for weeks or months. Attempts to treat such infections with antibiotics generally fail and removal of the prosthesis is required. Coagulase-negative staphylococci are also the commonest cause of postoperative endophthalmitis after intraocular surgery.

Laboratory diagnosis

The laboratory diagnosis of much infection with coagulase-negative staphylococci poses greater difficulties than the diagnosis of *S. aureus* infection. The clinician is advised to enlist the help of a competent microbiologist when assessing the validity of culture results of invasive specimens growing coagulase-negative staphylococci. A further problem with these organisms occurs with the use of broth enrichment cultures for specimens of excised tissue; a single contaminating staphylococcus will multiply in liquid medium, thereby misleading unwary clinicians.

Treatment

As well as the prescribing of antibiotics, an integral part of the successful treatment of infections with coagulase-negative staphylococci is a critical clinical assessment of the need for removal of any prosthetic material with which so many infections are associated. So many nosocomial infections are caused by resistant strains that the only reliable initial therapy is vancomycin or teicoplanin. The length of treatment in most instances is somewhat arbitrary and the same principles apply to infections with these organisms as to those with *S. aureus.* Community-acquired infections, usually endocarditis, can often be treated with b-lactam antibiotics, sometimes with penicillin. As with serious *S. aureus* infections, combination therapy is often used.

7.11.5 Meningococcal infections

P. Brandtzaeg

Neisseria meningitidis infection remains a major public health problem worldwide by causing clusters or epidemics of meningitis and acute lethal sepsis. Case fatality has gradually declined from 80 to 90 per cent to approximately 10 per cent but has remained at this level since the introduction of antimicrobial chemotherapy in 1937.

Bacterium

Neisseria meningitidis is an obligate human Gram-negative diplococcus normally located in the mucous membrane of the upper respiratory tract. Invasive isolates from blood or cerebrospinal fluid are encapsulated and express pili. Capsular polysaccharides that inhibit phagocytosis and bacterial adhesion are divided into 12 different serogroups (A, B, C, 29-E, H, I, K, L, W-135, X, Y, and Z). Serogroups A, B, and C account for more than 90 per cent of all invasive isolates. Less than 10 per cent of clinical isolates are from serogroups W-135 and Y.

The bacterial cell wall consists of an outer lipid bilayer containing lipopolysaccharides (endotoxin) and outer membrane proteins, a thin peptidoglycan layer, and the cytoplasmic membrane. Lipid A is a glycolipid that anchors the lipopolysaccharide to the lipid membrane. It is the major inflammatory (toxic) component of *N. meningitidis*. It can activate a variety of cells via CD14–toll-like receptor-4 interaction or indirectly through activation of blood coagulation, fibrinolysis, kallikrein–kinin, and complement systems. During growth, meningococci release outer membrane vesicles containing large amounts of lipopolysaccharides.

Outer membrane proteins are classified according to electrophoretic mobility into five major classes. Por A (class 1 protein) and Por B (class 2 or 3 proteins) are cation- and anion-selective porins, respectively. Surface exposed loops of Por B and Por A define serotype and serosubtype, respectively. Loops 1 and 4 in Por A are

major epitopes inducing bactericidal and opsonophagocytic antibodies when exposed to the human immune system.

Meningococci are fastidious bacteria that readily autolyse. They grow well on blood agar, supplemented chocolate agar, trypticar soy base, Mueller–Hinton agar, and selective GC-medium. Optimal growth occurs at 35 to 37°C in a humid atmosphere with 5 to 10 per cent carbon dioxide. The convex colonies (diameter: 1 to 4 mm) are transparent, non-pigmented, and non-haemolytic. They produce cytochrome oxidase and ferment glucose and maltose, but not lactose and sucrose, to acid without gas formation.

Practical handling of clinical specimens

Blood culture (10 ml for adults, 2 to 4 ml for infants/children) and swabs from the nasopharynx and the tonsils are collected immediately. Media for blood culture and transportation of swabs should be optimal for recovery of meningococci. Cerebrospinal fluid is best cultured by direct plating of 0.1 ml on supplemented chocolate agar or a similar medium, incubated at 35 to 37°C in 5 to10 per cent carbon dioxide. If direct plating is impossible or delayed, the sample should be stored at +4°C to +20°C, preferably at refrigerator temperature. Recovery of live meningococci may increase if some drops of the cerebrospinal fluid are stored on a sterile swab in transport medium or injected into blood culture medium and incubated at 35 to 37°C.

Direct visualization of *N. meningitidis* in clinical specimens

Intra- and extracellular diplococci can be observed in the cerebrospinal fluid, peripheral blood buffy coat (fulminant septicaemia), and biopsies of haemorrhagic skin lesions using Gram or acridine orange stains.

Polymerase chain reaction

Using primers that recognize various DNA sequences coding for different genes in *N. meningitidis*, it is possible to detect and classify meningococci in cerebrospinal fluid and blood without positive cultures.

Epidemiology

Industrialized countries

Infection presents as single cases or in small clusters. The incidence is usually 1 to 3 per 100 000 inhabitants per year. Strains belonging to specific clonal complexes may cause a hyperendemic situation characterized by a much higher incidence than usually observed (4 to 30 per 100 000 per year). This epidemiological situation may last for more than a decade in defined geographical areas before slowly declining. Serogroup A has disappeared as a cause of significant epidemics. Outbreaks in Finland in the 1970s and in New Zealand in the 1980s were exceptions.

Developing countries

Large-scale epidemics are confined to developing countries, primarily in sub-Saharan Africa. The incidence approaches 10 to 25 per 100 000 inhabitants per year. During epidemic peaks in Africa, as many as 500 to 1000 per 100 000 inhabitants may contract meningococcal infections. Serogroup A and to lesser extent serogroup C dominate the isolates of large epidemics.

The meningitis belt in sub-Saharan Africa

The area stretches from the Gambia in the west to Ethiopia in the east including Senegal, Guinea, Mali, Burkina Faso, Ghana, Togo, Benin, Nigeria, Niger, Chad, Cameroon, The Central African Republic, and Sudan. Mainly serogroup A strains belonging to a few clonal complexes cause the increased attack rate. In some of these countries large-scale epidemics occur every 8 to 12 years.

Season

In temperate climates most cases occur during the winter and early spring. In the sub-Saharan African meningitis belt the incidence increases from the middle and reaches its maximum at the end of the dry season (harmattan). New cases decline rapidly after the start of the rainy season.

Preceding infections

Influenza A predisposes to invasive meningococcal infections. Mycoplasma infections and rubella have been associated with outbreaks.

Age distribution

Cases are seen in all age groups. However, most occur from 0 to 4 years with a smaller peak from 13 to 20 years. During epidemics the median age appears to increase. Complement-deficient patients may contract the infection when they are older than others.

Genetic diversity

N. meningitidis can exchange and incorporate DNA from other *Neisseria* or closely related species. It reveals more genetic diversity than many other human pathogens. However, strains from certain clonal complexes may persist for many decades over wide areas, retaining their pathogenicity. Strains from seven clonal complexes have predominated since the late 1960s.

Predisposing factors for invasive disease Table 1)

Lack of protective antibodies

Antibodies against serogroups A, C, W-135, and Y capsule polysaccharides are bactericidal and confer protection at concentrations of 1 to 2 µg/ml of serum. Serogroup B polysaccharide induces a weak, transient IgM response that is not protective. Bactericidal and opsonophagocytic antibodies recognizing surface-exposed epitopes of the outer membrane protein, in particular Por A, developing after infection, are important for protection. Antilipopolysaccharide antibodies, recognizing commonly shared epitopes among virulent and non-pathogenic *Neisseria* and closely related species, presumably play a role in protection.

Defects in the complement system

Defects in the complement system can increase susceptibility to meningococcal infections up to 6000 times. The commonest are absent or malfunctioning properdin or late complement components C5 to C9. Properdin defects predispose to rapidly progressing, overwhelming septicaemia. Defects in C5 to C9 are associated with recurrent meningococcal infections. Previous studies suggested that the case fatality rate was reduced in those with late complement defects. However, a recent Dutch study found case fatality rates of 16 per cent and 32 per cent among patients with late complement defects and properdin defects, respectively—a difference that was not statistically significant, compared with 7.7 per cent in the general population. Defects in the classical pathway do not predispose to meningococcal infection. Complement defects are rare. They play a minor role in the development of serogroup A, B, and C systemic meningococcal disease, but are over-represented in patients with the uncommon serogroups W-135, X, Y, and Z.

Defects in the mannan-binding lectin

Mannan-binding lectin is a calcium-dependent, opsonizing, acute-phase protein. Mutations in codons 54, 57, and 52 in the mannan-binding lectin gene result in low

serum levels. Defects in this protein have been associated with 1/3 of all meningococcal cases in England and Ireland.

Polymorphism of Fcg-receptor II and Fcg-receptor III

Polymorphisms of Fcg-receptor II (Fcg-RIIa, CD32) and Fcg-receptor III (Fcg-RIIIb, CD16) on phagocytic cells are associated with reduced binding of antibodies. They are over-represented in patients with defects in the late complement components and in children with fulminant meningococcal sepsis. Fcg-RIIa receptors where arginine has replaced histidine at position 131 are associated with reduced binding of IgG2 subclass (antipolysaccharide) antibodies.

Nasopharyngeal colonization

Upper respiratory tract mucosa is the natural habitat of *N. meningitidis*. It is spread from person to person by droplets and direct mucosal contact. Most colonizing meningococci are non-pathogenic, genetically and phenotypically different from virulent invasive strains. Only a small minority of those colonized with virulent strains will develop invasive disease. Colonization is asymptomatic. It induces local and systemic immune responses within 1 to 2 weeks.

Carriage

Cross-sectional studies in England and Norway in the 1980s and 1990s indicated that approximately 10 per cent of the population harboured meningococci in the upper respiratory tract. However, only 1 per cent of the healthy normal population carried strains from typical virulent clones prevalent at the time. The acquisition rate leading to carriage appears to be independent of season, whereas invasive meningococcal infections peak in the winter and early spring in temperate countries.

The carriage rate in England is low (2 to 3 per cent) in the first 4 years of life, rising in children 10 to 14 years of age (9 to 10 per cent), reaching a maximum among young adults of 15 to 19 years (20 to 25 per cent), and than gradually declining to less than 15 per cent in persons above 25 years. It increases in closed or semi-closed communities and is particularly high in military camps where strains change frequently. In university communities with bar and catering facilities the carriage rate is high. Smoking increases the carriage rate.

Reservoir of virulent meningococci

Healthy adults carrying virulent strains of *N. meningitidis* are the main reservoir. Household members and kissing contacts of a patient harbour virulent strains more often than the average population. In industrialized countries, infants and children are usually infected by a local adult carrier. Spread from patients to medical staff is very uncommon. In Africa, children may more commonly infect each other with serogroup A strains.

Invasive infection

Most patients appear to develop invasive disease 2 to 4 days after acquiring the virulent strain in the upper respiratory tract, but some are carriers for up to 7 weeks before invasive infection develops. *N. meningitidis* adheres to specific structures on the epithelial cells in the nasopharynx and on the tonsils. During a period of adaptation and proliferation, meningococci presumably alter various surface structures (lipopolysaccharides, pili, outer membrane proteins) by phase variation before starting transepithelial migration. They reach submucosal tissue and via capillaries gain access to the circulation.

The initial bacteraemic phase

Bacteraemia is a prerequisite for systemic meningococcal infection. Meningococci may be eliminated from the blood by phagocytosis of opsonized bacteria and lysis induced by bactericidal antibodies and complement. Persistent bacteraemia allows meningeal invasion.

Bacterial proliferation and an inflammatory response may occur predominantly in either the subarachnoid space, causing meningitis, or in the circulation, causing meningococcaemia with or without shock.

The rash

Haemorrhagic skin lesions are the hallmark of systemic meningococcal disease, occurring in 70 to 80 per cent of all cases in industrialized countries. They appear as red or bluish petechiae. These lesions are larger and more irregular in size than the petechiae of thrombocytopenic purpura. Each lesion represents a local nidus of meningococci within the endothelial cells, thrombus formation, and extravasation of erythrocytes. The petechial rash indicates meningococcaemia, not necessarily severe sepsis. However, in fulminant meningococcal septicaemia the haemorrhagic lesions are larger (ecchymoses) with a propensity to locate on extremities (Plate 1). Some patients develop relatively large, non-specific, maculopapular lesions, with or without haemorrhagic lesions, at an early stage (Plate 2, Plate 3). The petechial lesions are difficult to discover on dark skin but may be observed in the conjunctivae.

Clinical presentations

Initial symptoms of systemic meningococcal infection are attributable to meningococcaemia. This may persist as a low-grade bacteraemia or develop into septic shock and multiple organ failure in a few hours. Most commonly the patient develops meningococcaemia without circulatory impairment which gradually evolves to meningitis within 12 to 72 hours. Occasionally, patients develop meningitis and persistent shock simultaneously. Based on easily recognizable clinical symptoms, meningococcal infections can be classified as (i) meningitis without shock, (ii) shock without meningitis, (iii) meningitis and shock, and (iv) meningococcaemia without shock or meningitis. Each clinical presentation is associated with a distinct pathophysiological background and prognosis (Table 2).

Distinct meningitis without persistent shock

Meningism dominates the clinical presentation. The onset is often insidious. The patients, particularly children, may complain of general malaise, nausea, and headache. They vomit and become febrile. The temperature may fluctuate and can be normal at times. Many patients are initially diagnosed as 'gastric flu', gastroenteritis, or upper respiratory tract infection. Gradually, the symptoms of meningitis dominate the clinical picture. The patient complains of headache, vomits, develops nuchal and back rigidity, photophobia, and in more advanced cases altered consciousness. Kernig's and Brudinski's signs become positive. Many patients are lethargic, some are agitated. The blood pressure is normal or slightly elevated by stress. Occasionally it is low but can be restored to normal by infusion of a limited volume of fluid. In untreated cases brain oedema develops, the intracranial pressure rises, and the central circulation is increasingly compromised. Finally, herniation of the cerebellum occurs with arrest of the brain circulation. The case fatality rate is usually less than 5 per cent.

Meningococcal meningitis without persistent shock accounts for more than 50 per cent of all cases of systemic meningococcal infections in industrialized countries and an even higher proportion of cases reaching hospitals in developing countries. The combination of multiple petechiae and symptoms of meningitis supports a diagnosis of meningococcal meningitis.

Pathophysiological background

In untreated patients, *N. meningitidis* can be cultivated from cerebrospinal fluid and blood. The concentration of lipopolysaccharides, reflecting the microbial proliferation, is 100 to 1000 times higher in cerebrospinal fluid than plasma. Levels of bioactive inflammatory mediators such as tumour necrosis factor-a, interleukins 1b, 6, 8, 10, and 12, and soluble receptors of these interleukins are much higher in cerebrospinal fluid than plasma. Plasma proteins, mainly albumin, leak into the cerebrospinal fluid. The influx of mainly neutrophils causes the pleocytosis. The glucose level of the cerebrospinal fluid is reduced mainly as a result of increased central glucose consumption rather than the pleocytosis.

Laboratory findings

The erythrocyte sedimentation rate, C-reactive protein, and leucocyte count in the peripheral blood are markedly elevated with increased numbers of band forms. Sodium, potassium, calcium, and magnesium ions, pH, renal, hepatic, and coagulation parameters are usually within normal range. Cerebrospinal fluid shows a

marked pleocytosis (more than 100 × 10^6 leucocytes/l), with increased levels of protein and decreased level of glucose. Intra- and extracellular Gram-negative diplococci can be detected by direct microscopy.

Persistent septic shock without distinct meningitis

Fulminant meningococcal septicaemia (Waterhouse–Friderichsen syndrome) is characterized by persistent circulatory failure and severe coagulopathy leading to thrombosis and extensive haemorrhage of the skin, thrombosis and gangrene of the extremities, and impaired renal, adrenal, and pulmonary function.

Symptoms develop very rapidly. Six to 12 hours after recognizing their first symptoms the patients are often desperately ill. Initially, they complain of 'flu-like' symptoms, such as fever, aching muscle, prostration, abdominal pain, and nausea. The temperature rises rapidly, commonly to between 39.0 and 41.5°C, but occasionally lower. Diarrhoea is quite common during the first few hours. The patient appears worryingly sick to relatives. Before the appearance of petechiae and ecchymoses the symptoms are often misinterpreted as influenza or acute gastroenteritis.

The haemorrhagic skin lesions are first seen as bluish petechiae, which rapidly increase in size and number. They are distributed all over the body but are often more pronounced and detected earliest on the extremities. Occasionally they are seen on the conjunctivae and other mucous membranes.

The circulation is severely impaired. The extremities are often cold and cyanotic. The blood pressure is low despite tachycardia. The tissue perfusion remains inadequate despite extensive fluid and pressor therapy. Initially, the circulation is hyperdynamic, but gradually becomes hypodynamic from persistent vasodilatation and gradually reduced myocardial performance. The heart becomes dilated with a reduced ejection fraction.

Patients usually lack nuchal and back rigidity. Kernig's sign is negative. Despite impaired circulation, many patients remain awake and alert on hospital admission, being able to communicate their complaints. They hyperventilate to compensate for the pronounced metabolic acidosis. Urine output gradually dwindles. They may develop acute respiratory distress syndrome (ARDS), i.e. pulmonary oedema after fluid volume repletion.

Circulatory collapse dominates the clinical picture during the first 48 to 96 h. Death is usually within 48 h. Later, ARDS, renal failure, and the consequences of the diffuse thrombosis of the extremities and the skin dominate the picture. The case fatality rate ranges from 29 to 53 per cent.

Rapidly evolving symptoms with fever, circulatory shock, and extensive skin haemorrhages in a person without a history of splenectomy makes the diagnosis of fulminant meningococcal septicaemia likely. The same clinical picture is, however, observed in cases of overwhelming *Streptococcus pneumoniae, Haemophilus influenzae, Streptococcus pyogenes*, and *Capnocytophaga canimorsus* infections and with viral haemorrhagic fevers (Plate 4).

Pathophysiological background

There is very rapid microbial proliferation in the circulation, generating large amounts of bacterial lipopolysaccharides in a few hours, but with limited or no bacterial growth in the subarachnoid space. The levels of lipopolysaccharides in the plasma predict the development of persistent septic shock, multiple organ failure, and death. Among 100 Norwegian patients with systemic meningococcal disease, admission levels of lipopolysaccharides in the plasma of less than 1000 pg/ml (10 endotoxin units/ml) were associated with no mortality caused by septic shock, rising to 100 per cent mortality in patients with more than 15 000 pg/ml (150 endotoxin units/ml), that is, 1.2 log higher (Fig. 1).

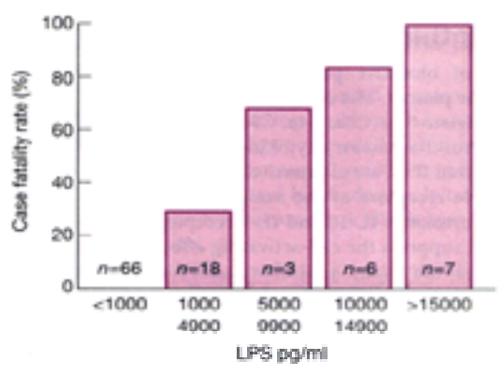

Fig. 1 The relationship between the levels of bacterial lipopolysaccharides in plasma and case fatality rate related to the development of septic shock and multiple organ failure in 100 Norwegian patients with systemic meningococcal disease.

Coagulopathy

Coagulation is activated primarily via the extrinsic (tissue factor–FVIIa) pathway. In patients with fulminant meningococcal septicaemia, there are increased levels of tissue factor in monocytes and on microparticles released from monocytes. The platelets disappear rapidly and remain at a low level for many days due to extensive consumption and a presumably altered endothelial surface. The activation of the coagulation system, as measured by formation of fibrin, is gradually reduced after antibiotic and fluid therapy is initiated (Table 3).

Inhibited fibrinolysis

Concurrent with activation of coagulation, fibrinolysis is inhibited by high levels of plasminogen activator inhibitor 1 (**PAI-1**), released from activated endothelial cells and platelets. High levels of PAI-1 are associated with development of persistent septic shock and a fatal outcome. Allelic variations in the promoter region of the PAI-1 gene enhance production and are associated with an increased risk of dying.

Thrombus formation

Thrombosis occurs particularly in the skin, kidneys, adrenals, muscles, peripheral extremities, and to some extent in the lungs. Levels of the natural coagulation inhibitors antithrombin III and protein C decline due to consumption, whereas tissue factor pathway inhibitor rises. Low levels of protein C are associated with diffuse thrombosis and necrosis of the skin even in non-septic patients.

Pro- and anti-inflammatory mediators

A multitude of bioactive pro- and anti-inflammatory mediators are released into the plasma. The complement and the kallikrein–kinin systems generate anaphylatoxins (C3a, C4a, C5a) and bradykinin, which are potent vasodilators. Proinflammatory cytokines, notably tumour necrosis factor-a, IL-1b, IL-6, and IL-8, are all massively upregulated. Concomitantly, high levels of soluble receptors of the same cytokines are released. The anti-inflammatory cytokines IL-10 and IL-1 receptor antagonist are present in high levels and suppress the cell-activating effect of the bacterial lipopolysaccharides and the many proinflammatory cytokines. It is uncertain whether inducible nitric oxide synthase, augmenting the production of nitric oxide in the endothelial cells, plays a role in meningococcal septic shock.

The subarachnoid space

Microbial proliferation is limited or absent although meningococci may be cultured from cerebrospinal fluid in as many as 50 per cent of untreated cases. The inflammatory response is very limited with a leucocyte count usually in the range of 10 to 100 × 10^6/l and normal contents of protein and glucose.

Laboratory findings

The erythrocyte sedimentation rate and C-reactive protein are only moderately elevated on admission, rising to high levels within 48 h. The leucocyte count is usually low with a marked shift to young band forms of neutrophils. There is evidence of a partly compensated metabolic acidosis with decreased levels of pH and PCO_2. Creatinine and urea are elevated, serum glucose is variable (high, normal, or low), potassium, calcium, and magnesium are low. Potassium rises with the renal failure. Serum aspartate aminotransferase and alanine aminotransferase are slightly elevated, whereas g-glutamyl transferase remains normal. Creatine kinase rises within 1 to 3 days, indicating rhabdomyolysis. Prothrombin, activated partial thromboplastin, and thrombin times are prolonged. The levels of platelets, fibrinogen, coagulation factors VII, X, and V, and prothrombin are low. Antithrombin III and protein C are low whereas tissue factor pathway inhibitor is elevated. Fibrin(ogen) degradation products, thrombin–antithrombin complexes, and PAI-1 are elevated. Lumbar puncture should be avoided in view of the bleeding diathesis.

Distinct meningitis and persistent shock

There are meningeal and circulatory symptoms. Usually the symptoms from the inflamed meninges dominate the picture. On admission there are classic signs and symptoms of meningitis such as headache and nausea, nuchal and back rigidity, and a positive Kernig's sign. The blood pressure remains low despite fluid volume repletion.

Circulating levels of bacterial lipopolysaccharide and inflammatory mediators are lower than in patients with fulminant septicaemia, and case fatality is lower. However, it is higher than in patients with meningitis without compromised circulation.

Meningococcaemia without distinct meningitis and persistent shock

The patient is febrile and usually presents with a rash but without symptoms of persistent septic shock or meningitis. It is a composite group of patients. Many of these patients have been admitted to hospital early, 12 to 24 h after their first symptoms. The case fatality rate is zero. Left untreated they might have developed symptoms of meningitis or fulminant shock.

Transient benign meningococcaemia

These patients develop fever and often an uncharacteristic rash, but no meningism. They are diagnosed as most likely having a viral infection and receive no antibiotic. When the blood culture results are known, the symptoms have disappeared spontaneously, usually within 1 to 3 days. This syndrome may occur in infants and young children.

Subacute meningococcaemia

A few patients develop fever, an uncharacteristic maculopapular rash, general malaise, and arthralgia but no signs of meningitis or shock. They feel uncomfortable but are not severely ill. Meningococci are isolated from blood cultures. Untreated the symptoms may last for days to several weeks but disappear within 1 to 2 days after penicillin therapy is initiated.

Chronic meningococcaemia

The patient develops undulating fever, arthralgia, and maculopapular rash. At times the symptoms may disappear completely. The symptoms may last for months. Blood cultures are sometimes repeatedly negative. Patients are often treated with corticosteroids because an underlying autoimmune disease is suspected. The fever disappears temporarily before reappearing. At this stage meningococci may well be isolated from blood cultures. Antibiotic treatment clears the symptoms within a few days.

Other organ manifestations

Pericarditis

The pericardium is seeded during meningococcaemia. Subsequent inflammation and exudate may lead to cardiac tamponade if left untreated. The patient is febrile, nauseated, and may complain of epigastric pain. The condition is often misdiagnosed as an acute abdominal condition. Blood cultures may be negative. *N. meningitidis* can be cultured and seen in aspirated pus by direct microscopy. Treatment consists of evacuating the pus and benzylpenicillin. The condition should be followed daily by ultrasound examination. Serogroup C organisms have been particularly implicated in these cases.

Arthritis

Acute meningococcal arthritis is an uncommon clinical manifestation of a preceding, often low-grade, meningococcaemia. It is usually located to one, or more rarely, several large joints. If the characteristic petechial rash is absent, isolation of meningococci from blood or joint cultures is necessary for a correct diagnosis. Arthritis caused by *Neisseria gonorrhoeae* is considerably more common than primary meningococcal arthritis. The symptoms disappear rapidly after penicillin treatment without long-term complications.

Arthritis induced by immune complexes

This is more common than the meningococcal arthritis. One or several large joints become swollen and painful. The symptoms usually develop at the end of the first week of treatment. Blood and joint cultures are negative. The temperature and inflammatory markers may rise after an initial decline. The symptoms disappear gradually after some days of treatment with non-steroidal anti-inflammatory drugs. Extended antibiotic therapy is not necessary.

Cutaneous vasculitis and episcleritis

This appears simultaneously with the immune complex arthritis and is commonly observed in sub-Saharan Africa. The vasculitis causes multiple blisters that readily rupture leading to multiple superficial skin ulcers.

Ocular infections

Conjunctivitis or panophthalmitis may precede other symptoms of invasive meningococcal infection. They are primarily observed in infants and children. The patient develops a red eye which in the case of panophthalmitis becomes painful with impaired vision. Local formation of microthrombi may complicate the infection.

Pneumonia

Strains belonging to serogroup Y and W-135 or more rarely other serogroups may cause pneumonia in adults and children. The diagnosis depends on detecting meningococci in a representative specimen from the low respiratory tract. It cannot be differentiated from pneumonia caused by other agents on the clinical symptoms alone.

Treatment

Prehospital antibiotic treatment

Health authorities in many countries advise general practitioners to start prehospital antibiotic treatment (i.e. benzylpenicillin) in suspected cases of meningococcal

infection. The doses in Table 4 rapidly lead to bactericidal concentrations in plasma.

The penicillin is injected laterally in one or both thighs in infants and children. The primary goal is to stop rapid growth of meningococci in the circulation before the intravascular inflammation becomes irreversible or causes grave sequelae. The patients most likely to benefit from this strategy, if applied early enough, are those who are distant from the hospital and have rapidly evolving symptoms leading to a compromised circulation and extensive haemorrhagic skin lesions. Retrospective studies in England suggest that prehospital penicillin treatment reduces case fatality.

Initial evaluation in hospital

The patients should be regarded as emergency cases. The main clinical presentation and severity should be evaluated immediately. A variety of prognostic scores have been developed. The Glasgow Meningococcal Septicaemia Prognostic Score is the one most commonly used. Scores can be used to select patients for intensive care treatment. They should never be used to justify withholding treatment as they often overestimate case fatality.

Antibiotic treatment

Adequate doses of benzylpenicillin, cefotaxime, ceftriaxone, or chloramphenicol effectively stop further proliferation of *N. meningitidis* in the circulation, cerebrospinal fluid, and other extravascular sites. Induction of an explosive release of bacterial lipopolysaccharides leading to a Jarisch–Herxheimer reaction has never been documented in patients receiving antibiotics for meningococcal infection. Plasma levels of lipopolysaccharides and the levels of important inflammatory mediators decline immediately after treatment with antibiotics is initiated in these patients (Table 5).

Benzylpenicillin, chloramphenicol, cefotaxime, ceftriaxone, and meropenem are bactericidal to *N. meningitidis*. Benzylpenicillin remains the drug of choice in most countries. It is effective, cheap, and non-toxic in high doses as long as renal function is normal. High doses are necessary since it penetrates the cerebrospinal fluid relatively poorly. In patients with fulminant septicaemia and severe renal dysfunction the doses should be reduced after 24 to 48 h.

Strains whose sensitivity to penicillin is reduced because of altered penicillin-binding protein 2 are an increasing problem. In most industrialized countries they account for less than 5 per cent of all meningococcal isolates, but the frequency is higher in Mediterranean countries, particularly Spain. Patients infected with these strains have been adequately treated with benzylpenicillin as long as dosage is adequate. Penicillinase-producing meningococci remain extremely rare.

Chloramphenicol is a good alternative in patients hypersensitive to b-lactam antibiotics. In developing countries it is the best and cheapest alternative to benzylpenicillin. Meningococcal strains resistant to chloramphenicol have recently emerged in France.

In many industrialized countries cefotaxime or ceftriaxone is combined with vancomycin as empirical treatment of bacterial meningitis until the aetiological agent has been identified. Cefotoxime and ceftriaxone are highly effective antibiotics that penetrate the blood–brain barrier better than benzylpenicillin. Meningococci remain fully sensitive to both drugs. Meropenem is a carbapenem highly active against *N. meningitidis*, *H. influenzae*, and *S. pneumoniae*. It does not induce seizures as observed with the imipenem–cilastatin combination.

In each country the health authorities and microbiological laboratories should recommend the optimal and affordable drug regimen.

Antibiotic treatment should be initiated promptly. Immediately after the first clinical evaluation and collection of the necessary samples for microbiological diagnosis, therapy should start. If there are contraindications to lumbar puncture or if it is delayed until after brain imaging, antibiotic treatment should be started immediately. Five days of treatment is adequate to eradicate sensitive meningococci.

Supportive treatment

Patients with persistent shock should be given extensive volume replacement, whereas patients with meningitis should receive a moderate amount of fluid. All patients should be monitored closely to detect early signs of a deteriorating circulation, renal and pulmonary failure, or increasing intracranial pressure.

Volume treatment

Patients with persistent hypotension and signs of inadequate peripheral circulation require massive fluid volume repletion. The extensive capillary leak syndrome increases the volume required. Children and adults may require an infused volume that is one to several times their circulating blood volume in the first 24 h. The optimal solution has not yet been defined. Colloids are often combined with crystalloid. Albumin and fresh frozen plasma were previously extensively used. However, the use of albumin in septic shock is controversial, expensive, and was not supported in a recently published meta-analysis. In many countries the use of fresh frozen plasma is no longer recommended because of the risk of transmitting pathogens, especially HIV.

Patients presenting with distinct signs of meningitis without shock should receive the basic daily requirement of fluid supplemented with extra volume for dehydration and loss due to vomiting and fever. Excessive hydration should be avoided since it may precipitate irreversible brain oedema and cerebellar herniation. In patients with persistent shock and meningitis, treatment of shock is the priority.

Inotropic support

If initial volume repletion fails to improve the circulation, inotropic support should be added. Dopamine, dobutamine, noradrenaline, and adrenaline are used. Most physicians start with dopamine at 2 to 10 µg/kg.min, or dobutamine at 1 to 10µg/kg.min. Ideally, patients should be infused through a central line.

Corticosteroid therapy

The use of corticosteroids in meningococcal septic shock is controversial. Methylprednisolone in pharmacological doses did not increase 28-day survival in two large series of patients with septic shock of various causes. Adrenal haemorrhage is common in patients with fulminant meningococcal septicaemia. It is also present in surviving patients. In most fatal cases of meningococcal infection, plasma cortisol levels are normal or high. Few patients have low levels. However, serial measurements of plasma cortisol and adrenal stimulation tests suggest a relative deficiency. Corticosteroids are not recommended routinely unless a deficiency is documented.

The benefit of dexamethasone in meningococcal meningitis is controversial. Efficacy has never been evaluated in double-blind, randomized, controlled clinical trials involving enough patients with meningococcal meningitis to allow a firm conclusion. In an open randomized study in Egypt involving 267 patients, dexamethasone injected every 12 h for 3 days did not improve the outcome. Corticosteroid treatment has been associated with relapse of the meningitis in patients who had otherwise been adequately treated. At present, dexamethasone is not recommended for routine use in patients with meningococcal meningitis.

Ventilatory support

Patients receiving volume treatment for profound shock are in danger of developing ARDS from capillary leak syndrome and volume overload. Increasing oxygen demand, decreased pulmonary compliance, and the appearance of diffuse infiltrates on chest radiograph indicate the development of ARDS. Some paediatricians advocate elective intubation and mechanical ventilation if more than 40 ml/kg per 24 h resuscitation fluid is needed to combat the septic shock, even if the oxygenation is normal.

Renal support

Patients with persistent septic shock and coagulopathy develop renal dysfunction from acute proximal tubular necrosis. Thrombosis in the small peritubular vessels, in glomeruli, and myoglobinaemia may contribute to the renal dysfunction. Serum creatinine and urea are elevated on admission and continue to increase for many days without adequate treatment. Hyperkalaemia, which may develop during the first 24 to 48 h, is an immediate threat. If possible, continuous haemofiltration should be

used. Peritoneal dialysis, although less effective, is an alternative to continuous haemofiltration.

Treatment of disseminated intravascular coagulation

P>The first priority is to stop further bacterial proliferation with antibiotics. In the 1970s heparin was extensively used. Two small controlled trials did not document any survival benefit in patients receiving heparin. Infusion of a continuous low-dose unfractionated heparin (10 to 15 IU/kg.h) has recently been advocated as supplement to treatment with concentrated protein C. The antithrombin III levels should be kept above 35 to 40 IU/ml.

Infusion of the natural anticoagulant protein C (loading dose: 100 IU/kg, followed by 15 IU/kg.h for days to keep the plasma concentration between 0.8 and 1.2 IU/ml) may possibly limit thrombus formation, skin necrosis, and the need for amputation. If used it should be started early. In the few uncontrolled studies that have been published, several patients treated with protein C concentrate still needed amputation. Randomized controlled trials have not been carried out.

Routine transfusion of platelets is controversial. In patients with life-threatening bleeding, massive platelet transfusion may be life saving. However, it may also aggravate thrombus formation by increasing levels of PAI-1 released from the platelets.

Fibrinolysis

To overcome inhibition by PAI-1, recombinant human tissue plasminogen activator (0.25 to 0.5 mg/kg in 1.5 to 4 h) has been infused to enhance fibrinolysis. Dramatic improvement was observed in some children. Recombinant human tissue plasminogen activator increases the risk of an intracerebral haemorrhage. If used, it should be started early. Efficacy has never been evaluated in a randomized controlled trial.

Plasmapheresis and blood exchange

Plasmapheresis or exchange blood transfusion have been tried, to remove pathologically activated plasma and leucocytes; 50 ml plasma/kg body weight has been exchanged with fresh plasma. These techniques do not increase the clearance of bacterial lipopolysaccharide substantially. Results suggest improved survival but adequate control groups are lacking. Even desperately ill patients have tolerated the procedures.

Extracorporal membrane oxygenation

A limited number of children have been treated with extracorporal membrane oxygenation in a few centres with apparently good results. However, equally good results have been achieved in another paediatric intensive care unit without using the procedure, suggesting that the experience of the intensive care unit is more important than the procedure *per se*.

Neutralization of bacterial lipopolysaccharides

Three different antiendotoxin principles, the anti-J5 serum, the human monoclonal IgM (HA-1A) antibody, and the recombinant bactericidal/permeability increasing protein (BPI_{21}) have been evaluated in randomized, double-blind, controlled clinical trials. None increased survival significantly. However, fewer patients treated with BPI_{21} required multiple severe amputations and more patients had a functional outcome similar to that before illness 60 days after treatment. None of the principles are presently commerically available.

Antimediator therapy

Strategies to neutralize tumour necrosis factor-a, IL-1, bradykinin, platelet-activating factor, and prostaglandins in patients with septic shock have not increased the 28-day survival rate. They have not been specifically evaluated in meningococcal septic shock.

Sequelae

Meningitis

Neurogenic deafness occurs in 1 to 10 per cent of the patients. It develops at an early stage and is usually irreversible. Reversible paresis of brain nerves IV, VI, or VII is occasionally observed. Epilepsy, hydrocephalus, and diffuse brain damage are at present rare complications in industrialized countries.

Persistent headache, altered sleep pattern, concentration difficulties, irritability, and neurasthenia may persist in 5 to 8 per cent of all patients.

Shock and coagulopathy

Most long-term complications are related to development of gangrene of the extremities requiring amputation and necrotic skin lesions requiring extensive grafting. The renal failure is usually reversible. Permanent adrenal insufficiency develops very rarely in survivors. Acute respiratory distress syndrome may lead to permanent pulmonary fibrosis and reduced function.

Vaccination

Capsule polysaccharide vaccine (A, C, Y, and W)

The serogroup A polysaccharide vaccine is immunogenic from 6 months of age. Infants vaccinated at 3 and 7 months develop higher antibody levels than do infants vaccinated only at 7 months, suggesting a booster effect. The serogroup C polysaccharide vaccine induces a short-lived immune response at 3 months but normal immune response in children above 18 months. No booster response is present. Revaccination may reduce the antibody level. When vaccination is required for serogroup A infection, infants of less than 24 months should receive two doses with at least a 1-month interval, whereas those above 2 years should receive one dose. For serogroup C infection, one dose should be given from 18 months. In children with malaria, the immune response is reduced. An antibody level of 1 to 2 µg/ml appears to be necessary for protection.

Indications for vaccination

Routine immunization with the A, C, Y, and W polysaccharide vaccine is advocated for people with documented deficiencies in the late complement components and properdin.

Non-outbreak situation

Indications for vaccination with A or C polysaccharide vaccine are, according to Peltola: close contacts of an index case, travellers to high-risk areas, military recruits, persons with asplenia, and alcoholics.

Outbreak situation

Vaccination has been recommended if two or more are attacked by the same strain in a school class or day-care centre, the attack rate exceeds 10 cases/100 000 population per 3 months, or the attack exceeds 1/1000 with 3 or more cases in a closed group setting.

Epidemic situation

An advocated threshold for mass vaccination is 15 cases/100 000 population per week for 2 consecutive weeks caused by the same strain. A steadily increasing number of cases and an increase in the median age of the patients indicate an epidemic.

Conjungate polysaccharide protein vaccine

Serogroup C polysaccharide conjugated to a protein carrier induces a significant booster response in infants vaccinated at 2, 3, and 4 months of age. The same has been shown for toddlers. The United Kingdom is the first country to start mass vaccination with serogroup C conjugate vaccine of infants, children, and adolescents owing to the increasing number of serogroup C cases.

Outer membrane vesicle vaccine

Since the capsule polysaccharide of serogroup B strains induces a short-lived IgM but no lasting IgG response, several groups have developed an outer membrane vesicle vaccine. The protection rate after two doses is lower (57 to 80 per cent) than for the polysaccharide A, C, Y, and W vaccines and is relatively strain specific. The protection rate in children below 4 years of age is much lower than for adults. Three doses induce a significantly better immune response than two doses given with a 6-week interval. Only one vaccine is available for sale.

Secondary prophylaxis

Antibiotic prophylaxis

Household contacts of an index case have a 100 to 1000 times increased relative risk for developing meningococcal infections. Usually the second case occurs within 2 weeks of the index case if no eradication treatment is given. However, there is doubt about the effectiveness of eradication treatment when the causative strain belongs to serogroup B.

Health authorities in most countries advise that close contacts have eradication treatment with rifampicin at 10 mg/kg, maximum dose 600 mg every 12 h for 48 h. Recently, 500 mg of ciprofloxacin or 400 mg of ofloxacin as a single dose has replaced rifampicin for adults in many countries. Pregnant women should receive 250 mg, and children of less than 12 years 125 mg, of ceftriaxone as one intramuscular injection.

Future prospects

The development of effective and affordable conjugate vaccines covering serogroups A and C will be a major step forward. They will cover the age group 2 months to 2 years where protection is most required and pave the way for routine vaccination. Development of a serogroup B vaccine with documented effect for infants and children is urgently needed.

7.11.6 Neisseria gonorrhoeae

D. Barlow and C. Ison

Neisseria gonorrhoeae, the gonococcus, has changed in three important ways since the advent of effective treatment: sensitivity to antibiotics has decreased (and continues to do so); its symptom-producing capabilities have lessened; and its incubation period has lengthened. A study from the United Kingdom in the early nineties gave a mean incubation period of 5.6 days and a median of 8.6 days in men.

Pathogenesis

N. gonorrhoeae is a particularly successful pathogen, with mechanisms that evade host defences and cause repeated infection. The major antigens of the outer membrane (**OM**) of the gonococcus that are exposed to the immune response are pili, lipo-oligosaccharide (**LOS**), and three major OM proteins, Por, Opa, and Rmp. *N. gonorrhoeae* primarily colonizes columnar epithelium of the lower genital tract and only occasionally progresses to the upper genital tract or invades to cause systemic disease. Successful colonization requires attachment and invasion of the epithelial layer to avoid being swept away by cervical secretions in women or urine in men. *N. gonorrhoeae* expresses receptors on the cell surface for transferrin or lactoferrin from which iron is released, unlike many other bacteria that produce soluble sideropores. Lack of iron can be a growth-limiting factor. For invasion to occur, gonococci must resist the bactericidal activity of serum. *In vivo* gonococci are serum resistant as a result of sialylation of LOS. *In vitro* most strains revert to serum sensitive, although a few remain resistant suggesting an additional unidentified mechanism.

Pili, Opa, and LOS have the ability to alter the surface-exposed part of the molecule and hence present a new antigen to the immune system. In the gonococcus this alteration occurs at a frequency higher than the normal mutation rate and is known as antigenic variation. On each encounter between the organism and the host, the gonococcus presents a range of immunologically distinct proteins which are not recognized by the host. The interaction of these bacterial receptors with the host cell is complex and the host-cell receptors are currently being unravelled, ranging from complex carbohydrates and glycosamines to lipoproteins and glycoproteins.

Epidemiology

Gonorrhoea is almost exclusively transmitted by sexual activity and, like HIV infection, is not evenly distributed amongst the sexually active population. The highest incidence is found in young (teenaged women, men in their twenties), urban, socio-economically deprived persons and ethnic minorities. Figure 1 shows the number of cases in England up to 2000, the drop in reported cases since 1974 being reversed in the early nineties. Use of antimicrobials has less effect on endemic levels than might be expected, although it reduces the incidence of complications. Gonorrhoea facilitates HIV transmission, producing an increase in detectable virus in urethral secretions when infection is present; this is reversed following antibiotic treatment.

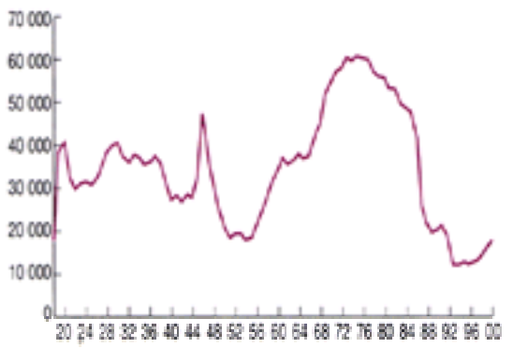

Fig. 1 Reported cases of gonorrhoea in England between 1918 and 2000 (Department of Health).

The incidence and prevalence of gonorrhoea serve as useful surrogates for unsafe sexual behaviour since diagnosis is swift and accurate and the infection can be treated and reacquired repeatedly. The incidence of neonatal gonococcal ophthalmia and the prevalence of antenatal infection measure the success, or otherwise, of a control programme. By both criteria, gonorrhoea is not a serious problem in the United Kingdom.

The infectivity of the gonococcus is probably higher from male to female and may reach 80 per cent. Condoms, when used invariably and throughout sexual contact, prevent transmission of gonorrhoea.

Symptoms, signs, and complications

Gonorrhoea in women

Because of the lack of specific symptoms there is no meaningful incubation period for uncomplicated gonorrhoea in women . The sites most commonly affected are cervix (90 per cent), urethra (75 per cent), rectum (40 per cent), and oropharynx (5 to 15 per cent). Signs at all these sites are unhelpful—the 'cervicitis' ascribed to gonorrhoea being found in other conditions and in healthly individuals. Symptoms likewise are absent or non-specific, including alteration in vaginal discharge or, rarely, mild dysuria. Women with gonorrhoea depend on notification by a partner or development of complications to alert them to the possibility of infection. Spread of the gonococcus to infect the endometrium, fallopian tubes, and pelvic adnexas is the most common complication (5 per cent of infections) and occurs at or soon after the menstrual period, probably resulting from retrograde flow of menses. Coincidental infection with *Chlamydia trachomatis* is common enough to warrant treatment of both organisms. Gonococcal infection of Bartholin's, Skene's, or periurethral glands is rare in the United Kingdom.

Disseminated gonococcal infection is four or five times more common in women than men, a reflection of women's lack of genital symptoms. Almost always caused by penicillin-sensitive organisms, disseminated gonococcal infection is a comparatively benign bacteraemia affecting joints and skin. The shoulder and knee are most commonly affected followed by the wrist, elbow, and small joints of the hands and feet, often with an associated tenosynovitis. The pathognomonic, painless, skin

lesions, usually 4 to 10 in number, evolve through vesicular, pustular, and haemorrhagic stages before healing (Plate 1, Plate 2). Erythema nodosum-like lesions have been described. The constitutional upset tends to be minimal and the white cell count and erythrocyte sedimentation rate are not greatly raised. Response to antibiotic treatment is rapid but joints may need to be aspirated. Blood or joint fluid culture may yield gonococci but the quickest diagnosis comes from anogenital and throat culture.

Perihepatitis, the FitzHugh–Curtis syndrome, more frequently appears with *C. trachomatis* than *N. gonorrhoeae*. Right hypochondrial pain, referred to the shoulder, occasionally with pleural effusion and rub, results in referral to a surgeon or a general, rather than geniturinary, physician.

Gonorrhoea in men

Affected sites are the urethra and oropharynx, and the rectum in homosexual men. Rectal and throat infections tend to be silent while discharge is the commonest urethral symptom. When the infection is fully developed, the discharge is white/yellow/green and profuse, staining the underwear. Differential diagnosis includes foreign body and, unusually, non-gonococcal urethritis. Scanty mucoid or mucopurulent discharge is seen in early infection. Discomfort on urination no longer seems to be severe or as common as before, with one large United Kingdom study eliciting dysuria as a presenting symptom in only 50 per cent of men. Asymptomatic patients (less than 10 per cent) include presymptomatic, post-symptomatic, and unobservant men. Urethral gonorrhoea acquired following fellatio is increasingly seen in gay men practising 'safe' sex and may be passed on as rectal gonorrhoea to a regular partner. Infection spreading to the epididymis and testis is more often due to *C. trachomatis* than the gonococcus, and other complications—tysonitis, prostatitis, periurethral abscess, or infection of the median raphe—constitute very few cases in the United Kingdom.

Diagnosis

Microscopy

Even in genitourinary medicine departments, the majority of patients will not have gonorrhoea. Much time and effort is spent excluding rather than diagnosing the disease. Investigations therefore need high sensitivity. The diagnosis of gonococcal infection is easier in men than in women.

Microscopy of a suitably stained specimen is the first line in diagnosis. The organisms must be Gram-negative, intracellular (within the cytoplasm of a leucocyte), and diplococci (GNID) (Plate 3). In samples from the male urethra, microscopy is highly sensitive (identifying 98 per cent of positives) and highly specific (less than 1 per cent will be found on culture to be *Neisseria meningitidis* or other species).

Microscopy of stained samples from rectum, cervix, and female urethra although much less sensitive, with identification of only 55 per cent or less of true positives, should still be performed since it has the advantage, where positive, of enabling immediate diagnosis and treatment. Because of the preponderance of other neisserias in the oropharynx, microscopy of samples from this site is not helpful.

Routine culture of samples from the male urethra provides an important means of quality control of the laboratory service, so crucial for diagnosis in women. It also enables assessment of antibiotic sensitivities and other characteristics of the organism for epidemiological and management purposes.

Laboratory detection of *N. gonorrhoeae*

Isolation of the causative organism, *N. gonorrhoeae*, has been regarded as the gold standard for the diagnosis of gonorrhoea for many years. However, the application of molecular techniques, such as polymerase chain reaction or the ligase chain reaction, are being more widely used.

Isolation and identification of *N. gonorrhoeae*

N. gonorrhoeae is fastidious in its growth requirements. It needs an enriched medium, such as Thayer–Martin or Modified New York City, which consist of GC agar base supplemented with a source of iron (lysed horse blood) and essential amino acids and glucose (IsoVitaleX or Vitox), and incubation in moist conditions with 5 to 7 per cent carbon dioxide at 37°C. Good specimen collection and efficient transport to the laboratory are crucial to successful isolation.

Specimens are taken using disposable loops or swabs and inoculated in the clinic or sent to the laboratory in transport medium. The isolation rates vary little if the specimen is dealt with rapidly. Isolation is enhanced by the addition of antibiotics to the medium to suppress other organisms that colonize the anogenital tract. While occasional problems can arise due to antibiotic-sensitive strains, a selective medium is essential and non-selective media should only be used as an adjunct not as a replacement.

After incubation, colonies that are oxidase positive (presence of cytochrome c oxidase), Gram negative, and cocci are considered to be *Neisseria* spp. In many parts of the world this would be considered presumptive identification of *N. gonorrhoeae*. However, in the industrialized world confirmation of identity as *N. gonorrhoeae* is usual. Historically, this has been achieved using carbohydrate utilization tests; *N. gonorrhoeae* differs from other species in that it alone produces acid from glucose. Identification kits combining carbohydrate utilization and enzyme profiles are commonly used. An alternative approach is to use immunological reagents; two reagents are available which contain antibodies raised to epitopes on the two types of the major outer membrane protein, Por or PI, linked to fluorescein (GC Microtrak, Syva Company, USA) and to staphylococcal Protein A (Phadebact Monoclonal GC OMNI test, Boule AB Sweden). These sensitive and specific reagents can identify colonies direct from the primary isolation medium and a result can be obtained on the same day as the organism is isolated. Correct identification of *N. gonorrhoeae* is most important in cases of sexual or child abuse. In such instances it is sensible to use more than one of the identification tests available to confirm an isolate as *N. gonorrhoeae*.

Molecular detection of *N. gonorrhoeae*

Antigen detection assays for *N. gonorrhoeae*, both immunological and molecular, have been largely unsuccessful because they offer little advantage over the Gram stain and culture and they cannot provide an organism for susceptibility testing. However, the sensitivity and specificity of detection assays by DNA amplification, polymerase chain reaction (**PCR**) and ligase chain reaction (**LCR**), now appear to be equal or superior to conventional techniques and may be less affected by suboptimal handling or transport. These assays may also be useful on non-invasive specimens such as urine or self-taken swabs. Currently there are no molecular tests available for determining antibiotic susceptibility, but the sequence of the appropriate resistance genes or mutations is known and could be detected using PCR or LCR. Assays that offer the combination of detection of *N. gonorrhoeae* and susceptibility to antibiotics are likely to be available in the near future.

Typing

Typing is useful for studying reinfection, treatment failure, coinfection, and to show correlations with pathogenicity and antimicrobial susceptibility patterns. Auxotyping is the determination of nutritional requirement. A large number of auxotypes have been described but in most studies three or four types predominate: non-requiring (NR) or prototrophic (Proto), proline-requiring (Pro), arginine-requiring (Arg), and those requiring arginine, hypoxanthine, and uracil (AHU). Serotyping, using a panel of monoclonal antibodies, divides strains into 24 IA serovars and 32 IB serovars. Auxotyping and serotyping are often used in combination to produce auxotype/serovar (A/S) classes giving greater discrimination. A variety of genotypic methods have also been used, from plasmid analysis, which is poorly discriminatory, to pulse-field gel electrophoresis or DNA sequencing, which are highly discriminatory.

Antibiotic resistance

Penicillin has been used as first-line therapy for gonorrhoea for many years. *N. gonorrhoeae* is inherently sensitive to most antibiotics such as penicillin, but with increased usage both chromosomally-mediated and plasmid-mediated resistance has developed. Resistance is most prevalent in the developing world where the incidence of gonorrhoea is high and appropriate antibiotics are often unavailable or misused. However, in the industrialized world these strains are often imported and then spread by the indigenous population. In 1989 the World Health Organization issued new guidelines for the treatment of gonorrhoea stating that penicillin should only be used as first-line treatment if the gonococcal population is known to be sensitive. If resistance is high or the susceptibility of the gonococcal population is unknown, alternative treatment is recommended: ciprofloxacin (a quinolone), ceftriaxone (a third-generation cephalosporin), or spectinomycin (a macrolide). Of these

antibiotics, ciprofloxacin is used increasingly is the United Kingdom because it is administered orally and is highly effective and inexpensive.

Chromosomally-mediated resistance

Decreased susceptibility to penicillin was detected as early as 1958, but this could be overcome by increasing the dose of penicillin and by adding probenecid. It was not until the 1970s that strains begun to appear with minimum inhibitory concentrations (**MICs**) to penicillin of greater than 1.0 mg/l and posed a therapeutic problem. Chromosomal resistance to penicillin in *N. gonorrhoeae* is the result of the additive effects of mutations at multiple loci, *penA*, *mtr*, and *penB*, the products of which reduce the permeability of the cell wall to penicillin.

Resistance to the alternative therapies—ceftriaxone, spectinomycin, and ciprofloxacin—has begun to emerge. Therapeutic failure to ceftriaxone has not yet been documented, but the loci responsible for chromosomal resistance to penicillin also confer decreased susceptibility to the earlier cephalosporins. If this type of resistance to penicillin continues to increase and is treated inappropriately, resistance to cephalosporins could emerge. Therapeutic resistance to spectinomycin has been reported sporadically, is high level, and due to a mutation on the chromosome that affects ribosomal binding. Spectinomycin has been an extremely useful antibiotic in treating resistant gonorrhoea and may be important in the future if mechanisms of resistance continue to evolve to newer antibiotics. Ciprofloxacin is now a popular alternative for the treatment of gonorrhoea because it is highly effective in a single oral dose of 500 mg. However, high-level resistance, resulting in therapeutic failure, has emerged in strains primarily originating from the western Pacific with mutations in the DNA gyrase gene, *gyrA*, and the topoisomerase IV gene, *parC*. The level of resistance may be enhanced by additional mutations in the *gyrB* gene or in changes in cell wall permeability, possibly due to efflux mechanisms. Surveillance of gonococcal isolates in the Western world should prolong the life of this useful antimicrobial agent.

Plasmid-mediated resistance

N. gonorrhoeae exhibiting plasmid-mediated resistance to penicillin were first described in 1976. Simultaneous reports appeared of two strains, one from Africa carrying a plasmid of 3.2 megadaltons (MDa) and the second from the Far East carrying a plasmid of 4.4 MDa. Both plasmids encode for the TEM-1 type b-lactamase (penicillinase). The smaller plasmid of 3.2 MDa has a deletion from the 4.4 MDa plasmid in a non-functional region. Penicillinase-producing *N. gonorrhoeae* carrying the 3.2 MDa and 4.4 MDa plasmids have now disseminated worldwide, although their prevalence is greatest in countries of the developing world. Penicillinase-producing *N. gonorrhoeae* carrying plasmids of differing size (2.9, 3.0, and 4.8 MDa) have been described more recently but have not spread in the same manner.

In 1985 plasmid-mediated resistance to tetracycline was first detected. It is high-level (MIC ³ 16 mg/l) and is due to the acquisition of the *tetM* determinant by the conjugative plasmid of *N. gonorrhoeae* resulting in a plasmid of 25.2 MDa. Strains carrying this plasmid are known as tetracycline-resistant *N. gonorrhoeae*. Tetracycline is not the treatment of choice for gonorrhoea but is commonly used, particularly in African countries, because it is inexpensive and available.

Susceptibility testing

The primary aim of susceptibility testing of *N. gonorrhoeae* is to predict therapeutic failure. However, it is also important to monitor drifts in susceptibility and to detect the emergence of resistant strains to the main first-line therapies. There is much controversy over the correct method for achieving this for gonococci. Determination of zones of inhibition around antibiotic-containing discs has been the method chosen by most clinical laboratories, but gonococci vary in their growth patterns and this method can be difficult to control and interpret. In recent years the breakpoint agar dilution technique, which uses one or two concentrations of antibiotic to estimate the MIC and categorize strains into susceptible, reduced susceptibility, and resistant, has been used increasingly. Determination of the full MIC is not necessary for most laboratories and is best performed by reference centres.

Plasmid-mediated resistance to penicillin can be easily detected using the chromogenic cephalosporin (nitrocefin) test, which can be performed direct from the primary isolation plate. Plasmid-mediated resistance to tetracycline can be detected using either the absence of a zone of inhibition around a 10 µg tetracycline disc or presence of growth on GC agar containing 10 mg/l of tetracycline. In a similar manner, high-level resistance to ciprofloxacin can be detected by screening for isolates that can grow on agar containing 1 mg/l ciprofloxacin.

Treatment

Treatment of uncomplicated gonorrhoea in both sexes is ideally by a single dose of antibiotics, the choice of which will depend on where the infection was acquired and from whom. In the Far East and Africa, a high percentage of strains will have chromosomal and/or plasmid-associated resistance, whereas organisms in the United Kingdom, unless imported, are still largely sensitive to penicillin, and with doses less than those required, say, in America. Standard treatment should cure at least 95 per cent of presenting cases of gonorrhoea and, in the United Kingdom, 2 or 3 g of amoxycillin or ampicillin, with 1 g of probenecid achieves this aim. Alternatively, 500 mg of ciprofloxacin has the advantage of higher cure rates in oropharyngeal infection. Treatment with 250 mg of ceftriaxone, 500 mg of spectinomycin, or 500 mg of cefotaxime, all intramuscularly, is suitable for infections acquired outside the United Kingdom, cefotaxime being particularly useful for organisms with both plasmid and high chromosomal resistance such as those found in the Philippines.

Many physicians add 1 g of azithromycin, or 100 mg of doxycycline twice daily for 1 week, for possible coincidental chlamydial infection.

American and British guidelines suggest that gonococcal pelvic infection or perihepatitis be treated with parenteral antibiotics although the evidence for this is not strong. All are agreed that antichlamydial therapy should be included. A single intramuscular dose of 250 mg of ceftriaxone or 2 g of cefoxitin, followed by 100 mg of doxycycline and 400 mg of metronidazole, both twice daily for 2 weeks, is recommended. For infection acquired in the United Kingdom, with no foreign connections, cure should occur with any of the standard single-dose treatments followed by doxycycline with metronidazole for 2 weeks, as above.

Gonococcal epididymo-orchitis can be treated with 500 mg of ciprofloxacin followed by 100 mg of doxycycline twice daily (or 2 g of erythromycin stearate daily in divided doses) for at least 2 weeks. A scrotal support eases symptoms.

Tracing of contacts of all cases of gonorrhoea and exclusion of other sexually transmitted infections must be undertaken.

7.11.7 Enterobacteria, campylobacter, and miscellaneous food-poisoning bacteria

G. T. Keusch and M. B. Skirrow

Humans are colonized by a huge number of micro-organisms, prominent among which are the Enterobacteriaceae, a large grouping of small, facultatively anaerobic, Gram-negative bacilli capable of residence in the gastrointestinal tract, and therefore often grouped together as the enterobacteria. However, Enterobacteriaceae are not just commensals in the intestinal flora; they may also be important causes of disease, both locally in the gut and at times invasively in the blood and elsewhere in the body. This chapter begins with a short general description of enterobacteria and the infections they cause outside the intestinal tract. It then focuses on these organisms as enteric pathogens. In the latter role the enterobacteria most often cause diarrhoea, which remains a major cause of morbidity in advanced industrial economies and mortality in developing countries, especially among children.

Although *Salmonella typhi* and *S. paratyphi*, the causes of typhoid and paratyphoid fever, are enterobacteria, their special attributes are described in detail in Chapter 7.11.8. Likewise, *Yersinia* infections are described in Chapter 7.11.17. However, enteritis due to Gram-negative non-Enterobacteriaceae, namely *Campylobacter*, *Aeromonas*, *Plesiomonas* spp., *Vibrio parahaemolyticus*, and other non-cholera vibrios are included here. Descriptions of food poisoning due to the Gram-positive bacteria *Clostridium botulinum* and *C. perfringens* are provided in Chapter 7.11.21. *Bacillus cereus*, and *Staphylococcus aureus* food poisoning are presented here. An overview of infections of the intestinal tract is given in Chapter 14.17.

The enterobacteria

Definition and general description

Strictly speaking, the term 'enterobacteria' applies to members of the large family Enterobacteriaceae that are found in the intestinal tract of humans and animals, or are associated with plants and soil. Classical taxonomy based on biochemical and immunological criteria has resulted in a family that includes a number of major tribes with widely varying properties, including 30 genera and at least 120 species. Within these various tribes, the genera most likely to be encountered in medical practice are *Salmonella, Shigella, Escherichia, Klebsiella, Enterobacter, Citrobacter, Serratia, Hafnia, Edwardsiella, Erwinia, Kluyvera, Proteus, Providencia, Morganella*, and *Yersinia.* However, this classical schema is likely to be altered as DNA homology becomes the basis of microbial classification. *Escherichia coli*, *Salmonella* spp., and *Shigella* spp. are the principal enteric pathogens among these groups. The others may cause enteric disease but are more commonly the cause of systemic infection, usually through a specific portal of entry, especially in immunologically compromised hosts.

Enterobacteriaceae are Gram-negative, oxidase-negative, non-spore-forming straight rods, most of which are motile by means of peritrichous flagella. Although they are aerobes, many are capable of growth under anaerobic conditions. Microbiologists divide the group into those capable of mixed-acid fermentation resulting in the production of acetate from pyruvate (such as *Escherichia coli, Salmonella,* and *Shigella*) and those that produce butanediol as the end-product of fermentation (*Serratia, Enterobacter,* and *Erwinia*). They are easy to cultivate in the laboratory on simple bacteriological media (most can grow using D-glucose as the sole source of carbon, producing acid), indeed they often outgrow and mask the presence of more fastidious bacteria. However, they are vulnerable to environmental stress, such as heating to 60 °C for 20 min, and desiccation. Many are acid-sensitive, but some are resistant to acid pH, which may serve as a virulence factor in the gastrointestinal tract.

The clinical microbiology laboratory takes advantage of the inability of *Salmonella* and *Shigella* spp. to ferment lactose by screening cultures for the presence of non-lactose-fermenting organisms. This is a useful initial and simple distinguishing feature, because virtually all other enterobacteria—with the exception of *Proteus, Providencia*, and *Morganella*—ferment lactose freely. By including lactose and a pH indicator in a culture medium, the colonies of non-lactose fermenters stand out from the lactose fermenters, which produce acid and change the colour of the included pH-sensitive indicator dye. This makes it simple to pick the pale non-lactose-fermenting colonies for further study. The lactose-fermenting enterobacteria are commonly grouped together as 'coliforms', a clinically convenient term that has little logic to commend it. It is particularly unfortunate that this rubric may serve to hide significant pathogens, as the notation is often interpreted to mean harmless organisms resembling ordinary *E. coli*.

Microbial structure and antigenicity

The Enterobacteriaceae are typical Gram-negative rods, in that they possess a complex cell wall containing three major layers: (1) the inner cytoplasmic membrane; (2) an intermediate region made up of peptidoglycan; and (3) an outer cell membrane, which is itself composed of an inner phospholipid–protein layer and an outer covering of lipopolysaccharide (**LPS**). In addition, some members of the group possess an outermost antigenic carbohydrate capsule, while others possess one or more flagella and hence are motile. The cytoplasmic membrane functions, as it does for all micro-organisms, to regulate the transport of metabolites, sugars, amino acids, small peptides, and ions into and out of the microbial cell. Peptidoglycan, a long-chain linear polymer and structural element common to Gram-positive and Gram-negative bacteria, covers this membrane. It is composed of alternating *N*-acetylmuramic acid and *N*-acetylglucosamine residues with a pentapeptide side chain terminating in a D-alanyl- d-alanine dipeptide. This dipeptide is the site for the formation of crosslinking peptide bonds between adjacent linear aminosugar chains, providing structural stability to the bacterial cell. Crosslinking is catalysed by transpeptidase enzymes, which are the targets of action of the b-lactam antibiotics, such as the penicillins and cephalosporins.

A major difference in the peptidoglycan layer between Gram-positive and Gram-negative bacteria is the greater thickness of the structure in Gram-positive bacteria. The region between the peptidoglycan layer and the outer cell membrane is known as the periplasmic space. Critical cell functions also take place within this space, for example the assembly and modification of microbial proteins and antigens that are inserted in, or excreted through, the outer layer. The latter is a complex structure commonly referred to as endotoxin because it contains lipid A, the endotoxic moiety of LPS, linked to a common-core carbohydrate structure. A highly variable polymer of sugar residues, the O-specific oligosaccharide chain, is displayed on the outermost microbial surface, and contains critical, specific, heat-stable antigenic carbohydrate determinants designated O-antigens. Oligosaccharides, even when composed of just a few sugar residues, are well suited to express immunologically specific and recognizable antigens, because they permit a large number of small stereospecific changes that can be distinguished by antigen-specific antibodies. It is this structural feature of the O-specific oligosaccharides that permits the separation of many different O-antigen serotypes within a species—160 in *E. coli* alone. In the case of motile strains, flagellar proteins are also expressed well, so additional heat-labile protein (H) antigens are identifiable. Finally, some Enterobacteriaceae produce an outer capsular layer possessing yet more (carbohydrate) antigens designated K antigens. K antigens may cover and mask the underlying O-antigens and obscure the identity of the organism unless first removed by boiling the culture.

Taken together, these three types of antigen form the basis of a useful system for the identification and differentiation of enterobacteria in the laboratory, originally devised by Kaufmann and White. Because these antigens induce the formation of specific antibodies, which may be employed as immunoreagents that are specific for particular microbial structures, they turn out to be highly useful for the serological diagnosis of specific infections. When there is a rise in antibody to the O, H, and, if present, K antigens, which represent the 'signature' of particular members of the group, a serological diagnosis can be made. However, adding to the complexity, a single organism can express multiple O, H, and K antigens and individual antigens; moreover, O-specific oligosaccharides may be shared by two or more specific organisms within a genus or across species. Therefore immunological identification of individual organisms and serological diagnosis of an infection is based on the pattern of antigens detected, or on a significant rise in antibody titre to a particular battery of antigens. This serological 'fingerprint' is often supplemented by biological

and biochemical information for the purposes of identification. Capsular antigens, when present, can add additional information, for example the Vi antigen of *Salmonella typhi*, which is shared with just one organism, *Citrobacter freundii*. Serological identification of specific strains of enterobacteria is of enormous utility for epidemiological investigations.

Extraintestinal infections caused by enterobacteria and related organisms

Before proceeding to specific diarrhoeal diseases caused by enterobacteria, a brief account of their infective role elsewhere in the body is provided. It is convenient to include other non-fastidious Gram-negative bacilli that behave clinically in a similar manner to enterobacteria and which are often found in mixed infections with them. Chief among these is *Pseudomonas aeruginosa*, which is notorious as a 'hospital' organism and as a cause of opportunistic and sometimes fatal systemic infection in debilitated or immunosuppressed patients. *Ps. aeruginosa* is naturally resistant to most of the commonly used antimicrobials and also to many antiseptics. Indeed certain pseudomonads, notably *Ps. cepacia*, are capable of growth in antiseptic solutions stored at dilute working strengths in hospital wards. Other common opportunistic Gram-negative bacilli are found in the genera *Alcaligenes, Acinetobacter, Aeromonas, Flavobacterium*, and *Chromobacterium*.

Gram-negative sepsis occurs when these organisms reach the bloodstream and result in clinical symptoms. The incidence of Gram-negative sepsis steadily increased from the 1970s to the 1990s, particularly in hospital patients. The widespread use (and abuse) of broad-spectrum antibiotics, which were generally more active against Gram-positive bacteria, is one reason, but another is the increasing proportion of susceptible patients being treated: more elderly patients; more receiving immunosuppressive or cytotoxic therapy; more with catheters, pacemakers, and prostheses that provide favourable sites for infection; and more undergoing more complex and adventurous surgery. Enterobacteria, pseudomonads, and similar Gram-negative bacilli easily acquire resistance to antimicrobials, which helps them to colonize the hospital environment. Such organisms quickly replace the normal sensitive bowel flora of patients admitted to hospital, particularly if antibiotics are being given. In this way the patient's anus becomes the gateway to colonization and infection elsewhere in the body. Interestingly, during the past decade Gram-negative bacteraemia diminished relative to Gram-positive bacteraemia. Today, almost 50 per cent of bloodstream isolates are Gram-positive (Table 1). This reflects acquired resistance among the Gram-positives and the use of newer broad-spectrum drugs with better coverage of the Gram-negative bacteria, which are often given empirically for the treatment of presumptive infection without a specific known aetiology.

It is against this background that one must consider Gram-negative sepsis, and it is not surprising that these organisms turn up in a wide variety of clinical material. They are frequently found colonizing wounds, sinuses, ulcers, burns, and chronically discharging ears—in fact wherever the body integument is broken. In many cases they are probably of little consequence, but their presence deep in a wound may cause harm by consuming oxygen and enhancing the growth of anaerobes. This is a common finding in foot infections in diabetic patients, for example. Distinguishing between simple colonization and infections of consequence can be challenging. This is one reason why practice of the specialty of infectious diseases requires both knowledge and thoughtful analysis—reflex administration of antimicrobials can be harmful to the health of the patient.

Specific types of infection

Urinary tract infection (Chapter 20.12)

The urinary tract is the most common site for genuine infection as opposed to simple colonization. Such infections range from a simple cystitis to pyelonephritis and pyonephrosis. Most infections are caused by *E. coli*, but resistant strains of *Klebsiella*, *Enterobacter*, *Proteus*, and *Ps. aeruginosa* are more likely to be the infecting agents in patients with complications: those with indwelling catheters; those who have undergone genitourinary surgery; and those with recurrent episodes of urinary tract infection treated with many courses of antimicrobial therapy. Septicaemia may arise from such infections, particularly after surgery (Chapter 7.5); even the simple removal of a urethral catheter from an infected individual may cause bacteraemia. *E. coli* strains causing parenteral infection usually belong to one of only 12 or so serogroups. Proteus infections in male children should alert a clinician to the possibility of a congenital abnormality of, for example, a urethral valve.

Sepsis linked to the intestinal tract

In these infections coliform bacteria are usually found with other bowel flora such as *Bacteroides* spp. and microaerophilic streptococci. Peritonitis secondary to a perforated bowel, intraperitoneal abscess (for example, pelvic, subphrenic, retrocaecal), cholecystitis, cholangitis, and liver abscess are examples of such infections. Coliforms and other bowel flora may also cause remote focal infections such as endocarditis or cerebral abscess.

Respiratory tract infections (Chapter 17.5.2)

Coliform bacteria seldom cause significant respiratory tract infections, but they are often isolated from sputum samples due to a tendency to colonize the mouths and upper respiratory tract of ill patients, particularly babies, the elderly, and debilitated patients in the intensive-care unit. Such colonization is significantly encouraged by antimicrobial chemotherapy, but this is not essential. The presence of colonizing coliforms in sputum is therefore commonly of no immediate clinical consequence, although true pneumonia may result. A classical example is caused by *Klebsiella pneumoniae* subspecies *pneumoniae* (Friedlander's bacillus), which has a characteristic morphology in the Gram stain of sputum (a fat Gram-negative rod with a large capsule) and a particular radiological appearance in the lung (sagging fissure, presumably due to the weight of capsular polysaccharide present). However, this organism accounts for only a tiny proportion of all bacterial pneumonias; most of the klebsiellae isolated from sputum are of the common aerogenes type and are not endowed with the thick capsule that characterizes *K. pneumoniae*. Patients with bronchiectasis or cystic fibrosis are especially prone to chronic bronchial superinfection, notably with capsulated 'mucoid' variants of *Ps. aeruginosa*.

K. ozaenae and *K. rhinoscleromatis* are associated with the uncommon nasal diseases ozaena and rhinoscleroma (Chapter 7.11.9). In the tropics, *Chromobacterium violaceum* occasionally causes a potentially fatal, rapidly progressive, septicaemic illness, with pneumonia and multiple abscess formation.

Neonatal infections

Newborn babies are especially liable to suffer from serious Gram-negative infections. This may be partially due to the immaturity of some host defence mechanisms, for example the complement system. Gram-negative septicaemia, which usually arises from an infected umbilicus, invariably involves the meninges as an incipient, if not overt, meningitis (Chapter 24.15.1). Fortunately such events are rare, but coliforms are the most common cause of neonatal meningitis, a fact that contrasts sharply with the scarcity of coliform meningitis after the age of 1 month. *E. coli* is usually responsible, but any of the enterobacteria may be involved. *Proteus mirabilis* infections, which take the form of a meningoencephalitis, are particularly severe, and occasionally this common organism, for reasons that are not understood, has caused disastrous outbreaks in hospital nurseries.

Specific enterobacterial infections of the gut

Escherichia coli infections

We begin with *E. coli* because the genus illustrates the vast range of pathogenic mechanisms available to the enterobacteria, together with the varied pathophysiology and clinical manifestations that ensue from infection. Most *E. coli* do not cause human illness, but are merely commensals that colonize the lower intestine from the terminal ileum to the anus. It is this property that has given rise to the term 'coliforms'. However, some have acquired virulence factors that have placed them among the leading causes of diarrhoea, particularly in the developing world. The concept that *E. coli* might be capable of causing enteritis is not a recent one. In 1895 the German paediatrician, Escherich, suspected that certain strains of '*Bacterium coli*' caused infantile diarrhoea, but attempts to differentiate pathogenic from non-pathogenic strains were unsuccessful, mainly because adequate serological classification was not then available. In the past 25 years, the combined approach using epidemiology, clinical research, and molecular biology has identified at least five distinct groups of *E. coli* that cause disease when they colonize the intestine of non-immune subjects, typically young children, or less commonly adults with no prior contact with these organisms (Table 2).

Enterovirulent *E. coli* possess a number of specific virulence genes, in addition to sharing the general properties of *E. coli* encoded in the genome of K-12 strains (the minimal genome necessary to be classified as an *E. coli* species). These are often concentrated in islands of DNA known as 'pathogenicity islands', which are segments of DNA that differ significantly in base composition from the backbone *E. coli* K-12 genome, signifying that they have most likely been imported from other bacteria by DNA transfer, infecting phage, or via plasmids. It is the cluster of virulence genes present in strains of *E. coli* that give each the capacity to cause specific types of intestinal disease. These clusters of virulence genes are often associated with specific O and H serotypes, which thus may serve as surrogate and putative markers for pathogenic strains; although as discussed below, this is not always sufficient to define which *E. coli* are the pathogens (see Table 2). The five groups of

enterovirulent *E. coli* are now described.

Enteropathogenic E. coli (EPEC)

EPEC strains are most important as a cause of endemic diarrhoea in developing countries, where they primarily infect children between the ages of 6 and 18 months. In developed countries, EPEC infection has declined to low levels over the last several decades. Some EPEC can infect adults, often in the context of traveller's diarrhoea. Their discovery goes back to the early 1940s when certain *E. coli*, recognized by the production of a distinct odour when grown on agar plates, were associated with severe outbreaks of diarrhoea in neonatal nurseries. When the Kaufmann–White scheme for serotyping *E. coli* was subsequently developed, these original strains, designated EPEC, were found to be from serogroups O111 and O55. Over the years, additional serotypes have been added to the EPEC group (see Table 2), and the epidemiology has changed from that of a strong association with neonatal units to that of a watery diarrhoea in young infants and children between 6 months and 3 years of age. Hospital microbiology units were capable of serotyping the 12 most frequent O-antigen types associated with these infections using commercial kits. Hospital clinical laboratories could then report back that a potentially enteropathogenic serotype of *E. coli* was isolated.

The modern era in the study and definition of EPEC was ushered in by the first successful human experimental infections with EPEC strains in 1978. In this experiment, two of three EPEC strains (an O127 and an O142) previously isolated from neonatal diarrhoea outbreaks caused clinical illness in adult United States volunteers, whereas the third (an O128) as well as a classical 'normal flora' strain (HS) were clinically benign. This indicated that it was possible to distinguish between virulent and avirulent EPEC and explain the finding that had puzzled clinical investigators and microbiologists for quite some time, namely that EPEC serotypes were frequently isolated from clinically well individuals. The use of animal models and *in vitro* experiments with cultured human cells soon demonstrated that virulent EPEC caused a unique pathological lesion. This consisted of the close attachment of organisms to the host intestinal-cell membrane and a change in the structure of the microvillus, which effaced and mounded up to form a platform-like pedestal upon which the attached organism was found. This characteristic change was therefore designated the 'attaching and effacing' (**A/E**) lesion, and was soon shown to occur *in situ* in human patients from whom biopsy tissue was available.

Clinical features

After an incubation period of a few days, the duration being inversely related to the inoculum size, the onset of diarrhoea is abrupt or gradual, with a tendency for cases with an abrupt onset to be more ill than the others. The stools become loose and green, then orange-coloured, and eventually watery. Vomiting is common in more severely affected children and it may even be projectile. The combination of watery diarrhoea and vomiting quickly leads to dehydration. The child is at first irritable, may have convulsions, and the temperature rises to 39 to 40 °C. In the absence of prompt fluid replacement, dehydration and metabolic disturbances may become irreversible, with the result that the child becomes apathetic, hypotensive, hypoglycaemic, and dies. Yet the disease may be mild, and marked only by the passage of a few loose stools without vomiting or general illness; this is the usual pattern in healthy children in developed countries. Occasionally, especially in poorly nourished infants in developing countries, the loose stools persist for days or even weeks, but beyond this time it becomes increasingly likely that other factors are involved, and in these subjects enteroaggregative *E. coli* may be identified.

Enteroaggregative E. coli (EaggEC)

EaggEC are typically associated with infantile diarrhoea, and seem to be more commonly present in cases of persistent diarrhoea lasting more than 14 days. It is not clear whether these organisms are the cause of these persistent episodes, or whether they are simply able to colonize the intestine damaged by another cause of diarrhoea. Persistent episodes are associated with significant nutritional deficits, and in developing countries EaggEC are a major cause of diarrhoeal mortality in young infants. When investigators first began to classify isolates of *E. coli* associated with diarrhoea by determining the pattern of adherence to certain cells in tissue culture, three distinct types were identified: those attaching in discrete packets; those adhering diffusely to the whole perimeter of the cell; and those that appeared to autoaggregate, stacking upon one another like bricks in a wall. Initially, this phenotypic characteristic, and then molecular methods that were used to identify associated and putative virulence genes, helped to define the epidemiology of EaggEC. The precise pathogenesis of EaggEC infection remains to be defined. A heat-stable toxin designated **EAST** (enteroaggregative stable toxin) has been identified in many isolates and appears to be a marker of virulence.

Enterotoxigenic E. coli (ETEC)

ETEC are common causes of diarrhoeal disease at any age. Because they produce toxins related to cholera toxin, ETEC can result in a clinical illness that resembles cholera. For most of these infections, the source is usually contaminated food or water. The inoculum size is generally high, and therefore contaminated unrefrigerated food can be an excellent vehicle in which a small inoculum can multiply to sufficient numbers to cause disease.

In studying patients with clinical cholera from whom *Vibrio cholerae* could not be isolated, investigators working in Calcutta in the mid-1960s found certain *E. coli* serotypes which, to their great surprise, caused fluid secretion in animal diarrhoea models. Two major classes of enterotoxins have since been identified: heat-labile proteins called labile toxin (**LT**), of which several subtypes have been identified; and small heat-stable peptide toxins (**ST**), which possess multiple disulphide bonds that enhance their resistance to heat inactivation, of which several subtypes have also been identified. LT acts in a manner similar to cholera toxin, catalysing the ADP-ribosylation of adenylate cyclase, the host enzyme involved in the production of cyclic-AMP. This product is an intracellular signal which, in intestinal epithelial cells, leads to a reduction in sodium absorption and increase in chloride secretion. The accumulation of excess NaCl in the intestinal lumen results in the movement of water into the lumen to maintain isosmolarity, which results in diarrhoea when the volume exceeds the absorptive capacity of the gut. It was a surprise, however, when ST was found to activate the particulate guanylate cyclase of intestinal epithelial cells and to increase intracellular cyclic-GMP, which also increased the lumenal accumulation of NaCl to cause diarrhoea, because in most other systems the effects of cAMP and cGMP tend to offset one another, providing the basis for an effective feedback control system.

ETEC also colonize the small intestine by means of adherence factors termed 'colonization-factor antigens' (**CFAs**). These are plasmid-encoded proteins expressed on the surface of the bacterium, either on a pilus or as a surface-displayed antigen. Some *E. coli* express more than one CFA antigen. These adhesins are used by the organism to attach to host cells via specific binding-to-host-cell receptors. These events are essential for virulence, for without the adherence mechanism, ETEC would just pass through the small bowel instead of intensely colonizing the proximal small bowel, a feature essential to the production of enterotoxins such as LT and ST.

The main features of ETEC infection are diarrhoea and vomiting, but proportionally more older children are affected compared with EPEC infection, and the fluid losses usually result in mild to severe dehydration. There is nothing particularly distinctive about this presentation, and it is difficult to distinguish between ETEC and rotavirus diarrhoea in these young children.

Enteroinvasive E. coli (EIEC)

Enteroinvasive *E. coli* were first identified as a cause of bloody diarrhoea in an outbreak in the United States that was traced to contaminated imported French Camembert cheese. In subsequent studies, these organisms have been identified in a low percentage of diarrhoeal illnesses in children under the age of 5 years in developing countries. These infections are rarely bloody or dysenteric, although some serotypes have been associated with a shigella-like illness . These serotypes have been shown to possess genes similar to those of *Shigella*, conferring the property of invasion of epithelial cells (this is described more fully below in the section on *Shigella*). Suffice it here to say that the products of these genes induce normally non-phagocytic cells, such as intestinal epithelial cells, to ingest the organisms within a phagocytic vacuole. Intracellular multiplication of the organisms is associated with cell damage, possibly by an apoptotic mechanism, and altered host physiology leading to diarrhoea.

In some geographical locations, EIEC are identified in about 5 per cent of watery diarrhoea episodes. They may cause disease in adults as well as children. Foodborne outbreaks have also occurred in industrialized nations, sometimes due to the importation of food from other industrialized nations tainted with the pathogenic organisms. EIEC are not as well adapted as pathogens as are *Shigella* spp., which require fewer bacteria to cause illness and generally result in more severe symptoms and complications. Clinically, EIEC infection is indistinguishable from most other causes of watery diarrhoea.

Enterohaemorrhagic E. coli (EHEC)

These organisms appear to be an evolutionary development of EPEC, as they possess the genetic determinants for the A/E lesion, engage the same signal-transduction pathways, and produce the characteristic pathological changes in the gut mucosa as EPEC. They were first identified in the United States during 1982 associated with outbreaks of bloody diarrhoea traced to contaminated hamburgers from fast-food restaurants. A serotype of *E. coli*, O157:H7, previously

unknown as a cause of human illness, was isolated from these patients, who had a distinctive haemorrhagic colitis. This haemorrhagic colitis represents the most severe end of the spectrum of *E. coli* infections. It has taken the better part of the past two decades to determine that the colitis is not the only manifestation of infection with EHEC, that a number of different *E. coli* serotypes other than O157:H7 can be implicated, and that a common characteristic of the group is their ability to produce shiga toxins. Hence these organisms are now more commonly designated 'shiga-toxin-producing *E. coli*' or **STEC**. (It should be noted that in some parts of Canada, the United Kingdom, and Europe, shiga toxin from *E. coli* is known as verotoxin (**VT**), because Vero cells were used to characterize its properties. Those who use the VT terminology refer to the group as 'verotoxin-producing *E. coli*' or **VTEC**. (However, the term 'STEC' is more correct, as it is named for the gene designation for the prototype shiga toxin from *Shigella dysenteriae* type 1.) There is an important epidemiological distinction between the terms 'EHEC' and 'STEC'. The former refers to STEC associated with a distinctive clinical syndrome, haemorrhagic colitis, most commonly due to serotype O157:H7. Yet, other STEC can produce a range of diarrhoeal illnesses that do not fit this description. Thus, all EHEC are STEC, but only some STEC are EHEC, and STEC is a more comprehensive term.

Epidemiology

STEC are found in cattle, and occasionally in other farm animals, in which they appear to be part of the normal flora. Ground hamburger meat prepared in large lots at slaughterhouses, then quick-frozen for distribution and later cooking, have been implicated in outbreaks of human infection. Under these conditions, one carcass contaminated with STEC from its faeces can contaminate meat prepared from a number of carcasses. Freezing preserves the organisms, and cooking the meat rare allows bacteria in the interior of a hamburger patty to survive. Disease results because the required inoculum size is only between 50 and 100 organisms. Hamburgers prepared in supermarkets have become a major source for sporadic cases or small outbreaks associated with picnics, school meals, church barbecues, and other similar small gatherings. Salami, sausage, and raw milk have also been implicated in outbreaks. A huge outbreak affecting over 10 000 school-age children occurred in Japan during 1996 caused by contaminated prepared school lunches.

Organisms can also be disseminated from farm animals to ground water and adjacent crops; lettuce, alfalfa sprouts, apple cider, and unpasteurized apple juice have been vehicles of infection. In fact, non-beef foods have become increasingly important sources of STEC, accounting for approximately 50 per cent of all cases in the United States. Direct infection from contact with animals, notably in children on school visits to farms, is another form of transmission. Person-to-person transmission is also well documented, which reflects the small inoculum size needed to cause infection.

Clinical features

Perhaps as a consequence of the small inocula of STEC, the incubation period is often as long as 5 to 7 days. The initial watery stools become blood-tinged and then grossly bloody over the course of a day or two, and there are abdominal cramps and tenderness. This is due to a diffuse inflammatory colitis with vascular leaks, rather than ulceration as in shigellosis. Lesser degrees of colon involvement lead to milder symptoms with less blood in the stool, with mild infections remaining as a watery diarrhoea. Patients usually improve clinically in 5 to 7 days. However, at about this time, particularly in infections with O157:H7, microangiopathic haemolytic anaemia, thrombocytopenia, and oliguric renal failure—the haemolytic-uraemic syndrome (**HUS**)—develop in 5 to 10 per cent of patients. In some patients, these manifestations are mild and self-limited; in others, rapidly developing hypertension may lead to haemorrhagic strokes and death in the acute phase. In still others, management of renal failure becomes a major clinical problem, requiring peritoneal or even haemodialysis before improvement occurs. In a small, but unknown, proportion of patients, manifestations of chronic renal damage occur a decade or more after the initial episode. Because HUS is also associated with shiga-toxin-producing *Shigella dysenteriae* type 1, it is apparent that this toxin is a significant pathogenetic factor.

Laboratory diagnosis of pathogenic E. coli

Although identifying an organism as an *E. coli* is simple, diagnosis of the different *E. coli* strains causing intestinal disease is both hard and easy. It is hard because, with the exception of 0157:H7 STEC strains (see below), there are no simple screening tests for their identification. It is easy because the virulence genes that characterize the different groups can be readily identified by polymerase chain reaction (**PCR**) and other genotyping methods; the problem is that PCR is not yet suitable for routine use in the clinical laboratory. Serotyping, as noted previously, is not specific enough, even for the EPEC strains that have classically been identified by this method. There are tissue culture methods that detect some virulence properties, such as cell-adherence patterns, or the ability to polymerize actin and reorganize cytoskeletal microfilaments and the microvillus surface, but routine clinical laboratories do not perform these tests. Modernization of the laboratory is imperative to enable the full diagnosis of *E. coli* infections, but fiscal and other considerations are likely to limit the rapidity with which this can be achieved.

The identification of 0157:H7 STEC is more straightforward. Most *E. coli* O157:H7 do not ferment sorbitol and can therefore be detected on sorbitol–MacConkey (SMAC) agar. Other STEC can be detected by commercially available enzyme-linked immunosorbent assay (**ELISA**) tests for toxin production; however, most clinical laboratories do not seek these organisms.

The detection of systemically invading *E. coli*, for example as the cause of sepsis and circulatory shock, is not a problem for the laboratory as *E. coli* are not 'normal flora' except in the colon. Sampling normally sterile sites, such as the bloodstream, readily yields the organisms, unless the patients have been given antibiotics in advance. The organisms are not fastidious, they grow rapidly, and are easily identified and tested for antimicrobial sensitivity within 48 h.

Treatment and prevention of pathogenic E. coli

With the exception of STEC infection, the main danger to an infant with *E. coli* gastroenteritis is dehydration; thus, the most urgent need is to replace fluid and electrolyte losses. Infants may require parenteral fluids, particularly with ETEC infection, but oral rehydration fluids are generally sufficient.

With STEC infection, dehydration is not the prime concern as the fluid losses are typically not severe. It is the systemic complications—the microangiopathic haemolytic anaemia and renal failure (HUS)—that are the clinical challenge. The use of antimicrobial therapy, even in STEC infection, is neither generally necessary nor advocated. While some believe the early use of antimicrobials to treat STEC will prevent the late complications, there is sufficient evidence to the contrary to pause for consideration. Certain antimicrobials induce shiga-toxin production and may predispose to HUS or increase its severity, and many believe antibiotic treatment to be contraindicated. There is no definitive, controlled clinical-trial evidence to resolve this controversy. Antimotility agents do not diminish fluid losses, so much as they prolong the interval between stooling. There is some evidence that antimotility agents can exacerbate illness and increase its severity by prolonging the contact between the pathogen and the gut mucosa, particularly in young children, and therefore they are generally considered both ineffective and potentially harmful. Measures taken to prevent infection are the same as those for shigellosis, notably good personal hygiene, especially among medical staff caring for these patients; the risk among neonatal infants is particularly high.

Shigella infections

But for history, the genus *Shigella* would be another type of *E. coli*. This is because the identification of the prototype organism of the genus occurred in 1896 rather than in 1996 when it became known that *Shigella* and *Escherichia* could not be distinguished by DNA hybridization. This bacterium, ultimately named *Shigella dysenteriae* type 1, honours the Japanese microbiologist, Kiyoshi Shiga, who isolated it from patients with dysentery during a particularly severe epidemic in Japan. Shiga proved its aetiological significance by demonstrating a rise in agglutinating antibodies during convalescence. The epidemic affected at least 100 000 individuals, with a mortality rate close to 25 per cent. After World War I, this species declined in prevalence, and was only rarely isolated. However, in 1968 it re-emerged as the cause of a widespread epidemic of dysentery in Central America and Mexico. Early in the epidemic, mortality rates reached levels similar to those in Japan 60 years before, partly because the organism was initially not grown from stool and partly because the presence of amoebic cysts was interpreted to mean that the disease was amoebic dysentery. As a result, the use of emetine (a highly toxic drug) to treat victims contributed to the high mortality. Once better media for the isolation of this organism were employed, the true cause of the outbreak was identified, proper antibiotic treatment was given, and deaths were reduced. With time, strains with multiple antibiotic resistance emerged, but the epidemic had already waned.

Soon after the publication of Shiga's work, Flexner, Sonne, and Boyd described related groups of organisms. By 1938, four groups of dysentery bacilli could be differentiated according to their biochemical reactions and antigenic structure (Table 3). Shigellae, like the salmonellae, are non-lactose fermenters (albeit, *S. sonnei* does ferment lactose after 24 h in culture), but they are unusual among the enterobacteria in lacking flagella (non-motile) and, with one minor exception, they are anaerogenic—they do not produce gas from sugars. *S. sonnei* and *S. boydii* are the least pathogenic species and usually cause minor illness. *S. flexneri* is of intermediate pathogenicity.

Epidemiology

S. dysenteriae type 1 remains the most virulent of the shigellae. It is the principal species involved in major epidemics. It thrives under conditions of poverty, overcrowding, and squalor, particularly where there are no proper means of sewage disposal. However, the same can be said for the more requently encountered *S. flexneri* and *S. sonnei*. It is not clear, therefore, why *S. dysenteriae* disappeared after the First World War, to be replaced by *S. flexneri*, or why *S. flexneri* diminished in prevalence in industrialized nations after the Second World War, where it was replaced by *S. sonnei*. Nor is it clear why *S. dysenteriae* type 1 reappeared in Mexico and Central America during 1968, in the Indian subcontinent during 1975, or in Central Africa during 1985, where it is now an endemic cause of dysentery. Shigellosis differs from other common diarrhoeal diseases of the developing world in that it affects older children and adults rather than targeting young infants.

Sources and transmission

Unlike salmonellae, shigellae are only found naturally in humans and occasionally certain non-human primates, which probably acquire infection from humans. Shigellosis is the most communicable of all bacterial infections of the gut; in adult human-volunteer challenge studies, dysentery has been produced by as few as 10 to 100 bacteria. This is partly because it resists acid pH and is able to survive passage through the stomach. Not surprisingly, the principal route of transmission is person to person by the direct faecal–oral spread of bacteria, mainly via the fingers. Apart from the obvious contaminating action of finger-to-mouth contact after touching or scratching the anal area, or not washing one's hands after defaecation, infective doses of bacteria can also be transferred to food or water. These can be ideal vehicles for transmission because shigellae do not have to multiply in food to cause infection. Thus the greatest risk is from foods that are most handled during preparation, such as salads, sandwiches, and fruit.

The global market in foods has resulted in many new ways of transporting and transferring shigellae. For example, an outbreak in Europe was caused by injecting watermelons with contaminated water in North Africa in order to increase their market weight. Lettuce fertilized with human faeces ('night-soil') in Mexico has transmitted shigellosis in the United States, facilitated in some instances by the shredding of lettuce for distribution to fast-food restaurants. It is not clear how much shigellosis is transmitted by contact with fomites, such as lavatory seats, flushing handles, taps, door knobs, roller towels, and other objects in the toilet. Cool, dark, damp conditions favour the prolonged survival of shigellae deposited on hard surfaces in this way, and under such conditions organisms have been shown to survive for at least 17 days on wooden lavatory seats.

Occasionally, large outbreaks have arisen through the faecal pollution of municipal water supplies. In countries lacking flushing toilets and sewerage systems, flooding has coincided with simultaneous increases in dysentery as flood waters wash infected human faeces deposited in fields into well water or other sources of drinking water. Flies can also transmit infection from exposed human faeces to food, and in such settings fly control reduces the incidence of infection.

Pathogenesis

The cardinal pathogenic feature of shigellae is their ability to invade and multiply in epithelial cells. Invasion occurs by a process analogous to phagocytosis, mediated by a set of genes present in a large-virulence plasmid. A number of different mutations in these genes will impair or eliminate this property and result in attenuation of virulence. *S. dysenteriae* type 1 also produces a powerful exotoxin (shiga toxin), which is associated with the haemolytic-uraemic syndrome (HUS). As described above, certain *E. coli* (STEC) that are also associated with HUS produce structurally and functionally related toxins. In experimentally infected rhesus monkeys, colonization initially takes place in the jejunum and upper ileum, giving rise to secretory diarrhoea. This may be due to the action of one of two shigella enterotoxins (Shet-1 and Shet-2), distinct from shiga toxin, but not all diarrhoea-causing shigellae produce these proteins. Because a huge dose of organisms (>10^{10} bacteria) is required to cause symptomatic infection in these animals, this finding may not be representative of human infection.

The characteristic pathology produced by shigellae is an acute, locally invasive colitis. This ranges in severity from mild inflammation of the mucous membrane of the rectum and sigmoid colon, typical of *S. sonnei* infections, to severe, necrotizing lesions affecting the whole colon and sometimes the terminal ileum, such as are seen in the worst forms of *S. dysenteriae* type 1 infection. Shigellae penetrate and multiply in the submucosa and within the epithelial cells of the colon, close to the enteric vasculature, and yet bacteraemia is rare, though less rare in patients with malnutrition. In severe cases the colon may be so damaged that it is confused with a global ulcerative colitis.

Local mucosal changes consist of oedema, capillary engorgement, and neutrophil infiltration. Small haemorrhages are common and the submucous veins may be engorged or thrombosed. The mucous membrane becomes intensely red and blood-stained mucus may be present. In the most severe forms of the disease, areas of mucosa undergo coagulation necrosis, which appear as thickened, semi-rigid, greyish patches. These eventually separate to leave raw, ulcerated areas. Haemorrhage and perforation may also result from such lesions. Extensive lesions lead to considerable protein loss, which adds to the severe debility that accompanies these infections. Extensive production of inflammatory cytokines is responsible for these mucosal responses.

Clinical features

The incubation period is usually between 2 and 3 days, but exceptionally it may be as long as a week. The illness usually starts with fever, abdominal colic, and watery diarrhoea. In many *S. sonnei* infections these are the only features and there is spontaneous resolution. In the more severe forms of shigellosis, diarrhoea and fever is accompanied by headache, anorexia, myalgia, and malaise. After 1 to 3 days the diarrhoea becomes bloody, and in some cases it may progress further to dysentery, characterized by the very frequent passage of small amounts of blood-stained mucus ('red-currant jelly') and pus, with abdominal cramps and tenesmus—the classic dysenteric syndrome. In severe forms of the disease this sequence is telescoped so that bloody, mucoid stools are passed virtually from the outset. The patient becomes toxic and restless, the pulse rapid and feeble, and there is a risk of death from hyponatraemia, hypoglycaemia (Fig. 1), septic shock due to polymicrobial bacteraemia with other coliforms, or renal failure and hypertension associated with acute HUS. Recovery in such cases is invariably slow, and occasionally patients continue with chronic or relapsing infection resembling ulcerative colitis. Indeed, 50 years ago some experts believed shigellae were the cause of ulcerative colitis. Exacerbation of haemorrhoids and rectal prolapse may result from rectal oedema and straining at stool. Shigellae are usually excreted in the faeces for a few weeks after the illness. Malnourished individuals, particularly young children, may excrete the organisms for months.

Fig. 1 Bangladeshi child with pouting and upward deviation of the eyes associated with profound hypoglycaemia complicating shigellosis. (Courtesy of RE Phillips)

Children may show striking meningism, which, in the presence of fever and headache, can be misleading if it occurs before the onset of diarrhoea. Shigellosis in children may also be associated with appendicitis and occasionally with intussusception in infants. The catabolic response, protein-losing enteropathy, and anorexia that occur and persist in shigella infections in children in developing countries can lead to acute protein-energy malnutrition (kwashiorkor). This is associated with frequent intercurrent infections and high mortality rates. Shigellae are rare causes of vaginitis in children and, as this focal infection can develop without any obvious history of diarrhoea, it can easily pass unrecognized.

Reactive arthritis or full Reiter's syndrome, associated with the HLA-B27 haplotype, purulent keratoconjunctivitis, and neuritis are uncommon late complications of infection with any of the shigellae.

Laboratory diagnosis

Isolation in culture remains the standard method for detecting shigellae. Faecal samples rather than rectal swabs should be submitted. Shigellae are delicate bacteria, so it is necessary to plate samples rapidly or inoculate a buffered transport medium if there is to be any delay before a stool can be delivered to the laboratory and processed. Some bacteriological media are more inhibitory to shigellae than others. For example, Salmonella–Shigella (**SS**) agar is moderately inhibitory, whereas Hektoen enteric and xylose–lysine–deoxycholate agar are less so. Multiple agars should be used to maximize the chance of isolation.

Antimicrobial chemotherapy

Although antimicrobial therapy is seldom needed for *S. sonnei* and other mild self-limited forms of shigellosis, it is the mainstay of treatment for severe shigellosis, especially for *S. dysenteriae* type 1 and *S. flexneri* infections. Laboratory identification should always be sought, as well as antimicrobial susceptibility data. Strains showing multiple antimicrobial resistances are common, especially in developing countries. Suppression of the normal microbial flora by inappropriate antimicrobial therapy exacerbates infection.

Co-trimoxazole and ampicillin have for many years been the drugs of choice for shigellosis, but most strains are now resistant; many are also resistant to tetracycline and chloramphenicol. Nalidixic acid is effective and cheap, but high resistance rates have arisen where the drug has been used intensively. Resistance to ciprofloxacin, which is 100 times more active against shigellae than nalidixic acid, is currently uncommon. A single dose of 1 g is effective in adults infected with shigellae other than *S. dysenteriae* type 1, but 3 to 5 days of treatment is usually required for the latter species. The treatment of children with antibiotic-resistant shigella infection is difficult, as quinolones are potentially toxic for the young. A short course of a fluoroquinolone may be necessary to treat severely affected children, but parenteral ceftriaxone (50 mg/kg per day for 5 days) and pivmecillinam are alternatives that have been used successfully.

Prevention and control

The safe disposal of excreta, provision of purified water, and control of flies are fundamental to the control of shigellosis. Where these are lacking, the incidence can still be reduced by the promotion of personal and domestic hygiene, notably hand washing after defaecation and before handling food. Unpurified water can be made safe by boiling or by the addition of hypochlorite tablets; salads and fruit can be disinfected by soaking in water containing 80 parts per million of free chlorine from household bleach. Breast feeding substantially increases resistance to infection in children. Oral vaccines for use in developing countries are being developed.

Outbreaks of *S. sonnei* dysentery in schools are difficult to control, but measures should be aimed at preventing spread by the hands. Supervised washing and disinfection of hands after defaecation, and frequent disinfection of lavatory seats, taps, and door knobs are effective if rigorously applied. Only disposable hand towels should be provided in this setting. It is impracticable to detect and exclude all children excreting shigellae, and therefore children suffering from diarrhoea, regardless of whether or not *S. sonnei* is isolated from stool, should be restricted from school until recovered.

Food handlers suffering from diarrhoea or dysentery should be excluded from work until they have produced at least three consecutive negative stool samples taken not less than 24 h apart, and at least 2 days after the cessation of any antimicrobial chemotherapy.

Salmonella infections

The genus *Salmonella* is a large complex group of organisms that continues to challenge the ability of taxonomists to classify them. After many years, and many schemes, the genus *Salmonella* is now considered to comprise a single species designated *S. enterica*. All of the more than 2400 individually distinguishable strains (based on their possession of sets of microbiological, biochemical, and serological properties), such as *S. choleraesuis, S. typhi, S. paratyphi* A or B, *S. typhimurium*, *S. dublin,* and *S. enteritidis*, are now considered to be serovars of *S. enterica*. This leads to a complex nomenclature in which the particular strain previously known as *S. enteritidis* is now called *S. enterica* serovar enteritidis. While this is now taxonomically correct, it is clinically awkward and clinicians will no doubt continue to use the old nomenclature. *S. enterica* is divided into seven subspecies, which largely correspond to the old 'subgenera'. Members of subspecies I are predominantly parasites of warm-blooded animals and include almost all the salmonellae pathogenic for humans. The other subspecies include organisms found mainly in cold-blooded animals or the environment. Subspecies IIIa and IIIb (the 'Arizona' group) are a group of organisms that, in contrast to subspecies-I organisms, ferment lactose. This makes their recognition in the laboratory more difficult because they initially resemble normal flora coliforms.

Salmonella in subspecies I fall into three epidemiological groups:

1. those highly host-adapted to humans, such as *S. typhi* and *paratyphi* A, which cause the distinctive clinical syndromes typhoid and paratyphoid fever;
2. those that are highly host-adapted to animals but which cause no human illness (e.g. *S. pullorum* in chickens);
3. a large group that are not particularly host-adapted, such as *S. typhimurium, S. dublin, S. heidelberg*.

It is in the third group that the food-poisoning salmonellae are found. Many of them are named after the city or place where they were first identified. While there are a huge number of distinguishable strains included in this group, only a few are commonly found causing human illness. Identification of uncommon serovars can be extremely useful in determining their source and mode of transmission.

Epidemiology

Salmonellae are one of the major causes of foodborne illness throughout the world, but particularly in industrialized countries. This is because many processed foods contain animal products likely to be contaminated with salmonellae, such as poultry and egg products. The latter have been particularly effective vehicles for spreading *S. enteritidis* originating in egg-laying hens (see below). It is remarkable how many processed foods contain potential sources of *Salmonella*. The socioeconomic cost of salmonella infection is enormous. In the United States it is estimated to be $1.4 billion per annum. The cost of mounting an outbreak investigation may seem high, but it is trivial in relation to the savings that can be made in medical and social costs by rapid interventions.

Animal and food sources

The food-poisoning salmonellae are enzootic in a wide range of vertebrates, unlike the typhoid and paratyphoid bacilli, which are highly host-adapted to humans. Infection may be acquired from direct contact with infected animals. On the farm, the source is often scouring calves; and in the home, family pets—even terrapins and turtles. But in general, animals are more important as a source of infection through the food chain. In developed countries, intensive animal husbandry and mass production methods encourage the spread of salmonellae. In the example of poultry, modern mechanized plucking and eviscerating methods, which are capable of processing 5000 birds an hour, can readily lead to gross cross-contamination.

Animal feeds are often the portal of entry for new *Salmonella* serotypes. The appearance and spread of *S. agona* in Britain and the United States in the early 1970s was traced to its introduction via Peruvian fish meal used in poultry and pig feed. Similarly, in the late 1970s, *S. hadar*, formerly unknown in Britain, became well established in turkey stocks after its introduction in feedstuffs from abroad. The prevalence of serotypes is constantly changing. Since 1985, the incidence of *S. enteritidis* infection has risen to unprecedented heights in Europe (mainly phage type 4) and North America (mainly phage types 8 and 13a), and probably elsewhere. The main source is poultry, for which these strains are more than usually invasive, causing oviduct infection and contamination of fresh eggs through vertical transmission, a new epidemiological dimension that had far-reaching political consequences.

The net result of the enzootic state is that raw meat and animal products, especially poultry and eggs, are commonly contaminated with salmonellae of one or another serovar. The consequences are not always as serious as they might appear, for healthy adults are able to deal with small inocula and, in general, clinical symptoms are unlikely unless multiplication of the inoculum is allowed to occur in the food before consumption. Thus correct handling, preparation, and storage of food can prevent clinical infection. Unfortunately, this ideal is not always attained. Failure to handle raw meats separately from cooked foods leads to cross-contamination, and incomplete thawing of large frozen carcasses, such as turkeys, results in inadequate cooking and the multiplication of surviving bacteria. Raw milk is often contaminated at source and is a regular cause of infection in those unwise enough to drink it. Faults in food processing plants can lead to widespread outbreaks corresponding to the distribution of the product. Major incidents have been caused by failure of heat treatment, or contamination of a food after heat treatment. The list of foods implicated is long, but a few examples are liquid egg, dried egg, dried-milk infant food, desiccated coconut, bean sprouts, chocolate, and meat pies topped up

after cooking with jelly from contaminated dispensing machines.

Human sources

Infection is not readily transmitted from person to person because of the relatively high inoculum required, a consequence of the acid susceptibility of these organisms. Infants, old people, and patients living in closed communities such as nursing homes and institutions for retarded or mentally ill individuals, in whom it may be difficult to maintain high levels of sanitation, are at particular risk. Salmonellae can be especially troublesome in hospital maternity units.

The importance of a *Salmonella*-excreting food handler as a source of infection has been exaggerated. These individuals are more likely to be the victim of handling contaminated animal products at work than a source of infection. It is rarely necessary to suspend an otherwise healthy food handler from duty until clear of salmonellae, providing the stools are formed and good standards of hygiene are maintained. However, it is mandatory to suspend food handlers with diarrhoea, whatever the apparent cause.

Pathogenesis

The infective dose is governed by many factors. As noted above, the inoculum required to cause infection is several hundred thousand organisms, as determined in experimental infections in human volunteers, even when the organism is administered in buffered solutions. There are important exceptions. The inoculum is lowered when taken in a food meal, which buffers gastric acidity and protects the organisms in their journey through the stomach to the small bowel. In fact, as few as 50 bacteria contained in certain high-fat foods, notably chocolate, cheese, and salami, can cause illness. Anything that reduces gastric acidity, such as atrophic gastritis, treatment with H_2-receptor blocking agents, and previous gastric surgery, also lowers the infective dose. Broad-spectrum antibiotics increase susceptibility by suppressing the normal competitive microflora of the gut. The newborn are especially susceptible before the gut becomes colonized with the normal intestinal flora.

The distal small intestine is the main site of infection, but the colon can also be affected. Salmonellae provide chemical signals to intestinal epithelial cells, leading to bacterial uptake within vesicles and translocation across the cytoplasm to the lamina propria where the organisms multiply and invade the bloodstream. Whereas circulating bacteria are generally contained and quickly eliminated, bacteria in the mucosa result in an acute inflammatory response with polymorphonuclear leucocytic infiltration of the submucosa. Flattening or loss of secretory epithelium occurs adjacent to these inflamed areas. Inflammatory cells are usually present in the stools, which provides a diagnostic clue to the invasive process. The mechanism by which salmonellae cause tissue damage and fluid secretion is not well understood. Production of inflammatory products that alter electrolyte and fluid transport (for example, prostaglandins and enterotoxins), and described in some strains, are considered to be responsible.

Although bacteraemia probably occurs in most infections at the outset, positive cultures are obtained in only a few per cent of all laboratory diagnosed infections. Yet, certain strains are associated with high rates of bacteraemia, for example *S. cholerae-suis* (75 per cent), *S. dublin* (25 per cent), and *S. virchow* phage-type 19 (5.5 per cent). Some of these so infected patients suffer a typhoidal illness, or even the severe manifestations of septic shock, and focal infection may arise in almost any organ of the body. *S. cholerae-suis* has a particular predilection for the aorta, where it can cause life-threatening mycotic aneurysms.

Clinical features

There are broadly six major clinical manifestations of salmonella infection, the first of which is asymptomatic infection (Table 4). Most people ingesting salmonellae never become ill. In every food-poisoning outbreak, despite the likelihood of a high inoculum in the suspect food, there are unaffected persons who excrete the organism in their faeces. Others suffer a typical attack of acute febrile enteritis lasting 2 or 3 days, and there are usually a few who suffer a more severe, prolonged attack. The proportion of people who become ill is determined by the extent of contamination of the food and the characteristics of the infecting strain.

The incubation period is usually 24 h, but it may range from 6 to 48 h, depending on the size of the infecting dose. The onset is abrupt, with malaise, nausea, headache, abdominal pain, and diarrhoea. Some patients vomit, but seldom more than once or twice. Shivering and fever is common in those who are more than mildly affected. Occasionally there is severe diarrhoea, with fluid, green, offensive stools that may contain mucus and blood. Dehydration, with cramps, oliguria, and uraemia may occur, most likely among those at the extremes of age who are at risk of a fatal outcome. Patients whose distal colon and rectum are severely affected occasionally develop tenesmus with the passage of small, bloody dysenteric stools, and there may be tenderness over the sigmoid colon. Salmonella enterocolitis may trigger off an attack of non-specific colitis, acute appendicitis in the young, or mesenteric thrombosis in the elderly. Bacteraemia early in the course of infection can lead to focal infection in certain organ systems (see below).

Reactive arthritis is an occasional late sequel of infection. Estimates of its incidence range from 1.2 to 7.3 per cent of all infections. Patients with the HLA-B27 haplotype have a strong predisposition for this complication, in whom it sometimes becomes a chronic, destructive arthritis.

Convalescent excretion

Most patients continue to excrete small numbers of salmonellae in their faeces for a few weeks after infection—about 4 to 8 weeks for adults, and 8 to 24 weeks for infants. The number of organisms present is usually low, but excretors have been found with 10^5 to 10^7 organisms per gram of faeces. Carriage of salmonellae, other than typhoid or paratyphoid bacilli, for more than 6 months is rare.

Focal infection

Focal infections are often difficult to diagnose because they may first manifest themselves long after an episode of enteritis—or the original bowel infection may even have been silent. Focal infections have a tendency to chronicity and can mimic tuberculosis, particularly in cases of osteomyelitis of a vertebra or paravertebral abscess. Salmonella osteomyelitis and arthritis are strongly associated with sickle-cell disease, where bony infarcts can be infected during the asymptomatic bacteraemic phase of salmonella enteritis. Salmonella abscesses may develop in virtually any site: the liver, gallbladder, spleen, psoas muscle, uterus (after septic abortion), and the peritoneal cavity (for example, subphrenic, pelvic) are the most common. Patients with a deep-seated salmonella infection who remain untreated suffer high mortality.

Laboratory diagnosis

Definitive diagnosis depends on the isolation of the infecting organism, for salmonella enteritis cannot be distinguished from other forms of enteritis on clinical grounds alone. The isolation methods for salmonellae allow the detection of small numbers of organisms, even when greatly outnumbered by other bacteria. While most specific serovars can only be identified in reference laboratories possessing a full set of serotyping antisera, most clinical laboratories are able to narrow identification down to a short-list by the use of restricted sets of commercially available antisera. Some reference laboratories offer strain identification of *S. typhimurium, S. enteritidis*, and other common serovars by phage-typing techniques. Patients produce antibody to their infecting strain during convalescence, but this is seldom of diagnostic value.

Antimicrobial chemotherapy

The mainstay for the treatment of salmonella gastroenteritis is fluid replacement. This can usually be accomplished by the use of oral rehydration solutions, which are discussed more fully in Chapter 14.17. In the past, antimicrobials were not recommended for treating this infection since there was no apparent shortening of the clinical illness and there was a tendency for carriage to persist longer. None the less, more aggressive treatment should be considered for certain severely affected patients or in particular situations. Examples are patients with bloody diarrhoea and those with an underlying illness such as sickle-cell disease or AIDS, which predispose patients to more severe, focally invasive, and sometimes fatal infections.

The ever-increasing rates of antimicrobial resistance among salmonellae to chloramphenicol, co-trimoxazole, tetracyclines, and ampicillin mean that ciprofloxacin and other related 4-quinolones are now the agents of choice. At times, because the 4-quinolones rapidly sterilize the stool and stop transmission, treatment may be warranted during an institutional outbreak in order to reduce the excretion and spread of salmonellae. Ciprofloxacin has also been used with remarkable success to eradicate salmonellae from chronic carriers (including those with *S. typhi*) after other treatments have failed, probably because it is concentrated in bile and mucus. Treatment is essential for invasive and focal disease, which requires full dosage of the drug for several weeks, as the serovars causing invasive infection may be

more virulent than the run-of-the-mill serovars causing diarrhoea. Resistance to ciprofloxacin (and other quinolones) developing during treatment has been reported, thus emphasizing the need for close laboratory control. The drug is not recommended for use in children because of a concern that it may cause cartilage damage, although there is little evidence for this from human studies.

Prevention and control

The correct hygienic preparation, handling, and storage of food dramatically reduces the transmission of salmonella infection, but lapses are inevitable at home and in restaurants. The most common fault is the failure to appreciate that even the briefest contact between a raw animal product and other foods can transfer an inoculum to the latter and initiate a salmonella outbreak; strict separation of the two is a fundamental food-safety prerequisite. Ideally, animal products should be salmonella-free, but this is far from the case. Methods of animal husbandry, slaughtering, processing, marketing, and policies for the safe disposal of animal and human waste are all reflected in the incidence of human infection.

Examples of control measures in animals are the compulsory heat treatment of imported and recycled animal feeds, and the competitive exclusion of salmonellae from chicks by dosing with normal gut flora. There should be severe restriction on the use of antimicrobial agents in animal rearing, particularly those drugs that are especially valuable for treating human disease, such as the fluoroquinolones. Unfortunately, economic considerations of animal husbandry seem to count more than human health, and it has proven difficult to restrict the use of antibiotics in animal feed. Because of market globalization, restrictions in one country may not affect the movement of drug-resistant organisms elsewhere. Terminal disinfection of poultry carcasses by irradiation would eliminate all pathogens including salmonellae, but irradiation has gained a bad public image and it may be a while before this will change. However, just as there was initial opposition to the pasteurization of milk (a measure of unquestioned public health value and of no risk), irradiation may be more widely used in the future to reduce foodborne infections.

Campylobacter infections

The name Campylobacter (Greek, curved rod) was coined by French workers in 1963 for a group of small, curved or spiral, Gram-negative bacteria formerly classified as vibrios. They now form part of a unique superfamily of mainly spiral bacteria that includes *Campylobacter*, *Arcobacter*, and *Helicobacter*. Campylobacters have a single flagellum at one or both poles of the bacterial cell, giving them a characteristic, rapid darting motility (Fig. 2). The type species, *Campylobacter fetus* (originally *Vibrio fetus*), was first isolated in England in 1906 from aborted sheep fetuses. In the ensuing years it became clear that this species was a major cause of infectious abortion in cattle and sheep, but it was not until the 1970s that *C. jejuni* and *C. coli* were recognized as a common cause of enteritis in humans. The reason they escaped detection for so long was that special methods are required for their isolation from faeces. *C. fetus* occasionally infects humans, but only as an uncommon opportunist causing systemic infection, sometimes with diarrhoea, in patients with immune deficiency or a serious underlying disease. Exceptionally, *C. fetus*, as well as *C. jejuni* and *C. coli*, cause human fetal infection and septic abortion.

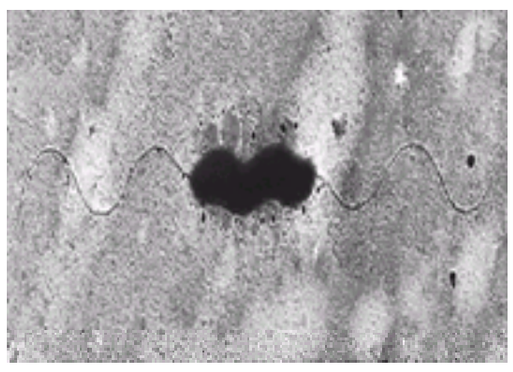

Fig. 2 Electron micrograph of a campylobacter (6650 ×). (By courtesy of Mr DR Purdham.)

Campylobacter enteritis

In industrialized countries almost all campylobacter enteritis is caused by *C. jejuni* and *C. coli*. These differ from most other *Campylobacter* species in having the high optimum growth temperature of 42 °C, in keeping with their adaptation to birds and other animals. In most regions about 90 per cent of infections are caused by *C. jejuni*. Many hundreds of strains exist, which are primarily defined serologically according to two classes of antigen: heat-stable O (lipopolysaccharide) antigens, and heat-labile surface and flagellar protein antigens. Serotypes can be further subdivided into phage types, and even finer discrimination can be attained by DNA analysis. In the United Kingdom, 473 serophage types were found among 9600 routine human isolates.

Several other campylobacters and related bacteria are associated with infection of the human intestinal tract. *C. lari* accounts for about 0.1 per cent of all cases of campylobacter enteritis. A subgroup of *C. jejuni* (*C. jejuni* subsp. *doylei*) and *C. upsaliensis*, *C. hyointestinalis*, and *Arcobacter butzleri* are scarce in industrialized countries, but more frequent in children in developing countries; although *A. butzleri* was implicated in an outbreak of abdominal pain, without diarrhoea, in an Italian school. *Helicobacter cinaedi* and *H. fennelliae* are associated with proctitis in homosexual men.

Epidemiology

Campylobacter enteritis is the most common bacterial infection of the gut in industrialized countries. Some 55 000 laboratory isolations per annum are currently reported in the United Kingdom, representing an annual incidence of 100/100 000, but the true incidence is likely to be at least ten times this figure. Incidences are similar in the United States, where the total number of cases is estimated to be 2.4 million per year, with 50 to 150 deaths. The economic burden of the disease runs to millions of dollars annually. In temperate zones there is a remarkably consistent and unexplained peak of incidence in early summer. In developed countries campylobacter enteritis affects people of all ages, especially young adults, but in developing countries it is almost entirely confined to children below the age of 2 to 3 years, after which they are immune through repeated exposure to infection.

Like salmonellosis, campylobacter enteritis is a zoonosis. Campylobacters are found in a wide variety of warm-blooded animals, especially birds, in which they form part of the normal intestinal flora. Pigs are the main host of *C. coli*. A few infections are acquired by direct contact with infected animals, either occupationally (farmers, slaughtermen, poultry processors) or domestically (typically contact with a puppy or kitten with campylobacter diarrhoea), but most are acquired indirectly via contaminated meat, milk, or water. Normal cooking destroys campylobacters, but the consumption of raw or barbecued meats, especially poultry, carries a distinct risk of infection.

Broiler chickens are the most prolific source of campylobacters. Retailed chickens are almost universally contaminated (frozen ones less so than fresh ones), so self-infection when handling them in the kitchen, or cross-contamination to other foods, readily occurs if good hygienic practice is not observed. Campylobacters do not multiply in food like salmonellae, but the infective dose is small enough for food to act as a passive vehicle, just as it does for shigellae. Foodborne infection therefore tends to be sporadic, or in small family outbreaks, rather than in the form of explosive outbreaks. Yet, major outbreaks of campylobacter enteritis affecting 3000 people at a time have been caused by the consumption of raw milk or contaminated municipally supplied water. The ubiquitous nature of campylobacters makes it difficult to pinpoint the sources of sporadic infections. There are probably many routes of infection yet to be discovered. For example, in certain areas of Britain during early summer, infections are caused by the consumption of milk contaminated by wild birds (magpies and jackdaws) pecking the foil caps of doorstep-delivered milk bottles.

Campylobacters do not survive well on inanimate objects, which is probably why person-to-person infectivity is low. Secondary cases are unusual in common-source outbreaks. Food handlers who are healthy excreters with formed stools are a negligible risk to others. The only human sources of consequence are toddlers with campylobacter diarrhoea and infected mothers at term, who may infect their babies during labour.

Pathology

Infection starts in the upper ileum and progresses distally to affect the terminal ileum and colon. The spiral configuration and motility of campylobacters enables them to penetrate, migrate, and colonize the mucus covering the intestinal epithelium in a way that conventional bacteria cannot. Histology shows an acute inflammatory response, with crypt abscess formation in the mucosa indistinguishable from that caused by salmonellae or shigellae. This, and the presence of mesenteric adenitis, suggest that campylobacters invade the mucosa. Bacteraemia is detected in only 0.1 to 0.2 per cent of infections; however, this figure probably underestimates the true incidence, as blood cultures are seldom taken from patients with diarrhoea early in the disease. Many strains produce a cholera-like enterotoxin and/or cytotoxins *in vitro*, but their role in the pathogenesis of the disease is unclear.

Specific antibodies to the infecting strain appear in patients' blood from about the fifth day of illness and remain detectable for several months.

Clinical features

After an incubation period of between 2 and 7 days (mean 3 days) the illness starts either with abdominal pain and diarrhoea, or with a prodromal period of fever, headache, and other influenza-like symptoms that precedes the diarrhoea by a few hours to a few days. A fever of 40 °C or more is not unusual and may be associated with convulsions in children and delirium in adults. Vomiting is not a conspicuous feature of the disease, except in infants, but nausea is common. Abdominal pain tends to be particularly severe and can be of a type and severity that suggests acute appendicitis (see below). Inflammatory cellular exudate can usually be detected microscopically in the stools and frank blood may appear after a day or two. Severe diarrhoea seldom lasts for more than 2 or 3 days, but loose stools and abdominal pain may persist for a while and patients feel 'washed out' and wretched. A brief relapse occurs in 10 to 15 per cent of patients. Death is rare and usually due to some associated disorder. Chronic disease or long-term carriage of campylobacters has not been recorded in normal subjects, but it has in patients with immune deficiency, such as hypogammaglobulinaemia or AIDS. The stools of most patients are culture-negative after about 5 weeks.

Misleading presentations and complications

Suspected appendicitis, particularly in older children and young adults, is the main reason for the referral of patients with campylobacter enteritis to hospital. If laparotomy is performed, the usual findings are an inflamed, oedematous ileum and enlarged, fleshy, mesenteric lymph nodes. Occasionally there is genuine appendicitis. In uncomplicated infection, abdominal tenderness may be present, but not the true signs of acute peritonitis.

Some patients present with the symptoms and sigmoidoscopic appearances of acute ulcerative colitis. The danger here is that they might be given steroids rather than antibiotics. On the other hand, campylobacter infection can exacerbate pre-existing ulcerative colitis and treatment must be given for both conditions.

Campylobacter biliary tract infection and cholecystitis are uncommon complications of infection and there are a few reports of pancreatitis and hepatitis. Other rare acute-stage complications are gastrointestinal haemorrhage, haemolytic-uraemic syndrome, glomerulonephritis, and rashes in the form of urticaria or erythema nodosum. Maternal infection and septic abortion is another rare complication that may arise without the mother having had obvious diarrhoea. Another consequence of maternal infection is neonatal infection occurring during labour. Infants may pass blood-stained stools and have symptoms that mimic intussusception. Outbreaks within neonatal units have been described, and some neonates have developed campylobacter meningitis, albeit of a relatively benign nature.

Reactive arthritis is a late complication arising 1 to 3 weeks after the onset of illness. It affects about 1 per cent of patients, or more if the frequency of the HLA-B27 haplotype in the population is high. Clinically, it is no different from the reactive arthritis following salmonella or other bacterial diarrhoeas.

Guillain-Barré syndrome

The link between campylobacter infection and Guillain-Barré syndrome (**GBS**), or postinfective polyneuropathy, was not recognized for several years. In fact, campylobacter enteritis is now the most frequently identified antecedent event in GBS (26–41 per cent of cases); moreover, patients with campylobacter-associated GBS have a worse prognosis than others. It is certainly the most distressing and dangerous of the regular complications of campylobacter enteritis. Like reactive arthritis, it arises 1 to 3 weeks after the onset of diarrhoea. Campylobacter infection is also associated with the Miller–Fisher variant of GBS, in which cranial nerves are affected, and the so-called Chinese paralytic syndrome. The demyelination of nerve sheaths that occurs in GBS is thought to be caused by an immunological crossreaction between parts of the lipopolysaccharide in the cell wall of certain *C. jejuni* strains, which initiates an autoimmune reaction. GBS and related diseases are described in Chapter 24.19.

Laboratory diagnosis

Diagnosis depends on the isolation of campylobacters from faeces, as the disease cannot be distinguished clinically from other forms of bacterial diarrhoea. The isolation of campylobacters is not difficult, but it does require special selective media and microaerobic atmospheric conditions. Campylobacters are labile bacteria, so faecal samples held for more than a few hours should be refrigerated. Faeces should be placed in transport medium if delays of more than a day are anticipated. A laboratory result is normally available in 48 h. It is conventional for laboratories to report the presence (or absence) of campylobacters without specifying whether the species is *C. jejuni* or *C. coli,* as the distinction is immaterial for clinical purposes. However, it could be important if an outbreak is suspected.

Methods for detecting campylobacters by DNA probes with PCR amplification work well, but they are currently too complex for use in routine clinical laboratories. In circumstances where a quick answer is required, such as a patient with suspected appendicitis or ulcerative colitis, the direct microscopy of faeces can be helpful—campylobacters are usually abundant in the acute stages of infection and their typical morphology and motility make them easily recognizable by a trained eye.

A retrospective serological diagnosis can be made in patients who have a late complication, such as reactive arthritis or Guillain-Barré syndrome, and in whom cultures are negative or were not performed.

Treatment

Oral rehydration and electrolyte replacement is all that is required for most patients with campylobacter enteritis. Antimicrobial therapy is of limited value because patients are usually recovering by the time a bacteriological diagnosis is made, yet it is effective if given early in the disease. Antimicrobials should be reserved for patients who are acutely ill or have complications. The choice is then between erythromycin (or another macrolide) if campylobacters are known or suspected to be the cause of illness, or ciprofloxacin given empirically if the cause of enteritis is unknown. Resistance to erythromycin rarely exceeds 5 per cent of strains in most countries (there are notable exceptions) and this figure has not changed substantially in years. Suitable dosage regimens are erythromycin stearate 500 mg twice daily for 5 days for adults, and erythromycin ethyl succinate 40 mg/kg per day for children. By contrast, resistance to ciprofloxacin and other fluoroquinolones has risen sharply in recent years; examples of current recent resistance rates are: United Kingdom, 20 per cent; United States, 24 per cent; Spain, 70 per cent. A major factor in the acquisition of quinolone resistance in *C. jejuni* is believed to be the extensive use of enrofloxacin in poultry. The traditional dosage of ciprofloxacin is 500 mg taken orally twice daily for 5 days, but shorter courses are probably effective.

For patients with life-threatening septicaemic infections, gentamicin or imipenem are the agents of choice. They are highly active against campylobacters and resistance is almost unknown. It should be noted that campylobacters are naturally resistant to most cephalosporins, and so must be considered as possible infecting agents in febrile patients who do not respond to these broad-spectrum antibiotics.

Prevention and control

As with any infection transmitted by the faecal–oral route, the safe disposal of sewage and the purification of water supplies are fundamental control measures. However, because campylobacter enteritis is a zoonosis, there is much more to its control. Prevention must be aimed at minimizing infection in food-producing animals and preventing their arrival and survival in food. Many of the measures taken to prevent salmonellosis, such as the pasteurization of milk, apply to campylobacters. Much could be done to reduce infection in broiler chickens, which are a major source of infection, but this is a complex matter that will cost money and require changes in attitude in the industry and the public. Good hygienic practice in the preparation and handling of chickens and other raw meats removes the risk of infection, but the public is largely ignorant of this and needs to be educated.

Miscellaneous food-poisoning bacteria

Although most infections of the intestinal tract are transmitted via food or water, only a limited number are typically classified under the heading of food poisoning. Of these, the minority are in fact due to microbial 'poisons' (or toxins) present in the food or water source. This convention is odd, as it groups both infections and toxin ingestions as a subset of foodborne infections. Yet the use of the term 'food poisoning' seems to be firmly fixed in the literature. For example, a Medline search for 'food poisoning' in February 2002 reveals 9086 citations, the vast majority of which refer to non-typhoidal *Salmonella* spp., enterotoxin-producing *Staphylococcus aureus*, *Clostridium* spp., *Bacillus* spp., or *Listeria monocytogenes*, as well as 1046 papers on mushroom and 588 papers on fish toxin (ciguatera) poisoning.

'Food poisoning' is most often recognized in the context of an outbreak involving a number of individuals exposed to the same food or water source. It is the number of cases that calls attention to the event and leads to the investigation that establishes a confirmed or probable aetiology. Because individual and sporadic cases are seldom investigated, particularly when symptoms are transient and insufficiently severe to lead to hospitalization or death, they are neither classified nor tabulated and remain epidemiologically invisible. However, the total number of such individuals affected in a given year probably greatly exceeds the total number of individuals involved in outbreaks.

Classification and differential diagnosis of food poisoning

Food poisoning episodes can be classified into three principal syndrome groups:

1. watery diarrhoea;
2. primarily vomiting and/or cramps; and
3. neurological symptoms.

A limited differential diagnosis (a listing of the possible causes of a clinical presentation) of food poisoning episodes can be constructed in this manner. Alternatively, a presumptive differential diagnosis can be developed by classifying the episode according to a critical epidemiological feature, for example the time elapsed between the ingestion of the presumed causative food or water and the appearance of symptoms, whatever nature they may take. In general, symptoms of food poisoning episodes occur in three time periods: within 4 h; between 8 and 16 h; 24 h or more. These periods correspond to distinct sets of common aetiologies. Therefore, simple outbreak epidemiology to determine when the suspect meal occurred in relation to the onset of symptoms can itself limit the differential diagnosis (Table 5). A third way to organize thinking about food poisoning agents is to separate them according to microbiological and taxonomic considerations, such as their Gram-stain reaction. There are certain advantages to each approach, but in clinical practice the most accurate diagnosis results from the integration of all three sources of information.

Non-cholera vibrios and vibrio-like organisms

Vibrio parahaemolyticus

This marine organism was first associated with human illness in Japan in 1963, since when it has come to be recognized as the most common cause of food poisoning in that country. Seafood is the main source of the organism, and the high incidence of infection in the Far East is doubtless due to the popularity of eating raw fish in the region. *V. parahaemolyticus* is most plentiful in warm waters, but it has been isolated from North Atlantic and Pacific coastlines, and cases of food poisoning have been reported from most continents, usually after the consumption of crabs, prawns, or raw oysters. Cooked shellfish may become contaminated after cooking, for a few bacteria picked up from a working surface contaminated with the raw product can multiply at atmospheric temperatures. This is one reason why the incidence in temperate regions is highest in summer.

After ingestion, *V. parahaemolyticus* multiplies in the gut to produce an enterotoxin, which causes watery diarrhoea and sometimes vomiting lasting for 1 or 2 days. The incubation period is usually 10 to 20 h (range 4–96 h). Despite excretion of the bacteria in enormous numbers in diarrhoeal stools, victims are not a significant source of infection. Tetracycline shortens the period of excretion (seldom more than 10 days), but antibiotics are not justified for such a short illness.

As marine vibrios fail to grow properly on routine media that are not supplemented with extra salt, it is essential for clinicians to notify the laboratory if *V. parahaemolyticus* is suspected. A positive Kanagawa test (b-haemolysis on medium containing human blood) is an indication of pathogenicity of the isolated strain.

Other non-cholera vibrios

Several other aquatic vibrios are capable of causing human gastroenteritis. A study in the southern United States showed that over half of the cases were linked to the consumption of raw oysters. Apart from *V. parahaemolyticus*, the species isolated were *V. mimicus*, *V. fluvialis*, *V. hollisae*, *V. vulnificus*, and *V. alginolyticus.* Half of the patients had fever and one-quarter had bloody stools. *V. vulnificus* is better known as a cause of severe, often fatal, septicaemic wound infection, which may arise from eating raw oysters or through damaged skin. *V. alginolyticus* also causes wound infection, but more typically otitis externa in swimmers. *Photobacterium damsela* (formerly *V. damsela*) causes a septicaemic infection like *V. vulnificus*. Again, as most of these bacteria are halophilic, it is essential to notify the laboratory of their possible presence so that high salt-containing media can be inoculated.

Aeromonas and Plesiomonas spp.

Aeromonads are ubiquitous in water, soil, and cold-blooded animals; some are major pathogens of fish. Their status as human pathogens is unclear, but it seems that some strains, mainly *Aeromonas hydrophila* (others are *A. sobria* and *A. caviae*) are capable of causing diarrhoea. Aeromonads are more frequent in hot climates, so most aeromonas infections are encountered in travellers visiting tropical and subtropical regions. Persistent aeromonas-associated diarrhoea with blood and mucus mimicking ulcerative colitis has been described in patients in Western Australia. These patients were treated successfully with trimethoprim. Most aeromonas infections are thought to be waterborne, but the absence of common-source outbreaks suggests their status as enteric pathogens is low.

Plesiomonas shigelloides is another aquatic vibrio-like organism that is occasionally associated with diarrhoea, usually of a mild nature. It has been implicated in outbreaks of diarrhoea in the Far East and has been isolated from sporadic cases throughout the world. Fewer than 100 cases a year are reported in the United Kingdom.

Gram-positive bacterial food poisoning

A limited number of Gram-positive bacteria are frequent causes of food poisoning in the strict sense of the term, namely the ingestion of preformed toxins in a meal that results in clinical illness. Gram-negative organisms do not cause 'food poisoning' in this manner even though they may produce toxins that are involved in the pathogenesis of clinical disease. The major Gram-positive causes are several species of rod-shaped bacilli (*Clostridium* spp., *Bacillus* spp.) and certain *Staphylococcus aureus* strains.

Clostridium botulinum

See Chapter 7.11.21 for further discussion.

Clostridium perfringens

See Chapter 7.11.21 for further discussion.

Bacillus cereus

This is another Gram-positive spore-forming bacillus like the clostridia, but it exhibits aerobic rather than anaerobic metabolism. It is normally and widely present in soil, hay, trees, and other plants and is frequently present in both raw and processed foods. As a spore former it is resistant to heat, chlorine, and other chemicals

used to eliminate microbial contamination, and humans are constantly exposed to this organism. While this provides an epidemiological edge for the organism, it is not a common cause of human disease, accounting for just 1 per cent of foodborne illness in Europe.

The virulence properties of *B. cereus* are not well studied. Some strains produce a chemically unique cyclic toxin, cereulide, and one or more enterotoxins acting on the intestinal mucosa by uncertain mechanisms. Cereulide is elaborated in food sources and thus causes a true food poisoning when preformed toxin is ingested in a food meal. Cereulide consists of three repeats of four different amino acids that have been modified so that every other residue and half the amino acids are a-hydroxy acid derivatives in ester, rather than amide, linkage. The cyclic structure provides heat stability, so that once elaborated by the organism the toxin is neither denatured nor detoxified by cooking. Systemically administered cereulide is a mitochondrial toxin that uncouples oxidative phosphorylation. While this may explain rare fatal cases of *B. cereus* food poisoning associated with liver failure, it does not offer any ready explanation for the self-limited emetic syndrome typical of human cases.

B. cereus also produces several distinctive enterotoxins that are suspected to cause watery diarrhoea by uncertain mechanisms. Spores induced to germinate in food by heating then develop into the replicating vegetative bacillary form in the intestinal tract where the enterotoxins are synthesized. These toxins are heterotrimers comprising three distinct polypeptides of an aggregate molecular weight greater than 100 000. A 41-kDa single peptide chain enterotoxin is present in some strains.

Food poisoning with the emetic toxin results in the rapid onset of profuse vomiting within hours of ingesting contaminated food. Most commonly this is boiled or fried rice prepared in Chinese restaurants in large amounts, stored at room temperature, and reheated before serving. Diarrhoea and abdominal pain due to enterotoxin production in the gastrointestinal tract is a longer 8- to 16-h incubation illness resembling *C. perfringens* food poisoning. It is transmitted by a number of food vehicles, including meats, stews, sauces, and dairy products. In some more recent outbreaks, the related organism *B. thuringensis*, producing similar enterotoxins, has been identified. This species is more commonly associated with its ability to produce a different toxin that kills insect larvae and is used for pest control in agriculture. However, were these strains of *B. thuringensis* to acquire the genes for enterotoxicity in nature, its use to control pest insects would be seriously compromised. The gene for this protein has been cloned into some genetically modified crops to endow them with insect-resistance properties, which, although a controversial strategy for pest control, would not carry the same risk.

Specific diagnosis depends on the isolation of high numbers of organisms from food, diarrhoea, or vomitus. Typically, however, the high temperature that induces germination and cereulide production kills the bacteria in the emetic form. Cell culture and ELISA tests for toxin are available in reference laboratories. Management of clinical cases is supportive, as symptoms are short-lived.

Listeria monocytogenes

See Chapter 7.11.34 for further discussion.

Staphylococcus aureus (see also Chapter 7.11.4)

Enterotoxin-producing strains of *Staph. aureus* are a classical cause of another true food poisoning, which results from the ingestion of preformed staphylococcal toxins produced in contaminated foods. The source of the bacteria is usually a food handler or preparer, as these organisms are ubiquitous colonizers of the skin, nasal, oral, and rectal mucous membranes. Fingers then readily transmit the bacteria from these sites to food in preparation. Such food handlers often have minor skin infections, such as boils, paronychia, impetigo, or an infected cut or skin abrasion, which facilitates the contamination of the food. The clinical illness is predominantly a short-incubation vomiting syndrome, with watery diarrhoea and abdominal cramps as less prominent symptoms. It is very common and is undoubtedly underdiagnosed.

Many foods can serve as a vehicle for the growth of *Staph. aureus*, including sliced meats, custards and cream pastries, potato and salads containing mayonnaise, and various dairy products. Organisms grow and elaborate toxins if the food is stored unrefrigerated or kept warm for serving. Staphylococcal food poisoning is not more common as relatively few isolates are toxin producers and because the ubiquitous coagulase-negative staphylococci are toxin-negative. There are eight serologically identifiable, small, structurally related, 22- to 28-kDa linear polypeptide toxins, designated staphylotoxin enterotoxins (**SE**) A to E and G to I (SEA, SEB, etc.). Another distinctive toxin, formerly identified as staphylococcal enterotoxin F, is uniquely able to translocate across mucosal surfaces and is now known as toxic-shock syndrome toxin-1 (**TSST-1**). The enterotoxin terminology is engrained in use, however inappropriate this now seems as these peptides are not prominent causes of diarrhoea. Rather they appear to target the stomach where they activate gastric emetic responses by, as yet, uncertain mechanisms. For example, it is not known what the gastric mucosal receptors for staphylococcal enterotoxins are, or even whether small quantities are absorbed to act centrally in the brain. Ultimately, however, it is the activation of medullary emetic centres in the brainstem via vagal or sympathetic-nerve transmitted signals that causes symptoms. Pathology in primates reveals inflammatory changes of the gastric mucosa, and to a lesser extent in the proximal jejunum. Brush-border alterations and mucopurulent exudates are also present. Some investigators theorize that the toxins induce mast-cell degranulation via direct binding to these cells, whereas others suggest that neuropeptides are first released from sensory nerves and secondarily stimulate mast cells to release inflammatory mediators.

Diagnosis is dependent on the isolation of high numbers of toxin-producing *Staph. aureus* from the suspect food. Stool culture is not diagnostic because *Staph. aureus* can often be found in stool in small numbers. None the less, stool culture can be useful epidemiologically if the same phage type of toxin-producing *Staph. aureus* is recovered from the food and the patient and other possible aetiologies are not found. If a food handler is suspected of being the source, culture of skin lesions for enterotoxin-producing *Staph. aureus* is also epidemiologically helpful. Treatment is supportive, as the symptoms are short-lived, generally just a matter of hours.

Summary

It is clear that Enterobacteriaceae constitute a clinically important group of organisms, primarily involved in intestinal infection, with a number of systemic syndromes due to microbial penetration of the intestinal mucosa. In addition, there are a number of foodborne illnesses due to Gram-positive organisms that overlap the spectrum of enteric disease caused by the Enterobacteriaceae. There has been considerable progress in understanding basic microbiology, epidemiology, clinical manifestations, and treatment and prevention strategies of all these organisms. Beyond the scope of this chapter, and therefore not discussed, are the general measures that are or could be taken to reduce the contamination of food and water sources of infection. These range from basic sanitation and safe food handling—for example, Hazard Analysis Critical Control Point (**HACCP**) systems to control microbial contamination of food in processing plants, or proper cooking and refrigeration of food in the home—to the use of large-scale, gamma-irradiation of food to diminish microbial counts, or other potential innovative methods to reduce the contamination of food and water sources with disease-causing micro-organisms. However, the physician must be familiar with all of these aspects of Enterobacteriaceae infections in order to properly diagnose and treat disease when prevention fails.

7.11.8Typhoid and paratyphoid fevers

J. Richens and C. Parry

Typhoid

Typhoid and paratyphoid, types A, B, and C (collectively known as enteric fevers) make up the group of salmonelloses whose main host is human. Their clinical features resemble other salmonelloses, ranging from gastroenteritis (more common with paratyphoid) to the septicaemic illness of severe typhoid.

Epidemiology

Worldwide, 15 to 30 million cases of typhoid occur each year with half a million deaths. In affluent countries, typhoid is seen in travellers or when food or water safety measures fail; with antibiotic treatment death is rare. High rates of transmission are seen in sub-Saharan Africa, the Indian subcontinent, central Asia, Vietnam, and Indonesia where annual incidence reaches 100 to 1000 cases per 100 000 population and up to 1 per cent of the population may carry *S. typhi*. In these countries, transmission has been exacerbated by antibiotic resistance. Peaks of transmission occur in dry weather or at the onset of rains. Case-fatality rates have exceeded 10 per cent in hospitalized patients in Indonesia and Papua New Guinea.

Pathogenesis

Aetiology

Salmonella enterica serovar *typhi* (*S. typhi*) is a Gram-negative bacillus capable of surviving in hostile environments and proliferating dangerously within dairy products, processed meats, and shellfish. Three antigens have been exploited for serodiagnosis; the somatic oligosaccharide O antigen (9 and 12), the protein flagellar H-d antigen, and the polysaccharide envelope Vi antigen which confers virulence by masking the O antigen from immunological attack. Antibiotic resistance is conferred by R plasmids, usually of the incompatibility group IncH-1 (chloramphenicol, amoxicillin, co-trimoxazole), and mutations in the chromosomal *gyrA* gene (fluoroquinolones). Many of the genes that give *S. typhi* its ability to survive in hostile extracellular and intracellular environments have been identified. The genome of *S. typhi* has a remarkable plasticity compared to other bacteria, which allows recombination of homologous rRNA operons as well as insertion of non-homologous DNA. The recent sequencing of an isolate of *S. typhi* will shed further light on the pathogenicity of this organism.

Transmission

Sources of typhoid transmission are excreting chronic or convalescent carriers and the acutely infected. Transmission occurs through contamination by carriers of food or water by effluents containing infected urine or faeces. 'Typhoid Mary' was a cook who infected 53 people early last century. The Aberdeen outbreak in 1964 was traced to a leaking corned beef tin which had been cooled with contaminated river water. Transmission of typhoid has also been attributed to flies, laboratory mishaps, unsterile instruments, and anal intercourse.

Infective dose

Hornick demonstrated that 10^7 organisms of Quailes strain of *S. typhi* infected 50 per cent of experimental subjects. Susceptibility is increased by antacids or vagotomy. The virulence of *S. typhi* varies. Infection may lead to acute disease, transient symptoms, or to a symptomless carrier state.

Multiplication and dissemination

Bacteria pass from the gut through the cytoplasm of enterocytes and M cells overlying lymphoid tissue (Peyer's patches) of the small intestine to reach the lamina propria from which they are conveyed to the mesenteric nodes, before reaching the blood stream via the thoracic duct. During a transient primary bacteraemia the organism is seeded to reticuloendothelial sites where intracellular multiplication occurs throughout a 7 to 14-day incubation period. A second bacteraemia follows, accompanied by symptoms as the infection spreads throughout liver, gallbladder, spleen, Peyer's patches, and bone marrow. Multiplication of *S. typhi* occurs mainly in macrophages. Concentrated sites of infection in reticuloendothelial tissues, known as typhoid nodules, are characterized by infiltrates of lymphocytes and macrophages. At post mortem, hypertrophy of lymphoid tissue is often visible within liver, spleen, mesenteric nodes, and Peyer's patches. Ulceration of Peyer's patches is seen where the inflammatory process has resulted in ischaemia and necrosis (Fig. 1).

Fig. 1 Typhoid at autopsy, showing transmural ulceration of Peyer's patches in the distal ileum.

Endotoxin plays a central role in stimulating the release of cytokines such as tumour necrosis factor and interleukins 1 and 6 from macrophages and neutrophils, by activating the complement cascade and upregulating the adhesive capacity of neutrophils and endothelial cells. These processes inflict inflammatory damage through the release of neutrophil proteases, free oxygen radicals, and arachidonic acid metabolites. Unlike in meningitis and malaria, no correlation between levels of tumour necrosis factor and clinical outcome has been demonstrated in typhoid. Levels of circulating tumour necrosis factor receptors are increased and the capacity of whole blood to produce proinflammatory cytokines following stimulation is reduced in patients with severe typhoid.

Immune response

In patients there is a cell-mediated immune response lasting about 16 weeks, a mucosal immune response lasting for up to 48 weeks, and persistent circulating anti-O and -H agglutinins for up to 2 years. The predominance of clinical typhoid among children and young adults in endemic areas suggests a degree of acquired immunity. Only 25 per cent of volunteers given a standard inoculum of *S. typhi* 20 months after an initial infection developed clinical illness. Prolonged elevation of Vi antibody occurs in typhoid carriers. Immunodeficiency reduces the ability to clear *Salmonella* infections.

Clinical features

Typhoid is predominantly an infection of children and young adults, affecting both sexes equally. The incubation period ranges from 3 to 60 days, but most infections occur 7 to 14 days after exposure.

The main focus of typhoid is in the small bowel, but systemic symptoms often overshadow abdominal symptoms. The predominant symptom is the fever which rises gradually to a high plateau of 39 to 40°C, and shows little diurnal variation. Rigors are uncommon, except in late or complicated typhoid or in patients treated with antipyretics.

Most patients complain of headache and malaise. Constipation is a frequent early symptom. Most patients will experience diarrhoea and typhoid can present as an acute gastroenteritis. Severe diarrhoea or colitis has been reported in HIV-infected patients. Bloody diarrhoea may be seen. The abdominal pain is usually diffuse and poorly localized but occasionally sufficiently intense in the right iliac fossa to suggest appendicitis. Nausea and vomiting are infrequent in uncomplicated typhoid but are seen with abdominal distension in severe cases. Other early symptoms include cough, sore throat, and epistaxes.

In developing countries, patients with typhoid in its second to fourth week present with accelerating weight loss, weakness, altered mental state, intestinal haemorrhage and perforation, refractory hypotension, pneumonia, nephritis, and acute psychosis. Those infected with multidrug resistant *S. typhi* may suffer more severe disease.

Physical examination is often unremarkable apart from fever. Careful examination may reveal splenomegaly, hepatomegaly, or rose spots. Tachycardia is common although temperature pulse-dissociation (relative bradycardia) is considered characteristic. Hypotension has important impli-cations (see below, Severe typhoid). A coated tongue is often observed. The lenticular rose spots, appear at the end of the first week. They form a sparse collection of maculopapular lesions on the abdominal skin, which blanch with pressure and fade after 2 or 3 days. Osler found them in 90 per cent of whites and 20 per cent of black skins. The rash may extend on to the trunk and arms. Melanesian typhoid patients develop purpuric macules that do not blanch (Plate 1).

Adventitious lung sounds, especially scattered wheezes, are common and may suggest pneumonia. These findings with a normal chest radiograph and high fever should prompt consideration of typhoid.

Abdominal examination may reveal the typhoid rash, distension, or a diffuse tenderness, occasionally localized to the area of the terminal ileum. Intra-abdominal inflammation sometimes provokes retention of urine. A moderate, soft, tender hepatosplenomegaly eventually develops in most patients but it less likely to be found early.

Patients with advanced illness may display the 'typhoid' facies (Fig. 2), a thin, flushed face with a staring, apathetic expression. Mental apathy may progress to an agitated delirium, frequently accompanied by tremor of the hands, tremulous speech, and gait ataxia. If the patient's condition deteriorates further the features described in the writings of Louis and Osler make their appearance—muttering delirium, twitchings of the fingers and wrists (subsultus tendinum), agitated plucking at the bedclothes (carphology), and a staring, unrousable stupor (coma vigil).

Fig. 2 Typhoid facies: 18-year-old male with severe typhoid.

Typhoid in children

Typhoid can develop in neonates born to infected mothers. The disease tends to take a milder course in children but case-fatality rates are higher in under-fives. The main differences, compared to adults, are a greater frequency of diarrhoea and vomiting, jaundice, febrile convulsions, nephritis (3 per cent in one series), or typhoid meningitis. Community-based studies in Chile and India have shown that unrecognized *S. typhi* and *paratyphi* bacteraemia can behave like a mild respiratory illness in very young children. Relative bradycardia is of greater diagnostic significance for typhoid in febrile children.

Diagnosis

A secure diagnosis of typhoid rests on the isolation of *S. typhi*. Many viral, bacterial, and protozoal infections as well as non-infectious conditions characterized by fever, such as lymphoproliferative disorders and vasculitides, resemble typhoid. Typhoid should always be considered when suspected malaria has not been confirmed or has not responded to antimalarial therapy.

Culture

S. typhi can be isolated from blood, bone marrow, stool, urine, bile, cerebrospinal fluid, and rose spots. Bone marrow gives the highest yield, including those exposed to antibiotics, but yields only marginally more than blood. For bone marrow culture the fine needle technique described by Hedley can be recommended (Hedley *et al.* (1982). *Lancet* **ii,** 415–16). Most clinicians culture blood, stool, and sometimes urine.

The median number of bacteria present in the blood of children are higher than adults and decline with increasing duration of illness. In mild typhoid, the number of bacteria may be as low as one colony forming unit per ml. Successful culture from blood can be achieved in 80 per cent of patients but depends on taking a generous volume of blood and using the correct volume of blood to broth (1:10). Automated continuously monitored culture systems (e.g. Bactec and Bact/Alert systems) can accelerate the culture from blood. Culture of bile obtained from an overnight duodenal string capsule gives a similar yield to blood and offers additional means to isolate *S. typhi* from children or from carriers. Rose spots, when present, can give a positive culture in 70 per cent of patients.

The number of organisms recoverable from faeces increases through the illness. Rectal swabs are less satisfactory than faecal samples. The results must be interpreted with caution in areas with many carriers. Isolation from urine is more common in areas endemic for schistosomiasis.

Serology

The use of a tube or slide agglutination test (the Widal test) to diagnose typhoid is cheaper and simpler than culture but fraught with pitfalls. The demonstration of a four-fold rise in titre of antibodies to *S. typhi* suggests typhoid but is too slow to help clinical decision-making and is not observed in all patients. Single measurements of antibody titres has been found useful in populations where accurate, up-to-date information about the predictive value of the test at specific cut-off points is available. False positive serological tests are obtained from persons with previous infection, infection with cross-reacting organisms, or following vaccination.

Other tests for typhoid

Many other tests for the detection of antibodies, *S. typhi* antigens, and salmonella DNA in body fluids have been described: these include passive haemagglutination, latex agglutination, counterimmune electrophoresis, radioimmunoassay, enzyme immunoassay, indirect fluorescent antibody tests, monoclonal antibodies, IgM capture, DNA probes, and PCR. Few have so far been adopted for routine use.

Other laboratory findings in typhoid

A mild normochromic anaemia, mild thrombocytopenia, and an increased erythrocyte sedimentation rate are common. The frequency of true leucopenia has been overstated in the past; most patients have a total white-cell count within the normal range. Leucocytosis suggests either perforation or another diagnosis. Laboratory evidence of mild disseminated intravascular coagulation is common but rarely of clinical significance. Common biochemical findings include hyponatraemia, hypokalaemia, and elevation of liver enzymes. The urine often contains some protein and white cells.

Management

The aims of management are to eliminate the infection swiftly with antibiotics, to restore fluid and nutritional deficits, and to monitor the patient for dangerous complications.

Antibiotics (see Table 1 for doses)

Effective antibiotic therapy in typhoid reduces mortality and complications and shortens the illness. Chloramphenicol was the first antibiotic found to be effective and the standard against which subsequent antibiotics have been measured. Ampicillin, amoxicillin, and co-trimoxazole have been shown to have comparable efficacy to chloramphenicol while having less toxicity. In many areas these drugs are no longer used because of the spread of multidrug resistant (MDR) strains of *S. typhi*. New antibiotics active against MDR *S. typhi* have emerged. Most active are the fluoroquinolones but resistance is again emerging. Other useful antibiotics are the extended-spectrum cephalosporins and azithromycin.

Most physicians start with a fluoroquinolone—ofloxacin, ciprofloxacin, fleroxacin, or pefloxacin. Treatment can be completed in a week or less with minimal toxicity In an analysis of 19 randomized trials of fluoroquinolones in the treatment of 788 patients with culture-confirmed enteric fever (>95 per cent *S. typhi* infection), the fever clearance was 2.5 to 5.2 days with a pooled cure rate of 97.3 (95 per cent CI, 96–98 per cent). Over half the studies reported no relapses and only one carrier (0.2 per cent) was detected among 591 patients followed up. Response rates in endemic areas may be better than those of non-immune travellers. For immunocompromised patients treatment may need to be extended for weeks or months. Questions remain about the safety of fluoroquinolones in children and during pregnancy. Careful follow-up studies of children in Vietnam following fluoroquinolone therapy have shown no toxicity and there is a growing consensus that the advantages of therapy outweigh the dangers. Ampicillin or amoxicillin is considered to be the safest drug to use in pregnancy with typhoid but should not be used in preference to a fluoroquinolone in patients likely to have MDR typhoid.

Strains of *S. typhi* with reduced susceptibility to fluoroquinolones are common in Asia and can be identified by being resistant to nalidixic acid. Patients infected with these strains may require longer courses of fluoroquinolones at the maximum dose or they may be treated with extended spectrum cephalosporins (ceftriaxone or cefixime). Azithromycin has recently shown to be effective in mild to moderate typhoid but currently cannot be recommended for severe disease.

Supportive care

Cooling is preferred to antipyretics for relief of fever. Simple analgesics may be used to relieve headache but note that paracetamol has been reported to lengthen the half-life of chloramphenicol five-fold. Most patients can eat and drink normally. Special diets do not protect the bowel from perforation. Daily assessment of the patient's mental and circulatory status are required plus examination of the abdomen for signs of impending perforation. Severely ill patients require intensive care with parenteral fluids, intravenous steroids (see below), inotropic support, and sedation.

Complications

Table 2 lists complications of typhoid. Most are rare and only likely to be encountered in patients who present with untreated disease lasting 2 or more weeks. Occasionally, a complication dominates the clinical picture and deflects attention from the underlying diagnosis of typhoid.

Severe typhoid

Studies from Indonesia and Papua New Guinea have revealed an important subgroup of patients with mental confusion or shock (defined as a systolic blood pressure of less than 90 mmHg in adults or less than 80 mmHg in children), with evidence of decreased skin, cerebral, or renal perfusion, who have a 50 per cent fatality and account for most typhoid deaths. In one study in Jakarta, high doses of dexamethasone substantially reduced the mortality of such severe cases. The criteria for severe typhoid were marked mental confusion or shock. In adults, dexamethasone, 3 mg/kg infused intravenously over half an hour, followed by eight doses of 1 mg/kg 6-hourly, resulted in a 10 per cent case-fatality compared to 55.6 per cent in controls.

Intestinal haemorrhage and perforation

Perforation of ileal ulcers occurs in less than 5 per cent of typhoid patients. The development of acute abdominal signs is often gradual, making diagnosis difficult. Severely ill patients display only restlessness, hypotension, and tachycardia. A chest radiograph may show free gas under the diaphragm. Ultrasonography is useful for demonstrating and aspirating faeculent fluid in the peritoneal cavity. To manage perforation start nasogastric suction, administer fluids to correct hypotension, and proceed to surgery promptly. Simple closure of perforations is adequate but experienced surgeons use procedures to bypass the worst-affected sections of the ileum in order to reduce postoperative morbidity. Closure of perforations should be accompanied by vigorous peritoneal toilet. Metronidazole or clindamycin should be added to the therapy of fluoroquinolone-treated patients. Metronidazole and aminoglycosides are recommended for patients receiving chloramphenicol, ampicillin, or co-trimoxazole. The survival of patients undergoing surgery for perforation is generally 70 to 75 per cent, but reaches 97 per cent in the best series. This compares with survival rates of around 30 per cent in conservatively managed patients.

Silent bleeding may be signalled by sudden collapse of a patient or a steadily falling haematocrit. Severe bleeding is sometimes seen in advanced typhoid. It is rarely fatal. Most bleeding episodes are self-limiting. A few require transfusion. In exceptional circumstances, surgery or intra-arterial vasopressin have been to halt haemorrhage.

Relapse

Relapse in typhoid is a second episode of fever, usually milder than the first, occurring a week or two after the recovery from the first episode. Isolates from relapsing patients usually have identical antibiotic susceptibility to those identified during the first episode. Relapse rates of 10 per cent have been described in untreated typhoid and chloramphenicol-treated patients. Relapse is managed with a similar or abbreviated course of the same therapy used in the initial episode.

Carriers

Many patients excrete *S. typhi* in their stools or urine for some days after starting antibiotic treatment. Convalescent carriers excrete for periods up to 3 months. Patients still excreting at 3 months are unlikely to cease and at 1 year meet the formal definition of 'chronic carrier'. Amongst carriers detected by screening, 25 per cent give no history of acute typhoid. Faecal carriage is more frequent in individuals with gallbladder disease and is most common in women over 40; in the Far East there is an association with opisthorchiasis. Urinary carriage is associated with schistosomiasis and nephrolithiasis. Acute typhoid in carriers has been reported. There is an increased risk of carcinoma of the gallbladder.

Patients discharged after treatment for typhoid with six negative stool and three negative urine specimens and negative Vi serology are considered free of infection. Most patients with positive stools at the completion of treatment excrete temporarily and can be safely followed up. Antibiotic eradication of carriage is advised in those still excreting at 3 months, or earlier in those at particular risk of communicating infection to others. The patient with a persistently elevated or rising Vi antibody titre is likely to be a carrier. Repeated checks of urine and faeces should be made and consideration given to obtaining bile cultures if these are negative. In Egypt, demonstration of H antibody in urine has been useful in identifying carriers.

Eradication of carriage requires prolonged, high-dose antibiotics (Table 1). Ampicillin, amoxicillin, and co-trimoxazole have been used with some success. More recently, good results have been reported with fluoroquinolones. Cholecystectomy and nephrectomy, once used to eliminate carriage (and not without operative mortality), are hard to justify on public health grounds alone, but can be considered if antibiotic methods fail and there are additional indications for operation. The success rates of surgery are increased by giving antibiotics as well.

Prevention

The elimination of typhoid from industrialized countries can be attributed to the provision of safe drinking water, safe disposal of sewage, legal enforcement of high standards of food hygiene, programmes to detect, monitor, and treat chronic carriers, and prompt investigation and intervention when these safeguards are breached. The tools of outbreak investigation are phage typing of isolates, DNA fingerprinting using pulse field gel electrophoresis or ribotyping, registers of known carriers and their phage types, and sewer swabs used to trace isolates back to their source.

Measures for individual protection are to kill *S. typhi* in water by heating to 57°C, iodination or chlorination, care with uncooked or reheated food, and immunization. Patients and convalescents with typhoid should be advised to wash their hands after using the toilet and before preparing food and to use separate towels.

Vaccines

The greatest need for typhoid vaccination is among children in endemic areas, especially where antibiotic resistance is increasing, and among laboratory workers handling *S. typhi*. In practice, vaccines are given mostly to travellers to endemic areas. A recent meta-analysis has suggested that whole cell vaccines (which are no longer widely available) are the most effective although side-effects are prominent. The most convenient is the Vi vaccine, as a single 25-µg intramuscular dose, giving 70 to 80 per cent protection for 3 years. An alternative is the live attenuated oral Ty21a vaccine which gives 65 to 70 per cent protection for 3 to 7 years. This vaccine can cause abdominal symptoms. Effectiveness can be reduced by mefloquine and antibiotics and it should not be given to immunosuppressed persons. Typhoid vaccines do not protect against paratyphoid infection and the protection afforded by vaccination can be overcome by large inocula of bacteria. Efficacy figures derive largely from trials conducted in partly immune populations and overestimate benefit in persons without prior exposure. The risks of typhoid among travellers are low (105–118 cases per million travellers to India) and the precise efficacy of currently recommended doses in previously unexposed adults remains unknown. A number of new vaccines are currently being evaluated, notably a Vi conjugate vaccine undergoing phase III clinical trials in Asia. For full details of typhoid vaccination readers should consult specialist texts.

Paratyphoid fever

Paratyphoid, type B has the widest distribution and resembles typhoid most closely. Paratyphoid A occurs chiefly in Asia and Africa and paratyphoid C in Asia and the Middle East. Paratyphoid A and C are more likely to present with a gastroenteritic than a typhoidal type of illness. *S.* Para*typhi* causes more asymptomatic infections than *S. typhi*. Outbreaks of paratyphoid are much more often food-borne than water-borne, probably because larger inocula are needed to establish infection. Paratyphoid has a shorter incubation period (4–5 days), shorter duration, and lower incidence of complications, including relapse and long-term carriage. Deaths are rare. The skin lesions of paratyphoid are larger, more numerous, and more extensive than those of typhoid. The management of paratyphoid is the same as that of typhoid. Paratyphoid organisms may display multidrug resistance as in *S. typhi*. Eradication of carriage with quinolones has been less successful in paratyphoid than in typhoid.

7.11.9 Intracellular klebsiella infections

J. Richens

Rhinoscleroma

Rhinoscleroma or scleroma in an infection of the upper airways characterized by inflammatory growths and caused by *Klebsiella pneumoniae*, subspecies *rhinoscleromatis.* Small endemic foci have been described in Africa (especially Egypt and Uganda), Siberia, Turkestan, the Middle East, the Indian subcontinent, China, the Philippines, Indonesia, and Papua New Guinea. There are many foci in South and Central America; it remains common in Guatemala where it has been identified in terracotta Maya heads of AD 300 to 600. The disease has retreated in Eastern and Central Europe where it was first described by Hebra and Kaposi in 1870.

Aetiology

K. rhinoscleromatis can be isolated from about 60 per cent of patients and is seen as intracellular inclusions in material taken from lesions. Patients show high titres of antibody which react with this organism and with the inclusions seen in sections.

Pathogenesis

Transmission is believed to occur from person to person in endemic areas. No incubation period has been defined. Initially patients infected with this organism may develop an atrophic rhinitis with squamous metaplasia, hyperkeratosis, and atrophy. The most characteristic phase of the disease is the nodular stage during which a granulomatous reaction to the organisms within macrophages leads to the development of bulky masses within any part of the respiratory tract from nares to tracheal bifurcation. The process can extend into and destroy neighbouring soft tissues, cartilage, bone, and skin. Histology shows a dense infiltrate of plasma cells among which are seen large foamy histiocytes (Mikulicz cells) containing Gram-negative bacteria and Russell bodies which are thought to be effete plasma cells. Patients with late-stage disease are liable to develop fibrosis and strictures.

Clinical features

Rhinoscleroma runs a slow, fluctuating course over several years, progressing through atrophic, nodular, and fibrotic stages. Systemic symptoms are not seen. The usual presentations are with nasal obstruction and bleeding and nasal deformity (splaying of the lower nose, often with a visible growth extending down to the upper lip known as Hebra nose) (Fig. 1). Some patients present with ozaena, which is an atrophic rhinitis accompanied by a foul smell and formation of crusts within the nose. Patients with tracheal involvement may present with stridor. With the help of sinus endoscopy and newer imaging techniques it is not unusual to find evidence of spread into the sinuses, orbits, cranial cavity, middle ear, and regional lymph nodes.

Fig. 1 Rhinoscleroma in a 30-year-old man from Papua New Guinea causing characteristic nasal splaying (Hebra nose) and obstruction of the left nostril. (Reproduced from Cooke R (1987). *Colour atlas of anatomical pathology*, p. 31. Churchill Livingstone, Edinburgh, with permission.)

Diagnosis

The diagnosis is usually made by demonstrating intracellular organisms in Giemsa or silver-stained sections taken from typical lesions combined with culture. Haemagglutination tests for Klebsiella capsular antigen III have high sensitivity and specificity. CT scanning and endoscopic techniques provide useful ways to define the extent of the disease.

Treatment

Rhinoscleroma is usually managed by ear, nose, and throat specialists using a combination of antibiotic therapy and surgery for obstructing lesions. Atrophic rhinitis may benefit from nasal lavage with saline. Treatment with ciprofloxacin, 250 mg twice daily for 4 weeks, appears to be substantially superior to previously used antibiotic regimens (rifampicin, streptomycin, tetracyclines, ampicillin and co-trimoxazole). The efficacy of fluoroquinolones may derive from their excellent intracellular penetration. For the same reason, azithromycin would be a logical choice for rhinoscleroma, particularly in view of its excellent results in donovanosis, which is caused by a very closely related intracellular Klebsiella infection. Debulking operations may be needed if there is obstructing nasal and tracheal disease and tracheostomy may be required as a temporary measure. Reconstructive surgery may be needed to deal with late fibrotic stenosis.

Donovanosis (granuloma inguinale)

Donovanosis is a sexually transmitted infection characterized by ulcers of the anogenital and inguinal areas. The name of the causative organism has recently been changed from *Calymmatobacterium granulomatis* to *Klebsiella granulomatis.* The disease is also known by the names granuloma inguinale and granuloma venereum, but should not be confused with lymphogranuloma venereum. The intracellular Gram-negative bacteria found within lesions (Donovan bodies) were first described by

the same Charles Donovan who found protozoal inclusions in visceral leishmaniasis (Leishman–Donovan bodies).

Aetiology

Recent research has indicated that it is possible to isolate an unusual Gram-negative bacillus in HEp-2 cells or human peripheral blood mononuclear cells from patients with characteristic lesions. This organism will not grow on conventional solid media. Previously named *Donovania* and subsequently *Calymmatobacterium*, it has now been classed as *Klebsiella granulomatis* on the basis of close DNA homology with other *Klebsiella* species. *Klebsiella granulomatis* shows morphological identity with Donovan bodies observed within clinical lesions of donovanosis and patients with characteristic lesions have high levels of antibody that react equally with Donovan bodies and with *K. granulomatis*. *K. granulomatis* is pathogenic only to man. Experimental transmission has been reported with lesion material, but to date not with a pure culture of this organism. Donovanosis shows a close macroscopic and microscopic similarity to rhinoscleroma which produces granulomatous lesions of the upper airways containing intracellular clusters of the closely related organism, *Klebsiella rhinoscleromatis*.

Epidemiology

Donovanosis is found in small endemic foci. The best known of these are in Papua New Guinea, India, southern Africa, Brazil, and among Australian aborigines. Smaller foci have been described in the Caribbean region and China. Where endemicity is greatest it is unusual for donovanosis to account for more than 20 per cent of genital ulcers. In most parts of the world donovanosis seems to be retreating, raising hopes of eventual eradication. Where it occurs, donovanosis appears particularly linked to poverty, poor hygiene, and prostitution. Dark-skinned persons appear to have greater susceptibility. Infectivity is believed to be low and sexual partners often remain free of infection despite prolonged exposure. The highest rates reported in partners have been 50 per cent. In the past, epidemics of donovanosis have occurred in New Guinea where they were linked to ritual homosexual and heterosexual promiscuity. The predilection of lesions for the anogenital region of sexually active adults and the frequent association with other sexually transmitted infections point to most transmission being sexual. Goldberg has put forward arguments for non-sexual transmission of an opportunistic rectal pathogen based on a single questionable isolation of the causative organism from faeces. Perinatal transmission has been observed in a few cases.

Pathogenesis

Transmission requires direct contact with an infected lesion and is thought not to occur through intact skin. The organism has a special tropism for dermal macrophages, in which it is able to avoid damage by lysosomal enzymes and toxic oxygen metabolites. The response to infection is characterized by vigorous granulomatous inflammation that damages the skin and subcutaneous tissues. Extension of the infection is predominantly a local process of spreading ulceration. The frequent inguinal lesions are probably seeded by lymphatic spread but, in general, involvement of lymphatics and lymph nodes in donovanosis is much less prominent than in lymphogranuloma venereum. Haematogenous dissemination and spread to the upper genital tract of women occur exceptionally and demonstrate the organism's ability to survive in deeper tissues. Lesions in women tend to be more extensive and may progress rapidly during pregnancy.

Clinical features

The best estimates of the incubation period range from 3 to 40 days. The early lesion is most common on the distal penis in men and near the introitus in women. Starting as a non-specific papule, the early lesion soon becomes an ulcer displaying a deep red colour, contact bleeding, low levels of pain and tenderness unless secondary infection is present, and a well-defined, rolled edge. Frequently lesions take the form of hypertrophic masses that pout outwards from the surrounding skin. Lesions are often accompanied by local oedema, particularly in women. Atypical lesions include: dry, warty, hypertrophic lesions with a cobblestone appearance; painful, excavated ulcers; and lesions with an ill-defined edge showing diffuse subcutaneous infiltration. Chronic lesions tend to expand gradually along skin folds and across to apposed skin surfaces forming a large, continuous area of ulceration, with a characteristic serpiginous outline (Fig. 2). Inguinal lesions are common, especially in men. They start as firm, subcutaneous swellings and often go on to ulcerate. The term 'pseudobubo' was originally coined to describe a subcutaneous inguinal abscess in donovanosis (rare) but tends to be used now to describe the more common ulcerating inguinal lesions. Primary lesions of the cervix are notorious for simulating carcinoma of the cervix. The uterus, fallopian tubes, ovaries, and adnexas may all be involved, simulating other forms of pelvic inflammatory disease with abscess formation or simulating malignancy with development of a frozen pelvis, large, hard masses, or hydronephrosis. Anal lesions in women commonly spread directly from the introitus; in men they are associated with anal intercourse. Involvement of the rectum very seldom occurs.

Fig. 2 Characteristic serpiginous ulcer in female patients with long-standing donovanosis.

Extragenital lesions of donovanosis occur most often in and around the mouth and sometimes on the neck. Haematogenous dissemination of donovanosis is associated especially with the trauma to an infected uterine cervix during pregnancy. The manifestations include lytic bone lesions, psoas, and perinephric abscesses. Spread to liver, spleen, and lung occurs exceptionally. Lesions in infants tend to involve the ears and regional lymph nodes.

Complications of donovanosis include extensive scar formation, lymphoedema of the genitalia, penile autoamputation, and the development of squamous carcinoma in active or healed lesions. Secondary infection with fusospirochaetal organisms can cause rapid, extensive, and sometimes fatal tissue destruction.

Diagnosis

Donovanosis is traditionally diagnosed by demonstrating the presence of Donovan bodies lying within histiocytes in material taken from a typical lesion (Fig. 3). The number of Donovan bodies present varies considerably so that sometimes a swab or scraping is sufficient to make a diagnosis whilst at other times a careful search must be made of biopsy material. Donovan bodies show well with Giemsa, Leishman, and Wright stains but poorly with haematoxylin and eosin. Histology typically shows a heavy plasma cell infiltrate and epithelial hyperplasia in addition to histiocytes containing Donovan bodies. The use of tissue culture, serological tests, and polymerase chain reaction to diagnose donovanosis have all been described recently, but are not yet commercially available. All patients should be offered screening for other sexually transmitted infections, especially syphilis and HIV. Donovanosis often causes diagnostic confusion when encountered outside endemic areas. Common misdiagnoses are squamous carcinoma of the cervix, vulva, or penis, secondary syphilis, and conditions that produce genital lymphoedema such as filariasis and lymphogranuloma venereum.

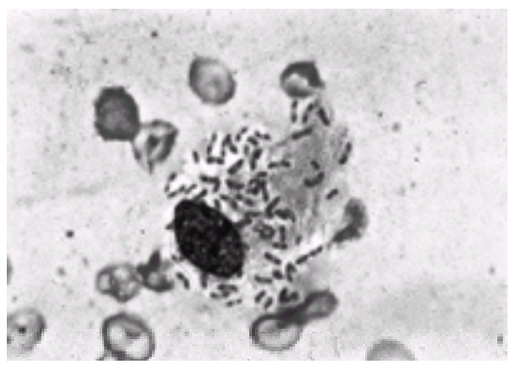

Fig. 3 Donovan bodies: Giemsa-stained smear from donovanosis lesion demonstrating the characteristic 'closed safety pin' appearance of encapsulated organisms within a large histiocyte.

Treatment and prevention

Recently published guidelines for the management of donovanosis recommend the use of azithromycin, ceftriaxone, ciprofloxacin, doxycyline, erythromycin, or co-trimoxazole. No randomized comparative trials have been conducted. Antibiotics are given at standard dosage until lesions have re-epithelialized. Expert opinion suggests that azithromycin gives the best results at a daily dose of 500 mg or weekly doses of 1 g. Antibiotic susceptibility testing is not currently feasible. Treatment failure with older antibiotics, such as doxycyline and co-trimoxazole, is well documented in individual cases. Erythromycin is safe and gives good results in pregnant women. Women in labour found to have untreated lesions of the cervix should be delivered by caesarian section to reduce known risks of haematogenous dissemination and transmission to the neonate. Patients with genital deformity may benefit from plastic surgical procedures. Partners of patients should be examined and treated if infected. A week of epidemiological treatment may be offered to healthy contacts to abort incubating infections. The main hopes for the control of donovanosis lie in strengthening services for patients with sexually transmitted infections in endemic areas, the use of newer antibiotics such as azithromycin coupled with health education and condom promotion. Eradication is currently being attempted in Australia.

7.11.10Anaerobic bacteria

S. J. Eykyn

Definition of an anaerobe

The definition of an anaerobe is not entirely straightforward microbiologically. Anaerobes vary in their tolerance of oxygen and some strains will grow only in a very low concentration while others are relatively aerotolerant. In practice in the routine microbiology laboratory, bacteria that fail to grow on the surface of solid medium in 10 per cent CO_2 in air are classified as anaerobes. Confusion sometimes arises with organisms that while preferentially anaerobic (that is, they usually grow only on the anaerobic plate on primary isolation from a clinical specimen) are actually microaerophilic or capnophilic; these include *Actinomyces* which are often erroneously referred to as anaerobes. In this case the confusion is compounded as the clinical infection of actinomycosis (see Chapter 7.11.26) is usually caused by both *Actinomyces* and anaerobes. Preferentially anaerobic bacteria also include the 'milleri' group of streptococci which can readily be mistaken for anaerobic streptococci.

Incidence of anaerobic infection

Anaerobic infections are common, even if not always recognized as such, and may affect any tissue or organ and thus present to most clinicians regardless of specialty. Postoperative anaerobic sepsis was dramatically reduced when the prophylactic use of highly effective antianaerobic antibiotics was introduced in the 1970s. Although anaerobic bacteria were extensively studied in Europe in the late 19th and early 20th centuries, they were then largely ignored for many years. Anaerobes (with the exception of *Clostridium perfringens* and the occasional *Bacteroides fragilis*) were seldom isolated in clinical laboratories until the mid-1970s when an 'anaerobic renaissance' was initiated by American researchers and the anaerobes were 'rediscovered' as common and important human pathogens. This coincided with the advent of highly effective antianaerobic antimicrobials. Since then enormous advances have been made in the isolation, taxonomy, clinical diagnosis, management, and prevention of anaerobic infection.

Taxonomy

The classification and characterization of many anaerobic bacteria presents considerable difficulties and only dedicated anaerobists can hope (or need) to be abreast of current taxonomy. The many synonyms for some of these organisms bear witness to these difficulties; Finegold, for example, quoted over 50 for the organism now classified as *Fusobacterium necrophorum*. Such taxonomic confusion is further compounded by the many reports that refer to any Gram-negative anaerobic bacillus as a 'Bacteroides' and to those resistant to penicillin and ampicillin as *B. fragilis.* The use of genetic techniques has resulted in the reclassification of many anaerobes. The genus *Bacteroides* is limited to the *Bacteroides fragilis* group. The saccharolytic species previously included in the *B. melaninogenicus–oralis–ruminicola* group have been assigned to the new genus *Prevotella* which includes both pigmented and non-pigmented species. The asaccharolytic, pigmented, Gram-negative rods are now in the new genus *Porphyromonas*. Other taxonomic changes have affected the anaerobic Gram-positive cocci which have almost all become *Peptostreptococcus*. As these taxonomic changes affect some clinically important anaerobes, the new nomenclature will be used in this chapter. Table 1 lists some of the clinically important anaerobes and their old and new names where appropriate. Of the many hundreds of anaerobic species, only a small number are likely to be relevant to clinical practice and specifically reported by clinical microbiology laboratories.

Anaerobic commensal flora of man

The commensal flora of man is largely anaerobic; anaerobes are found on all the mucosal surfaces and on the skin.

Skin

It is surprising that although the skin is constantly exposed to the air, it still supports a considerable anaerobic microflora, predominantly 'anaerobic diphtheroids' that is the propionibacteria, including the lipolytic species *Propionibacterium acnes* associated with acne.

Mouth

Anaerobes are found in the tonsillar crypts, tongue crypts, gingival crevices, and dental plaque. Although some anaerobic species are found in young infants, the variety and number of anaerobes increases markedly with the eruption of the teeth. Predominant members of the oral anaerobic flora include *Prevotella*, *Fusobacterium*, *Peptostreptococcus*, *Veillonella*, and various anaerobic Gram-positive bacilli. The group *B. fragilis* group of anaerobes are rarely found in the mouth

and *Porphyromonas* only in small numbers if at all.

Intestine

The stomach and upper small intestine are normally sterile or contain transient, small numbers of anaerobic organisms derived from food, saliva, and nasopharyngeal secretions. The terminal ileum resembles the colon with a vast and diverse anaerobic flora which is established by the second year of life. Anaerobes account for about 99 per cent of the bacterial faecal mass and *Bacteroides* spp. are the commonest species. *B. vulgatus* and *B. thetaiotaomicron* are more frequently encountered than *B. fragilis*. Clostridia are also found in large numbers. Many hundred different species of anaerobe are found in the colon.

Genitourinary tract

The normal flora of the vagina is predominantly anaerobic, mostly lactobacilli, but also small numbers of *Prevotella*, fusobacteria, and peptostreptococci are found. The urethral flora consists of similar anaerobes.

Pathogenesis

The anaerobic bacteria that cause human infection are almost always derived endogenously from the host's own commensal flora. Exceptions to this include: bite and punch injuries, in which the anaerobic oral flora of assailant or victim is involved; animal and human bites (animal oral flora has large numbers of anaerobes as well as aerobic bacteria specific to animals such as *Pasteurella*); and neonatal sepsis in which the maternal vaginal anaerobes cause infection in the new-born baby. Many clostridia are found not only as normal gastrointestinal flora in man and animals but also in the soil. Clostridia are sporing anaerobes and cause infection in man in two distinct ways: firstly certain species produce potent toxins and these cause specific toxin-mediated infections that will be considered elsewhere; secondly, Clostridia, including sometimes *Clostridium perfringens,* often occur with non-sporing anaerobes in a variety of anaerobic infections in which they do not exert their toxic potential, and their presence or absence has no effect on the course of the disease. Most anaerobic infections are polymicrobial with not only several anaerobic species involved but usually aerobic species as well. The anaerobic component of these mixed infections seems to be the more important. Predisposing factors include disruption of normally intact cutaneous or mucosal barriers, tissue injury and necrosis, impaired blood supply, and obstruction. Virulence factors are also involved and include adhesins, capsules, lipopolysaccharide, hydrolytic and other enzymes, soluble metabolites, and growth factors. Precise virulence determinants for most anaerobic infections have not been established.

Adhesins

Surface attachment structures such as fimbriae have been described in some strains of *B. fragilis* and in other anaerobic species and may enable adherence to epithelial cells, an important factor in the initiation of colonization and infection.

Capsules

Capsule formation has been described in *B. fragilis* and some other anaerobes. Capsules confer resistance to phagocytosis, inhibit the migration of macrophages, and potentiate abscess formation.

Lipopolysaccharide

The lipid A component of the *B. fragilis* lipopolysaccharide differs chemically in certain respects from lipid A and this may account for its low endotoxic activity. *F. necrophorum* and *F. nucleatum* interestingly have conven-tional endotoxic lipopolysaccharide.

Enzymes

Most anaerobic pathogens produce numerous enzymes, including immunoglobulin proteases, enzymes capable of inactivating plasma proteins important in the initiation and control of the inflammatory response, and enzymes that degrade tissue components.

Diagnosis of anaerobic infection

Clinical

A working knowledge of the nature and whereabouts of the normal human commensal anaerobic flora is invaluable to the clinician as anaerobic infection frequently arises in association with this. Putrid discharge characterizes some, though not all, anaerobic infections and this results from the metabolic products of the bacteria. No other group of organisms can produce pus with such a foul, nauseating smell. Anaerobic infections, particularly necrotizing infections, are sometimes associated with cellulitis and gas formation. The former may be mistaken for streptococcal cellulitis and the latter for clostridial gas gangrene but anaerobic gangrene with gas formation generally causes far less toxaemia and prostration than clostridial infection in which the patient is alarmingly ill. Nor is the formation of gas in tissues confined to anaerobes, as aerobes are occasionally also involved. Another useful clue to the presence of anaerobes in a specimen is a report from the laboratory of 'sterile pus' despite the presence of organisms on a Gram-stained film. Lastly, in any patient who is receiving antibiotics inactive against anaerobes such as aminoglycosides, and still remains septic, an anaerobic infection should be considered.

Collection and transport of specimens for anaerobic bacteriology

All anaerobic bacteria are sensitive to oxygen but they vary in their aerotolerance. *B. fragilis* and *C. perfringens* will tolerate 2 to 4 per cent oxygen but fusobacteria and some peptostreptococci are much more sensitive to oxygen, hence more difficult to grow in the laboratory, and less likely to survive the journey from patient to culture medium. Until the renewed interest in anaerobes in the 1970s few laboratories ever isolated the more fastidious species. The best specimens for the isolation of anaerobes are aspirates, pus (in a universal container), or excised tissue and, although rapid delivery of specimens to the laboratory is desirable, in practice, anaerobes (even fastidious species) survive well in pus and tissue. Swabs are less satisfactory but are often all that is available, and for them a transport medium should be used. Complex commercial systems for the collection and transport of specimens for anaerobic bacteriology have been devised but are expensive and unlikely to appeal to clinicians. Many clinical specimens will be routinely cultured for anaerobes and no specific directive from the clinician will be required. One exception is expectorated sputum and clinicians should be aware that the microbiological diagnosis of anaerobic pleuropulmonary infection is best made from an invasive specimen.

Laboratory

The putrid smell of the pus in many anaerobic infections has been mentioned, and even swabs in such cases will be noticeably foul when processed. The Gram-stained smear of anaerobic discharge is often diagnostic to the experienced microscopist as it characteristically contains a variety of different bacteria, Gram-negative and Gram-positive rods and cocci. Filamentous or spindle-shaped Gram-negative rods (often hard to see) confirm the presence of fusobacteria. Successful culture of anaerobes requires fresh media and a reliable anaerobic atmosphere with 10 per cent carbon dioxide. Most laboratories now have either special anaerobic cabinets or automated systems using anaerobic jars. Relatively aerotolerant species will often grow in 24 to 48 h but fastidious anaerobes require undisturbed anaerobiosis for much longer (3–5 days) and if inoculated anaerobic culture plates are left out on the bench in the laboratory, such anaerobes will die. Even with the availability of commercial identification systems the definitive identification of many anaerobes is a technically demanding process and taxonomic exactitude has minimal appeal to clinicians. In clinical practice it is usually sufficient to recognize the *B. fragilis* group and Clostridia but it is clearly important that a limited number of laboratories (increasingly reference or research laboratories) retain sufficient skill to advise on the more unusual species and to define the patterns of infection associated with different sites.

Clinical spectrum of anaerobic infection

Infections of the head and neck

Acute necrotizing ulcerative gingivitis

This condition, also known as Vincent's disease, Vincent's angina, Vincent's gingivostomatitis, trench mouth, and fusospirochaetosis, affects the gingiva and buccal mucosa and was one of the earliest anaerobic infections described. The characteristic symptoms of painful bleeding gums, sometimes with a pseudomembrane, and foul breath readily suggest the diagnosis which can be confirmed with a Gram-stained smear in which large numbers of spirochaetes, fusiform, and other bacteria are seen.

Dental sepsis

The anaerobic oral commensal flora is found (with aerobic and microaerophilic bacteria) in periodontal infection, dental abscesses, and in postoperative infections associated with maxillofacial surgery.

Infections of the neck and jaw

These unusual necrotizing infections are frequently anaerobic and may be accompanied by marked cellulitis and oedema and cause respiratory embarrassment. Ludwig's angina is infection involving the main anterior compartment of the neck, the submandibular space. The source of the infection is usually the lower molar teeth, but it can arise from tonsillar infection as in the patient shown in Fig. 1. These infections spread via the fascial planes and may involve the chest with mediastinal abscess and empyema formation.

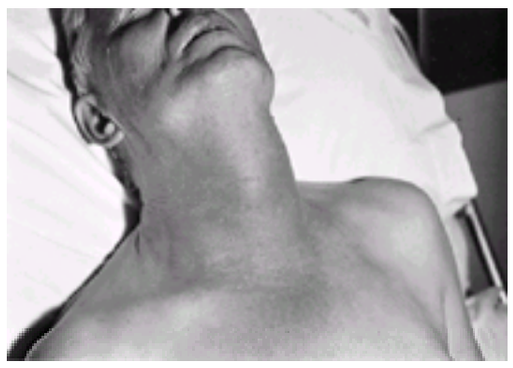

Fig. 1 Spreading cellulitis of the neck resulting from tonsillar sepsis (fatal)—'anaerobic neck'.

Ear, nose, and throat infections

Anaerobes are frequently isolated from tonsillar tissue in recurrent streptococcal tonsillitis and are also involved in peritonsillar abscesses (quinsy). They are commonly found in chronic infection of the sinuses, middle ear, and mastoid. Chronic sinus infection occasionally results in acute orbital cellulitis.

Infections of the central nervous system

Anaerobic bacteria are the major pathogens in cerebral abscesses other than those that follow surgery or trauma. Otogenic cerebral abscesses are most common and involve the temporal lobe or cerebellum. *B. fragilis* is usually isolated and aerobes, particularly *Proteus* spp. are often present. Frontal lobe abscesses of sinusitic or dental origin are usually caused by *S. milleri* group although oral anaerobes may also be found.

Pleuropulmonary infection

Anaerobic pleuropulmonary infection usually results from oropharyngeal aspiration but also occasionally from haematogenous seeding, particularly by fusobacteria (see necrobacillosis). Anaerobic pleuropulmonary infections include aspiration pneumonia, necrotizing pneumonitis, lung abscess, and empyema, as well as infection secondary to bronchiectasis and bronchial carcinoma. The anaerobes involved in these infections are the oropharygeal commensals. Patients with an anaerobic lung abscess will usually admit to the revolting taste (as well as smell) of their sputum. Definitive bacteriological diagnosis of anaerobic pleuropulmonary infection usually requires culture of an invasive specimen obtained either by bronchoscopy or percutaneous transthoracic aspiration. Expectorated sputum is rarely suitable. Specimens should preferably be obtained before antibiotics are given.

Intra-abdominal infections

These infections are usually associated with intra-abdominal pathology such as perforated gastric or duodenal ulcers, appendicitis, diverticulitis, inflammatory bowel disease, or malignancy and produce peritonitis or abscesses. Most are polymicrobial and the predominant anaerobes are those of the *B. fragilis* group. Before the advent of effective antianaerobic prophylaxis for intestinal surgery, anaerobic postoperative wound infection, abscess formation, and even septicaemia were commonly seen on surgical wards.

Hepatic and biliary tract infection

Hepatic abscesses are rare but likely to be caused by anaerobic bacteria (usually fusobacteria and *B. fragilis*) as well as by *S. milleri* group. They result from biliary tract infection, haematogenous spread from an intestinal source or direct extension of contiguous infection. Anaerobes are found in the bile in obstructive disease with stasis, and may cause cholangitis in patients who have had previous enterobiliary anastomoses.

Infections of the female genital tract and neonatal infection

Anaerobic bacteria cause bacterial vaginosis, tubo-ovarian sepsis, Bartholin's abscess, endometritis, septic abortion, and infection associated with intrauterine contraceptive devices. Vaginal hysterectomy carries a high risk of postoperative anaerobic infection, but wound infection after abdominal hysterectomy is uncommon and likely to be caused by *S. aureus.* Prolonged rupture of the membranes is associated with anaerobic infection and foul smelling liquor is often noted. Anaerobes, of vaginal origin, can be cultured from the liquor, the placenta, and the nasogastric aspirate, ear, and other surface swabs of the baby, which may develop anaerobic pneumonitis.

Infections of the male genitalia and prostate

The commensal anaerobic flora of the urethra is found in balanoposthitis, whose foul odour is well known to genitourinary physicians. Anaerobes also cause secondary infection of penile lesions. Scrotal abscesses are usually caused by anaerobes unless they follow acute epididymo-orchitis. Anaerobic scrotal abscesses which are often recurrent arise either *de novo*, and probably result from secondary infection of blocked apocrine glands or after surgery to the genitalia or urethra.

The eponymous term Fournier's gangrene was originally used at the end of the 19th century to describe necrotizing infections involving the penoscrotum and perineum that occurred in young, previously healthy men; these infections were almost certainly caused by *S. pyogenes*. Since then the term has been used for anaerobic (synergistic) necrotizing infections of the scrotum and perineum that sometimes also involve the thighs and abdominal wall. These infections are characterized by sudden intense pain and swelling with foul discharge and gas in the tissues as well as marked systemic disturbance and occur in middle aged or elderly men, particularly diabetics and alcoholics. There is a cutaneous, anorectal, or genitourinary source for the anaerobes.

Acute prostatic abscesses are rare but are sometimes caused by anaerobes. Anaerobes may also be relevant in chronic prostatitis, and can sometimes be cultured from prostatic secretions.

Infection of the urinary tract

Anaerobic urinary infection is very rare, so much so that urine is not routinely cultured anaerobically. Anaerobes can be recovered from the urine when there are abnormalities within the urinary tract such as vesicocolic fistulae, tumours, pyonephrosis, or perinephric abscess, and sometimes from ileal conduit specimens.

Bone and joint infection

Anaerobes are uncommon pathogens in acute haematogenous osteomyelitis and septic arthritis. Acute anaerobic osteomyelitis affecting long bones is likely to be caused by fusobacteria, whereas vertebral osteomyelitis, a infection occurring mainly in elderly patients, is likely to be caused by *B. fragilis*. Anaerobic septic arthritis usually occurs in patients with rheumatoid arthritis or other joint pathology and is also likely to be caused by *B. fragilis*. It can also result from bite and punch injuries to the hand in which the pathogens are oral bacteria, both anaerobic and aerobic. Anaerobes are sometimes isolated (with aerobes) in chronic osteomyelitis.

Skin and soft tissue infection

Diabetic foot ulcers

These often grow anaerobes, and the infections may be associated with underlying chronic osteomyelitis and sometimes with cellulitis, necrotizing fasciitis, and gas formation.

Venous ulcers

Anaerobes, particularly peptostreptococci, are often isolated from venous ulcers but are secondary invaders and are not relevant to the aetiology or perpetuation of the ulcer.

Decubitus ulcers

These are frequently infected with anaerobes, particularly *B. fragilis*, and anaerobic bacteraemia may occasionally result.

Sebaceous cysts

Anaerobes, especially peptostreptococci, are often isolated from infected sebaceous cysts.

Axillary abscess and hidradenitis suppurativa

Most axillary abscesses are caused by *S. aureus*, but some are anaerobic. Anaerobic abscesses are recurrent and more indolent than staphylococcal abscesses. Recurrences can result in hidradenitis suppurativa (Fig. 2). Anaerobic axillary abscesses and hidradenitis suppurativa result from apocrine blockage and infection is secondary. Hidradenitis suppurativa is not confined to the axilla but can affect the perineum, groins, buttocks, and back. Patients afflicted with this condition complain bitterly of the foul smell of their lesions.

Fig. 2 Hidradenitis suppurativa of axilla.

Perirectal abscess

These abscesses are frequently caused by anaerobes and when associated with an underlying fistula yield gut-specific anaerobes of the *B. fragilis* group and coliforms. Perirectal abscesses without a fistula are usually also caused by anaerobes but not gut-specific anaerobes; they may result from infection of blocked apocrine glands.

Breast abscess

Breast abscesses are usually assumed to be staphylococcal but in the non-puerperal woman are as likely to be anaerobic. Anaerobic breast abscesses are secondary infections of an underlying blocked duct, and are usually recurrent, subareolar, and associated with inverted nipples.

Human and animal bites

Human bites have been mentioned with reference to infection of the joints of the hand, but they may involve other parts of the body. Animal bites can also give rise to anaerobic infection but are more likely to become infected with *Pasteurella multocida* (see Chapter 7.11.17).

Paronychia

Paronychia can be caused by anaerobes, usually with aerobes. The anaerobes are oral commensals and are probably transferred to the fingers by licking or biting. Anaerobic paronychias are usually less acute than those caused by *S. aureus* or *Streptococcus pyogenes*.

Synergistic necrotizing infections

Anaerobic bacteria, usually with aerobes, cause a range of 'synergistic' infections. These infections can involve skin, fascia, and sometimes muscle and affect many areas of the body, occurring either spontaneously or after trauma or surgery (Fig. 3 and see Fournier's gangrene above).

Fig. 3 Necrotizing fasciitis involving perineum, buttock, and thigh 3 weeks after gastrectomy for carcinoma.

Bacteraemia and endocarditis

Anaerobic infection at any site, but particularly intra-abdominal infection, can cause bacteraemia sometimes with shock but anaerobes only account for less than 5 per cent of positive blood cultures, with the *B. fragilis* group most common. Anaerobes are also found in polymicrobial bacteraemia. Anaerobic endocarditis is very rare.

Fusobacterial bacteraemia, necrobacillosis, and Lemierre's postanginal septicaemia

Although most anaerobic infections are polymicrobial with not only several anaerobic species but also several aerobic species frequently isolated, fusobacteria, that is *F. necrophorum*, *F. nucleatum* and possibly other species, can be sole pathogens and produce severe infections. Their virulence is probably attributable to their lipopolysaccharide which is similar to that of Gram-negative aerobic bacteria. Although these serious infections are rare, they were well-described in the preantibiotic era. They are now being constantly 'rediscovered' by different clinicians and microbiologists, each convinced that they are describing a new disease. The species most often isolated from septicaemic disease is *F. necrophorum* and it is to this species that the term necrobacillosis refers.

Necrobacillosis

The earliest reports of necrobacillosis in man were of zoonotic skin infections acquired from animals with local infection with *F. necrophorum* usually in mixed culture, but in 1930 two fatal cases that presented 'hitherto undescribed clinical and pathological features of systemic infection' were described: a girl of 19 who died of lung abscesses, septic arthritis of the hip, and jaundice six days after a sore throat with rigors, and a man of 64 who died of a retropharyngeal abscess with gangrene and extension into the peritracheal and subcutaneous tissues. The former case is the 'postanginal septicaemia' later described by Lemierre (see below). The latter sounds like necrotizing fasciitis. Further clarification of the entity of necrobacillosis was provided in 1955 by Alston who recognized four different types of infection caused by *F. necrophorum*: those involving the skin and subcutaneous tissues, a large group where the infection started with a sore throat or otitis media, a third group associated with the female genital tract, the alimentary tract, or the urinary tract, and a fourth with empyema. Pyaemia and abscesses were very common in the last three groups. Alston's second group corresponds to Lemierre's postanginal septicaemia although Lemierre considered septicaemias arising from otitis media and mastoiditis to be a separate group. Since Alston's study, there have been numerous sporadic case reports of necrobacillosis but quite large series were published from the United Kingdom in 1989 and from Denmark in 1998. The term necrobacillosis is best used for any septicaemic infection with *F. necrophorum,* and postanginal septicaemic infection designated Lemierre's disease since this is a distinct clinical entity.

Lemierre's postanginal septicaemia (Lemierre's disease)

This unique manifestation of necrobacillosis occurs in previously healthy young people, usually adolescents or in their twenties. Lemierre suggested that it affected both sexes equally but recent series found a male predominance. There is an antecedent sore throat, often severe, and sometimes acute tonsillitis. Painful cervical lymphadenopathy is usual and septic jugular thrombophlebitis can occur. Within days, sometimes only hours, of the onset of sore throat, rigors develop with marked systemic upset and often impaired renal and hepatic function. Metastatic spread is characteristic, most commonly involving the lung, but also bone, joint, liver, brain, and heart valves. The 'pneumonia' is often severe and extensive, and cavitation of the septic infarcts and empyema may occur. Unless the relevance of the antecedent sore throat is appreciated, the diagnosis will be missed. There are occasional reports of coincidental Epstein–Barr virus infection in Lemierre's disease and viral infection might act as a trigger for fusobacterial invasion. Figure 4 shows the chest radiograph taken on admission to hospital of a 21-year-old heating engineer with rigors and severe shortness of breath about a week after a sore throat. He was thought to have Legionnaire's disease hence given erythromycin (to which fusobacteria are usually resistant); *F. necrophorum* was isolated from blood cultures. Although *F. necrophorum* is very sensitive to both penicillin and metronidazole, the infection responds only very slowly to antibiotic treatment, a reflection of the innate virulence of the organism.

Fig. 4 Chest radiograph taken on admission to hospital of a 21-year-old heating engineer who had developed rigors and severe shortness of breath about a week after a sore throat. He was thought to have possible Legionnaire's disease, hence given erythromycin (to which fusobacteria are usually resistant); *F. necrophorum* was isolated from blood cultures.

Sensitivity of anaerobic bacteria to antimicrobial agents

The susceptibility of most anaerobic bacteria to antimicrobial agents is remarkably uniform. Intrinsic resistance is often predictable and acquired resistance uncommon.

Metronidazole (and other nitroimidazoles)

Metronidazole is unique amongst the antimicrobial agents that are active against anaerobic bacteria as it is only active against anaerobes, with no activity against aerobes. Although it has been used to treat anaerobic infections for nearly 40 years, most clinically important anaerobes remain sensitive. There is little to choose between the activity of the different nitroimidazoles.

b-Lactam antibiotics

Contrary to popular belief, many anaerobes are still very sensitive to penicillin including many strains of *Prevotella*, *Porphyromonas,* and fusobacteria as well as clostridia, peptostreptococci, and spirochaetes. The *B. fragilis* group are almost uniformly resistant to penicillin, and resistance is also increasing amongst *Prevotella* and *Porphyromonas.* These penicillin-resistant anaerobes are also resistant to ampicillin, amoxycillin, piperacillin, ticarcillin, and most cephalosporins; cephamycins

such as cefoxitin and carbapenems such as imipenem and meropenem have some useful activity. The addition of the b-lactam inhibitor clavulanic acid to amoxicillin, ticarcillin, and piperacillin renders the *B. fragilis* group susceptible to these antibiotics.

Other agents

Most anaerobes are sensitive to clindamycin, and the antianaerobic activity of clindamycin is similar to that of metronidazole. Chloramphenicol is also highly active against anaerobes. Other agents with useful activity include erythromycin (though not against most fusobacteria), co-trimoxazole, and tetracyclines. The glycopeptides vancomycin and teicoplanin, whilst inactive against most Gram-negative anaerobes, possess useful activity against clostridia and peptostreptococci. Anaerobic bacteria are resistant to aminoglycosides and quinolones.

Treatment of anaerobic infections

Surgical intervention, particularly drainage of pus and excision of necrotic tissue, is of paramount importance in anaerobic infections and in many cases this will be all that is required to treat the infection. Indeed failure to carry out effective surgery will often result not only in the persistence of the infection but also in extension of this whatever antibiotic is given. Since most anaerobic infections are mixed with aerobes, it may be necessary to treat both groups of organisms. For anaerobic infections other than those of the *B. fragilis* group there is a wide choice of agent, but few clinicians think of anaerobes in distinct groups, and it is easier to recommend overall anaerobic cover which is best provided by metronidazole.

Prevention of anaerobic infection

Antibiotic prophylaxis for operations likely to be followed by postoperative anaerobic wound infection did not become routine until the mid 1970s but since then many trials bear witness to the efficacy of such prophylaxis in surgery involving sites with an anaerobic commensal flora and the putrid wound infections so familiar to gastrointestinal surgeons in the past are now rare. The patient in Fig. 5 featured in the trial of intravenous metronidazole versus placebo (saline) in elective colorectal surgery that took place at St Thomas' Hospital in 1976; he received saline! Such a trial would be quite unethical today. Most prophylactic regimens include cover for both aerobes and anaerobes. Antianaerobic prophylaxis is given for many different types of surgery, but particularly for that involving the gastrointestinal tract, genital tract, and upper respiratory tract. Such prophylaxis should be perioperative, intravenous, and of short duration (1–3 doses). There are many possible regimens but cefuroxime and metronidazole are widely used in the United Kingdom.

Cholera

Michael L. Bennish

Introduction

Cholera has caused millions of deaths during seven pandemics affecting all six inhabited continents over the past 200 years. Cholera can cause massive diarrhoea, dehydration, and death in healthy persons within 12 h of the onset of illness. Epidemics only occur where hygiene and social conditions are poor. This has made cholera a metaphor for death and decay in both the public ('cholera zoll der treppen'—'may the cholera strike you' is the traditional Yiddish curse) and the literary (*Love in the time of cholera* by Gabriel Garcia Marquez) imaginations. Cholera continues to cause tens of thousands of death annually in poor countries, despite ample evidence that the provision of clean water prevents disease and that inexpensive and simple-to-administer fluid therapy prevents death in those infected. That this is so is an indictment of our continuing neglect of global public health.

Aetiology

Cholera is caused by infection with one of two serogroups of *Vibrio cholerae*—O1 or O139—having been identified as the causative agent of cholera by Robert Koch in 1883. *V. cholerae* O1 and O139 are facultatively anaerobic, motile, curved Gram-negative rods that contain polar flagella and grow best in media containing increased concentrations (5 to 15 mmol/l) of sodium chloride when compared to most pathogenic micro-organisms. Hence their predilection for brackish environments—such as the Ganges Delta in the Indian subcontinent, the historic home of cholera. In addition to serogroup (determined by the somatic antigen type, of which more than 150 have been identified), *V. cholerae* serogroup O1 can be further divided into two biogroups, classical and El Tor (determined by their phenotypic characteristics) and three serotypes—Inaba, Ogawa, and Hikojima. Differences in virulence and epidemiological pattern have been described by biogroup (classical being more virulent than El Tor) but not for serotype.

Before 1992, all cholera was caused by infection with the O1 serogroup, the only serogroup then known to produce cholera toxin. In 1992, a new cholera toxin-producing serogroup—O139—was identified. This serogroup arose from the horizontal transfer of genes encoding the O139 lipopolysaccharide into a toxigenic El Tor *V. cholerae* strain. After explosive epidemics following its emergence (immunity to serogroup O1 did not protect against infection with O139) the new O139 serotype is now largely restricted to the Indian subcontinent. Despite fears that it would cause a new pandemic, it has not become endemic or epidemic elsewhere.

V. cholerae virulence genes have a number of recently defined mechanisms for horizontal transfer. The genes for cholera toxin are encoded on a filamentous phage, the receptor for which is the toxin co-regulated pilus. The latter is itself encoded by a lysogenic inovirus. In addition to being an example of evolutionary co-adaptation, the mobility of these virulence elements raises the concern of additional pathogenic strains arising.

Epidemiology

As convincingly demonstrated by the seminal epidemiologist John Snow in 1855, cholera occurs where clean drinking water is not available. *V. cholerae* resides in brackish surface water (perhaps in association with zooplankton), and initial infections during outbreaks most often stem from drinking such water. Once infection is established in a community, subsequent infections may occur by dissemination from infected individuals via contaminated food, or from drinking water newly contaminated by faecal pollution from a *V. cholerae*-infected individual. Since *V. cholerae* infections are more often asymptomatic than symptomatic, asymptomatic people may play a role in transmission. Chronic carriers are rare and do not play an important role in transmission. Because of the high inoculum required, infection rarely occurs directly from person-to-person without contaminated water or food as an intermediary vehicle. *V. cholerae* may remain viable on food (and multiply under favourable conditions) for days.

Although cholera has been present in the Indian subcontinent for centuries, the worldwide spread of cholera in modern times has been categorized as having occurred during seven pandemics. The first pandemic was recorded as starting in 1817, when Western observers became aware of the spread of cholera outside the Indian subcontinent. The current seventh pandemic, caused by an El Tor strain, started during 1961 in Sulawesi, Indonesia. Classical strains are now confined to Bangladesh.

Currently, cholera is periodically epidemic in many parts of Asia, Africa, and in Latin America, where it returned in 1991 after an absence of almost 100 years. Cholera is endemic and seasonally epidemic in the Ganges Delta, including most of Bangladesh and West Bengal, India. In 2000, 56 countries reported 137 071 cases of cholera and 4908 cholera deaths to the World Health Organization: 87 per cent of cases were in Africa. These figures are gross underestimates, both because of incomplete ascertainment and incomplete reporting. For instance, Bangladesh, where hundreds of thousands of cases of cholera occur annually, does not report cases to the World Heath Organization, presumably because of concerns about the effect on food exports.

Epidemics can be particularly severe in refugee camps, where crowding is common, and hygiene and clean water are often absent. Some 12 000 persons died in 3 weeks from a cholera outbreak in Rwandan refugee camps in Goma, Zaire.

Sporadic cases of cholera occur in the Gulf Coast region of the United States, Naples Bay in Italy, and other estuaries where *V. cholerae* lives. Infection in these areas is often linked to eating raw seafood. Because of good sanitation, epidemics no longer occur in industrialized countries following these sporadic cases. Because the infectious dose of *V. cholerae* is very high (10^9 or greater in normal hosts) infections in travellers with normal gastric acid secretion (*V. cholerae* are acid-labile—hypochlorhydria reduces the infective dose 3- or more fold) are exceedingly rare, and occur only when there are gross errors in standard hygienic practices.

Where cholera is endemic it disproportionately affects children, as many adults are immune. During epidemics in non-endemic regions, adults and children share similar risks of disease. Patients with blood group O are also thought to be at a moderately (20–100 per cent) increased risk of contracting the disease.

Pathogenesis

Depending on the inoculum and the host response, ingestion of *V. cholerae* can fail to establish infection, cause infection but not illness, or can result in disease. The incubation period between the ingestion of *V. cholerae* and the emergence of symptoms ranges from 12 to 72 h.

V. cholerae O1 or O139 cause disease by colonizing the small bowel and producing an enterotoxin—cholera toxin—that causes a massive secretion of electrolytes and water into the gut lumen. This results in the profound diarrhoea that is the hallmark of cholera. The toxonosis is the only gut derangement during *V. cholerae* infection. *V. cholerae* organisms do not invade the gut epithelium (with the exception of the antigen-processing M cells), there is no histological change in the mucosa

during infection, and no inflammatory response.

Two virulence factors have been demonstrated in all cholera causing *V. cholerae* O1 or O139: toxin co-regulated pilus and cholera toxin. Toxin co-regulated pili are essential for colonization of the intestinal epithelium brush border, an essential step for proliferation in the intestinal milieu. Cholera toxin is composed of two subunits, A and B. The monomeric A subunit is non-covalently linked to a pentameric B subunit. The B subunit binds to a glycolipid receptor present on enterocytes (and many other eukaryotic cells), ganglioside GM_1. This binding becomes rapidly irreversible at body temperature. The A subunit is the active moiety, being internalized in the cell following proteolytic cleavage into two polypeptide chains (A_1 and A_2).

The A_1 subunit alters concentrations of cyclic AMP, an important intracellular messenger. It does this by catalysing the ADP-ribosylation of a protein—G_s—that upregulates adenylate cyclase activity. The latter mediates the transformation of ATP to cyclic AMP. Cyclic AMP in turn activates a protein kinase that causes protein phosphorylation, which affects ion channels and ion movement. There is increased Cl^- secretion from intestinal crypt cells into the gut lumen (which drags water with it by changing the osmotic gradient) and decreased NaCl-coupled water absorption in the villus cells.

Virulence genes in *V. cholerae* exist in two clusters—the CTX element, containing the toxin genes, and the TCP pathogenicity island, where genes coding for the toxin co-regulated pilus reside. Expression of these genes, and a number of other putative virulence factors in these gene clusters, are controlled by the transmembrane ToxR regulatory protein. ToxR directly affects transcription of the genes coding for toxin, and indirectly controls transcription of other virulence genes by initiating a cascading system of regulatory factors. Expression of ToxR occurs in response to environmental factors present in the gut lumen. This co-ordinated expression of virulence factors is required for pathogenesis, and also perhaps for survival of *V. cholerae* in the intestinal lumen, giving the *V. cholerae* that possess virulence factors a selective advantage.

An increased secretion of fluid and electrolytes in crypt cells, and decreased absorption in villus cells, results in isotonic fluid accumulation in the small-bowel lumen. The rate of fluid loss is greatest in the jejunum, where fluid losses of 11 ml/cm of jejunum per hour may occur. Diarrhoea results when the amount of fluid produced exceeds the colon's absorptive capacity (approximately 6 litres/day). Because water and ions are lost in equal proportion, the resulting dehydration affects all compartments—intracellular, extracellular, and intravascular—equally.

Clinical and laboratory features

Signs and symptoms

Cholera is one of the most distinctive of clinical illnesses, and its severe form is immediately recognizable. Dr William O'Shaugnessy's description of a patient with cholera in Sunderland in 1831, during the second pandemic of cholera, captures the clinical features of disease as well as any description in the ensuing 170 years:

> On the floor...lay a girl of slender make and juvenile height, but with the face of a superannuated hag. She uttered no moan, gave no expression of pain, but she languidly flung herself from side to side...her eyes were sunk deep into her sockets, as though they had been driven an inch behind their natural position; her mouth was squared; her features flattened; her eyelids black; her fingers shrunk, bent and inky in their hue. All pulse was gone at the wrist, and a tenacious sweat moistened her bosom.

Vomiting and watery diarrhoea are the initial signs of cholera. Diarrhoea may be modest at first—and consist of faecal matter and watery stool. In the majority of infected persons the illness will not advance beyond this stage, and the disease will not be distinguishable from other more common causes of diarrhoea, such as that caused by enterotoxigenic *Escherichia coli*.

In some patients, the diarrhoea becomes profound—exceeding 200 ml/kg body weight per day. In these patients the stool will become 'rice-watery' in character—in other words, it resembles the opaque white water discarded after rice has been washed—it will not contain fecal matter, and is not malodorous. Diarrhoea is painless and patients are often incontinent of stool. In the absence of antimicrobial treatment, the total stool volume during the illness can exceed total body weight.

Vomiting—following by retching as the stomach contents are emptied—almost always occurs in patients with severe diarrhoea. The vomiting tends to abate after the first 24 h of illness. The cause of the vomiting has not been well established—being attributed to both direct effects of *V. cholerae* on intestinal motility, and to acid–base disturbances.

In the absence of effective fluid replacement, dehydration and prostration occurs in those patients with high rates of fluid loss. The features of dehydration in cholera are unmistakable. They include markedly diminished skin turgor, reflecting diminished interstitial fluid. Alterations in skin turgor are demonstrated most graphically by pulling the abdominal subcutaneous tissues between the thumb and forefinger. In the dehydrated patient the tissues will tent (Fig. 1). Other signs of dehydration in patients with cholera include wrinkled fingers ('washerwoman's hands'), sunken eyes, dry mucous membranes, tachypnoea, altered consciousness (apprehensiveness, lethargy, stupor), diminished urine volume, and tachycardia with a diminished or absent radial pulse. Blood pressure is often not recordable.

Fig. 1 Young girl with severe dehydration as fluid infusion is begun. In this picture the sunken eyes and lassitude of severe dehydration can be appreciated, as can the abdominal skin tenting following the assertive pinching of the abdominal subcutaneous tissues.

For purposes of management, dehydration is divided into three categories—none or mild, moderate or some, and severe—based upon the presence and severity of clinical findings (Table 1).

Abdominal cramping can occur, presumably because of gut distension. Cramping of the extremities is a common symptom. Carpopedal spasm and tetany may occur because of alterations in calcium homeostasis resulting from rapid changes in the acid–base status. The presence of coma may indicate severe hypoglycaemia.

Laboratory features

Laboratory abnormalities in patients with cholera result from the intravascular volume contraction and resultant prerenal azotaemia. Creatinine and blood urea nitrogen values are elevated as a result of the prerenal failure, and the packed cell volume and serum protein concentration are elevated as a result of haemoconcentration. Patients are acidaemic because of bicarbonate loss in the stool and lactic acidosis from volume contraction and hypoperfusion. There is no inflammatory response, although leucocyte numbers may be mildly increased because of the haemoconcentration.

Laboratory diagnosis

Cholera is a clinical diagnosis, especially because most cases of cholera occur in locations where laboratory facilities are not readily available. Because the treatment of any severely dehydrating diarrhoea is the same—fluid replacement—identification of the pathogen is not essential for patient management. As severe dehydration

is rare in adults, in the right epidemiological setting the existence of adults with severe dehydration should alert the clinician and public health authorities to the presence of cholera.

A definitive diagnosis is made by isolating *V. cholerae* from stool or rectal swab samples on selective media, and then using sera to identify the pathogenic serogroups 01 and 0139 and Ogawa or Inaba serotypes using slide agglutination tests. Since routine enteric media are not appropriate for the identification of *V. cholerae*, a more-selective media such as thiosulphate–citrate–bile salts–sucrose agar (**TCBS**) should be used. Because TCBS is expensive, and not always available, some laboratories in developing countries rely on less selective and efficient media, such as gelatin, meat extract, or MacConkey agar.

Specimens for dispatch to a laboratory distant from the site of patient care should be placed in a transport media: Cary–Blair medium is the most effective because of its high pH and ready commercial availability. Alkaline peptone water can be used when the time required for transport to laboratory is 6 h or less. When patients are in the same facility as the laboratory, plating should be done at the bedside. Because *V. cholerae* are excreted in such high numbers in stool (>10^7 organisms/ml of stool) enrichment of samples before plating is not routinely required.

Serological tests (vibriocidal or antitoxin antibodies) are useful only for retrospective epidemiological studies.

Treatment

This section will focus on treatment under conditions in which most cholera patients present—clinics or hospitals in developing countries with few resources. Only 35 cases of cholera were reported in Europe during 2000, and 9 cases in North America, and so the chances of physicians caring for patients with cholera in industrialized countries are remote.

Initial intravenous therapy

Treatment of the severely dehydrated patient with cholera is a medical emergency. With appropriate therapy, no patient with cholera who reaches a treatment facility alive should die; without adequate therapy, the death rate may be as high as 50 per cent.

The cornerstone of the treatment of cholera patients is rapid replacement of the fluid deficit. Estimates of the degree of dehydration should be made using the categories listed in Table 1, and the corresponding fluid deficit replaced in 2 to 4 h. Patients with severe dehydration should have their fluid volume replaced using intravenous fluid. The composition of the fluid used should closely resemble that lost in the cholera stool (Table 2). Such fluids have been developed in areas where cholera is common (Dhaka solution and Peru polyelectrolyte solution). Ringer's lactate is the commercially available intravenous solution that most closely meets these requirements. In the absence of an appropriate solution, the emphasis should still be on volume replacement. The maxim 'the dumbest kidney is smarter than the smartest intern' is appropriate here; if the intravascular volume (and renal perfusion) is restored, the kidney will achieve, albeit more slowly, electrolyte and acid–base homeostasis.

Deaths due to cholera usually occur because of the failure to realize the extent of fluid requirements in severely dehydrated patients (7 to 10 litres required during the first 2–4 h for a 75-kg severely dehydrated individual) and the need for close monitoring and continued high-volume fluid replacement after initial rehydration (Table 3). Patients who are not closely monitored can quickly again become dehydrated—and this time not in the high-visibility area of the triage or admission desk, but in the far corner of a rehydration tent set up for delivering care during an epidemic. Patients should be monitored every 1 to 2 h during the first 24 h of illness. Stool and urine volume should be collected and quantified. This can be most expeditiously achieved using a cholera cot—a simple cot with a plastic sheet and a hole in the middle so that stools and urine drain into a calibrated bucket. Rectal catheters can also be used for stool collection. Fluid replacement should then be adjusted to match continued fluid losses.

Although large-volume intravenous replacements are best accomplished using large-bore needles, any fluid replacement is better than none: even small-calibre needles can be used to initiate therapy. If an intravenous line cannot be established, oral rehydration solutions should be given by mouth if the patient is alert, or otherwise using a nasogastric tube.

Antimicrobial therapy

Antimicrobial therapy can halve the duration and volume of diarrhoea. All patients requiring intravenous therapy, or admission to clinic or hospital, should receive an antimicrobial agent. Almost all patients given an effective antimicrobial drug can be discharged within 24 h of admission, in contrast to 72 h or more if they are left untreated. Especially during epidemics, this reduction in hospital stay, and the associated reduction in demand for intravenous and oral fluids, can be critical for an effective response by already strained healthcare services.

Single-dose therapy—of which there are a number of options—is the preferred regimen, especially in epidemic settings (Table 4). Resistance in *V. cholerae* is not predictable, and hence the need to obtain isolates for susceptibility testing during an outbreak. Since outbreak strains are usually clonal, empirical therapy can be based upon a limited number of isolates. Resistance to fluoroquinolones and azithromycin has not been reported, and if these drugs are available at generic prices they, along with doxycycline (if the strain is susceptible), are the drugs of choice.

Oral rehydration

Oral rehydration fluids containing glucose and salts were developed following the observation that, although cholera toxin poisons the neutral sodium-chloride absorption channels in the intestinal mucosa, the glucose-mediated cotransport of sodium (and water) remains intact. Oral rehydration fluids should be given immediately after the onset of diarrhoea in an effort to prevent the development of dehydration. They should also be used in severely dehydrated patients following rehydration. Most patients can be managed with oral fluids alone within 12 to 24 h of admission. Provision of oral rehydration fluids is an inexact art, but the amount provided should be somewhat more than the volume of stool lost.

The most readily available oral rehydration salts are the sachets distributed by UNICEF and the WHO containing 90 mmol of sodium for reconstitution in water. Homemade solutions—using sucrose and salt, or cereal and salt—are also effective. Oral rehydration solution can be drunk from a cup by adults or fed to young children and infants using a spoon (Fig. 2).

Fig. 2 Mother providing oral rehydration solution to her reluctant child using the recommended method of a cup and spoon. In the background note the cholera cots and the buckets placed underneath the cutouts in the cot ('poop-chutes') that allow stool to be measured. Cots are covered with a plastic liner that is changed daily.

Complications

Rapid correction of the acidosis in patients with cholera may reduce ionized calcium concentrations, resulting in tetany. If tetany occurs, the rehydration solution used should be changed to normal saline for a brief period. Rapid correction of the acidosis can also result in a drop in the serum potassium concentration, but this is rarely symptomatic.

Renal failure is rare. Most patients thought to have renal failure actually have inadequate fluid replacement. Even with rapid rehydration, most children and adults produce no urine during the first 4 h of treatment, and only a median of 1 ml/kg body weight in the next 24 h. Patients with diminished urine output should be followed, and their creatinine level measured if possible. Additional fluids should be given, and the patients followed closely for oedema and other signs of fluid overload.

Hypoglycaemia occurs because of a failure of gluconeogenesis in stressed children; in Bangladesh the rate of severe hypoglycaemia in children with dehydrating cholera was 0.5 per cent. Thus dextrose-containing solutions, such as Ringer's lactate with 5 per cent dextrose, are preferred for rehydrating patients with cholera. In the absence of such a solution, children should have their blood glucose measured with a glucometer, or be given a bolus of glucose if they are in a state of altered consciousness.

If the patient develops a fever, or appears septic, the most likely cause is contamination of the infusate and/or the intravenous apparatus. The treatment is to replace both. Adherence to infection-control techniques is an important part of the management of patients, especially in epidemic situations.

Prevention and future research

The provision of clean water is the primary means of preventing cholera. In the absence of potable water, chlorine or iodine can be added to drinking water. Alum potash has also been reported to be effective. All sterilizing agents are ineffectual in water that has a high turbidity from suspended organic material. Food is best eaten cooked, and not from street vendors.

There are currently three vaccines available for cholera: a parenterally administered vaccine containing whole cells killed by phenol; and two oral vaccines: a killed, whole-cell recombinant B-subunit toxin vaccine; and a live, attenuated, *V. cholerae* vaccine strain—CVD 103—that does not express the cholera-toxin A subunit. The parenteral vaccine is of uncertain efficacy and is toxic because of its lipopolysaccharide content; the two oral vaccines have minimal toxicity and provide limited protection for short periods to persons living in endemic areas. The oral vaccines are not widely available in developing countries, and are not licensed in the United States. These vaccines are of limited utility; travellers are at a miniscule risk of contracting cholera, and the limited long-term efficacy of these vaccines makes them inappropriate for routine use in developing countries. They may have more use during epidemics; but epidemics are likely to have run their course before supplies can be mobilized and immunity induced.

There is a need to develop a vaccine that provides long-duration, high-level protection against cholera. Perhaps the most pressing research need is for a better understanding of how resources can be mobilized to provide clean water and sanitation to the billions of persons who currently lack it.

7.11.12 Haemophilus influenzae

E. R. Moxon

General

Haemophilus influenzae, a Gram-negative bacterium, is a commensal and potential pathogen that resides in the nasopharynx, the conjunctivae, and occasionally the genital tract of humans. Carriage of one or more strains for periods of days to months is common and most carriers are, and remain, healthy. However, *H. influenzae* is pathogenic and can result in two distinct patterns of disease (Table 1). First, there are infections in which there is invasion of the bloodstream and dissemination to distant sites, for example the meninges or synovial joints. These are usually caused by encapsulated type b strains and occur typically in infants. Second, there are infections that occur as a result of contiguous spread of *H. influenzae* within the respiratory tract, for example otitis media, sinusitis, and pneumonia. These are usually, but not invariably, caused by unencapsulated or non-typeable (**NT**) strains and are relatively common in children; however, they also occur in adults.

Epidemiology, pathogenesis, and immunology

Humans are the sole reservoir of *H. influenzae*; person-to-person spread is therefore crucial to the survival of the species. Transmission occurs by airborne droplets, or by direct contagion with secretions. The age of acquisition is extremely variable. In socio-economically deprived countries, most children are densely colonized with *H. influenzae* immediately after birth, whereas acquisition may be delayed for several weeks in infants living in, for example, Europe or the United States. Most of the colonizing strains are unencapsulated or so-called non-typeable (NT) organisms, but in 3 to 5 per cent of people, the *H. influenzae* express one of six, antigenically distinct polysaccharide capsules, designated a to f, the basis of the major typing system. Carriage of several different strains concurrently has been well described. Over time, phenotypic changes in major surface antigens, such as outer membrane proteins, occur in response to host immune selection pressures. The factors influencing acquisition and colonization of *H. influenzae* include a variety of surface adhesins, including pili, the production of IgA1 proteases, the inhibition of host clearance mechanisms by the inhibitory effect of cell wall glycopeptides, and the production of both local and serum antibodies. Colonization is a permissive event in the pathogenesis of disease and the importance of the type b capsule as a crucial factor in systemic, bacteraemic infections has been well established in animal models. Capsule impedes the clearance of organisms by phagocytes and complement-mediated killing. The core sugars of lipopolysaccharide also play an important role in promoting survival of *H. influenzae* and another key component, endotoxin (lipid A), is critical in mediating the damage to tissues, such as inflammation and breakdown of the blood–meningeal barrier. Prior viral infections such as influenza potentiate infection and appear to facilitate both contiguous spread within the respiratory tract—as in otitis media, sinusitis, or lower respiratory tract infection—–and the probability of dissemination into the blood.

Serum antibodies to type b capsule mediate protective immunity against systemic infections in humans. The serum of newborn babies and young infants, up until the age of 3 months, generally has sufficient amounts of passively acquired maternal antibodies to afford protection. Thereafter, the natural decline of maternally derived antibodies is followed by a period lasting until the age of 2 to 4 years when the levels of antibody are absent, or inadequate to provide protection.

In contrast to systemic type b infections where deficiencies in opsonophagocytic mechanisms are paramount, impairment of non-specific host defence mechanisms (e.g. impaired ciliary clearance) is the most obvious feature of those who have disease caused by NT *H. influenzae*. Other predisposing factors include smoking, viral infections, immunodeficiency, or chronic lung disease such as cystic fibrosis.

Haemophilus influenzae type b

Meningitis

Despite the availability of antibiotics, and more recently the highly effective conjugate vaccines, type b meningitis remains the commonest cause of purulent meningitis in early childhood worldwide, and the cause of many deaths and permanent central nervous system damage in survivors. The majority of the cases occur in young children aged less than 5 years, the peak incidence being from about the age of 3 months to 2 years. Reported risk factors include male sex, black rather than white race, absence of breast feeding, socio-economic deprivation, winter months, siblings (often asymptomatic carriers), and attendance at day-care or preschool nurseries.

Typically, meningitis presents after a few hours or days of antecedent symptoms, most commonly those of an upper respiratory tract infection in a young child; an associated or preceding otitis media is common. The most common symptoms and signs are fever, lethargy, vomiting, neck stiffness, and altered nervous system function, ranging from irritability to coma, but young babies may be afebrile and have few symptoms or signs. Raised intracranial pressure produces headache and vomiting and may cause a bulging fontanelle in young infants. Seizures are common in children; subdural effusions are present in about 33 per cent of children and occur most frequently in young infants. The key to diagnosis is to perform a lumbar puncture and examine the cerebrospinal fluid. This typically reveals inflammatory cells, raised protein and lowered glucose concentrations, and there are often organisms that can be seen by microscopy after staining with Gram's stain or methylene blue.

If diagnosis and treatment are prompt, more than 95 per cent of patients with *H. influenzae* meningitis will survive, but about 8 per cent of survivors have serious central nervous system sequelae, the commonest being sensorineural deafness. Before the advent of effective vaccines, this was said to be the most important cause of acquired mental handicap in the United States.

Epiglottitis

Acute respiratory obstruction, caused by a cellulitis of the epiglottis and aryepiglottic folds, usually occurs as a fulminating, life-threatening infection. Sore throat, fever, and dyspnoea progress rapidly to dysphagia, pooling of oral secretions, and drooling of saliva from the mouth. The child is toxic, restless, anxious or lethargic, and adopts a sitting position with an extended neck and protruding chin in an effort to to minimize airway obstruction. The voice and cry are muffled and the child may be reluctant to talk. Stridor is often absent; if present it is soft and wheezy. Cough is unusual. In the absence of adequate treatment death commonly occurs within a few hours. The course may be less dramatic with a prodromal illness of sore throat and hoarseness from one to several days preceding the onset of acute symptoms. The characteristic findings are that the epiglottis is red and swollen, obstructing the pharynx at the base of the tongue. Lateral radiographs reveal the swollen 'thumb-shaped' epiglottis. Examination of the larynx should be attempted only where there are facilities for immediate intubation/tracheotomy, since fatal respiratory obstruction may occur abruptly. The most important aspect of management of acute epiglottitis is the provision of an adequate airway and ventilation in addition to

antibiotic treatment.

Pneumonia and empyema

Lower respiratory tract infections occur most often in children aged less than 5 years and present as lobar pneumonia, often with pleural involvement. In many of the poorer countries of the world, such as New Guinea, *H. influenzae* type b pneumonia is second only to that caused by the pneumococcus and in these regions is a greater public health problem than *H. influenzae* meningitis. Type b pneumonia is also well recognized in adults as a primary cause of pneumonia, especially in alcoholics.

Cellulitis

This important infection occurs in young children who present with hectic fever and a raised, warm, tender area of distinctive reddish-blue hue, most often located on one cheek or in the periorbital region, that evolves over a few hours.

Septic arthritis

H. influenzae type b is one of the commonest causes of septic arthritis in children of less than 2 years of age. Typically, there is involvement of a single large, weight-bearing joint, usually without osteomyelitis. Response to drainage and appropriate systemic antibiotics is usually dramatic and apparently curative, but long-term follow-up is important since residual joint dysfunction occurs in a proportion of children.

Treatment of diseases caused by type b strains

Prior to the availability of antibiotic treatment, *H. influenzae* meningitis was invariably fatal. With the introduction of chloramphenicol in 1950, survival rates of 95 per cent or more have been possible. Overall, chloramphenicol remains an excellent drug for treating *H. influenzae* meningitis, but occasional isolates show resistance. Chloramphenicol carries a dose-related, reversible bone marrow toxicity, but this is rarely clinically a problem and can be completely avoided if blood levels are monitored. Idiosyncratic bone marrow aplasia has been reported but is extremely rare. Ampicillin, formerly considered an ideal treatment for *H. influenzae* meningitis, is no longer favoured because of the relatively high prevalence of resistant (b-lactamase producing) strains. The treatment of choice is parenteral third-generation cephalosporins such as ceftriaxone or cefotaxime; these have been shown to be highly effective as initial treatment of suspected bacterial meningitis. Cefuroxime is less effective.

Young children in the same household as a patient with invasive type b disease are at significantly increased risk of secondary invasive infection by *H. influenzae* type b. Rifampicin given orally once daily for 4 days is effective in eradicating nasopharyngeal carriage, and is recommended for all household contacts (children and adults).

Experimental and clinical studies support the administration of corticosteroids to reduce the incidence of neurological sequelae, especially sensorineural deafness. The presumed mechanism is the reduction of inflam-mation that results from release of bacterial cell wall fragments. Dexamethasone therapy (0.6. µg/kg.day) intravenously in four divided doses for 4 days is recommended for children older than 2 months of age.

Active immunization

In the 1940s, serum antibodies specific for the type b capsule were used as treatment of type b infection. Efforts to develop a vaccine for active immunization using purified type b capsule did not begin until the 1970s. However, by the 1980s, it was clear that this vaccine did not protect children aged less than 2 years old. Further research was directed towards developing conjugate vaccines in which type b capsule is covalently linked to a carrier protein, such as tetanus toxoid. Several commercially manufactured conjugate vaccines have been licensed and all have proved to be very safe and capable of affording high levels of protection to children immunized as early as 2 months of age. In the United Kingdom, conjugate vaccines have been given to infants as part of the routine immunization schedule since 1992 and their protective efficacy is more than 95 per cent.

Diseases caused by non-typeable *H. influenzae*

Pneumonia

Non-typeable strains are an important cause of pneumonia in children and adults, especially the elderly, and in those with established lung disease, such as chronic bronchitis. In many countries where adverse socio-economic circumstances are prevalent, acute lower respiratory tract infections in infants caused by NT *H. influenzae* represent an uncertain but probably major cause of morbidity and mortality.

It has been recognized for many years that exacerbations of chronic bronchitis correlate with an increase in the production of purulent sputum from which NT *H. influenzae* strains are cultured. Such episodes are often precipitated by prior viral infection. Progressive lung damage in conditions such as chronic bronchitis, cystic fibrosis, and hypogammaglobulinaemia is thought to result from heightened and protracted inflammatory response to a variety of bacteria, including NT *H. influenzae*, in people whose respiratory tract lacks the appropriate clearance mechanisms.

Maternal and neonatal sepsis

NT *H. influenzae* are a well-documented cause of tubo-ovarian abscess or chronic salpingitis. More ominously, the infants born to such mothers, often prematurely, may develop life-threatening neonatal septicaemia, meningitis, and a form of acute respiratory distress syndrome that is indistinguishable from that caused by group B streptococci.

Acute otitis media and sinusitis

H. influenzae accounts for about one-fifth of all cases of acute bacterial otitis media. More than 90 per cent of the organisms isolated from middle ear fluid are NT strains. Although such episodes occur at any age, they are most common in children aged 6 months to 5 years. Since more than two-thirds of children have one or more episodes of otitis media by the age of 3 years, a conservative estimate would indicate that more than 100 000 cases of *H. influenzae* otitis media occur each year in the United Kingdom. NT strains are also a common cause of sinusitis in both adults and children.

Conjunctivitis

H. influenzae is an important cause of purulent conjunctivitis. Most are NT strains that were formerly considered to be sufficiently distinctive to be referred to as *H. aegyptius*. Interest in these strains was heightened when, in 1984, an apparently new and serious disease was described in Brazilian children who developed a life-threatening infection known as Brazilian purpuric fever. Its peak age incidence is 1 to 4 years; purulent conjunctivitis, high fever, vomiting, purpura, vascular collapse, and a high mortality are characteristic.

Other infections

All of the diseases that are commonly caused by type b strains can, on rare occasions, be caused by strains of capsular serotypes a, c, d, e, and f as well as NT strains. A number of other unusual infections have been described including: endocarditis, pericarditis, peritonitis, and epididymo-orchitis. Two other closely related species, *H. parainfluenzae* and *H. aphrophilus*, are also causes of disease, such as endocarditis.

Treatment

Serious infections caused by NT strains such as meningitis, lower respiratory tract infections, tubal abscess, and neonatal sepsis require systemic treatment with third-generation b-lactams or co-trimoxazole. Chloramphenicol is highly effective but blood levels need to be monitored carefully, especially in young infants, because

of potential toxicity. Sinusitis and otitis media are often treated effectively with oral amoxycillin, but augmentin would be preferable, given the relatively high incidence of strains producing b-lactamase. Oral co-trimoxazole would be an equally sound or alternative choice for trimethoprim-susceptible strains. The use of antibiotics as pro-phylaxis or treatment of exacerbations of chronic bronchitis is controversial, but many advocate their use either to reduce the number of haemophili in the lower respiratory tract or to eradicate them. Drugs of the tetracycline group are effective, but are contraindicated in pregnancy, patients with impaired renal function, or children less than 10 years of age; amoxycillin and co-trimoxazole have also proved useful.

Passive immunization

People with increased susceptibility to infection with *H. influenzae*, but particularly NT strains, may have a deficiency of antibody synthesis. They benefit from immunoglobulin preparations administered either intramuscularly or intravenously. This form of immunoglobulin replacement undoubtedly decreases the incidence of systemic infections and the number of episodes of both upper and lower respiratory tract infections caused by NT *H. influenzae*.

7.11.13 Haemophilus ducreyi and chancroid

Allan R. Ronald

Introduction

Genital ulcer disease is the presenting feature of sexually transmitted diseases in about 5 per cent of patients in Western societies; in the developing world, 10 to 50 per cent of patients with sexually transmitted diseases present with genital ulcer disease. In the West, genital herpes and primary syphilis are the commonest aetiological agents. In the developing world *Haemophilus ducreyi* accounts for most genital ulcer disease. Granuloma inguinale and lymphogranuloma venereum are occasionally imported from remaining foci in sub-Saharan Africa and Asia.

The epidemiological association between genital ulcer disease, particularly chancroid, and the risk of transmission of HIV-1 and HIV-2 has increased interest in its control.

Soft chancre was differentiated from the hard indurated chancre of syphilis by Ricord in 1838. In 1889, the Neapolitan physician Ducreyi identified short-chaining streptobacillary rods in exudate from ulcers following inoculation with chancroid pus.

Aetiology

Haemophilus ducreyi is a faintly bipolar staining Gram-negative rod. Due to extracellular linkage of the bacteria, the organism forms chains and demonstrates a 'school of fish' arrangement. *H. ducreyi* colonies appear after 48 h of incubation, are yellow-grey, dome-shaped, and variable in size and opacity. Colonies are cohesive and can be nudged intact with a straight wire.

Epidemiology

Chancroid is endemic in eastern and southern Africa, India, and the Caribbean where the annual incidence in adult males can exceed 1/1000. It occurs sporadically in industrialized countries, most frequently at major ports of entry. During the last two decades, there have been over 20 discrete outbreaks in North America. Prostitutes are the usual reservoir for dissemination of *H. ducreyi* and the male to female ratio usually is 5:1 or higher. Male circumcision decreases susceptibility to infection by about threefold.

Asymptomatic carriage has no proven role in the spread of *H. ducreyi*. In one study of men with culture-positive chancroid, all source contacts had genital ulcers. *H. ducreyi* is rarely transmitted non-sexually. Chancroid lesions on the fingers or breasts reflect direct contact from a genital lesion on the sexual partner or autoinoculation.

Pathogenesis and pathology

After an incubation period of 3 to 10 days, an inflammatory papule develops which ulcerates. Bacterial virulence factors include a haemolysin and a cytolethal distending toxin that interferes with intracellular signalling. Both humeral and cell-mediated responses to *H. ducreyi* occur, but their role in preventing or modifying infection is unknown. On histological examination, perivascular and interstitial mononuclear cell infiltrates predominate with occasional giant cell granulomas. Endothelial disruption with neutrophil invasion occurs superficially.

Clinical features

Chancroid begins as a tender papule which ulcerates. It is painful, rarely indurated, irregular, and sharply demarcated, usually with no surrounding inflammation. The ulcer base is uneven with a greyish-yellow exudate which bleeds readily. About 50 per cent of men and most women have multiple ulcers.

Numerous variants of chancroid occur including giant rapidly spreading ulcers, dwarf chancroid resembling herpes, follicular chancroid that mimics pyogenic infection, transient ulceration associated with lymphadenitis similar to lymphogranuloma venereum, a painless single ulcer similar to primary syphilis, and raised indurated 'beefy' lesions not unlike granuloma inguinale. In the absence of laboratory investigation, in men as many as 25 per cent and in women at least 50 per cent of ulcers could be attributed on clinical surmise to aetiological agents other than *H. ducreyi*. The index of suspicion for chancroid increases where the disease is highly prevalent.

Chancroid occurs anywhere on the genitalia. However, in uncircumcised men, over 50 per cent of ulcers are on the prepuce. The coronal sulcus is a common site with a circle of ulcers surrounding the entire sulcal circumference. Contact lesions are common on adjacent cutaneous surfaces. In women lesions occur in decreasing frequency on the fourchette, labia majora and labia minora, perianal area, and medial aspects of the thighs. Cervical and vaginal ulcers are uncommon.

Inguinal lymphadenopathy appears in about 40 per cent of men and 20 per cent of women within 7 to 10 days of ulceration. The lymph nodes are discrete, very tender, and often bilateral. If untreated, lymphadenitis progresses to a suppurative bubo which may form an inguinal abscess. Abscesses can penetrate deeply into the groin.

Laboratory diagnosis

Definitive diagnosis of chancroid requires culture of *H. ducreyi*. The Gram stain is not sufficiently sensitive or specific to diagnose *H. ducreyi* infection. No serological test is available. Diagnostic nucleic acid probes are under investigation. The sensitivity of *H. ducreyi* culture is in the range of 50 to 80 per cent. However, specificity is high as asymptomatic carriage of *H. ducreyi* is rare. Two or more sexually transmitted pathogens are present in 10 to 15 per cent of patients presenting with genital ulcers; *H. ducreyi* may be cultured concomitantly with either *Herpes simplex* or *Treponema pallidum*. Although the classic features of syphilis and chancroid appear to place them at opposite ends of a spectrum of genital ulceration, in about 20 per cent of patients the presentations are indistinguishable.

Whenever possible, exudate from the ulcer or bubo should be inoculated directly on to the primary selective media. Organisms will survive longer on a swab at 4°C than at room temperature. *H. ducreyi* grows well on gonococcal agar with added vancomycin (3 mg/l) to inhibit growth of Gram-positive bacteria, a vitamin supplement, and 0.25 per cent activated charcoal. Cultures for *H. ducreyi* should be incubated at 33°C in 5 per cent carbon dioxide and maximum humidity. A candle extinction jar with a moist paper towel is adequate. Distinct colonies appear within 72 h. *H. ducreyi* is identified by its Gram stain and its ability to use nitrate, a positive oxidase test, and a requirement for X factor.

Agar dilution tests with *H. ducreyi* correlate with the clinical response. Plasmid-mediated resistance, as in *Neisseria gonorrhoeae* and *Haemophilus influenzae*, encodes for b-lactamase production; other plasmids enable sulphonamide, tetracycline, and chloramphenicol, kanamycin, and streptomycin resistance. These plasmids have spread rapidly.

Fortunately, all isolates remain susceptible to the third-generation cephalosporins, the fluoroquinolones, and the macrolides.

Treatment

In the absence of specific treatment, chancroid is a prolonged illness with slow resolution and frequent recurrence. Genital ulcers and inguinal abscesses have been reported to persist for years.

Circumcision, cleanliness, and saline soaks were used prior to the sulphonamides. Ampicillin, streptomycin, and tetracycline were each shown to be equivalent treatment regimens with a mean time to complete healing of 10 days. Trimethoprim/sulphonamide combinations became standard therapy, but the emergence and rapid spread of trimethoprim resistance has thwarted its continuing use.

Other treatment regimens include ceftriaxone (a single dose of 250 mg intramuscularly), ciprofloxacin (a single oral dose of 500 mg), fleroxacin (a single dose of 400 mg), erythromycin (250 mg three times a day for 7 days), and azithromycin (a single oral dose of 1 g). All cure over 95 per cent of HIV-seronegative men with chancroid. Patients with chancroid concurrently infected with HIV are more likely to fail to respond to treatment with b-lactam antibiotics.

Epidemiological associations between HIV-1 and*Haemophilus ducreyi*

Chancroid is a risk factor for the heterosexual spread of HIV-1 and HIV-2. Chancroid in women increases the risk of acquisition of HIV-1 following heterosexual contact with HIV-1-infected men by four- to eightfold. The presence of chancroid in HIV-1-infected individuals increases the shedding of HIV-1 and the probability that partners will become HIV-1 infected.

Prevention and control

The control of chancroid can reduce heterosexual transmission of HIV substantially, perhaps by 30 per cent or more, in societies where both pathogens are being spread, particularly from prostitutes to their clients. Effective control of chancroid has been achieved on numerous occasions by treating men with ulcers and their sexual contacts. Most women who are source contacts of men with chancroid have few symptoms, despite the presence of ulcers, and so contact tracing is essential. The use of condoms by clients dramatically reduces the acquisition of chancroid from prostitutes.

Chancroid control is an essential cost-effective intervention to slow the transmission of HIV-1.

7.11.14 Bordetella

Calvin C. Linnemann, Jr

Bacteria of the genus *Bordetella* are primarily pathogens of the respiratory tract of humans and animals because they can adhere to ciliated epithelial cells. The whooping cough syndrome or pertussis is characterized by paroxysmal coughing, an inspiratory whoop, and lymphocytosis. *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* can cause disease in man. *B. holmesii* has also been recovered from patients with whooping cough. Misattribution of pertussis to viral infection resulted from the difficulty in isolating *B. pertussis* and frequent coinfection with adenoviruses.

Bordetella infections should be suspected in patients with persistent lower respiratory tract infection and paroxysmal coughing, with or without an inspiratory whoop, or those with any respiratory symptoms after close contact with a documented infection. Most bordetella infections will go unrecognized because the symptoms are indistinguishable from other respiratory tract infections, and because appropriate diagnostic tests are usually done only in patients with typical pertussis. *B. bronchiseptica*, a common pathogen in animals, should be considered in animal handlers with respiratory tract infections.

The causative agent

Bordetella are small, aerobic, Gram-negative coccobacillary organisms. *B. pertussis* are slow growing and are inhibited by a variety of media constituents such as fatty acids that must be inactivated if culture is to be effective (see below). *B. parapertussis* and *B. bronchiseptica* are less fastidious and faster growing.

Bordetella pertussis adheres to ciliated epithelial cells in the respiratory tract. Attachment is followed by ciliostasis and subsequent loss of the ciliated cells. Biologically active components include filamentous haemagglutinin, fimbrias, pertactin, pertussis toxin (lymphocytosis-promoting factor), adenylate cyclase, and tracheal cytotoxin. Acellular vaccines, containing only selected components such as the filamentous haemagglutinin and pertussis toxin, protect against severe symptomatic infection. *B. pertussis* is non-invasive, usually remaining on the surface of the respiratory tract, but *B. parapertussis*, *B. bronchiseptica*, and *B. holmesii* bacteraemias have been reported.

Epidemiology

Humans are the only known reservoir of *B. pertussis* and *B. parapertussis*, whereas *B. bronchiseptica* is found in other mammals. *B. pertussis* is transmitted by droplets from symptomatic patients. Asymptomatic infections are not important in the spread of disease, and there are no chronic carriers. It is assumed that the transmission of *B. parapertussis* is similar to that of *B. pertussis.* Humans and other mammals may be reservoirs of *B. bronchiseptica*.

Before vaccine was available, epidemics of *B. pertussis* spread through schools, and were carried by the schoolchildren to their homes. Secondary attack rates in susceptible children were 25 to 50 per cent in schools, and 70 to 100 per cent in homes, reflecting the intense and prolonged exposure at home. Most children developed symptoms. Mild infections or reinfections in adults caring for sick children were known as 'grandmother's cough' or 'nurse's cough'.

In the vaccine era, major epidemics have disappeared in most developed countries. Mortality from *B. pertussis* was decreasing before the introduction of vaccine, but not the number of cases. In the United States and Canada, where effective vaccines have been widely used, the incidence of pertussis has decreased to 1 to 3/100 000 per year (Fig. 1). Results were less dramatic in the United Kingdom, related, perhaps, to early problems with vaccine efficacy and lower levels of vaccine usage. Pertussis did decrease in the United Kingdom, and the resurgence of *B. pertussis* in the late 1970s, following a decrease in vaccine usage, demonstrated the efficacy of vaccine.

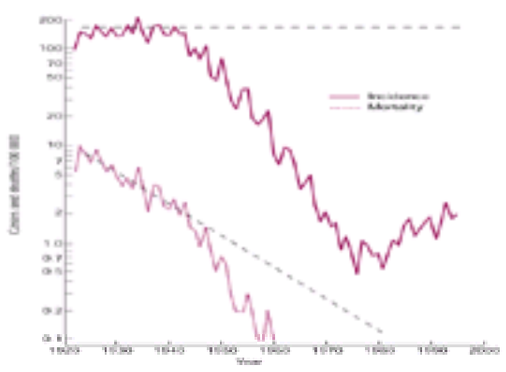

Fig. 1 The effect of pertussis vaccine on the incidence and mortality of pertussis in the United States. The lines superimposed on the graph indicate the trends prior to the vaccine and as projected if vaccine had not been introduced.

In a highly vaccinated population, older children and adults make up a larger proportion of cases and may play a more important part in the transmission of disease. Before vaccine was available, the source of infection could be identified in most cases as another child. It is now more difficult to trace the source, but in very young infants an adult family member frequently appears to be the source. Hospital epidemics have also demonstrated the part adults play in transmission. Doctors and nurses may acquire infection from a patient and then transmit it to other hospital staff and to patients.

The epidemiology of *B. parapertussis* has not been modified by vaccine usage. It is widespread in many countries, but it is seldom recognized because of the mildness of the disease. In Denmark epidemics occur every 4 years, alternating with epidemics of *B. pertussis*.

Clinical manifestations

In *B. pertussis* infection, non-specific upper respiratory symptoms, malaise, anorexia, and sometimes a low-grade fever begin 7 to 10 days after infection. This 'catarrhal stage' is indistinguishable from other mild respiratory infections. Towards the end of this stage a dry, hacking cough appears and progresses. Older, presumed partially immune, patients may not progress further. After 1 to 2 weeks, the paroxysmal stage begins and continues for several weeks. The cough is now paroxysmal. Prolonged coughing episodes may be followed by the characteristic 'whoop', produced by forced inspiration through a partially closed glottis. In severe cases, paroxysms of coughing are followed by vomiting, and may be associated with epistaxis, petechias, conjunctival or scleral haemorrhages, haemorrhagic myringitis, or periorbital oedema. Young infants may not have the whoop. Their paroxysms of coughing may be followed by cyanosis and apnoea. Fever is uncommon at this stage in uncomplicated infections. The convalescent stage begins after 2 to 4 weeks, with gradually resolving paroxysms of coughing. Patients may cough for weeks to months. Their whooping may be exacerbated by subsequent viral respiratory infections.

Leucocytosis with lymphocytosis appears toward the end of the catarrhal stage and continues in the paroxysmal stage. Lymphocytosis is most marked when coughing

is worst. There is a proportional increase in both T and B lymphocytes. Lymphocytosis may not occur in very young infants, older children, and adults.

Fever suggests a complicating bacterial infection. Otitis media and pneumonia are the most common. Atelectasis results from bronchial obstruction by the thick mucus. Bronchiectasis is uncommon. High pressures caused by paroxysmal coughing contribute to pulmonary, haemorrhagic, and gastrointestinal complications. These include mediastinal and subcutaneous emphysema, pneumothorax, inguinal hernias, and rectal prolapse. The extremely rare neurological complications include convulsions, paralysis, coma, blindness, deafness, and movement disorders.

B. parapertussis infections are clinically milder. Twenty per cent or less of children will develop the whooping cough syndrome. *B. bronchiseptica* rarely causes whooping cough. It is usually a non-pathogen in the respiratory tract but may cause bronchitis. In immunosuppressed patients, *B. bronchiseptica* can cause sinusitis, tracheobronchitis, and pneumonia. Bacteraemia, endocarditis, peritonitis, and meningitis have also been reported. *B. bronchiseptica* and *B. pertussis* have been reported in HIV-infected patients. *B. holmesii* septicaemia has been reported in compromised hosts.

Diagnosis

Definitive diagnosis is by isolation of the organism. Fluorescent antibody staining of material obtained by nasopharyngeal swabs from patients with *B. pertussis* infections provides only presumptive diagnosis. Polymerase chain reaction can be used for diagnosis, but assays are expensive and not standardized. Antibody responses can be measured in acute and convalescent sera by enzyme immunoassay.

The cough plate technique has been replaced by the nasopharyngeal culture technique. A wire calcium alginate swab is passed through the nose until it touches the posterior nasopharynx, allowed to remain for a few seconds, and removed. Cotton swabs may be used if the cotton has been shown to be non-bacteriostatic for *B. pertussis*. The swabs are streaked on to Bordet–Gengou agar plates, both with and without an antibiotic such as cephalexin. Multiple cultures increase recovery of *B. pertussis.* The organism has not been recovered from blood or other sites. Cultures must be held for 6 days before being discarded.

B. parapertussis, *B. bronchiseptica*, and *B. holmesii* can also be recovered on Bordet–Gengou medium and they also grow on routine media used for recovery of Gram-negative bacteria. These three organisms have been recovered from blood cultures, and *B. bronchiseptica* has been cultured from urine.

Treatment

Most patients can be managed at home. Very young children may need good nursing care in hospital. Cough medicines are useless as is passive immunization with available immunoglobulin preparations. Salbutamol and steroids may be useful. Sedation of young children is potentially dangerous but is practised by some paediatricians.

B. pertussis, *B. parapertussis*, and *B. holmesii* are sensitive to erythromycin, tetracycline, chloramphenicol, and trimethoprim–sulphamethoxazole. Early treatment, during the catarrhal stage, shortens the clinical illness. Treatment started at the paroxysmal stage is much less effective. The best results are achieved by treating symptomatic contacts of patients with diagnosed infections. Despite limited clinical benefit, patients in the paroxysmal stage should be treated to render them non-infectious. Erythromycin is the drug of choice: 40 to 50 mg/kg per day for children, 1.5 to 2 g per day for adults, for 14 days. Nasopharyngeal cultures become negative in the first few days of treatment, but the erythromycin should be continued to prevent bacteriological relapses (Fig. 2). Trimethoprim–sulphamethoxazole has been used in children who do not tolerate erythromycin, although its efficacy has not been proved. The newer macrolides, clarithromycin and azithromycin, at 10 mg/kg per day for 5 to 7 days may be as effective as erythromycin.

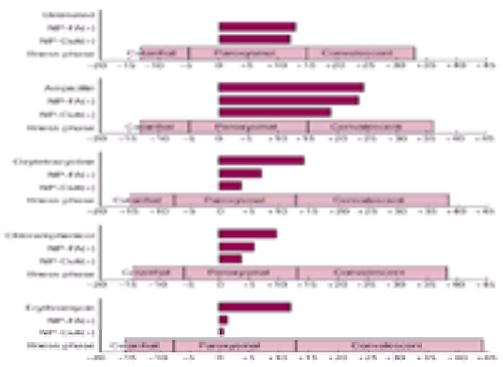

Fig. 2 Duration of excretion of *B. pertussis* as detected by fluorescent antibody staining and culture, and the effect of antimicrobial treatment. The graphs compare (group means) patients treated with antimicrobial agents with untreated control patients. (Reproduced from Bass JW *et al.* (1969), *Journal of Pediatrics* **75**, 768, with permission.)

B. bronchiseptica is sensitive to tetracycline and chloramphenicol but not to erythromycin. Antipseudomonal penicillins and aminoglycosides have been proved successful in serious infections.

Prevention

Patients with *B. pertussis* should avoid close contact with susceptible individuals to prevent droplet transmission. Untreated patients remain contagious for weeks. Communicability decreases rapidly after starting erythromycin. Nasopharyngeal cultures become negative within 48 to 72 h. Patients admitted to hospital are usually isolated for the first 5 days of treatment.

Chemoprophylaxis with erythromycin may be effective. Close contacts of patients with *B. pertussis* infection should be treated with erythromycin. Vaccination should continue according to routine schedules. Some recommend that, in addition to erythromycin, a booster dose of vaccine should be given to preschool children who have not received a booster within 6 months. Lower risk exposures, such as those occurring outside the home or day-care centre, require erythromycin only if respiratory symptoms develop.

Vaccination

Whole-cell pertussis vaccine prevents disease, but frequently causes local reactions, with or without fever, and rare neurological complications. Serious reactions occur less frequently after vaccination than with clinical disease. The killed whole-bacterial preparation is given with diphtheria and tetanus toxoids. An effective immunizing schedule includes three injections at 1- to 2-month intervals beginning at 6 to 12 weeks of age, and a fourth dose given 6 to 12 months after the third. A booster dose is given before entry to school. Acellular vaccines, containing three or four bacterial components—including pertussis toxoid, filamentous haemagglutinin, pertactin, and fimbriae—are replacing whole-cell vaccines, using the same immunization schedules.

Vaccination is usually restricted to children less than 7 years of age because of the local reactions, but immunity is neither complete nor lifelong. Protection may last only 12 years. Duration of immunity after acellular vaccines is unknown. Re-exposure to *B. pertussis* may induce continuing immunity in previously vaccinated patients. In future, acellular vaccines may be deployed in older children and adults. There are no vaccines generally available for *B. parapertussis* or *B. bronchiseptica*.

7.11.15 Melioidosis and glanders

D. A. B. Dance

Melioidosis

Definition and aetiology

Melioidosis is an infection of humans or animals caused by the saprophytic bacterium *Burkholderia* (previously *Pseudomonas*) *pseudomallei*. It is an ovoid, oxidase-positive, motile, Gram-negative bacillus that often exhibits 'safety-pin' bipolarity. It grows well on most standard culture media, producing wrinkled and smooth colony types and giving off a sweet, earthy smell. It has often been overlooked or discarded as a contaminant by bacteriologists unfamiliar with its characteristics. A pattern of resistance to aminoglycosides and polymyxins with susceptibility to co-amoxiclav is a useful clue to its identity.

Epidemiology

Distribution

Melioidosis is endemic throughout south and south-east Asia and northern Australia. Its incidence varies within these regions in both place and time, being particularly high in north-east Thailand during heavy monsoon years. It is likely to be underdiagnosed unless good laboratory facilities are available. Sporadic cases have been reported from sub-Saharan Africa, Central and South America, the Caribbean, and Iran. A unique outbreak occurred in France during the mid-1970s.

Reservoir and transmission

B. pseudomallei is an environmental saprophyte found in soil and surface water, particularly rice paddy, in endemic areas. A closely related, arabinose-assimilating, avirulent soil organism, *Burkholderia thailandensis*, has recently been recognized and may contribute to the high seropositivity rate in endemic areas (up to 80 per cent by the age of 4 years in north-east Thailand). Humans and animals are probably usually infected through contaminated scratches and abrasions or occasionally aspiration of fresh water, although a specific episode of exposure is rarely identified. Iatrogenic infections have also been described. Other possible modes of acquisition include inhalation and ingestion. Direct transmission from infected humans or animals is extremely rare.

Descriptive epidemiology and risk factors

Melioidosis is a disease of people in regular contact with soil and water, such as rice farmers. It has a bimodal age distribution, with a peak incidence between the ages of 40 and 60 years. Males outnumber females by 3:2 in Thailand but more in Australia and Singapore. The disease is markedly seasonal, some 80 per cent of cases presenting during the rainy season in north-east Thailand, when *B. pseudomallei* accounts for almost 20 per cent of cases of community-acquired septicaemia. Most such infections are probably recently acquired, although periods of latency as long as 29 years have been described, which is highly unusual for a bacterial infection. The proportion of seropositive people who are latently infected is unknown.

Pathogenesis

The outcome of contact with *B. pseudomallei* depends on the size of the inoculum, the virulence of the infecting strain, and the host response. Massive exposure will overwhelm a normal immune system, but most infections are self-limiting, resulting merely in asymptomatic seroconversion.

Host response

Clinically apparent melioidosis is an opportunistic disease, over 70 per cent of patients having underlying predisposition to infection. Diabetes mellitus is particularly strongly associated with melioidosis, but pre-existing renal disease and thalassaemia are also significant independent risk factors, and other reported associations include alcoholism and cirrhosis, malignant disease, immunosuppressive and steroid therapy, and pregnancy. In animal models, a T-helper type 1 immune response confers relative resistance to infection, and g-interferon plays a crucial role in protecting against overwhelming sepsis. However, an overexuberant host response may also be damaging, as serum levels of several cytokines have been associated with a fatal outcome in human melioidosis. Humoral immunity may also play a role in defence, since animals may be passively protected by antibodies to lipopolysaccharide and flagellin, and levels of antilipopolysaccharide II correlate with survival in human melioidosis.

Virulence factors

Many putative virulence factors have been described in *B. pseudomallei* and transposon mutagenesis is proving useful in identifying their relative importance. For example, mutants deficient in one of the two forms of lipopolysaccharide produced by *B. pseudomallei*, lipopolysaccharide II, lose the natural resistance to complement-mediated bacteriolysis of the species and are 10 to 100 times less virulent in animal models than their parent strains. Other characteristics which may contribute to the pathogenicity of *B. pseudomallei* include: the ability to enter and survive in eukaryotic cells; the secretion of various extracellular enzymes (e.g. protease, lecithinase, and lipase); peptide, protein, and glycolipid toxins; extracellular polysaccharide; pili; a siderophore (malleobactin); and acid phosphatase.

Clinical features

B. pseudomallei may cause acute, chronic, localized, or disseminated infections. A 'flu-like' illness associated with seroconversion has been reported from Australia. Latent infections (see above) usually relapse at times of intercurrent stress ('Vietnam time bomb').

Septicaemic melioidosis

Sixty per cent of cases of culture-positive melioidosis have positive blood cultures. Most are clinically septicaemic; some have a more typhoid-like presentation. There is usually a short history (median 6 days; range 1 day to 2 months) of high fever and rigors. Approximately half the patients have evidence of a primary focus of infection, usually pulmonary or cutaneous. Confusion and stupor, jaundice, and diarrhoea may be prominent features. Initial investigations typically reveal anaemia,

neutrophil leucocytosis, coagulopathy, and evidence of renal and hepatic impairment. Such patients often deteriorate rapidly, developing widespread metastatic abscesses, particularly in the lungs, liver, and spleen, and metabolic acidosis with Kussmaul's breathing. Once septic shock has supervened, case fatality approaches 95 per cent, many patients dying within 48 h of admission. Other poor prognostic features include absence of fever, leucopenia, azotaemia, and abnormal liver function tests.

If the patient survives this acute phase, multiple foci of dissemination become prominent. Cutaneous pustules or subcutaneous abscesses occur in approximately 10 per cent of cases and an abnormal chest radiograph is found in 80 per cent of patients, the most common pattern being widespread nodular shadowing ('bloodborne pneumonia'; Fig. 1). Other common sites for secondary lesions include the liver, spleen, kidneys, prostate, bones, and joints. Involvement of the central nervous system may also occur.

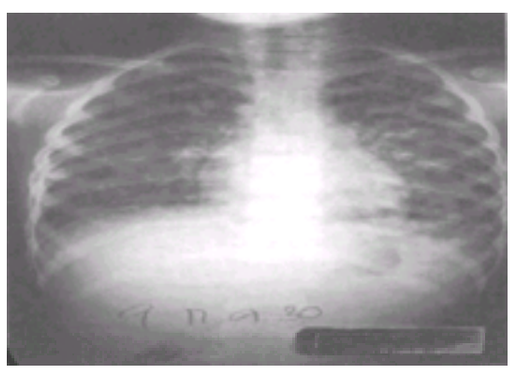

Fig. 1 Septicaemic melioidosis: widespread nodular shadowing—'bloodborne pneumonia' (by courtesy of Professor Sornchai Looareesuwan).

Localized melioidosis

The lung is the most frequent site. There is subacute, cavitating pneumonia accompanied by profound weight loss, often confused with tuberculosis (Fig. 2). Relative sparing of the apexes and infrequent hilar adenopathy may help to distinguish melioidosis from tuberculosis. There is a predilection for the upper lobes. Complications include pneumothorax, empyema, purulent pericarditis, and progression to septicaemia.

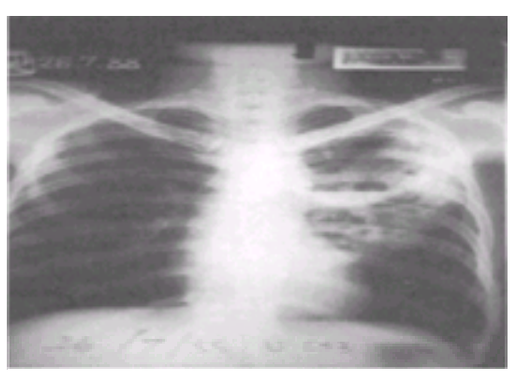

Fig. 2 Necrotizing *B. pseudomallei* pneumonia with central cavitation and fluid level in a rice farmer in north-east Thailand being treated with corticosteroids for nephrotic syndrome. Such patients are often misdiagnosed as having smear-negative tuberculosis, but fail to respond to antituberculous chemotherapy. (By courtesy of Professor Sornchai Looareesuwan.)

Acute suppurative parotitis is a characteristic manifestation of melioidosis in children, accounting for approximately one-third of childhood cases in north-east Thailand (Fig. 3). The reason is unknown. Most cases are unilateral and result in parotid abscesses requiring surgical drainage. They may rupture spontaneously into the auditory canal. Facial nerve palsy and septicaemia are rare complications.

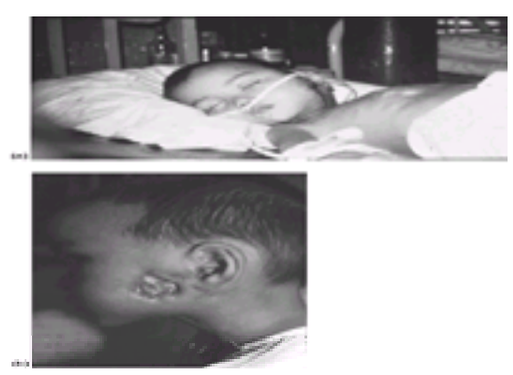

Fig. 3 (a) Acute suppurative parotitis—a common manifestation of childhood melioidosis in north-east Thailand. This child had parotid abscesses that required drainage despite having already ruptured into the auditory canal, extensive overlying ulceration, facial nerve palsy, and septicaemia. (b) Ulceration over healing parotid abscess.

Other sites of localized infection include cutaneous and subcutaneous abscesses, lymphadenitis, osteomyelitis and septic arthritis, liver and/or splenic abscesses, cystitis, pyelonephritis, prostatic abscesses, epididymo-orchitis, keratitis, and rarely, brain abscesses.

Pathology

B. pseudomallei is pyogenic, causing localized abscesses or granulomas, depending on the duration of the lesion. The presence of 'globi' of Gram-negative bacilli within macrophages and giant cells may give a clue to the aetiology.

Laboratory diagnosis

The diagnosis should be considered in any patient who has ever visited an endemic area and presents with septicaemia, abscesses, or chronic suppuration, particularly if there is evidence of an underlying disease such as diabetes mellitus. Specific diagnosis depends on the detection of *B. pseudomallei* or of corresponding antibodies. The laboratory should always be warned if melioidosis is suspected, both to enable appropriate methods and media to be employed, and to alert staff to the risk of infection (containment level 3 organism).

P>**Microscopy and culture**

Gram staining of smears of pus or secretions may reveal bipolar or unevenly staining Gram-negative rods, but this is neither specific nor sensitive. The most useful rapid diagnostic technique is immunofluorescent microscopy of smears. The mainstay of diagnosis is isolation and identification of *B. pseudomallei* from blood, pus, urine, sputum, or other specimens. The organism is not difficult to grow, although special selective media will increase the isolation rate from sites with a normal flora.

Serodiagnosis

Several tests for antibodies to *B. pseudomallei* have been described. The indirect haemagglutination test remains the most widely available. Assays that detect IgG give similar results. These tests are useful in patients from non-endemic areas in whom a single indirect haemagglutination titre in excess of 1:40 is highly suggestive of melioidosis. In populations continually exposed to *B. pseudomallei*, the high background seropositivity reduces the predictive value of the tests, and in such patients only a rising or very high titre suggests active melioidosis. Assays that detect specific IgM correlate better with disease activity but are not widely available.

Antigen and nucleic acid detection

Numerous antigen detection and polymerase chain reaction systems have been described, but all have problems of specificity and sensitivity.

Treatment

Treatment—general

Patients with septicaemic melioidosis require intensive supportive treatment, ideally in an intensive care unit. Particular attention should be paid to correction of volume depletion and septic shock, respiratory and renal failure, and hyperglycaemia or ketoacidosis. Abscesses should be drained whenever possible.

Antibiotic susceptibility

B. pseudomallei is intrinsically resistant to many antibiotics, including aminoglycosides and early b-lactams. Failure to respond to these agents may suggest the diagnosis of melioidosis.

Antibiotic therapy–acute phase

Five, randomized, controlled studies of regimens for the treatment of acute severe melioidosis have now been published. Two showed that regimens containing b-lactam approximately halved the mortality compared with conventional chloramphenicol plus doxycycline plus co-trimoxazole. Imipenem/cilastatin had a lower treatment failure rate than ceftazidime, which itself had a lower failure rate than co-amoxiclav. b-Lactam/co-trimoxazole combinations may have lower mortality and relapse rates than b-lactams alone, but larger studies are needed to confirm this. Unfortunately, all these b-lactams are too expensive to be practical in most endemic countries. The regimens used for acute treatment are listed in Table 1.

Antibiotic therapy—maintenance phase or mild disease

Long courses of oral antibiotics are needed to prevent relapse. Less than 12 weeks of treatment is inadequate, and the usual recommendation is 20 weeks. The conventional combination regimen was associated with a lower relapse rate than co-amoxiclav. The latter is preferable in children and pregnant women because of the risks of toxicity. Fluoroquinolones and doxycycline alone give unacceptable results, but co-trimoxazole alone warrants further evaluation. Regimens are given in Table 2.

Prognosis

In septicaemic melioidosis, the level of bacteraemia correlates with outcome. Even with optimal treatment, case fatality from acute severe melioidosis is high (25 to 40 per cent). Often survivors remain chronically ill both from the disease itself and the underlying conditions. At least 5 per cent of patients will still relapse despite long courses of antibiotics, particularly if compliance is poor. Antibiotic resistance may develop during treatment. Long-term follow-up should therefore be arranged. Monitoring of IgM titres or C-reactive protein may help early detection of relapse.

Prevention and control

No vaccines are available for human use. The only preventive measure is avoidance of exposure to the organism in soil for high-risk groups (e.g. people with diabetes). Both ciprofloxacin and doxycycline confer partial protection when given prophylactically to animals. Although person-to-person spread is rare, isolation of patients is recommended.

Glanders

Definition and aetiology

Glanders is a disease of horses caused by *Burkholderia mallei*, which may occasionally be transmitted to humans or other animals. Traditionally, glanders, a systemic respiratory tract disease, has been distinguished from farcy, a cutaneous infection.

In the early 1900s, equine glanders occurred worldwide. Over 200 000 horses were destroyed because of glanders during the First World War. However, no naturally acquired case has been reported in the United States or the United Kingdom since 1938.

It is thought still to occur in the Middle East, Africa, and Asia. Human infection, always uncommon, is confined to those in close contact with horses.

B. mallei is closely related to *B. pseudomallei* both taxonomically and antigenically, but it grows less luxuriantly in culture and is non-motile.

Clinical features

Glanders resembles melioidosis. Manifestations include septicaemia, wound infection, ulceration, lymphangitis with abscesses along the course of lymphatic drainage ('farcy buds'), ulceration of the respiratory (especially nasal) mucosa, polyarthritis, pneumonia and lung abscesses, nodular abscesses in any site, particularly muscle and subcutaneous tissue, and a widespread pustular rash.

Laboratory diagnosis

Diagnosis hinges on a history of contact with horses in an endemic area or laboratory exposure, and either the isolation of *B. mallei* or detection of specific antibodies. Like *B. pseudomallei* it requires handling in a containment level 3 laboratory.

Treatment

In vitro susceptibility is similar to that of *B. pseudomallei*, and so glanders should respond to the regimens used for melioidosis.

7.11.16

Plague

T. Butler

History

Plague may have caused more deaths than most other diseases and warfare combined; it was estimated to have killed a quarter of Europe's population in the Middle Ages. The present pandemic of plague began in China in the 1860s and was spread by rats transported on ships to California and to ports in South America, Africa, and Asia. The genus of the plague bacillus is called *Yersinia* because Alexandre Yersin (1863 to 1943) went to Hong Kong in 1894 and successfully isolated the causative organism in pure culture. Urban plague transmitted by rats was brought under control in most affected cities, but the infection was transferred to sylvatic rodents, allowing it to become entrenched in rural areas of these countries. In the 1960s and 1970s, Vietnam during its war became the leading country for plague, reporting more than 10 000 cases a year. In 1994 in Surat, India, an outbreak of primary pneumonic plague was reported. There were hundreds of suspected cases, with 50 deaths, and thousands fled the city. However, none of the cases were confirmed by sputum culture. In 1997, Madagascar experienced an epidemic of pneumonic plague in which 8 out of 18 infected persons died.

Bacteriology

Yersinia pestis (formerly *Pasteurella pestis*), the cause of plague, is an aerobic, Gram-negative bacillus of the family Enterobacteriaceae. It is readily identified by its failure to ferment lactose on MacConkey agar, an alkaline slant and acid butt in triple-sugar–iron agar, and negative reactions for citrate utilization, urease, and indole. *Y. pestis* is virulent because it carries a 45 MDa plasmid that encodes for V and W antigens, which confer a requirement for calcium to grow at 37°C. Additionally, it produces lipopolysaccharide endotoxin and a capsular envelope containing the antiphagocytic principle fraction I antigen.

Epidemiology

From 1990 to 1996, there were 16 000 cases of plague and 1214 deaths (7.6 per cent) reported to the World Health Organization. The countries that reported more than 100 cases were, in the order from greatest number to least: Tanzania, Madagascar, Vietnam, Congo, Peru, India, Myanmar, Zimbabwe, China, and Uganda. In the United States, all the 64 plague cases occurred in the south-western states of New Mexico, Arizona, Colorado, Utah, and California. Most of the American cases occur during the months of May to October, when people are outdoors coming into contact with rodents and their fleas. Each endemic region has a specific season when plague tends to occur.

Plague is a zoonotic infection transmitted among animal reservoirs by flea bites and ingestion of animal tissues. The major animal reservoirs are urban and domestic rats as well as rural field rodents including ground squirrels and prairie dogs. The oriental rat flea *Xenopsylla cheopis* is the most efficient vector. When bitten by a rodent flea humans become an accidental host and play no role in disease transmission except in rare epidemics of pneumonic plague. Epizootics usually accompany human cases and can cause large die-offs of susceptible rodent species. Human plague affects both sexes and children of all ages depending on their exposure to rodent fleas. Risk factors for acquiring plague include contact with rodents or carnivores and presence of refuges or food sources for wild rodents near the home.

Pathogenesis

Bacteria are inoculated into the skin by a flea bite and migrate to regional lymph nodes, where they multiply during an incubation period of 2 to 8 days. Inflamed lymph nodes called buboes show polymorphonuclear leucocytes, destruction of normal architecture, haemorrhagic necrosis, and dense concentrations of extracellular plague bacilli. Bacteraemia occurs and results in purulent, necrotic, and haemorrhagic lesions in many organs.

Clinical manifestations

Bubonic plague

The most common presentation is acute lymphadenitis called bubonic plague (Table 1). The people of plague endemic regions know the disease and have local names, such as *dich hach* in Vietnamese, that conjure up the horror of recalled fatalities during previous seasons. Patients are affected by the sudden onset of fever, chills, weakness, and headache. Usually, at the same time, after a few hours, or on the next day, they notice the bubo, which is signalled by intense pain in one anatomical region of lymph nodes, usually the groin, axilla, or neck. A swelling evolves in this area, which is so tender that the patients typically avoid any motion that might provoke discomfort. For example, if the bubo is in the femoral area, the patient will characteristically flex, abduct, and externally rotate the hip to relieve pressure on the area and will walk with a limp. When the bubo is in an axilla, the patient will abduct the shoulder or hold the arm in a splint. When a bubo is in the neck, patients will tilt their head to the opposite side.

The buboes are oval swellings that vary from 1 to 10 cm in length and elevate the overlying skin, which may appear stretched or erythematous. They may appear either as a smooth, uniform, ovoid mass or as an irregular cluster of several nodes with intervening and surrounding oedema (Fig. 1). There is warmth of the overlying skin and an underlying tender, firm, non-fluctuant mass. Occasionally, there is a large area of oedema extending from the bubo into the region drained by the affected lymph nodes. Although infections other than plague can produce acute lymphadenitis, plague is virtually unique for the suddeness of onset of the disease and fulminant clinical course that can produce death in 2 to 4 days after the onset of symptoms. The bubo of plague is also distinctive for the usual absence of a detectable skin lesion or ascending lymphangitis in its anatomical region.

Fig. 1 A right femoral bubo consists of an enlarged, tender lymph node with surrounding oedema.

The patients are typically prostrate and lethargic, and often exhibit restlessness or agitation. Occasionally, they are delirious with high fever, and seizures are common in children. Temperature is usually elevated in the range 38.5 to 40.0°C, and the pulse rate is increased to 110 to 140/min. Blood pressure is characteristically low, around 100/60 mmHg, and may be unobtainable if shock ensues. The liver and spleen are often palpable and tender.

About one-quarter of patients in Vietnam showed varied skin lesions including pustules, vesicles, eshars, or papules in the anatomical region that is lymphatically drained by the affected lymph nodes, and they presumably represent sites of the flea bites (Fig. 2). Purpuric lesions may develop and become necrotic, resulting in gangrene of distal extremities, the probable basis of the epithet 'Black Death' attributed to plague through the ages.

Fig. 2 A right axillary bubo was accompanied by a purulent ulcer on the abdomen, which was the presumed site of the flea bite.

Other plague syndromes

Less common presentations may accompany the bubo or occur without a bubo. Septicaemic plague refers to bacteremia without a bubo. Pneumonic plague occurs as a secondary pneumonia due to bacteremic spread in about 10 per cent of patients with bubonic plague. Person-to-person spread of pneumonia by a coughing patient is less common, and a few cases of inhalation pneumonia have occurred in persons who handled sick cats. Bacterial meningitis is a rare complication of plague. Acute pharyngitis may occur.

Laboratory findings

The white blood-cell count is typically elevated in the range of 10 000 to 20 000 cells/mm ^{3}, with a predominance of immature and mature neutrophils. Occasionally, some patients, especially children, may develop myelocytic leukaemoid reactions with white cell counts as high as 100 000/mm ^{3}. Blood platelets may be normal or low in the early stages of bubonic plague. Although patients with plague rarely develop a generalized bleeding tendency from profound thrombocytopenia, disseminated intravascular coagulation is common in this infection. Liver function tests, including serum aminotransferases and bilirubin, are frequently abnormally high. Renal function tests may be abnormal in hypotensive patients.

Diagnosis

Plague should be suspected in febrile patients who have been exposed to rodents or other mammals in the known endemic areas of the world. A bacteriological diagnosis is readily made by Gram stain and culture of a bubo aspirate. The aspirate is obtained by inserting a 20-gauge needle on a 10-ml syringe containing 1 ml of sterile saline into the bubo and withdrawing it several times until the saline becomes blood tinged. Because the bubo does not contain liquid pus, it may be necessary to inject some of the saline and immediately reaspirate it. The Gram stain will reveal polymorphonuclear leucocytes and Gram-negative coccobacilli and bacilli ranging from 1 to 2 µm in length (Fig. 3). Smears of blood, sputum, or spinal fluid can be handled similarly (Fig. 4).

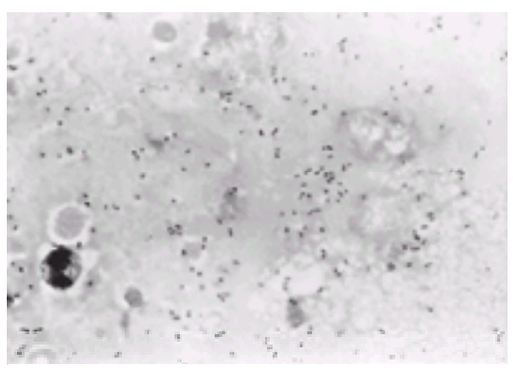

Fig. 3 Bubo aspirate shows bipolar bacilli stained with methylene blue (Wayson's stain).

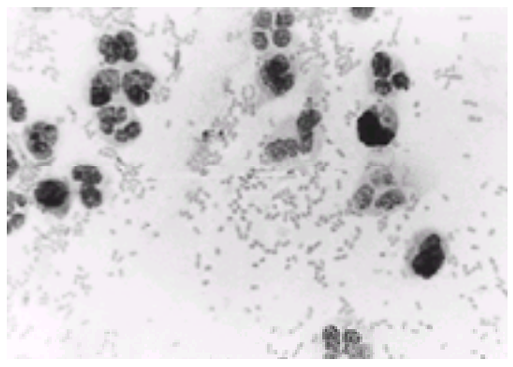

Fig. 4 Gram stain of spinal fluid in plague meningitis shows numerous Gram-negative bacilli.

The aspirate, blood, and other appropriate fluids should be inoculated on to blood and MacConkey agar plates and into infusion broth for bacteriological identification. At some reference laboratories, a serological test, the passive hemagglutination test or an ELISA utilizing fraction I of *Y. pestis*, is available for testing acute- and convalescent-phase serum. A fourfold or greater increase in titre or a single titre of 1:16 or higher is presumptive evidence of plague.

Treatment and prevention

Antimicrobials

Untreated plague has an estimated mortality rate of more than 50 per cent. Therefore, the early institution of effective antimicrobial therapy is mandatory following appropriate cultures. In 1948, streptomycin was identified as the drug of choice for the treatment of plague by reducing the mortality rate to less than 5 per cent. Streptomycin should be given intramuscularly in two divided doses daily, totalling 30 mg/kg body weight per day for 10 days. Most patients improve rapidly and become afebrile in about 3 days. The 10-day course of streptomycin is recommended to prevent relapses because viable bacteria have been isolated from buboes of patients with plague during convalescence.

When an oral drug is preferred, tetracycline is a satisfactory alternative. It is given orally in a dose of 2 to 4 g/day in four divided doses for 10 days. Tetracycline is contraindicated in children younger than 7 years of age and in pregnant women because it stains developing teeth. It is also contraindicated in renal failure. As an alternative drug that is especially suitable for meningitis, chloramphenicol can be given intravenously as a loading dose of 25 mg/kg of body weight followed by 60 mg/kg of body weight per day in four divided doses. After clinical improvement, chloramphenicol can be continued orally in a dose of 30 mg/kg to complete a total course of 10 days. There is no rationale for using multiple antibiotics to treat plague.

Other antimicrobial drugs have been used in plague or in experimental animal infections with varying success. These include sulphonamides, trimethoprim–sulphamethoxazole, kanamycin, gentamicin, ampicillin, cephalosporins, and fluoroquinolones. These drugs either are less effective than streptomycin or have not been subjected to adequate clinical studies and, therefore, should not be routinely chosen. An isolate from a 16-year-old boy in Madagascar in 1995 was resistant to streptomycin, tetracycline, chloramphenicol, and sulphonamide but was susceptible to trimethoprim–sulphamethoxazole. He recovered after receiving trimethoprim–sulphamethoxazole. Other than this case, antibiotic resistance in *Y. pestis* from humans has never been reported, nor has resistance emerged during antibiotic therapy.

Supportive therapy

Intravenous 0.9 per cent saline solution should be given to most patients for the first few days of the illness or until improvement occurs. Patients in shock will require additional quantities of fluid, with haemodynamic monitoring and use of vasopressors. The buboes usually recede without local therapy. Occasionally, however, they may enlarge or become fluctuant during the first week of treatment, requiring incision and drainage.

Precautions and prevention

Patients with plague who are promptly treated present no health hazard to other people. Those with a cough or other signs of pneumonia must be placed in respiratory isolation for at least 48 h after starting therapy or until the sputum culture is negative. The bubo aspirate and blood must be handled with gloves and with care to avoid aerosolization. Vaccines have been developed but at present are not available. Health departments advise personal protection against rodents and fleas, including living in rat-proof houses, wearing shoes and garments to cover the legs, and dusting houses with insecticide. For persons who report close contact with a coughing patient, prophylaxis with oral doxycycline or trimethoprim–sulfa-methoxazole is advised.

Yersiniosis

Definition

Yersiniosis is a disease caused by two species of enteric bacteria, *Yersinia enterocolitica* and *Yersinia pseudotuberculosis.* They cause a wide spectrum of clinical manifestations, which includes acute watery diarrhoea, acute mesenteric adenitis, extraintestinal infection, and bacteraemia. Postinfectious sequelae such as arthritis or erythema nodosum are also common.

The organisms

Yersinia sp. belong to the family Enterobacteriaceae. They are aerobic facultative and anaerobic, Gram-negative coccobacilli which grow on bile-containing media. There are three human pathogens within the genus, *Y. pseudotuberculosis*, *Y. enterocolitica*, and *Y. pestis*. The last, the causative organism of plague, is considered elsewhere (Chaper 7.11.16). Yersinia are usually non-lactose fermenting, catalase positive, and oxidase negative. The recovery of yersinia from stool samples can be improved by use of cefsulodin–irgasan–novobiocin (**CIN**) agar, cold enrichment, or potassium hydroxide pretreatment, but such manoeuvres are only occasionally necessary for clinical specimens. *Y. enterocolitica* can be divided into five biovars on the basis of biochemical reactions. The clinical and epidemiological significance of these biovars remains uncertain. Over 50 serogroups of *Y. enterocolitica* have been described, on the basis of O (somatic lipopolysaccharide) and H (flagellar) antigens. Six serotypes of *Y. pseudotuberculosis* have been described.

Virulence and pathogenicity

There are clear differences in virulence between strains of *Y. enterocolitica*; human disease is caused by a limited number of serotypes. A number of important factors have been identified. The possession of a 40 to 50 MDa plasmid is associated with virulence *in vitro* and the VW antigen complex and plasmid-encoded yersinia outer membrane proteins (YOPs) appear to be important in pathogenesis. The ability of yersinia to utilize exogenous iron by a number of mechanisms, including binding of exogenous siderophores, also appears to be an important factor in virulence; serious yersinia infections are much more common in patients with iron-overload syndromes. The vast majority of isolates produce enterotoxin, which is related to the enterotoxin of *Escherichia coli*. However, the role of enterotoxin in the production of diarrhoea remains uncertain and enterotoxin production does not correlate with other tests of virulence.

Most yersinia infections result from invasion via the gastrointestinal tract. Organisms adhere to the surface of the ileum and may invade the intestinal mucosa, via a bacterial outer membrane protein, invasin, which binds to a ligand on the cell surface. Bacteria multiply within intestinal epithelial cells and may reach Peyer's patches, where further multiplication occurs, with the potential for systemic spread.

Epidemiology

Y. enterocolitica causes infection throughout the world, but appears most common in the temperate regions, particularly northern Europe and North America. Both sporadic infections and outbreaks occur. Infection with serotypes 03 and 09 predominate in Europe whereas 08 and 03 are more commonly responsible for infection in North America. Yersiniosis is a zoonotic infection but usually causes foodborne illnesses. Animal reservoirs of *Y. enterocolitica* include pigs, rabbits, goats, cattle, horses, rodents, dogs, and cats. Animals may carry the organism asymptomatically in the oropharynx or gastrointestinal tract. The most important source of infection for man is the pig, although contact with household pets has also been implicated. Humans are infected via the faecal–oral route, usually after eating or drinking contaminated food or water; incompletely cooked pork is a major risk factor. Infection may also occur by person-to-person or direct animal-to-person contact and transmission through contaminated blood products has been reported. Infants and young children appear to be more susceptible to infection with *Y. enterocolitica* than adults. Most infections are sporadic but a number of specific outbreaks have been identified, following ingestion of contaminated foods such as pork chitterlings (intestines), water, or dairy products.

Infection with *Y. pseudotuberculosis* is less common, although cases are increasingly reported from Japan. Infection results from contact with both sylvatic and domestic animals and a number of birds. It most commonly affects patients aged between 5 and 20 years.

Clinical features

The usual incubation period for the acute manifestations of yersiniosis is 3 to 7 days. Common clinical syndromes are shown in Table 1. The most common manifestation of infection with *Y. enterocolitica* is an acute gastroenteritis, which particularly affects young children. Diarrhoea, fever, and abdominal pain may all be prominent. Stools contain mucus, leucocytes, and red blood cells; the organism can usually be detected on stool cultures. Clinically, the syndrome is indistinguishable from salmonella or campylobacter infection. Symptoms may last for up to 3 weeks and patients remain infectious over this period with continuous shedding of organism in the faeces. Rare complications include diffuse ulceration of the small intestine and colon, perforation, intussusception, toxic megacolon, cholangitis, and mesenteric vein thrombosis.

Older children more often develop mesenteric adenitis and terminal ileitis with either *Y. enterocolitica* or *Y. pseudotuberculosis* infection; this is the most common manifestation of *Y. pseudotuberculosis* infection. The presentation mimics appendicitis with fever, abdominal pain, right lower quadrant pain, and leucocytosis. Diarrhoea is unusual. Ultrasound and/or computed tomography may be helpful in demonstrating a normal appendix and enlarged mesenteric nodes. The infection is

usually self-limited. At laparotomy, enlarged mesenteric lymph nodes are found in the iliocaecal angle and there may be swelling of the terminal ileum or caecum. This presentation must be distinguished from acute appendicitis, or diseases causing terminal ileal disease such as Crohn's, tuberculosis, and rarely, neoplasia.

Y. enterocolitica may cause focal infection both in the absence of detectable bacteraemia and following bacteraemia. Isolated focal infection has been described in many sites, including the pharynx, skin and subcutaneous tissues, bones and joints, the conjunctiva, the renal tract, lungs, and peritoneum. *Y. enterocolitica* bacteraemia most often occurs in patients with chronic conditions such as diabetes, chronic liver disease, malignancy, and conditions causing immunosuppression. There is also a strong association with iron-overload syndromes or the treatment of iron overload (*Y. enterocolitica* is able to use exogenous iron chelators such as desferrioxamine to acquire iron itself). Over half of systemic bacteraemias are in patients with iron-overload syndromes; multiple hepatic abscesses may occur and the case fatality rate may reach 50 per cent in this population. Overall, the case fatality rates for *Y. enterocolitica* bacteraemia have ranged from 7.5 to 25 per cent over the last decade. Bacteraemia may lead to metastatic infections including endocarditis, intravenous line infection, meningitis, and septic arthritis.

Y. pseudotuberculosis bacteraemia is much less common, but is often associated with chronic illness. Case fatality rates are extremely high in the immunocompromised population. In Japan, *Y. pseudotuberculosis* infection has been associated with renal failure in young children.

Secondary, postinfective, complications are common following yersinia infection. In Scandinavia, they have been reported in up to 30 per cent of patients with *Y. enterocolitica* infection. A reactive polyarthropathy or erythema nodosum are the most common manifestations, classically occurring 1 to 2 weeks after an acute illness. Reiter's syndrome, glomeru-lonephritis, and myocarditis have also been described. The arthritis is polyarticular and asymmetrical, typically affecting the large joints of the lower limbs. There is a strong association with the possession of HLA B27. Synovial fluid culture is normally sterile although yersinia antigens can be found in the synovial tissue of patients. Symptoms of reactive polyarthritis may take several months to settle. The exact immunological mechanism of these postinfectious manifestations remains uncertain.

Diagnosis

Yersinia infection should be considered in anyone with fever and abdominal pain. A definitive diagnosis of yersiniosis may be made by culture of the organism from stool, lymph nodes, or blood depending upon the clinical presentation. However, isolation from stool may sometimes be slow because of the overgrowth of other faecal flora. Cold enrichment or CIN media may be used to optimize recovery from faecal samples.

A number of serological techniques, including tube agglutination assay, radioimmunoassays, and enzyme immunoassays, have been used to diagnose infection with yersinia. High titres in a previously healthy individual are suggestive of infection, but fourfold rises in titre are rarely found. Interpretation may be made difficult by cross-reactivity with *Brucella*, *Rickettsia*, and *Salmonella* spp. and possibly thyroid tissue antigens; some populations also have a high background prevalence of positive serology. Negative or minimal titres can occur following yersiniosis in infants or immunocompromised patients. Definitive diagnosis therefore depends upon the culture of the organism. However, serology is often the only way of diagnosing postinfectious complications as stool cultures may be negative by the time of appearance of symptoms such as arthritis. *Y. pseudotuberculosis* may be found in sterile site samples, but is rarely isolated from stool. Serology is often the only mode of diagnosis available; antigens cross-react with those of *Y. enterocolitica*.

Treatment

Antimicrobial therapy is not indicated in uncomplicated disease and treatment does not shorten the course or severity of enterocolitis. Localized infection, bacteraemia, and systemic disease, or enterocolitis in an immunocompromised patient, should be treated. *Y. enterocolitica* is resistant to most penicillins and first-generation cephalosporins due to the production of chromosomally encoded b-lactamases. Minimum inhibitory concentrations for amoxycillin/clavulanate combinations vary considerably; this drug should not be used for the treatment of infections. Aminoglycosides, chloramphenicol, tetracycline, and co-trimoxazole are all effective *in vitro* and have been used clinically with success. Third-generation cephalosporins are also effective, although in one recent study they were only successful in 85 per cent of cases, even when used in combination with other drugs. Fluoroquinolones have very good *in vitro* activity against yersinia and have been used successfully in clinical practice, but the optimal antibiotic therapy for the treatment of *Y. enterocolitica* has still to be determined. *Y. pseudotuberculosis* is sensitive to ampicillin and cephalosporins in addition to the drugs already discussed.

Pasteurella

Introduction

Pasteurella spp. are Gram-negative coccobacilli which cause a wide spectrum of disease in humans, ranging from local infection and abscesses to severe systemic infection. The majority of human infections are caused by *P. multocida*. They are most often acquired from contact with domestic animals.

The organism

Pasteurella spp. are small, non-motile, Gram-negative coccobacilli. They grow aerobically or as facultative anaerobes on standard media at 37°C; growth is enhanced by enrichment with carbon dioxide. They are oxidase and catalase positive and may stain bipolarly on Gram stain, sometimes being confused with *Haemophilus*, *Neisseria*, or *Acinetobacter* spp. *Pasteurella* spp. are a major veterinary pathogen, but only four species have been associated with human disease. The vast majority of human infections are caused by *P. multocida*, subspecies *septica* and subspecies *multocida*. Four capsular antigens and 15 somatic antigens of *P. multocida* have been identified. The capsule appears to be important in pathogenesis; heavily capsulate strains are resistant to phagocytosis.

Epidemiology

P. multocida is widely distributed as a nasopharyngeal or gastrointestinal commensal of animals and birds. The organism is carried by 70 to 90 per cent of cats and 50 to 70 per cent of dogs, but is also found in a large number of other domestic and wild animals. The organism can survive in water or soil for up to a month. *P. multocida* is a major animal pathogen, causing a number of different diseases, including fowl cholera and haemorrhagic septicaemia in wildstock.

Humans usually acquire infection with *P. multocida* from bites, scratches, or licks of dogs and cats, or close contact with these animals. However, in up to 15 per cent of cases, no known animal contact occurs. *Pasteurella* spp. can be isolated from 20 to 30 per cent of dog bite wounds and 50 per cent of cat bite wounds, although only a small proportion will become clinically infected. In clinically infected wounds, *Pasteurella* spp. are identified in 50 per cent of dog bites and 75 per cent of cat bites. Person-to-person spread has not been recorded, although *P. multocida* can occasionally be found in the nasopharynx of healthy humans exposed to animals.

Clinical features

P. multocida has been associated with a wide variety of different clinical presentations, outlined in Table 2. The vast majority of infections are due to animal bites which cause local soft tissue infection manifesting with remarkable rapidity. Symptoms and signs may develop within several hours of the bite. Local erythema, swelling, and purulent discharge are common; fever, lymphangitis, and local lymph node swelling may also occur. Soft tissue infections may also involve deeper tissues, causing abscesses, tenosynovitis, septic arthritis, or osteomyelitis.

The second most common site of isolation of *P. multocida* is the respiratory tract. Some of these patients have no history of animal contact, but over 90 per cent have chronic respiratory tract disease, particularly chronic obstructive pulmonary disease, bronchiectasis, or malignancy. Isolation of *Pasteurella* spp. may sometimes represent long-term colonization, but acute upper and lower respiratory tract infection does occur. Acute pneumonia, tracheobronchitis, empyema, and occasionally, lung abscess are the most commonly reported clinical syndromes. Most patients with pneumonia are elderly and bacteraemia occurs in 25 to 55 per cent of cases of respiratory infection with a reported case fatality rate of 29 per cent. There are no specific diagnostic features of *P. multocida* pneumonia; although lobar consolidation is the commonest chest radiograph appearance, multilobar and diffuse infiltrates also occur. Spread of Pasteurella infection from the upper respiratory tract may occasionally cause tonsillitis, sinusitis, pharyngitis, and epiglottitis.

Bacteraemia occurs in association with localized infections in many different sites. It is more common in patients with liver dysfunction. Bacteraemia is most often associated with meningitis (53 per cent of cases), respiratory disease, and septic arthritis (24 per cent). Endocarditis has been reported but appears to be relatively rare. Pasteurella meningitis affects mainly infants or the elderly. Septic arthritis normally affects already damaged joints. It is sometimes associated with bites distal to

the joint, but also occurs in patients with no trauma or even in some who have no pets. A number of different intra-abdominal infections have been reported; bacterial peritonitis is a particular problem in patients with liver disease.

Diagnosis

A history of animal exposure should always suggest the possibility of Pasteurella infection. *Pasteurella* spp. can be identified as small Gram-negative rods which may stain bipolarly and can be isolated from sputum, pus, blood, or cerebrospinal fluid. Differentiation from *Haemophilus*, *Acinetobacter*, and *Neisseria* spp. is important.

Prevention and treatment

The most important factor in avoiding Pasteurella infections is the adequate treatment of bites. Thorough cleaning and debridement of wounds is crucial. The role of prophylactic antibiotics is controversial; approximately 5 to 15 per cent of dog bites and up to 50 per cent of cat bites become infected. Most clinicians advocate prophylactic antibiotics for 'high-risk' bites, crush injuries, deep puncture wounds, and wounds to the hands. Patients who are immunosuppressed, who have asplenism, or have alcoholic liver disease should certainly be treated. One recent meta-analysis suggested that routine antibiotics reduced the incidence of infection with a number needed to treat (NNT) of 14 to prevent one infection. In view of the strong association of Pasteurella infection with domestic animal contact, some clinicians have suggested that patients who are immunocompromised or who have chronic disease such as cirrhosis should try to avoid contact with dogs or cats.

Penicillin is the treatment of choice for established infections, although occasional clinical isolates that produce b-lactamase have been reported. Oral agents with good *in vitro* activity include tetracyclines, amoxycillin, amoxycillin/clavulanate, co-trimoxazole, and most fluoroquinolones. Azithromycin appears to be the most effective macrolide. Erythromycin has poor activity and *P. multocida* is resistant to clindamycin and many first-generation cephalosporins. Penicillin, third-generation cephalosporins, particularly cefotaxime, and chloramphenicol have all been used successfully in severely ill patients admitted to hospital.

Although penicillin has good activity against *Pasteurella* spp., prophylactic antibiotics for bites need to cover other organisms commonly found in the oral flora of dogs and cats, for instance *Staphylococcus aureus*, other staphylococcal species, anaerobes, and *Capnocytophaga canimorsus*. Amoxycillin/clavulanate is the prophylactic drug of choice. Treatment options in penicillin-hypersensitive patients include tetracycline or a combination of clindamycin and a fluoroquinolone.

Tularaemia

Introduction

Tularaemia is a zoonotic, arthropod-, and water-borne disease caused by *Francisella tularensis*, a small Gram-negative bacterium that has a natural lifecycle in mammalian hosts and may be transmitted by ticks and biting flies. Human infections occur predominantly in the northern hemisphere causing several different clinical syndromes, ranging from the combination of a fever, cutaneous ulcer, and lymphadenopathy to severe systemic disease and pneumonia. Three biogroups of *F. tularensis* can be distinguished by their geographical distribution, epidemiology, and virulence.

Bacteriology

Francisella spp. are small, non-motile, pleomorphic, Gram-negative coccobacilli. The organism has a thin capsule and may stain only faintly or exhibit bipolar staining with Gram or Giemsa stains. *Francisella* spp. grow only on media that contains cystine or cysteine and are strict aerobes. Optimal growth occurs at 35°C with carbon dioxide enrichment. They are oxidase negative and weakly catalase positive. Several species exist within the genus, but the major human pathogen is *F. tularensis*. Several biogroups of *F. tularensis* can be distinguished by biochemical characteristics; these biogroups vary markedly in their geographical distribution, epidemiology, and virulence for humans. *F. tularensis* biogroup *tularensis* and *F. tularensis* biogroup *palearctica* cause the vast majority of human disease. *F. tularensis* biogroup *novicida* causes milder forms of tularaemia and *F. philmiragia* has occasionally been reported to cause infection in specific host groups.

Epidemiology

Although foci of disease occur throughout the world, the vast majority of cases have occurred in the northern hemisphere. The distribution of *F. tularensis* throughout Europe is shown in Fig. 1. A significant number of cases have also been reported from Japan. In North America, tularaemia has been reported from all states of the United States, Canada, and Mexico. However, the disease is now particularly associated with the Midwest in summer owing to transmission by tick bites and east of the Mississippi in winter from rabbit hunting. Transmission of the disease does not occur in the United Kingdom. Although tularaemia was extremely common in the United States, former Union of Soviet Socialist Republics, and Scandinavia in the middle of the last century, the recognition of occupational hazards and vaccination campaigns have reduced the incidence considerably. In the United States, the number of cases has declined from around 2000 per year in the post-war era to an average of 146 cases per year from 1990 to 1994, the last year for which tularaemia was a notifiable disease. Hundreds of thousands of cases occurred in the Union of Soviet Socialist Republics around the time of the Second World War, but the Russian Federation only reported 2019 cases in the 10 years from 1987 to 1997.

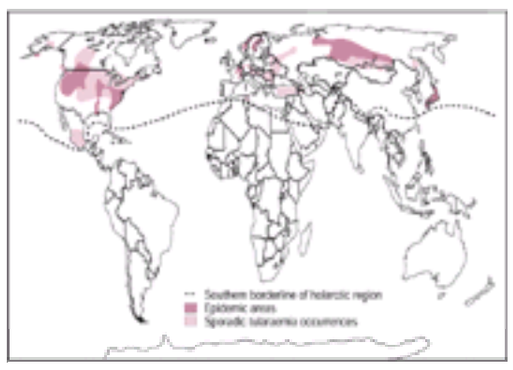

Fig. 1 Tularaemia foci in Europe.

Infection in humans is predominantly caused by two biogroups; *F. tularensis* biogroup *tularensis* (synonymous with type A or *nearctica*) and *F. tularensis* biogroup *palearctica* (synonymous with type B or *palearctica*). Ninety-five per cent of North American human infections are due to biogroup *tularensis.* In Europe, infection is by the less virulent biogroup *palearctica*, which has a greater variety of reservoirs and vectors than the North American biogroup.

In the United States, biogroup *tularensis* particularly infects ground squirrels, cottontail rabbits, hares, and jackrabbits, but also occurs in other wild and domestic animals. Human infections usually arise from contact with affected animals or following tick or fly bites. Hunting, skinning, or eating infected animals is a particular risk factor. Inoculation through the skin or airborne transmission may occur during preparation of carcasses and infection can also be acquired by ingestion of infected meat or contaminated water and through mammal bites. *F tularensis* biogroup *tularensis* may be transmitted by a wide range of arthropod vectors, including ticks of the genera *Dermacentor* and *Amblyomma*.

Biogroup *palearctica* is less common in the United States; strains of this type have been isolated from muskrats, in which they cause epizootics. In northern Europe, biogroup *palaearctica* infects a wide variety of mammals, mainly rodents, as well as hares. The main insect vectors are mosquitoes of the genus *Aëdes*, but ticks and biting flies also transmit the disease. Outbreaks of disease have often been reported. Human infections arise by a number of different mechanisms, apart from hunting and arthropod bites. Outbreaks have occurred from exposure to water contaminated by dead bodies or excreta of infected animals and from airborne dissemination of infection acquired by the inhalation of contaminated particles, such as dust from rodent-infested hay.

Pathogenicity

F. tularensis is primarily an intracellular pathogen that can multiply within mononuclear cells. Experimentally, as few as 50 organisms may cause infection through inoculation or inhalation; higher numbers are need to cause infection following ingestion. The organism spreads to regional lymph nodes from where it may be disseminated. Immunity is primarily cell mediated; focal necrosis and granulomas may be found in affected tissue. Little is known of the molecular basis of virulence, but loss of the capsule is associated with decreased virulence.

Clinical presentations of tularaemia (rabbit fever, deerfly fever, Ohara disease)

The clinical presentation of tularaemia depends on the route of transmission and virulence of the organism. Although clinical disease traditionally has been classified differently in the United States and Europe, manifestations of infection by *F. tularensis* biogroups *tularensis* and *palearctica* are essentially similar, except that biogroup *palaearctica* in Europe is clearly less virulent. The incubation period for tularaemia is usually between 3 and 5 days, but may be as long as 3 weeks. Most patients describe fever, chills, and prostration, and have a relapsing, protracted illness unless treated or vaccinated. A number of different discrete clinical syndromes (Table 3) have been described but there is considerable overlap between them.

Ulceroglandular tularaemia (Plate 1, Plate 2, Plate 3)

This is the most common presentation, particularly in North America. Patients present with sudden chills, fever, and often severe headache. An indurated and ragged ulcer evolves at the site of the initial entry of the organism; this is usually small and causes little pain. The ulcers are occasionally multiple and their site is related to the mode of contact. Local lymph nodes are tender, steadily increase in size, and frequently suppurate. If untreated, the ulcer may heal over several weeks leaving a scar.

Glandular tularaemia

Tularaemia may also present with lymphadenopathy without an obvious skin ulcer. Small lesions may be missed or have healed before presentation. Nodes may sometimes persist for weeks before the diagnosis is made. The differential diagnosis of glandular and ulceroglandular tularaemia includes pyogenic bacterial disease, cat-scratch disease, syphilis, mycobacterial infection, plague, and toxoplasmosis.

Oropharyngeal tularaemia (Plate 4)

This may occur due to oral contact with infected material and causes a pharyngitis, sometimes with ulceration, and enlargement of local lymph nodes. It may be more common in children than in adults. Pharyngitis and enlarged nodes may also occur in other forms of tularaemia. Pharyngeal tularaemia must be distinguished from other bacterial and viral causes of pharyngitis.

Oculoglandular tularaemia

This is a relatively rare form of tularaemia. The primary lesion is in the conjunctiva or cornea; infection usually occurs from splashing the face while cleaning infected animals, swimming in contaminated water, or from laboratory accidents. Conjunctivitis occurs along with chemosis and lid oedema. Unilateral preauricular lymphadenopathy is commonly observed. The differential diagnosis includes viral and bacterial causes of conjunctivitis including herpes simplex and syphilis.

Typhoidal tularaemia

This form of tularaemia occurs following any mode of acquisition of infection. Lymphadenopathy is not a feature. It appears to be more common in patients with pre-existing chronic illness. A febrile illness is associated with systemic symptoms which include fevers, chills, pharyngitis, myalgia, and gastrointestinal symptoms including watery diarrhoea. Meningism may occur. Patients may become severely ill and secondary pneumonic involvement occurs in over 40 per cent of patients.

Pulmonary tularaemia

Pulmonary disease may be primary, resulting from the inhalation of infected aerosols, or secondary from haematogenous spread. Pneumonia is commonly associated with typhoidal disease and also occurs in around a third of patients with ulceroglandular disease. Some patients have respiratory symptoms and signs of pneumonia, but a significant number of patients with tularaemia have asymptomatic radiological abnormalities. The commonest radiological finding is multiple parenchymal infiltrates in one lobe, but bilateral infiltrates and pleural effusions also occur. Hilar lymphadenopathy may be present. Examination of the sputum is rarely helpful. Most infiltrates clear rapidly on therapy. Tularaemia should be considered in any patient in an endemic area who presents with a community-acquired pneumonia which is resistant to standard therapy. The disease needs to be distinguished from all other causes of atypical pneumonia.

Secondary rashes have been reported following acute infection in all forms of tularaemia. Erythema nodosum has particularly been associated with pneumonic forms. *F. tularensis* biogroup *novicida* has low virulence for humans but may cause mild forms of tularaemia. *F. philmiragia* has been reported to cause severe infection in patients with chronic granulomatous disease or myeloproliferative disease and victims of near drowning.

Complications

Suppuration of lymph nodes is common in glandular forms, even after antibiotic treatment. Some patients may be unwell with malaise and fatigue for several months. In severe disease, impaired renal and hepatic function, elevated creatine kinase levels, and disseminated intravascular coagulation may occur. Severe disease is more common in patients with pre-existing illness and the elderly. Bacteraemia, renal impairment, pulmonary involvement, and elevated creatine kinase levels are all associated with a poorer prognosis. Overall case fatality rates for tularaemia in North America are approximately 2 to 3 per cent in patients treated with appropriate antibiotics. Deaths are rare in biogroup *palearctica* infections.

Diagnosis

In regions where *F. tularensis* is endemic, a provisional clinical diagnosis can often be made from the patient's exposure history and clinical signs. However, if there is no local ulcer, and if the patient has left the area in which the infection was acquired, patients who present with a persistent fever, lymphadenopathy, pneumonitis, or tonsillitis may be more difficult to diagnose. A detailed travel and epidemiological history may help. Routine laboratory investigations are rarely helpful, although sterile pyuria has been noted in up to 20 per cent of cases.

A definitive diagnosis can be made by isolation of the organism, but *F. tularensis* will not grow on routine plating and samples require inoculation on to supportive media. The organism can be isolated from blood, lymph nodes, wounds, and occasionally sputum, but even in optimum conditions, the organism grows slowly and prolonged culture may be needed. Clinicians should inform the laboratory if tularaemia is suspected; laboratory aerosols cause serious, occasionally fatal, laboratory-acquired infection. Swabs or aspirates from local lesions and lymph glands should be transported in approved containers. Immunofluorescence methods may be more sensitive for identification of organisms in smears and tissues, and reduce the risk to laboratory staff.

Traditionally, most diagnoses have been made serologically using various agglutination assays. A fourfold rise in titre, or a titre of 1:160 in a single sample by the end of the third week of illness, is considered to be diagnostic of tularaemia. Antibody may persist for years after infection. Cross-reactivity with *Brucella* and *Yersinia* antibodies occurs. Enzyme-linked immunosorbent assay (**ELISA**) techniques are more sensitive for the early detection of tularaemia and can detect class-specific immunoglobulins. Delayed hypersensitivity skin testing has been used for diagnosis, but antigens have not been standardized. The polymerase chain reaction (**PCR**) has been used for the detection of *F. tularensis* DNA in animal tissues and initial studies on clinical wound specimens suggest that the technique may be more sensitive than culture. *F. tularensis* DNA has also been detected in patients who are serologically negative but have other evidence of infection with *F. tularensis*. Further study is need to determine the role of PCR and improved ELISA techniques in the diagnosis of tularaemia.

Treatment

Aminoglycosides have been used most widely for the treatment of tularaemia because of their bactericidal activity against *F. tularensis.* Streptomycin is the drug of

choice and usually produces a dramatic clinical response. Gentamicin is an effective alternative, although relapses are more common than with streptomycin, occurring in 6 per cent of patients. Treatment is normally given for 10 to 14 days; shorter courses are associated with relapse. Tetracycline and chloramphenicol have been used successfully for the treatment of tularaemia, although relapse rates of 12 and 21 per cent, respectively, have been reported. Tetracyclines may be adequate for mild infections with biogroup *palaearctica* when given in high oral doses for 2 weeks.

Francisella spp. are resistant *in vitro* to most b-lactam antibiotics with the exception of third-generation cephalosporins. However, clinical experience with ceftriaxone has been disappointing. Quinolones have good *in vitro* activity against *F. tularensis* and successful clinical outcomes have been reported in a number of patients who have been treated with ciprofloxacin. Further study is required to define the role of these drugs in the treatment of tularaemia.

Prevention

Most important is reduction in human contact with infected animals and vectors in endemic areas. Protective clothing and insect repellent should be used when walking in endemic areas. Ticks should be sought out regularly and removed. Gloves should be worn when skinning or preparing rabbits; meat should be thoroughly cooked and sick animals should not be handled or eaten. Care should be taken in the laboratory to prevent transmission from potentially infective samples; *Francisella* spp. are category 3 pathogens and should be handled accordingly. Vaccines developed from live attenuated strains of biogroup *palearctica* are effective and should be considered for laboratory workers who regularly handle *F. tularensis* or for others with repeated occupational exposure. There is no evidence of efficacy of chemoprophylaxis for exposed individuals.

---

Anthrax

Thira Sirisanthana

Introduction

Anthrax is an acute bacterial infection caused by *Bacillus anthracis*. Herbivores are particularly susceptible to anthrax. They acquire the infection after coming into contact with soil-borne spores. Humans are infected when spores of *B. anthracis* enter the body through contact with infected animals or animal products, ingestion, or inhalation. The disease occurs in three clinical forms: cutaneous, gastrointestinal, and inhalation. Septicaemia and meningitis may occur from any of these primary foci. Other names for anthrax include malignant pustule, Siberian ulcer, charbon, malignant oedema, Milzbrand, and woolsorter's disease.

Anthrax has been known since antiquity. The fifth and sixth plagues described in the Bible are most likely outbreaks of anthrax in cattle and humans. Several distinguished scientists in the nineteenth century characterized the pathogenesis of the disease. In 1877, Robert Koch grew the organism in pure culture. He defined the stringent criteria needed to prove that the organism caused anthrax (Koch's postulates), then met them experimentally. Koch also discovered the spore stage that allows persistence of the organism in the soil. Louis Pasteur, in 1881, made a convincing field demonstration at Pouilly-le-Fort to show that vaccination of sheep, goats, and cows with heat-attenuated strain of *B. anthracis* prevented anthrax. In 1939, Sterne developed an animal vaccine that is a spore suspension of an avirulent, non-capsulated live strain. This is the animal vaccine still in use today.

Anthrax practically disappeared from North America, Western Europe, and Australia after the disease was eradicated in livestock following extensive vaccination programmes. However, it is still prevalent in developing countries, especially in Asia and Africa, where livestock are only poorly subjected to veterinary control, and where environmental conditions are favourable for an animal–soil–animal cycle to be established.

Recent interest in anthrax has been excited by fear of the use of anthrax spores as a biological weapon both in the battlefield and in a terrorist strike. An accident involving aerosolized anthrax spores at a Soviet military compound in 1979 (see below), and the revelation that Iraq had produced weapons containing anthrax spores during the 1991 Gulf War, confirm this fear.

Aetiology

B. anthracis is a large, non-motile, encapsulated, Gram-positive, aerobic, spore-forming bacillus that grows well in most nutrient media at 35°C. Spores are not produced in living animals. In the clinical laboratory, *B. anthracis* is recognized by its tendency to form very long chains of rods with elliptical central spores. The rectangular shape of the individual bacteria gives chains of *B. anthracis* a 'joint bamboo rod' appearance (Fig. 1 and Plate 1). On blood agar, *B. anthracis* forms non-haemolytic or weakly haemolytic greyish-white, rough colonies. In the presence of excess carbon dioxide, the organisms form capsules, and colonies are smooth and mucoid. The colonies produce a typical 'medusa head' or 'curled hair' appearance caused by chains of bacilli growing out from the edge of colonies. *B. anthracis* are pathogenic for small rodents. White mice, rabbits, and guinea pigs develop fatal infections after subcutaneous inoculation of very small numbers of the virulent organisms. The virulence factors of *B. anthracis* include a capsule that inhibits phagocytosis and three proteins collectively called anthrax toxin. The organism can be further identified by determination of susceptibility to bacillus phage g and by demonstration of species-specific antigens (including the capsule and the anthrax toxin). The spores of *B. anthracis* are very resistant and will resist dry heat at 140°C for 1 to 3 h or moist heat at 100°C for 5 min. They can persist in nature for many years. Boiling for 10 min, treatment with oxidizing agents such as potassium permanganate, or with formaldehyde will kill the spores. Most strains of *B. anthracis* are susceptible to penicillin. During growth inhibition by penicillin, the cell cylinders of *B. anthracis* tend to bulge, resulting in the classic 'string of pearls' reaction.

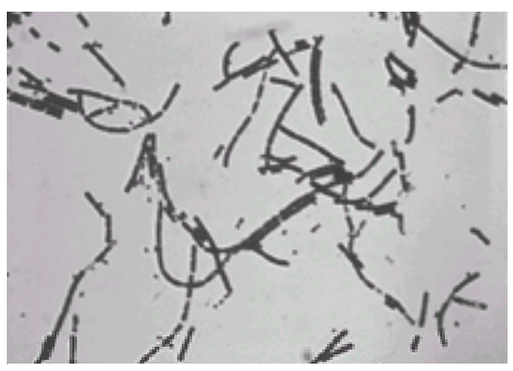

Fig. 1 Large Gram-positive bacilli in chains are typical of *B. anthracis*. An individual bacillus is 3 to 5 µm long and 1 to 1.25 µm wide with a flattened end. (See also Plate 1.)

Epidemiology

Anthrax is usually acquired through unrecognized breaks in skin or mucous membranes to which spores of *B. anthracis* gain access. The spores germinate to yield vegetative cells, which multiply and produce either localized or severe systemic infection depending on the animal species infected. Different species of animals are susceptible to varying degrees. Herbivores such as horses, sheep, goats, and cattle are most susceptible and develop fatal systemic disease. Dying herbivores have overwhelming bacteraemia and often bleed from the nose, mouth, and bowel, thereby contaminating soil with vegetative *B. anthracis*, which can sporulate and persist in the soil for a long time. The carcasses of infected animals provide additional potential foci of contamination. *B. anthracis* spores become part of the normal soil flora and can undergo bursts of local multiplication that increase the number of organisms in the soil. The cause of this local multiplication of anthrax bacilli is not known, but it is usually associated with major changes in the soil microenvironment such as those seen after abundant rainfall or a drought.

Human cases may occur in agriculture or industry. Agricultural cases result from direct contact with infected animals (herders, butchers, and slaughterhouse workers) and those who consume contaminated meat. Industrial cases involve those in contact with infected animal product such as hides, wool, goat's hair, or bone. All human cases are zoonotic in origin. No human-to-human transmission has been reported. The worldwide incidence of human anthrax is not known because many cases, especially in developing countries, do not receive medical attention and are not reported. However, one estimate puts the incidence at between 20 000 and 100 000 cases annually. Cutaneous anthrax typically follows skin exposure to infected animals or animal products. It is the most common form of the disease. Gastrointestinal anthrax follows ingestion of *B. anthracis*- contaminated food. Although rarely reported, gastrointestinal anthrax may not be uncommon in parts of Asia and Africa. Inhalation anthrax is a result of spore deposition in the lungs. Historically, woolsorters at industrial mills were at highest risk. Naturally occurring inhalation anthrax is

now a rare disease.

Recent important epidemics of human anthrax include those from Zimbabwe between 1978 and 1982, from Switzerland in 1991, and from Sverdlovsk in the former Soviet Union in 1979. The outbreak in Zimbabwe is the largest reported agricultural outbreak. There were more than 10 000 cases. Most patients had cutaneous infections, but some gastrointestinal cases were also reported. This happened after a cattle outbreak during the Rhodesian civil war that caused disruption to veterinary anthrax vaccination programmes. In the Swiss outbreak, 25 workers in one textile factory contracted the disease. Twenty-four cases had cutaneous and one inhalation anthrax. The factory had imported *B. anthracis*-contaminated goat hair from Pakistan. This outbreak shows that the potential for industrial transmission of *B. anthracis* still exists in the Western world. In the former Soviet Union, the health authorities initially attributed the outbreak in Sverdlovsk to meat from infected animals. It is now known that deaths were in fact due to inhalation anthrax, the result of an accidental aerosolized release of anthrax spores from a microbiology laboratory in the local military facility. There were at least 77 cases of anthrax and 66 deaths.

Pathogenesis

Pathological changes result from tissue invasion by *B. anthracis* and effects of its exotoxin. The organism is an extracellular pathogen that multiplies rapidly, invades the bloodstream and kills quickly. Virulent strains of *B. anthracis* possess two virulence factors: a capsule and a three-component protein exotoxin (anthrax toxin) that is made up of protective antigen (**PA**), oedema factor (**EF**), and lethal factor (**LF**). The capsule, which is composed of D-glutamic acid polypeptide, enhances virulence by making the organism resistant to phagocytosis. The genes encoding the anthrax capsule are carried on an extrachromosomal plasmid. A second plasmid carries the gene for the three proteins: PA, EF, and LF. PA is so named because it is the main protective constituent of anthrax vaccines. PA binds to a cell-surface receptor on the target cell and is cleaved by a protease into two fragments. After the cleavage, the larger membrane-bound fragment displays a binding site for EF and LF and mediates their entry into the target cell. EF, a calmodulin-dependent adenylate cyclase, increases intracellular cyclic adenosine monophosphate levels. The biological effects of EF include the formation of oedema characteristic of the disease. A mixture of EF and PA, known together as oedema toxin, also inhibits phagocytosis by polymorphonuclear leucocytes. The action of LF, believed to be a metalloproteinase, is less understood. Its exact intracellular target is not known. One recent study showed that LF inactivates an enzyme responsible for activating mitogen-activated protein kinase (**MAPK**). Thus, LF blocks the MAPK signal transduction pathway, an evolutionarily conserved pathway that controls cell proliferation and differentiation. Injection of a mixture of PA and LF, known together as lethal toxin, causes death in many species of experimental animals. Lethal toxin has been shown at high concentration to kill macrophages and at low concentration to cause macrophages to release tumour necrosis factor and interleukin 1.

When spores of *B. anthracis* are introduced subcutaneously, they germinate and multiply. The antiphagocytic capsule facilitates local spread. The oedema and lethal toxins impair leucocyte function and contribute to tissue necrosis, oedema, and relative absence of leucocytes in the skin lesion. The bacilli spread to the draining lymph node resulting in the typical findings of haemorrhagic, oedematous, and necrotic lymphadenitis. Gastrointestinal anthrax follows ingestion of contaminated and undercooked meat. Multiplication of the bacilli in the oropharynx and the draining lymph nodes causes the oropharyngeal ulcer and neck swelling. When the organisms are deposited in the duodenum, ileum, or caecum, they cause mucosal inflammation and ulcers. Transport of the bacteria to the mesenteric lymph nodes results in the development of haemorrhagic adenitis and ascites. Inhalation anthrax follows deposition of spore-bearing particles of 1 to 5 µm into alveolar spaces. They are phagocytosed by alveolar macrophages and transported to the tracheobronchial and mediastinal lymph nodes, where they germinate. Production of toxins leads to haemorrhagic, oedematous, and necrotic lymphadenitis and mediastinitis.

In all primary forms of anthrax, especially inhalation anthrax, the bacilli can spread through the blood causing septicaemia and at times haemorrhagic meningitis. Autopsies show numerous bacteria in blood vessels, lymph nodes, and other organs.

Clinical features

Cutaneous anthrax

The cutaneous lesion in anthrax is most often found on exposed areas of skin such as the face, neck, arms, or hands. The incubation period is 1 to 7 days, usually 2 to 5 days. Initially a small papule develops at the site of infection. During the next week, the lesion typically progresses through vesicular and pustular stages to the formation of an ulcer with a depressed black eschar (Fig. 2 and Plate 2). A striking degree of non-pitting oedema surrounding the lesion is typical. The early lesion may be pruritic. The fully developed lesion is painless. Small satellite vesicles may surround the original lesion. Lymphangitis and painful regional lymphadenitis is common. Associated systemic symptoms are usually mild, and the lesion heals after the eschar separates. In about 10 to 20 per cent of the patients, the disease progresses with massive local oedema, toxaemia, and bacteraemia, and a fatal outcome if untreated. Cutaneous anthrax should be considered when patients have painless ulcers associated with vesicles, oedema out of proportion to the size of the lesion, and have had contact with animals or animal products. The differential diagnosis includes staphylococcal skin infections, tularaemia, plague, cutaneous diphtheria, orf, rickettsial pox, and scrub typhus.

Fig. 2 Cutaneous anthrax lesion on the forearm on day 10 showing an ulcer with a depressed black eschar. (See also Plate 2.)

Gastrointestinal anthrax

Because gastrointestinal anthrax develops following consumption of contaminated meat, it can occur as familial clusters. The disease has been described in two forms. The incubation period is 2 to 5 days. Oropharyngeal anthrax follows deposition of the bacteria in the oropharynx. Patients present with fever, neck swelling, sore throat, and dysphagia. The neck swelling is caused by enlargement of the lymph nodes together with subcutaneous oedema as in diphtheria. The lymph node enlargement commonly involves the upper group of the jugular chain. There is an inflammatory lesion in the oral cavity or oropharynx. The lesion starts as an inflamed mucosa, progressing through necrosis and ulceration to the formation of a pseudomembrane covering the ulcer (Fig. 3 and Plate 3). In severe cases, the subcutaneous oedema extends to the anterior chest wall and axilla, with the overlying skin showing signs of inflammation. Toxaemia and death may follow. Oropharygeal anthrax should be considered in patients who present with fever, neck swelling, sore throat, and oropharyngeal ulcer and who give a history of eating raw or undercooked meat. The differential diagnosis includes diphtheria and peritonsillar abscess.

Fig. 3 Oropharyngeal anthrax on day 9 showing a pseudomembrane covering an ulcer. (See also Plate 3.)

In another form of gastrointestinal anthrax, the organisms are deposited in the duodenum, terminal ileum, or caecum. The onset is with fever, nausea, vomiting, and abdominal pain, followed by rapidly developing ascites and bloody diarrhoea. Haematemesis, melaena, haematochezia, and/or profuse watery diarrhoea may occur in some patients. In severe cases, toxaemia, shock, and death follow. It is difficult to make a diagnosis in the early stage, except in an epidemic setting.

Inhalation anthrax

Inhalation anthrax (woolsorter's disease) has been described as a two-stage illness. The incubation period is 1 to 5 days. It starts with malaise, myalgia, fever, and non-productive cough, symptoms similar to those of viral respiratory diseases. Signs of illness and laboratory results are non-specific. In some patients there is a transient improvement after 2 to 4 days. The second stage begins with severe respiratory distress, cyanosis, stridor, and profuse sweating. Subcutaneous oedema of the chest and neck may develop. A characteristic radiographic finding is symmetric mediastinal widening with or without pleural effusion. Blood culture will grow *B. anthracis*. Up to half of patients develop anthrax meningitis. Shock and death typically follow in less than 24 h. The initial phase of the disease is very difficult to diagnose in the absence of a known outbreak. Advanced disease may be suspected in the presence of a characteristically widened mediastinum despite otherwise normal chest radiographic findings. Inhalation anthrax must be distinguished from pneumonic plague.

Meningeal anthrax

Anthrax meningitis, frequently a consequence of overwhelming *B. anthracis* bacteraemia, may complicate any primary form of anthrax. Rarely, a case of anthrax meningitis has been reported in which the primary site was not identified. Within a few days of the primary lesion, the patient develops sudden onset of confusion, loss of consciousness, and focal neurological signs. The cerebrospinal fluid is haemorrhagic, purulent, or both. The disease is almost always fatal.

Laboratory diagnosis

Clinical specimens taken before antibiotic therapy is instituted will grow *B. anthracis* in culture. Gram stain of these specimens may show Gram-positive rods. These specimens include vesicular fluid (cutaneous anthrax), swabs from oropharyngeal lesions, ascitic fluid (gastrointestinal anthrax), and cerebrospinal fluid (meningeal anthrax). Severe cases of anthrax, especially the inhalation form, may have bacteraemia, but by the time blood cultures become positive many patients will have died. Because *Bacillus* species are frequent laboratory contaminants, most laboratories do not identify them further unless specifically asked to do so. Thus, it is important to notify the laboratory when *B. anthracis* infection is suspected. Laboratory confirmation can also be made by demonstration of *B. anthracis* in the clinical specimens by direct fluorescent antibody staining.

Serological tests are helpful in making a diagnosis, especially when prior antibiotics have eradicated the bacteria before cultures or smears were obtained. However, patients with severe disease, especially inhalation anthrax, die so quickly that these tests may not be helpful to the clinician. Useful tests include an enzyme-linked immunosorbent assay (ELISA), which detects antibodies to the capsular antigen and/or PA, and an electrophoretic immunotransblot test (Western blot), which detects antibodies to PA and/or LF. These tests are only available at national reference laboratories.

Treatment

Most strains of *B. anthracis* are susceptible to penicillin, which should be started as soon as possible. Mild cases of cutaneous anthrax may be treated with oral penicillin at the dose of 250 mg 6-hourly for 5 to 7 days. For extensive lesions, parenteral penicillin G, 2 million units 6-hourly, should be given until systemic toxicity subsides. The patient may then take oral penicillin for a total treatment period of 7 to 10 days. Ciprofloxacin, erythromycin, doxycycline, or chloramphenicol can be used in penicillin-sensitive patients. Antibiotics decrease systemic toxicity, but the skin lesions will continue to progress to the eschar phase. The skin lesion should be covered with a sterile dressing. Used dressings should be decontaminated. In gastrointestinal or inhalation anthrax or in anthrax meningitis, intravenous penicillin G, 4 million units 4-hourly, should be administered. Other drugs are intravenous ciprofloxacin (800 mg/day) or intravenous doxycycline (200 mg/day). Many patients will require intensive supportive care including vigilant monitoring and correction of electrolyte and acid–base disturbance, mechanical ventilation, and vasopressor administration.

Prognosis

A case fatality rate of 10 to 20 per cent has been reported for untreated cases of cutaneous anthrax. With appropriate antibiotic treatment, fatalities are rare. Almost all cases of inhalation anthrax and anthrax meningitis are fatal. Oropharyngeal anthrax causes death in about 15 per cent of the patients. The case fatality rate of the other form of gastrointestinal anthrax is not known.

Prevention and control

Control of anthrax in animals is essential to control of the disease in humans. Routine immunization of animals should be instituted in areas with continuing cases of animal anthrax. All cases of animal or human anthrax should be reported to the appropriate authorities. During an outbreak, suspected animals should be quarantined and infected herds sacrificed. Carcasses of animals that have succumbed to anthrax are buried intact or cremated to avoid sporulation and further contamination of the environment. Gastrointestinal anthrax can be prevented by public education about consumption of contaminated meat. Anthrax vaccines should be given to those at risk of acquiring the disease such as agricultural workers or veterinarians who have contact with potentially infected animals, laboratory workers who work with *B. anthracis*, and workers involved in the industrial processing of animal products. The incidence of industrial anthrax has been further decreased by educating workers about how anthrax is transmitted, improvement in industrial hygiene, better manufacturing equipment and environmental control, as well as the decline in using fibres of animal origin as raw material.

Current anthrax vaccines for human use include cell-free preparations consisting of alum-precipitated and aluminum hydroxide-adsorbed extracellular components (primarily PA) of uncapsulated *B. anthracis*, available in the United Kingdom and the United States, respectively. A live attenuated anthrax spore vaccine is available in countries of the former Soviet Union, but is not used elsewhere because of safety concerns. The current cell-free vaccines are manufactured from an undefined crude culture supernatant. They must be given several times to ensure protection and local reactions have been reported. These drawbacks and the potential use of *B. anthracis* as a biological weapon have stimulated efforts to develop improved vaccines. A minimally reactogenic, recombinant PA vaccine has been investigated. Other approaches, made possible by modern molecular biology technology, include cloning the PA gene into other bacteria or viruses and development of mutant avirulent strains of *B. anthracis.*

7.11.19

Brucellosis

M. Monir Madkour

Brucellosis is a common, classic zoonotic disease of worldwide distribution. It is transmitted to man from infected animal reservoirs. Human brucellosis may be caused by one of four species: *Brucella melitensis* (the most common cause) from goats, sheep, and camels; *B. abortus* from cattle; *B. suis* from pigs; and *B. canis* from dogs. Brucella organisms are small, non-encapsulated, non-motile, non-sporing, Gram-negative, aerobic bacilli, which are facultative intracellular parasites. They can survive for up to 8 weeks in unpasteurized, white, soft goat's cheese. They tend to die within 60 to 90 days in cheese that has undergone lactic acid fermentation during the period of maturing. Freezing milk or its products does not destroy the organism, but they are killed by boiling or pasteurization. Brucella organisms are shed in urine, stools, vaginal discharge, and products of conception. They remain viable in dried soil for up to 40 days and for longer if the soil is damp.

Epidemiology

There are only 17 countries in the world that are brucellosis free: Norway, Sweden, Finland, Denmark, Switzerland, the former Czechoslovakia, Romania, the United Kingdom including the Channel Islands, the Netherlands, Japan, Luxembourg, Cyprus, Bulgaria, Iceland, and the Virgin Islands of the United States. Canada and New Zealand are about to be declared brucellosis-free countries. However, the overall incidence of brucellosis in the world is increasing. With the ease of modern travel, patients may contract the disease while visiting endemic countries. The true global incidence of human brucellosis is difficult to determine because of the lack of essential statistics, disease reporting, and notification systems in many countries. Even in developed countries there are reports indicating that the incidence of human brucellosis is estimated to be 3 to 26 times higher than official figures.

The risk to public health

In endemic areas of developing countries, brucellosis affects predominantly males and younger age groups. Farm animals such as goats, sheep, camels, and cattle are kept in the backyards of houses and considered as pets. Childhood brucellosis indicates endemicity of the disease in that area. Serious human maternal morbidity and fetal loss through abortion, intrauterine death, and premature delivery, or active disease in neonates, are public health risks in endemic areas of developing countries. Where brucellosis is controlled in animals, human brucellosis is mostly an occupational disease, particularly among workers in meat-processing industries and in farmers, veterinarians, and laboratory workers.

Modes of transmission

In endemic areas, animal contact through inhalation of organisms is the most frequent cause of infection, and affects herdsmen, dairy-farm workers, and laboratory workers. *Brucella melitensis* is included among 10 types of biological warfare or bioterroristic agents which can be released as aerosols. Ingestion of untreated milk or its products, or raw meat, liver, or bone marrow, is a common route of infection through the gastrointestinal tract, particularly among those taking antacids. Penetration of intact or abraded skin is a common route of infection among abattoir workers in developing and developed countries. Accidental autoinoculation or conjunctival splashing of live brucella vaccine during animal vaccination are well-recognized routes of infection among veterinarians. Laboratory infections have been described. Transplacental transmission of infection from mother to fetus may occur. Brucella organisms have been isolated from human breast milk and nursing mothers may infect their infants through breast feeding. Sexual transmission in man is similar to that in animals, and has recently been reported, with isolation of the organisms from human semen. Other uncommon routes of transmission include blood transfusion and bone marrow transplants.

Pathogenesis

Polymorphonuclear cells and activated macrophages migrate to the site of entry of brucella organisms. During the early phase of invasion, extracellular killing is carried out by IgM and complement-mediated mechanisms.

However, brucella organisms can resist such killing. During invasion and phagocytosis, the organisms are killed inside macrophages by oxidative burst or oxygen-based killing using the myeloperoxide–hydrogen peroxide–halide system. The interaction between the organisms and macrophages will determine the severity and outcome of infection. Organisms surviving within or escaping from phagocytic cells multiply and reach the bloodstream via the lymphatics to enter body organs rich in reticuloendothelial cells. Other organs and tissues are also invaded through the bloodstream. Inflammatory responses with or without granulomas and caseation or even abscess formation may occur. The cytotoxic activity of natural killer cells, with decrease in the CD4+ and increase in the CD8+ lymphocyte subpopulations, is depressed in patients with active brucellosis. Cytokines including interleukin12 and tumour necrosis factor-a appear to play an important role in host defence against brucella infection.

Clinical features

The incubation period is about 1 to 3 weeks but may extend up to several months. Brucellosis is a disease of protean manifestations that may simulate other febrile illnesses. Its clinical features are not specific. In endemic areas, diagnosis is relatively easy. However, in non-endemic areas of developed countries, clinicians should remember brucellosis in the differential diagnosis of a febrile illness. A history of travel to endemic areas should be obtained, as well as the patient's occupational history. The clinical features of brucellosis largely depend on the species of the organism and may vary widely. *B. melitensis* has a high pathogenicity, producing more intense symptoms. The onset may be sudden (1 to 2 days) or gradual (1 week or more). It presents as a febrile illness, with or without localization to particular organs. Brucellosis is classified according to whether or not the disease is active (i.e. history, clinical features, and significantly raised brucella agglutinins with or without positive blood cultures) and whether or not there is localized infection. Evidence of active disease and the presence of localization have a significant impact on recommended treatment. Classification of brucellosis as acute, subacute, chronic, serological, bacteraemic, or mixed types serves no purpose in diagnosis and management. The term 'active brucellosis with/without localization' is recommended. The most frequent symptoms are given in Table 1. The fever has no distinctive pattern that could differentiate it from other febrile illnesses, despite the old name 'undulant fever'. It usually shows diurnal variation, being normal in the morning and

high in the afternoon and evening. Chills or rigors with profuse sweating may simulate malaria. Patients with brucellosis commonly look deceptively well and, less frequently, may look acutely ill. Physical signs may be lacking despite the multiplicity of symptoms, which may be labelled as psychological. The frequency of physical signs is shown in Table 2.

Localizations

Bones and joints

Reactive arthritis may occur in brucellosis. Septic arthritis may result from bloodborne spread to the synovium or from extension of brucellar osteomyelitis in a neighbouring long bone. Brucella spondylitis starts in the superior end-plate, an area of rich blood supply. The infection may either regress and heal or progress to involve the entire vertebra, disc space, and adjacent vertebrae. Early lesions are localized in the anterior aspect of the superior end-plate at the disc–vertebral junction, leading to a small area of bone destruction. Bone healing takes place at the same time, leading to sclerosis.

Arthritis is commonly polyarticular and migratory, affecting mainly the large joints including the knee, hip, sacroiliac, shoulder, sternoclavicular, wrist, ankle, and interphalangeal joints in decreasing order of frequency. Septic monoarthritis may lead to destruction of the affected joint if undiagnosed. Joints affected include the knee, hip, sternoclavicular, and sacroiliac joints and the shoulder. Spondylitis may involve single or, less frequently, multiple sites. The lumbar spine, particularly L4, is the most frequent site. The average age of onset of brucella spondylitis is 40 years; it is extremely rare during childhood.

Extraspinal brucella osteomyelitis is rare. Long bones, particularly the femur, tibia, humerus, or manubrium sterni, may be affected. Bursitis, tenosynovitis, and subcutaneous nodules may also occur. Unlike with septic arthritis and osteomyelitis due to other organisms, the peripheral white-cell count is normal and the erythrocyte sedimentation rate is normal or accelerated. The total white-cell count in synovial fluid ranges from 4000 to 40 000/mm ^{3} with 60 per cent polymorphonuclear cells. Glucose in synovial fluid may be reduced, but protein is usually raised and culture is positive in about 50 per cent of the cases.

Cardiovascular

These localizations may include endocarditis, myocarditis, pericarditis, aortic-root abscess, mycotic aneurysms, thrombophlebitis, and pulmonary embolism. The most frequent of these is endocarditis, which used to be the leading cause of death. The outcome is now more favourable with recent advances in diagnosis, cardiac surgery, and treatment. Brucella endocarditis usually occurs on a previously damaged valve or a congenital malformation, but can occur even on normal valves. The clinical features are similar to those caused by other organisms. Patients who live in endemic areas and have what has been labelled as 'sterile infective endocarditis' should have their blood culture extended for a period of up to 6 weeks.

Respiratory

Respiratory symptoms are common but, because they are usually mild, clinicians tend to overlook them. A flu-like illness with sore throat and mild dry cough is a common feature. Other rare foci of infection include hilar and paratracheal lymphadenopathy; pneumonia, with solitary or multiple nodular lung shadowing or even with abscess formation; soft-tissue miliary shadowing; pleural effusion; empyema; or mediastinitis.

Gastrointestinal

Gastrointestinal infections are usually mild and are rarely a presenting feature of the disease. They include tonsillitis, and hepatitis with mild jaundice (either non-specific or granulomatous with suppuration and abscess formation). Actual cirrhosis is rare. Deep jaundice is not a feature of brucellosis. Splenic enlargement with abscess formation is rarely reported. Mesenteric lymphadenopathy with abscess formation, cholecystitis, peritonitis, pancreatitis, and ulcerative colitis are described. The liver transaminases, alkaline phosphatase, and serum bilirubin may be mildly raised. The clinical and biochemical evidence of liver involvement is far less frequent than liver biopsies have indicated. The diagnostic significance of splenomegaly becomes doubtful in countries where malaria and bilharzia are also common.

Genitourinary

Genitourinary localizations may be the presenting feature of brucellosis. They include unilateral or bilateral epididymo-orchitis in children and in adults, prostatitis, seminal vesiculitis, dysmenorrhoea, amenorrhoea, tubo-ovarian abscesses, chronic salpingitis, and cervicitis. Acute nephritis or acute pyelonephritis-like features, renal calcifications, and calyceal deformities may occur. Renal granulomatous lesions with abscess formation, with caseation and necrosis may occur, as may cystitis and posterior urethritis.

Urine culture may be positive in about 50 per cent of patients with brucellosis. Brucella organisms have recently been isolated from human semen during investigation of possible sexual transmission.

Neurobrucellosis

Neurobrucellosis is uncommon but serious. Despite the multiplicity of symptoms, abnormal neurological findings may be lacking. They include meningoencephalitis, multiple cerebral or cerebellar abscesses, ruptured mycotic aneurysm, cranial nerve lesions, transient ischaemic attacks, hemiplegia, myelitis, radiculoneuropathy and neuritis, Guillain–Barré syndrome, a multiple sclerosis-like picture, paraplegia, sciatica, granulomatous myositis, and rhabdomyolysis.

The psychiatric features of brucellosis are no more severe than those caused by other infections. Neurobrucellosis may be caused by direct bloodborne invasion by brucella organisms, pressure from destructive spinal lesions, vasculitis, or an immune-related process. In meningoencephalitis the cerebrospinal fluid pressure is usually elevated and the fluid may look clear, turbid, or rarely, haemorrhagic; the protein, cells (predominantly lymphocytes), and oligoclonal immunoglobulin are raised, while glucose may be reduced or normal. Brucella organisms may be cultured from cerebrospinal fluid.

Pregnancy

In endemic areas the outcome of pregnancy in humans is similar to that in animals: normal delivery, abortion, intrauterine fetal death, premature delivery, or retention of the placenta and other products of conception.

Skin

Skin manifestations are uncommon. They include maculopapular eruptions and contact dermatitis, particularly among veterinarians and farmers assisting animal parturition. Other dermatological manifestations include erythema nodusum, purpura and petechias, chronic ulcerations, multiple cutaneous and subcutaneous abscesses, vasculitis, superficial thrombophlebitis, discharging sinuses, and rarely, pemphigus.

Ocular

Direct splashing of live brucella vaccine into the eyes may cause conjunctivitis. Keratitis, corneal ulcers, uveitis, retinopathies, subconjunctival and retinal haemorrhages, retinal detachment, and endogenous endophthalmitis with positive vitreous cultures are well documented. Neuro-ophthalmic complications of brucella meningitis may lead to papilloedema, papillitis, retrobulbar neuritis, optic atrophy, and ophthalmoplegia due to lesions on the IIIrd, IVth, and VIth cranial nerves.

Endocrine

Localization of brucella infection with or without abscess formation in the endocrine glands is commonly reported in the testicle and epididymis. Other endocrine gland localizations with or without abscess formation are well documented but rare. These include the thyroid, ovaries, mammary glands, the adrenals, and the prostate. Reported cases of endocrine gland localizations are commonly not associated with disturbed hormonal secretions, perhaps with the exception of the adrenals. The

syndrome of inappropriate secretion of antidiuretic hormone as well as raised serum calcium are reported in patients with active brucellosis.

Diagnosis

The diagnosis of brucellosis depends on the presence of clinical features and brucella agglutinins in a significantly raised titre. A positive blood or tissue culture is not always present. The organism's identity is confirmed by phage typing, DNA characterization, or metabolic profiling. Use of a carbon dioxide detection system (such as BACTEC; Becton Dickinson, Sparks, MD) for blood culture provides a more sensitive and rapid culture result than standard methods, with positivity usually apparent after only 2 to 5 days of incubation. Alternatively, extended incubation of blood cultures for up to 6 weeks (incubated at 37°C with and without an atmosphere of 10 per cent carbon dioxide) should be requested. Most authorities will consider an agglutination titre of 1/160 or higher to be significant in a symptomatic patient living in a non-endemic area. However, in endemic areas only titres of 1/320 to 1/640 or higher are considered significant. In endemic areas, otherwise asymptomatic individuals offering to donate blood may be found to have high brucella titres and should not be considered to be suffering from active brucellosis. Follow-up 2 to 4 weeks later is necessary in such individuals to exclude subclinical infection.

The presence of brucella antibodies in the patient's serum can be detected by the standard tube test, rose bengal plate test, 2-mercap-toethanol test, antihuman globulin test (Coomb's), radioimmunoassay, enzyme immunoassay, and polymerase chain reaction (**PCR**). The PCR is specific and highly sensitive for the detection of brucella agglutinins (the DNA used for the amplification is either phenol purified or comes directly from a suspension of brucella organisms). The antigens commonly used for serological screening are prepared from *B. abortus*, which cross-reacts with *B. melitensis* and *B. suis* antibodies as well. However, they do not cross-react with *B. canis* antibodies. To detect these antibodies, antigen prepared from *B. canis* organisms is needed, but they are not available commercially. A cross-reaction with tularaemia and cholera may occur. This can be distinguished by testing simultaneously for brucella, tularaemia, and cholera antibodies. Occasionally, brucella agglutination tests are negative in patients with positive tissue cultures. The prozone phenomenon is a false-negtive standard tube test caused by the presence of blocking antibodies in the a-globulin (IgG) and in the a $_2$-globulin (IgA) fractions. This phenomenon can be avoided by screening sera at low and high titres. An elevated IgM antibody indicates recent infection, while low titres indicate previous contact with the organism. An elevated IgG indicates active disease.

Haematological changes

The total white-cell count is usually normal and leucopenia with relative lymphocytosis does not always occur. Thrombocytopenia is less common and haematological features of disseminated intravascular coagulation are rare. The erythrocyte sedimentation rate is of no diagnostic value. Liver function tests, liver biopsies, and cerebrospinal and synovial fluid changes have been discussed under pathogenesis and localizations.

Treatment

Control and prevention of brucellosis should be directed primarily towards eradication of the disease in animals. The brucella organism is intracellular and therefore relatively inaccessible to antimicrobials. A combination of a tetracycline and an aminoglycoside remains the most effective regimen because of its synergistic effect. Oral doxycycline (100 mg, twice daily) is preferred to other tetracyclines (500 mg, 6-hourly) because of its rapid and complete absorption from the duodenum, longer half-life (18 h), and more efficient tissue penetration (it is more lipid soluble). Suitable aminoglycosides are streptomycin, netilmicin, or gentamicin. Streptomycin is given intramuscularly in a dose of 1 g/day for patients under 45 years of age and 0.5 to 0.75 g/day for older patients. The plasma trough concentration should be 1 to 2 µg/ml. Netilmicin, 4 to 6 mg/kg a day intramuscularly in two divided doses, can be used for outpatient treatment. The plasma trough concentration should be 2 to 4 µg/ml. Gentamicin is only used for patients in hospital as it is usually given as an intravenous infusion of 2 to 5 mg/kg daily, in divided doses, 8-hourly. The plasma trough should be 1 to 2 µg/ml. Combined therapy with a tetracycline and an aminoglycoside should be given for 1 month, followed by a tetracycline and rifampicin (600 to 900 mg/day as a single oral dose) or a tetracycline and co-trimoxazole (two tablets, 480 mg each, twice daily) for a further 1 to 2 months. This regimen has a relapse rate of 7 per cent. A three-drug regimen in combination with urgent surgical intervention is required in those with endocarditis, aortic root abscess, spondylitis, osteomyelitis, and abscesses in organs or other tissues. Neurobrucellosis without abscesses formation will require a three-drug regimen. The combination of doxycycline–netilmicin/gentamicin–rifampicin should be given for 4 weeks. A doxycycline–rifampicin combination should be continued for a further 4 to 8 weeks. Single daily dosing of netilmicin or gentamicin has been successfully used for other infections. Such dosing is being assessed at present for treatment of brucellosis and results are not yet available. Shorter periods of treatment have a higher relapse rate. Most patients with brucellosis are treated as outpatients and only those with localizations (e.g. endocarditis, neurobrucellosis, osteomyelitis, septic arthritis, and renal impairment), or who are pregnant or are infants, require admission to hospital.

Ciprofloxacin (750 mg, 12-hourly, orally) and other fluoroquinolones are synthetic broad-spectrum antibiotics with intracellular penetration used by some for treatment of brucellosis. There are reports of the development of resistance and cross-resistance with other quinolones and high relapse rates. Quinolones showed no synergism with other agents.

Children

Infants and children under 7 years of ages should be treated with a combination of rifampicin and co-trimoxazole for 2 to 3 months. However, in those with serious localizations in endemic areas where some discoloration of the teeth is of secondary importance, doxycycline can be used, in combination, as described above—doxycycline, 50 to 100 mg/day orally; gentamicin: infants aged up to 2 weeks, 3 mg/kg every 12 h; aged 2 weeks to 12 years, 2 mg/kg every 8 h intramuscularly or by slow intravenous injection or intravenous infusion; netilmicin: infants aged up to 1 week, 3 mg/kg every 12 h; aged over 1 week, 2.5 to 3 mg/kg every 8 h intramuscularly or by intravenous injections or infusions; rifampicin, 10 to 20 mg/kg a day, either orally or by slow intravenous injection as a single daily dose; co-tri-moxazole paediatric suspension (240 mg/ml) is given 12-hourly orally as follows: 6 weeks to 5 months of age, 120 mg; 6 months to 5 years, 240 mg; 6 to 12 years, 480 mg. Intravenous infusion: 54 mg/kg daily in two divided doses.

Renal impairment and pregnancy

Patients with renal impairment should be carefully monitored for serum concentration of aminoglycoside. If such monitoring is not available, then a doxycycline–rifampicin regimen should be administered. In pregnancy, co-trimoxazole–rifampicin for 8 to 12 weeks is the most suitable regimen.

Response to treatment

Patients become afebrile and other constitutional symptoms greatly improve within 4 to 14 days. The liver and spleen become impalpable within 2 to 4 weeks. Patients may experience an acute, intense flare-up of symptoms—the Jarisch–Herxheimer reaction—shortly after starting treatment, particularly with tetracyclines. This reaction is only transient and does not necessitate discontinuation of therapy. Follow-up of clinical, blood culture, and serological tests should be done every 3 to 6 months for 1 to 2 years.

Human vaccine

Human vaccine for brucellosis, used in the former Soviet Union, China, and France, was found to be effective in reducing markedly the rate of infection. Two injections, each of 1 mg of phenol-insoluble fraction, were given 2 weeks apart. It provides effective but short-lived immunity and should be repeated every 2 years. Vaccination is indicated in workers with an occupational risk of developing brucellosis. The outer membrane proteins (OMPs) are showing promise in experimental work on the development of a new vaccine.

Tetanus

7.11.20

F. E. Udwadia

Tetanus is an acute, often fatal disease, resulting from the contamination of a wound by *Clostridium tetani*, a spore-forming, Gram-positive, motile, rod-shaped, obligate anaerobic organism. Under anaerobic conditions the vegetative form of the organism produces a powerful exotoxin, which on reaching the central nervous system causes the increased muscle tone and spasms that characterize the disease.

Epidemiology

The spores of *Cl. tetani* are ubiquitous, but the natural environment is soil, particularly cultivated soil rich in manure. Spores are commonly found in animal faeces, may also be detected in human faeces, and can occasionally be recovered from house dust or from the air of occupied buildings, slums, and even hospitals and operating theatres.

Tetanus is a killer disease chiefly afflicting the poor, uneducated, and underprivileged people of the world. It is thus widely prevalent in India, Bangladesh, Pakistan, parts of South-East Asia, Africa, the eastern Mediterranean region, and South America. In these countries where immunization programmes are inadequate, the disease is most common in the young and newborn and is more frequent in males than in females. In the 1980s, 1 million newborn babies died of tetanus every year. The annual worldwide mortality had declined to 480 000 by 1994 and to 277 400 in 1997. However, neonatal tetanus still accounts for 23 to 73 per cent of neonatal deaths in developing countries. An estimated 70 000 cases continue to occur in India every year. The decline in incidence of the disease in the nineties is largely due to the substantial increase in immunization coverage of pregnant women with a protective dose of tetanus toxoid. It is estimated that effective vaccination programmes have prevented 500 000 deaths in the South-East Asia region out of the 700 000 deaths prevented globally. Ninety per cent of the deaths prevented in South-East Asia are in India, Bangladesh, and Indonesia. In the West the disease is increasingly rare, fewer than 60 cases being reported annually from the United States between 1991 and 1994. The disease in the West is more frequent in people older than 60 years, in whom effects of immunization have worn off, in the unimmunized, impoverished, and in drug addicts.

Physiopathology

Under anaerobic conditions (e.g. presence of necrotic tissue, active infection, foreign body), the tetanus bacillus within a wound produces two toxins—tetanospasmin and tetanolysin. Only tetanospasmin has clinical effects. Tetanospasmin is a 150 kDa protein consisting of a heavy (100 kDa) chain and a light (50 kDa) chain joined by a single disulphide bond. The mechanism of spread of tetanospasmin is illustrated in Fig. 1. The released toxin spreads to underlying muscles and is bound by its heavy chain to receptors containing gangliosides on the neuronal membranes of presynaptic nerve terminals. The toxin is then internalized and transported intra-axonally and retrogradely within the peripheral nerves to cells of motor neurones of that segment of the cord supplying those muscles. The toxin almost always also enters and circulates in the bloodstream. It does not cross the blood–brain barrier, but by haematogenous spread binds to nerve terminals in muscles throughout the body. It is then transported retrogradely within numerous axonal pathways of all peripheral nerves to reach the a motor-neurone cell bodies of the whole spinal cord and brainstem. It thereby also reaches the sympathetic chain, the preganglionic sympathetic neurones in the lateral horns of the spinal cord, and the parasympathetic centres.

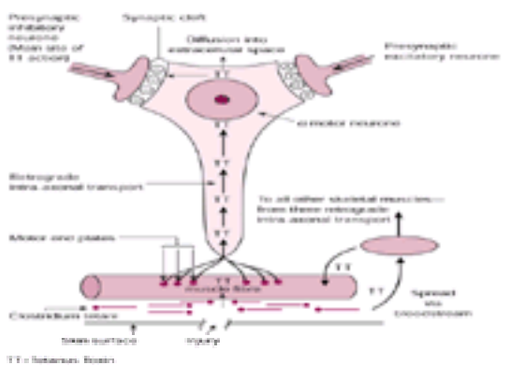

Fig. 1 Retrograde intra-axonal transport of tetanospasmin and its main site of action in the central nervous system.

After reaching the cell bodies in the spinal cord and brainstem, the toxin, by an unknown mechanism, passes retrogradely across the presynaptic cleft to bind to ganglioside receptors on presynaptic nerve terminals of inhibitory interneurones. The light chain of the toxin now acts to block the release of the inhibitory neurotransmitters, chiefly glycine and g-aminobutyric acid (**GABA**), from synaptic vesicles within nerve terminals of inhibiting neurones. This blockage releases motor and autonomic neurones from inhibitory control. The molecular mechanism behind this action is unknown. The toxin may well alter a calcium-dependant process necessary for neurotransmitter release. The uncontrolled excessive, disinhibited efferent discharge from motor neurones in the cord and brainstem to both agonist and antagonist muscles leads to widespread muscle rigidity and to reflex spasms characteristic of generalized tetanus. Muscles of the jaw, face, and head are involved first because the toxin has to travel along shorter axonal pathways to reach their controlling motor neurones in the brainstem. Muscles of the trunk and limbs are involved a little later because the toxin travels along longer axonal pathways to their controlling motor cells in the cord. Disinhibited autonomic discharge leads to disturbances in autonomic control, particularly to sympathetic overactivity with excessive catecholamines in the blood. Medullary centres and hypothalamic centres may also be affected by tetanus toxin. Myocardial dysfunction and disturbances in impulse conduction may occur.

When, rarely, tetanus toxin does not reach the bloodstream but spreads from the site of the wound along regional axonal pathways to motor neurones in a localized segment of the cord; local tetanus results. Rigidity and spasms are restricted to a group of muscles.

Tetanus toxin can also produce a peripheral neuromuscular blockade by preventing release of acetylcholine, similar to the effect of botulinum toxin. This peripheral paralytic effect is observed in cephalic tetanus.

Altered haemodynamics

Severe tetanus without complications is characterized by a high-output, hyperkinetic circulatory state with marked tachycardia, increased stroke-volume index, increased cardiac index, and a normal, left ventricular stroke-work index (Fig. 2). There is also an increase in the compliance of the vascular system due to arteriolar, capillary, and venous dilation, chiefly in skeletal muscle. These changes have been attributed to increased muscle contraction, increased sympathetic tone, and a rise in core temperature.

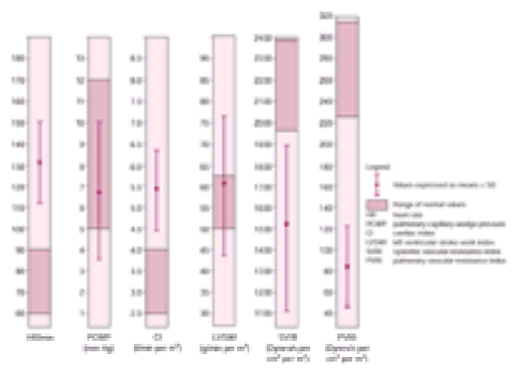

Fig. 2 Haemodynamic observations in 19 patients with severe uncomplicated tetanus.

Disturbances in the autonomic nervous system lead to marked cardiovascular instability with wide fluctuation in heart rate, systemic vascular resistance, and blood pressure.

Clinical features

Some 15 to 25 per cent of patients with tetanus have no evidence of recent wounds, for the disease can result from the most trivial of wounds. Contamination of the wound with garden soil or manure, or injury by rusty metals, are particularly dangerous. Tetanus can complicate burns, ulcers, gangrene, necrotic snake bites, frostbite, discharging middle-ear infections, septic abortions, childbirth, ritual scarification, and female circumcision. It can occur after intramuscular injections, particularly of drugs producing tissue necrosis (such as quinine), and after surgery. Tetanus neonatorum is most often due to non-sterile obstetric techniques, and in India to the dreadful practice of applying cow dung to the cut surface of the umbilical cord.

The clinical features of tetanus are rigidity, muscle spasms, and seizures. Severe tetanus is invariably associated with autonomic disturbances.

Muscle stiffness or rigidity

Stiffness of the masseters is often the first manifestation of the disease, resulting in difficulty in opening the mouth—trismus or lockjaw. Typically, stiffness extends to the muscles of the face, all skeletal muscles, and often involves muscles of swallowing, causing dysphagia. The facial expression in tetanus is diagnostic. The eyes appear partially closed, the forehead is furrowed, the corrugator muscle contracted, the nostrils flared, nasolabial folds prominent, and the lips pursed, thinned, and stretched, with the angles of the mouth extending outwards and often turned slightly down, producing a 'risus sardonicus' (Fig. 3 and Plate 1). This smile is perhaps more pathetic than sardonic. The expression is one of pain, anguish, and fear. Stiffness of the neck muscles results in retraction of the head. The muscles of the chest are stiff and the breathing movements are restricted. The abdomen often shows board-like rigidity. The arms and legs are often ramrod stiff and in children marked stiffness in the muscle of the back can lead to opisthotonos similar to that observed in meningitis (Fig. 4 and Plate 2).

Fig. 3 Facies in tetanus. (See also Plate 1.)

Fig. 4 Opisthotonos in severe tetanus during seizures. (See also Plate 2.)

Muscle spasms

Mild cases of tetanus exhibit only stiffness without spasms. Spasms or seizures are characterized by a marked reflex exaggeration of the underlying rigidity, producing tonic contraction of the stiff muscles. They are frequently brought on by touch but may also be triggered by visual, auditory, or emotional stimuli. Seizures vary in severity and frequency. They may be mild, infrequent, and brief (lasting a few seconds) or severe, protracted, painful, and spontaneous, the patient appearing to be in a state of perpetual convulsion. Severe protracted spasms render breathing impossible or shallow, irregular, and ineffective, so that the patient becomes very hypoxic and even cyanosed. Spasm of pharyngeal muscles prevents swallowing of saliva, so that pharyngeal secretions accumulate and are often aspirated into the lungs, causing atelectasis and aspiration pneumonia. Laryngeal spasm may occur by itself; it may accompany generalized spasms and can produce unexpected sudden death from asphyxia.

Patients with severe tetanus have fever, tachycardia, and often, an unstable cardiovascular system. Unless expertly managed, they usually die of respiratory complications, circulatory failure, or cardiac arrest.

Autonomic nervous system disturbances

In severe tetanus there is invariably involvement of the sympathetic and parasympathetic nervous systems. Features include tachycardia exceeding 150 beats/min, drenching sweats, frequent modest elevation in systolic and/or diastolic arterial blood pressure, increase in salivary and tracheobronchial secretions, and evidence of increased reflex vagal tone and activity.

Severity of tetanus

Grading the severity of tetanus is not just an academic exercise; it is useful both in prognosis and in the management of the disease. The criteria listed below are subjective and arbitrary but have stood the test of time in our unit.

Grade I (mild)

There is mild to moderate trismus, general spasticity, no respiratory embarrassment, no spasms, and little or no dysphagia.

Grade II (moderate)

There is moderate trismus, well-marked rigidity, mild to moderate short-lasting spasms, moderate respiratory embarrassment with tachypnoea in excess of 30 to 35/min, and mild dysphagia.

Grade III (severe)

There is severe trismus, generalized spasticity, reflex and often spontaneous prolonged spasms, respiratory embarrassment with tachypnoea in excess of 40/min, apnoeic spells, severe dysphagia, and tachycardia in excess of 120/min.

Grade IV (very severe)

The features are the same as grade III plus violent autonomic disturbances involving the cardiovascular system.

Cephalic tetanus

This occurs after an injury to the head and is confined to muscles innervated by the cranial nerves. It is characterized by unilateral facial palsy (Fig. 5 and Plate 3), trismus, facial stiffness of the unparalysed half, nuchal rigidity, pharyngeal spasms causing dysphagia, and frequent laryngeal spasms with danger of death from asphyxia. Rarely, facial palsy is bilateral. Paresis of the glossopharyngeal, vagus, and rarely of the oculomotor nerves may also occur. Cephalic tetanus may graduate to generalized tetanus.

Fig. 5 Brazilian patient with local tetanus confined to muscles innervated by the left VIIth cranial nerve and with trismus, showing the wound causing the infection. (By courtesy of Dr Pedro Pardal, Belém, Brazil.) (See also Plate 3.)

Tetanus neonatorum

The earliest symptom is a difficulty or inability to suckle and swallow owing to stiffness of muscles of the jaw and pharynx. There is increasing stiffness, with the classic tetanus facies (Fig. 6 and Plate 4), flexion at the elbows with the fists clenched and drawn to the thorax, extension of the knees with plantar flexion of the ankles and toes, and opisthotonos. Muscle spasms make breathing difficult; autonomic disturbances are frequent and death results from cardiorespiratory failure.

Fig. 6 Characteristic facies in neonatal tetanus. (See also Plate 4.)

Local tetanus

Rarely, rigidity and spasms may be localized to muscles adjacent to the wound or confined to a limb.

Natural history

The incubation period of tetanus (time between the injury and the first symptom) averages 7 to 10 days, but may range from 1 to 2 days to 2 months. The period of onset is the time between the first symptom and onset of spasms, and ranges from 1 to 7 days. The shorter the incubation period and the period of onset, the greater the severity of the disease. The disease peaks over 7 to 10 days, plateaus over the next 3 weeks, and then subsides over the next 2 weeks. Muscle stiffness and ankle clonus may persist for months after recovery. Severe tetanus is a markedly catabolic disease and significant weight loss is always observed even in patients who recover.

Complications

Complications in tetanus are frequent and numerous. The respiratory and cardiovascular systems are chiefly involved.

Respiratory

These include atelectasis, aspiration pneumonia, pneumonia, and bronchopneumonia. Bronchopulmonary infections are generally due to Gram-negative organisms—chiefly *Klebsiella* spp.and *Pseudomonas aeruginosa*. Prolonged laryngeal spasms if unrelieved can cause death. Severe hypoxia and respiratory failure due to incessant spasms are a certainty if these patients are not given curare-like drugs and ventilated. Episodes of severe unexplained tachypnoea and respiratory distress are probably central in origin. The acute respiratory distress syndrome can be caused by tetanus *per se* or may be due to complicating sepsis. Complications related to tracheostomy and ventilator support are also observed.

Cardiovascular and autonomic

Sustained tachycardia (more than 160/min), persistent hypotension, labile or sustained hypertension, and 'autonomic storms' complicate severe tetanus. Autonomic storms are due to wild fluctuations in sympathetic activity causing episodes of hypertension and tachycardia alternating within minutes or hours with hypotension and bradycardia. Such cardiovascular instability may be a forewarning of cardiac arrest and death. Increased vagal tone can cause bradycardia and sudden death, particularly during suctioning of tracheal secretions. Supraventricular arrhythmias, ventricular tachycardia, and infranodal conduction defects can also occur. Hyperthermia and rarely hypothermia suggest hypothalamic involvement.

Sudden death

Sudden cardiac arrest causing death remains the single most dreaded complication of moderate and severe tetanus. It may be related to cardiovascular instability due to fluctuating autonomic tone, excessive vagal activity, severe hypoxia, sudden hyperpyrexia, impaired infranodal conduction, massive pulmonary embolism, or no obvious reason.

Other complications

These are generally incidental to prolonged management of critically ill patients on ventilator support. They include: iatrogenic sepsis with multiple organ failure; gastrointestinal bleeds, ileus, or diarrhoea; renal insufficiency; fluid, electrolyte, and acid–base disturbances; fractures generally of one or more thoracic vertebrae during severe spasms; miscellaneous complications—bedsores, thrombophlebitis, rhabdomyolysis, peripheral neuropathy, corneal ulcers, anaemia, hypoproteinaemia, and deep vein thrombosis which may cause pulmonary embolism.

Diagnosis

Diagnosis is based solely on clinical features. Absence of a wound does not exclude tetanus. Trismus produced by tetanus should be distinguished from masseter spasm due to an alveolar or peritonsillar abscess. Dystonic reactions caused by phenothiazines and metoclopramide, spasms due to hypocalcaemic tetany, and seizures due to strychnine poisoning may superficially mimic tetanus. Meningitis and meningoencephalitis can also produce trismus, rigidity, seizures, and opisthotonus, but can be differentiated by a cerebrospinal examination, which is normal in tetanus. Cephalic tetanus can be mistaken for rabies because of severe dysphagia—however, hydrophobia never occurs in tetanus.

Mortality

Tetanus neonatorum carries a mortality of 60 to 80 per cent. Mortality in adult tetanus ranges from 20 to 60 per cent. It is higher in the older age group and in those with a short incubation period (under 4 days). A short period of onset (under 2 days) more reliably prognosticates severe disease. The introduction of critical care and ventilator support in severe tetanus has led to a drop in overall mortality from 30 to 12 per cent, and the mortality in fulminant tetanus from near 100 to 23 per cent, in our unit. In a good, well-equipped, critical care unit in Bombay, the mortality in severe tetanus in adults remains as low as 6 per cent.

Management

Mild tetanus (grade I) poses no serious problems. However, grade I (mild) tetanus can over a period of days graduate to grade II (moderate) or even grade III and grade IV (severe) tetanus. Such patients merit close observation. Wherever possible, all patients with tetanus should be admitted to an intensive care unit. Unfortunately this is not always feasible in poor developing countries. However, motivation and training for better patient care coupled with basic equipment for respiratory care and support can work wonders in reducing mortality even in the absence of full intensive care facilities.

The use of antiserum

Equine antiserum is generally available in poor countries; 10 000 units are given intravenously on admission after first doing a sensitivity test. However, fatal anaphylaxis can occur even when skin sensitivity is not observed. Human tetanus immunoglobulin is superior to equine antiserum, produces no hypersensitivity reactions, and if available should be given in preference to the equine antiserum in a dose of 5000 units intravenously. The intrathecal use of tetanus antiserum is best avoided as claims of its efficacy remain unproven. Local infiltration of 3000 units of antitoxin around an obvious wound is practised in some units, but its value is

uncertain. Antitoxin has no action on the toxin that has already been fixed to the nervous tissue; at best, it serves to neutralize newly liberated tetanus toxin. Antitoxin should be given before local manipulation of the wound, which is treated according to usual surgical principles with debridement of necrotic tissue and delayed primary suturing.

Antibiotics

Two mega-units of penicillin are given intravenously four times a day for 8 days. Though effective against *C. tetani in vitro*, its use in this disease is disappointing. Clindamycin or erythromycin are alternatives for penicillin-sensitive patients. Metronidazole at a dosage of 500 mg four times a day for 10 days is currently preferred. Other appropriate antibiotics may be necessary to counter secondary complicating infections.

Management strategies

Mild or grade I tetanus should be treated conservatively with the use of sedatives and muscle relaxants. Patients with grade II or moderate tetanus should, in addition to sedatives and relaxants, have a tracheostomy. Patients with grade III or IV (severe) tetanus require sedation, tracheostomy, and continuous ventilatory support after they have been paralysed with curare-like drugs, until spasms relent and recovery ensues.

Use of sedatives and muscle relaxants

The use of sedatives and muscle relaxants remains the cornerstone of management in grade I and grade II tetanus. The aim is to reduce rigidity and control spasms without significantly depressing respiration. Diazepam, a benzodiazepine and a GABA antagonist, is the drug of choice in most units. The dosage is 5 to 20 mg thrice daily in children and adults, and 2 mg thrice daily in neonates. In mild tetanus it is given orally; in moderately severe tetanus it is given in a slow intravenous infusion over 24 h. It is best not to exceed 120 to 150 mg/24 h in adults even in the presence of marked rigidity. Higher doses will inevitably depress respiration. Lorazepam with a longer duration of action and midazolam with a shorter half-life may also be used, but offer no advantage over diazepam. Chlorpromazine and phenobarbitone are second-line drugs that can be used in combination with diazepam when there is no alternative. The ideal sedative and muscle relaxant dosage schedule for each patient should be tailored to ensure continuous sedation at a level that ensures sleep, but that allows the patient to be aroused to obey commands. An objective guide, particularly in moderately severe tetanus, is relaxation of the abdominal muscles, which feel much less stiff to palpation.

Tracheostomy

Tracheostomy is mandatory for severe (grade III, IV) tetanus. Preferably, it should also be done in moderate tetanus simply because, even in an intensive care unit setting, the most important preventable cause of death is a sudden prolonged laryngeal spasm leading to asphyxia. The patient's inability to handle upper respiratory secretions in the presence of dysphagia, and the use of heavy sedation in many cases of moderately severe tetanus are both indications for elective tracheostomy.

Induced paralysis with ventilator support

Severe tetanus has a forbiddingly high mortality if management is conservative and confined to the use of high doses of sedatives and muscle relaxants. These patients require a tracheostomy, induced paralysis by curare-like drugs (pancuronium or vecuronium), and ventilatory support in an intensive care unit. In poor countries, this management strategy can also be implemented in the absence of good monitoring facilities provided the unit or ward has basic equipment for respiratory care and a trained medical and nursing staff. Results in such units may not be as good as in well-staffed and -equipped intensive care units but are still far superior to those observed with conservative management. Pancuronium is used in a dose of 2 to 4 mg intravenously every 30 min to 2 h; the dose of vecuronium is 0.1 mg/kg intravenously. Alternatively, either of these drugs may be given in a slow intravenous infusion, the dose being titrated to produce a degree of neuromuscular blockade and paralysis that allows efficient ventilator support. As the patient improves, pancuronium or vecuronium are given at longer intervals or the infusion rate is reduced. In fulminant tetanus with continuous spasms it may be almost impossible to induce complete paralysis. Twitches invariably break through within 30 min of the use of the drug, but these do not interfere with efficient ventilatory support. The average period of ventilatory support in severe tetanus is around 3 to 4 weeks, but may vary from 10 days to 6 weeks. Once spasms cease, the neuroparalytic drug is stopped; ventilator support is continued until such time as the patient is deemed fit to be weaned.

It is unnecessary, unwise, and probably dangerous in our opinion to use large doses of intravenous diazepam (a frequent practice in many units) in paralysed patients on ventilator support. A dose of 40 to 60 mg of diazepam intravenously over 24 h suffices to counter anxiety without dangerously depressing vital centres.

In poor countries the correct mode of management in severe tetanus is often constrained by a paucity of trained staff and material resources (particularly ventilators). Ethical considerations then restrict the use of ventilator support to: (i) patients with grade IV tetanus; (ii) patients with grade III tetanus whose spasms are uncontrolled on a conservative regime and whose $P(a)O_2$ is less than 55 mmHg on 6 to 8 litre/min of oxygen; and (iii) patients who develop any serious complication that in itself merits ventilatory support.

Treatment of autonomic circulatory disturbances

Intravenous b-blockers, heavy sedation, intravenous morphine sulphate, intravenous labetalol, intravenous infusion of magnesium sulphate, and intravenous clonidine have all been used to control autonomic storms in severe tetanus. These drugs do not alter the high mortality. It is best to rely on good overall critical care and efficient cardiorespiratory support and avoid drugs that strongly depress the central and autonomic nervous systems. Hypotensive spells are treated by a volume load and if this is ineffective or contraindicated, by inotropic support with dopamine or dobutamine to maintain a systolic pressure just above 100 mmHg. Hypertensive episodes with a systolic blood pressure in excess of 200 mmHg or a diastolic in excess of 100 mmHg are treated with a small oral dose of propranolol (10 mg) or 5 mg of sublingual nifedipine. Intravenous propranolol is dangerous and can cause sudden death, but a titrated infusion of esmolol (a b-blocker with a very short half-life) is useful in a hypertensive crisis. Bradyarrhythmias are treated with intravenous atropine, and persistent sinus tachycardia of more than 170/min with 40 mg of verapamil orally twice or thrice daily. In this situation it is best not to use more than 50 mg of diazepam ntravenously per day. Sedatives and drugs used at a dosage that strongly depresses the central or autonomic nervous system probably contribute to a high mortality by predisposing to cardiac arrest (particularly after sudden hypotensive spells and sudden bradyarrhythmias) and by preventing successful resuscitation. These management principles have achieved a very low mortality (6 per cent) in severe tetanus.

Treatment of other complications

Complications may involve almost every system in the body. These should be promptly recognized and treated.

Critical care and nursing

Good critical care and expert nursing play a vital role in reducing complications and preventing death. The following are of particular importance:

1. ensuring patency of the airway and care of the tracheostomy in scrupulous detail;
2. ensuring an adequate arterial oxygen saturation and oxygen transport to tissues through efficient cardiorespiratory support;
3. expert physiotherapy to the chest timed specifically during periods of drug-induced muscle relaxation;
4. maintaining fluid, electrolyte, and acid–base balance;
5. prevention, early detection, and prompt control of infection and sepsis with appropriate antibiotics;
6. supporting nutrition, if necessary by intravenous alimentation;
7. detection (by frequent monitoring) and treatment (by physical methods and by paracetamol) of hyperpyrexia—a surreptitious killer in tetanus.

Use of tetanus toxoid

Tetanus does not confer immunity. Active immunization is necessary and is achieved by giving the first dose of tetanus toxoid during convalescence and the next two doses at the recommended intervals.

Prevention

Tetanus is a preventable disease through active immunization with adsorbed tetanus toxoid (**ATT**) and by proper management of wounds.

Active immunization

The following regime is advocated. In infancy and childhood, three doses of triple vaccine (tetanus, diphtheria, pertussis) are given at monthly intervals, and a booster dose is given at 4 to 6 years of age. Unimmunized individuals older than 7 years should be given triple vaccine in three doses: the first and second 6 weeks apart, and the third dose 6 months after the second. Booster doses of ATT are advocated every 10 years, but this remains a practical impossibility in poor countries.

Immunization after minor, uninfected wounds

Passive immunization with equine or human tetanus antitoxin is not indicated for minor, clean wounds. Active immunization (with 0.5 ml ATT) is indicated if immunization status is unknown or more than 10 years have elapsed after the last dose of ATT. Under the above circumstances, especially in poor countries, ATT is also administered prior to emergency surgery, deliveries, and obstetric procedures.

Immunization after infected or major wounds

Passive immunization (250 to 500 units of human tetanus immunoglobulin or 5000 units of equine antitoxin, intramuscularly) is recommended in all individuals who are not immunized, partially immunized, or whose immunization status is unknown. Indication for administration of ATT is the same as for minor, uninfected wounds. However, it would be safer to use a booster dose of ATT even in a well-immunized individual if more than 5 years have elapsed since the last dose of ATT.

Prevention of tetanus neonatorum

Primary immunization of pregnant patients with two injections of ATT a month apart, preferably during the last two trimesters, together with education of nurses and midwives on sterile obstetric techniques, would further reduce the incidence of tetanus neonatorum in developing countries.

7.11.21 Botulism, gas gangrene, and clostridial gastrointestinal infections

H. E. Larson

Botulism

Definition

Botulism is an acute, symmetrical, descending paralysis caused by a neurotoxin produced by *Clostridium botulinum*. Food contaminated by *C. botulinum* spores and elaborated toxin produces illness when ingested. Wound infections with *C. botulinum* or intestinal tract colonization in infants and adults occasionally cause botulism.

Occurrence

C. botulinum is ubiquitously distributed in soil and mud. The surfaces of potatoes, vegetables, and other foods are easily contaminated with spores, which survive brief heating at 100°C. The anaerobic conditions characteristic of canning, smoking, or fermentation facilitate clostridial growth and toxin release. Spores germinate in sausage or cheese if they are kept for extended periods at room temperature. An eighteenth century report associated paralytic illness with eating sausages, hence *botulus*, Latin for a sausage. Cases have been associated with fermented milk in Africa, cheese sauce on baked potatoes in North America, fermented stew in Japan, and imported fish in the United Kingdom.

Although past outbreaks typically involved small groups of people, home-canned peppers served in a restaurant caused two large outbreaks in the United States. Outbreaks caused by commercially processed foods are infrequent, but contamination of hazelnut purée added to commercially produced yoghurt caused 27 cases of botulism in Wales and north-west England in 1989, the largest recorded outbreak in the United Kingdom. Most of the contaminated cartons could not be accounted for, suggesting that the attack rate varied or that mild symptoms were not diagnosed as botulism. Commercially prepared, chopped garlic in soybean oil caused 36 cases dispersed over eight provinces and states in North America.

Some outbreaks involved only single contaminated items, such as in the Loch Maree episode in 1922 where eight people died after eating duck paste, the 1978 outbreak in Birmingham involving four people who ate tinned Alaskan salmon, and one case in 1989 following a meal on a commercial airliner. Uneviscerated fresh fish have been associated with botulism, usually where there have been deficiencies in refrigeration.

Purified botulinum toxin has recently come into therapeutic use. Toxin injections produce temporary muscle weakness in the treatment of strabismus, blepharospasm, torticollis, and for cosmetic purposes. Treatment doses are considered too small to account for systemic symptoms. Under experimental conditions aerosolized botulinum toxin causes illness in monkeys and the toxin has been mooted as an effective agent for biological warfare or terrorist activity. Botulinum toxin was loaded into SCUD missile warheads by Iraq during the Gulf War and stockpiled by the Aum Shinrikyo cult in Japan.

The toxin

There are seven serological types of botulinum toxin (A–G). Types A, B, and E account for nearly all human cases. Serotypes implicated in outbreaks of botulism parallel the geographical distribution of soil spores. Type E is nearly always associated with fish, but outbreaks caused by fish products involve types A and B. Spores of *C. botulinum* can survive up to 2 h of boiling (100°C), but are killed rapidly at autoclave temperatures (120°C).

C. botulinum toxin is heat labile and rapidly inactivated at ordinary cooking temperatures. It is a protein neurotoxin, and a dose as small as 0.1 µg has been estimated to cause death in a human being. The 150-kDa molecule is composed of two peptide chains connected by disulphide bonds. One chain binds to and penetrates the neurone, the other cleaves a protein essential for neurotransmitter release, reducing acetylcholine availability for impulse transmission. Toxin types A, C, and E hydrolyze a protein in the presynaptic membrane while types B, D, F, and G hydrolyze a protein in the synaptic vesicle.

Pathogenesis

Botulinum toxin is absorbed directly across mucous membranes. Locally acting toxin may produce some symptoms but cranial nerve paralysis results from blood stream distribution. Cranial nerves are preferentially affected because botulinum toxin binds more rapidly to sites where the cycles of depolarization and repolarization are frequent. Binding is irreversible and the toxin cannot thereafter be neutralized by antitoxin. Recovery occurs when nerve terminals sprout from the axon to form new motor end-plates.

Botulinum toxin blocks impulse transmission mediated by acetylcholine at myoneural junctions, at autonomic ganglia, and at parasympathetic nerve terminals. Transmission is blocked because the toxin prevents release of acetylcholine from the presynaptic membrane. Impulse conduction within peripheral nerves and muscle contraction are not affected. Synthesis of acetylcholine and impulse transmission within terminal nerve fibrils remain intact. On the other hand, the miniature end-plate potentials spontaneously generated by release of acetylcholine in a resting nerve decrease and eventually disappear in the presence of toxin. If a poisoned nerve is stimulated repetitively, temporary summation of acetylcholine release occurs, producing an augmented response.

History

The symptoms of botulism vary from mild fatigue to severe weakness and collapse leading to death within a day. Initially, nausea, vomiting, abdominal bloating, and dryness in the mouth and throat may suggest gastrointestinal tract illness. Diplopia, blurred vision, dizziness, unsteadiness on standing, and difficulty with speech or

swallowing are common early neurological symptoms. Subsequently, there is progression to weakness or paralysis in the limbs, and generalized weakness and lassitude. The dryness of the mouth and throat may become so severe as to cause pain. Eventually there may be difficulty holding up the head, constipation, urinary hesitancy, and problems in breathing. The incubation period is between 12 and 72 h. Patients with short incubation periods are likely to have ingested large amounts of toxin. However, individuals are known to have ingested large amounts of contaminated food without developing symptoms.

Physical examination

Negative findings in botulism are pertinent. Higher mental functions are preserved, although sometimes patients are drowsy. Sensation is intact. Fever is unusual. The mouth is dry and the tongue is furrowed. Lateral rectus weakness in the eyes produces internal strabismus. Failure of accommodation is common and the pupils may be fixed in mid position or dilated and unresponsive to light. Ptosis, weakness of other extraocular muscles, and inability to protrude the tongue or to raise the shoulders are other early findings. Weakness in the limbs is of the flaccid, lower motor neurone type and deep tendon reflexes are initially preserved. Facial muscles may be spared; gag and corneal reflexes are not lost.

Weakness of the respiratory muscles develops early in relation to other findings and deterioration can be rapid. Paralysis descends symmetrically from cranial nerves to upper extremities to respiratory muscles to the lower extremities in a proximal to distal pattern. Hypotension without compensatory tachycardia, intestinal ileus, and urinary retention are evidence of the widespread autonomic paralysis. Symptoms and signs can be confined to the autonomic nervous system.

Diagnosis

The diagnosis in the first case of an outbreak can be missed because cranial nerve symptoms and signs are ignored in what is apparently a gastrointestinal disturbance. The differential diagnosis usually lies between botulism and the descending form of acute inflammatory polyneuropathy or Guillain–Barré syndrome. There can be similarities in the clinical presentation and progression of symptoms in the two diseases. Patients with botulism have normal cerebrospinal fluid findings and respiratory weakness and failure develop early, prior to the presence of severe limb weakness. Patients with the Guillain–Barré syndrome have marked limb weakness prior to the development of respiratory failure. Sensation and mental status are preserved in botulism.

Other diagnoses that may be considered include diphtheria, intoxication with atropine or organophosphorus compounds, myasthenia gravis, cerebrovascular disease involving the brainstem and producing bulbar palsy, paralytic rabies, tick paralysis, and neurotoxic snake bite. Botulism is distinguished from polymyositis and periodic paralysis by its rapid progression and cranial nerve abnormalities. Sometimes patients with other types of poisoning are thought to have botulism, most often with an outbreak of staphylococcal food poisoning. Individuals with carbon monoxide poisoning have been mistakenly been thought to be poisoned by food, but they invariably have headaches and altered consciousness. Poisoning from chemicals or fish produces rapid onset of symptoms. Mushroom poisoning is characterized by severe abdominal pain.

The diagnosis of botulism can be confirmed by testing for botulinum toxin in the patient's serum, urine, stomach contents, or in the suspect food. Mice are inoculated intraperitoneally with 0.5 ml of sample, with and without mixing with polyvalent botulinum antitoxin, and observed for signs of botulism. Electromyography can be helpful in confirming a diagnosis of botulism. Single or low-frequency stimuli evoke muscle action potentials that are reduced in amplitude; tetanic or rapid stimuli produce an enhanced response. Nerve conduction velocities are normal. This result readily differentiates botulism from the Guillain–Barré syndrome. Patients with myasthenia gravis usually have muscle action potentials of normal or minimally decreased amplitude.

Treatment

The priorities in management are assessment of respiratory function followed by administration of antitoxin. Respiration should be monitored closely with a view to elective intubation since deterioration can occur rapidly. Prolonged respiratory support may be required. Profound hypotension can be secondary to hypoxaemia, acidosis, and accumulated fluid deficits or be a feature of the autonomic paralysis. Treat autonomic paralysis by expanding the intravascular volume using whole blood, protein, and/or saline while monitoring central venous pressure or by infusing low dose dopamine.

Trivalent (types A, B, and E) antitoxin has been shown to reduce case fatality and shorten the course of the illness. To be useful it must be given early, before free circulating toxin has bound to its peripheral targets and before the diagnosis can be confirmed by animal tests. Multivalent equine antitoxin is available from designated regional hospitals in the United Kingdom; half the dose is given intramuscularly and half intravenously. An intradermal 0.1-ml test dose is given, but most serum reactions are not predicted by this test. Human botulism immune plasma can be obtained from the Centers for Disease Control, Atlanta, Georgia, United States.

Many years ago it was shown that patients dying of botulism carried bacilli in their intestine. The discovery that clinical disease can result from toxin formed within the gastrointestinal tract of infants and adults makes antimicrobial treatment theoretically appealing. Gastric lavage, repeated high enemas, and cathartics have been given to attempt to remove unabsorbed toxin. Drugs capable of reversing neuromuscular blockade have been used to treat patients with botulism, but without any noticeable effect on respiratory muscle weakness or tidal volume.

The mortality from botulism in the early part of the twentieth century was 60 to 70 per cent, but this improved to 23 per cent for cases reported between 1960 and 1970 since the use of respiratory support. In a single, large outbreak in 1977 there were no deaths among 59 cases. Recovery from botulism depends upon the formation of new neuromuscular junctions; clinical improvement thus takes weeks to months. One severe case required respiratory support for 173 days with eventual recovery. Very prolonged fatigue and dyspnoea on exertion can be due to factors other than the neuromuscular blockade.

Wound botulism

Symptoms and signs of botulism can develop in people with injuries. Recognition may be complicated by the presence of fever from wound infection or gas gangrene, or by the absence of gastrointestinal symptoms. The diagnosis is confirmed by electromyography; botulinum toxin is detected in serum in only about half of the reported cases. The incubation period averages 7 days with a range of 4 to 17 days. Clinical findings and management are the same as for patients with food-borne botulism. Since 1991, wound botulism has increasingly become a complication of injection drug abuse; small abscesses at injection sites yield *C. botulinum.* An epidemic of wound botulism in the United States has been associated with the injection of black tar heroin. *C. botulinum* can be recovered from wounds in the absence of clinical botulism.

Infant botulism

Sporadically, cases of botulism are recognized in infants under 6 months of age. Previously healthy babies develop constipation, which progresses over 3 to 10 days to poor feeding, irritability, a hoarse cry, and weakness in head control. Examination shows a generally weak, hypotonic, afebrile infant. Abnormalities in eye movements and pupillary reactions are sometimes present and deep tendon reflexes are reduced or absent. There is considerable range in severity; respiratory failure can develop but most recover completely.

The diagnosis can be confirmed by finding *C. botulinum* and toxin in the faeces, and by electromyography. Botulinum toxin is not present in the serum. The disease is thought to follow ingestion of *C. botulinum* spores, which multiply in the infant's gastrointestinal tract and produce toxin. Excretion of *C. botulinum* and toxin may continue for as long as 3 months. Honey has been a source of spores for some cases. Other than supportive measures, no consistent pattern in treatment using antitoxin, antibiotics, cathartics, or enemas has been established.

Gas gangrene

Definition

Gas gangrene is a rapidly developing and spreading infection of muscle by toxin-producing clostridial species, especially *C. perfringens* (formerly known as *C. welchii*). It is accompanied by profound constitutional toxicity and is invariably fatal if untreated.

Aetiology

Although gas gangrene conjures up visions of battlefield injury, cases occur after civilian and iatrogenic trauma. Disease occurrence depends upon a conjunction of factors. Viable forms of clostridia must be present and the wound environment must be conducive to their growth. Proximity to faecal sources of bacteria is a risk factor, as in hip surgery, adrenaline injections into the buttock, and amputation of the leg for ischaemic vascular disease. Wound contamination with dirt, shrapnel, or bits of clothing reduces local oxygen concentrations. Similarly, wounds involving large muscle masses in the shoulder, hip, thigh, and calf, damage to major arteries, crush injuries, open fractures, and burns carry a higher risk. High-velocity missiles and impacts are regular features of modern injuries in both wartime and civilian life and such injuries produce extensive tissue damage.

The incidence of gas gangrene after trauma reflects the speed at which injured people can be evacuated and receive appropriate treatment. During the Vietnam and Falklands conflicts there were very few cases of gas gangrene among American and British wounded cared for by highly organized surgical teams. In comparison, when a jet airliner crashed in the Florida everglades, eight of the 77 injured survivors developed the disease.

Gas gangrene is caused by anaerobic, Gram-positive, spore-forming bacilli capable of producing potent exotoxins. Most cases are caused by *C. perfringens* type A, but some are due to *C. novyi* and a few to *C. septicum*. *C. histolyticum*, *C. sordelli*, and *C. fallax* cause few cases and not uncommonly more that one species is isolated. Clostridia are mainly saprophytes, occurring naturally in soil and in the gastrointestinal tracts of man and animals. Oxygen inhibits their growth and prevents toxin production. Possession of superoxide dismutase can permit the organisms to survive in the presence of small amounts of oxygen. Necrotic tissue, foreign bodies, and ischaemia in a wound reduce the locally available oxygen. Infrequently, gas gangrene occurs without preceding trauma. It can be a primary infection of the perineum or scrotum, or present in a limb, secondary to seeding from clostridial colonization of a colonic neoplasm. *C. septicum* is found in a higher percentage of these cases than where there is a history of trauma.

C. novyi and other clostridia cause soft tissue infections at injection sites in drug addicts. An epidemic of these infections was reported in Scotland, Ireland, England, and the United States in 2000 associated with hypotension, severe constitutional toxicity, and a high case fatality rate.

Toxins

The clostridia responsible for gas gangrene elaborate a wide range of toxin activities, with from four to more than 12 separate toxins described for *C. septicum*, *C. novyi*, and *C. perfringens*. The principal toxin of *C. perfringens* is a toxin; the toxic action has been shown to be due to an ability of the molecule to insert into and interact with a phospholipid membrane. Electron microscopy shows gaps of 7.5 to 18 nm appearing in the plasma membrane as early as 1 h. These plasma membrane defects increase with time and can be visualized adjacent to toxin molecules that have been labelled with ferritin. Toxin is not detected in the tissues or serum of patients with gas gangrene, possibly because the toxin binds rapidly and irreversibly.

History

The incubation period of gas gangrene is usually less than 4 days, often less than 24 h, and occasionally as short as 1 to 6 h. Pain is the most characteristic symptom. Patients describe this as severe or excruciating and sudden in onset. Evolution of symptoms and signs can be very rapid. Toxicity may prevent the patient from giving an adequate history.

Physical examination

Early on it may be difficult to account for the patient's pain by objective physical findings. Swelling, bluish discoloration, or darkening of the skin occurs at the affected site. The traumatic or surgical wound becomes oedematous and a thin, serous ooze emerges. Pain steadily increases in severity: the overlying skin becomes stretched and develops a brown or 'bronzed' discoloration. Haemorrhagic vesicles and finally areas of frank necrosis appear. A sweet odour from the wound has been described. In spite of the name, gas is not invariably present, especially early. Later, crepitus and exquisite tenderness are present in the wound.

Profound constitutional changes occur. Patients become sweaty and febrile, and though alert and oriented, are very distressed. The pulse is elevated out of proportion to the fever. Death may occur within 48 h. At operation, infected muscle appears dark red with purple discoloration; frank gangrene and liquefaction may be seen. Involved muscle does not contract after direct stimulation.

Clostridial myonecrosis must be distinguished from anaerobic cellulitis and from anaerobic streptococcal myositis. Anaerobic cellulitis occurs where putrefying anaerobic clostridia produce a purulent infection in traumatized muscle and other tissues. Streptococcal myositis is a spreading muscle infection with anaerobic streptococci and either *Streptococcus pyogenes* or *Staphylococcus aureus*. Neither is associated with the constitutional toxicity characteristic of gas gangrene and neither requires as radical excision. Diabetic patients develop gas gangrene due to ischaemic vascular disease. Numerous micro-organisms, both aerobic and anaerobic, produce gas in tissues.

Diagnosis

The diagnosis of gas gangrene has to be made on clinical grounds. Prompt recognition and treatment improves the prognosis. Sudden deterioration in a postoperative patient or following trauma requires examination of the wound and surrounding tissue. Cases of primary gas gangrene and cases following elective surgery may have a higher fatality because recognition is delayed. Gram stain of the wound discharge, of an aspirate, or of a needle biopsy may aid diagnosis. In gas gangrene there are many large, plump, Gram-positive bacilli, usually without spores. Few, if any, polymorphonuclear leucocytes are present. On the other hand, both anaerobic streptococcal myositis and anaerobic cellulitis show many leucocytes and the former is characterized by long chains of Gram-positive cocci.

CT scanning can detect gas deep in muscle, but the absence of gas does not exclude the diagnosis. Culture of clostridia does not confirm a diagnosis of gas gangrene, as simple colonization without clinical disease occurs in up to 30 per cent of wounds. Efforts to establish a portal of entry for cases of spontaneous, non-traumatic gas gangrene may improve the prognosis.

Treatment

Surgical removal of all affected muscle is essential. Although not substitutes for surgery, antimicrobials, hyperbaric oxygen, and administration of antitoxin have been thought to be helpful adjunctive therapies. Penicillin has been the drug of choice, but there is experimental evidence that clindamycin and metronidazole might be superior to penicillin, perhaps by inhibiting toxin production. This has led to the use of penicillin and clindamycin as combination therapy. Ceftriaxone or erythromycin are alternative choices for severely penicillin-allergic patients.

Hyperbaric oxygen is used to treat gas gangrene. An effect on mortality has never been shown by controlled trials, and comparable mortality rates have been achieved without using it. One hundred per cent oxygen is given at 303 kPa for 60 to 120 min, two to three times daily. Therapeutic administration of gas-gangrene antitoxin made from horse serum is controversial. Use during the Second World War reduced mortality but serum sickness and other allergic reactions occur. It is no longer produced in the United States. Shock, blood loss, dehydration, and septicaemia with micro-organisms such as *Escherichia coli* should be treated appropriately. *C. perfringens* septicaemia in association with gas gangrene is not common.

Prevention

The mortality of established disease still ranges between 11 and 31 percent. Prophylactic antibiotic treatment effectively eliminates this risk. A first generation cephalosporin is given intravenously before surgery and for three doses postoperatively. Metronidazole may be useful in patients who are hypersensitive to b-lactam antibiotics. Antibiotic levels can be detected in ischaemic tissues.

Traumatic wounds are treated to eliminate the conditions that allow gas-gangrene bacilli to grow. High-velocity missiles distribute energy radially from their path, producing more extensive tissue damage than missiles at low speeds or with a small mass. Wounds should be excised widely by resection back to healthy, viable muscle and skin. Closure is delayed for 5 to 6 days until it is certain that the wound is free of infection. Military surgeons usually give penicillin in high dosage over

this period. Experimentally, active immunization protects, but in man this requires the clear definition of risk categories.

Clostridial infections of the gastrointestinal tract

Pseudomembranous colitis

Definition

Pseudomembranous colitis is an acute exudative infection of the colon caused by *C. difficile*. The name derives from plaques of necrotic membrane that adhere to the mucosal surface in the clinically most severe form of the disease.

Aetiology

Pseudomembranous colitis was described as a clinical and pathological entity in 1893 with its clostridial aetiology becoming known in 1977. *C. difficile* is an anaerobic, spore-forming, bacillus found in the environment. Healthy adults are only rarely colonized with *C. difficile*. Antimicrobial treatment reduces resistance to intestinal colonization. Colonization and toxin production produce colitis. Because colonization and antimicrobial treatment may occur at different times, antibiotic-susceptible strains of *C. difficile* are able to produce disease. Resistance to colonization requires viable intestinal bacteria, but it is not known which species or combination of species determines this resistance. Usually resistance to colonization will spontaneously reconstitute itself unless an antimicrobial effect persists within the gut. Infants and young children can be asymptomatically colonized even in the absence of antimicrobial treatment.

Clinical history

The single most pertinent detail of the medical history is previous antimicrobial treatment. Direct questioning may be needed to elicit this history; antimicrobials may have been self-administered, taken for trivial complaints, or used as long as 3 or 4 weeks before the start of diarrhoea. Pseudomembranous colitis has been reported to follow the use of every antimicrobial in common medical practice, but its association with lincomycin, clindamycin, ampicillin, amoxacillin, and cephalosporins is strongest. It occasionally occurs in individuals with no history of antimicrobial treatment or as a complication of chronic colonic obstruction, carcinoma, leukaemia, or uraemia. Pseudomembranous colitis was identified as a pathological entity before any clinical use of antimicrobials. Community-acquired cases occur sporadically but case clustering in hospitals or nursing homes is not uncommon. The disease is more common in older patients but the typical syndrome has been described in people of all ages including infants.

Initial symptoms vary from mild, self-limiting diarrhoea to acute fulminating toxic megacolon. Illness can begin surreptitiously where persistent diarrhoea resists all efforts at symptomatic relief. Community-acquired cases tend to have a week or more of diarrhoea before seeking medical attention. Stools are described as watery or porridge-like, or patients may be obstipated. Other initial symptoms are sudden chills, fever, and signs of an abdominal catastrophe. Elderly patients may have diarrhoea that resolves and then recurs at intervals of one to several days. Severe abdominal pain is not common and a history of frank blood in the stools suggests a different type of colitis.

Physical examination

Elderly patients appear tired, toxic, and ill. Low fever, a dry furred tongue, and abdominal tenderness, sometimes with peritonism, are the most common clinical signs. Signs of dehydration may be present, but hypotension attributable to hypovolaemia is not common. Spiking temperatures may also be seen and a distended, tense, abdomen can suggest colonic obstruction. Reactive arthritis, IgA nephropathy, and hypoproteinaemia are potential complications of *C. difficile* colitis.

Diagnosis

Many patients show polymorphonuclear leucocytosis, sometimes with counts of 30 000/ul or more. Leucocytes are present in the faeces. Chemical findings in patients with prolonged diarrhoea include azotaemia and hypoalbuminaemia; the azotaemia may appear to be out of proportion to the dehydration. The presence of *C. difficile* toxin establishes a mechanism for the diarrhoea.

Sigmoidoscopy can be helpful in making an early diagnosis because the raised, mucoid to opaque yellow plaques (0.2–2 mm across) are diagnostic. If the mucosa appears normal, biopsy and multiple sectioning may reveal microscopic lesions. Some patients with *C. difficile* colitis do not have pseudomembranes, either because lesions are distributed unevenly in the colon or because the illness is mild. In these cases the diagnosis can only be confirmed by testing for toxin and *C. difficile*. Rarely, patients with pseudomembranes on sigmoidoscopy or rectal biopsy may fail to yield *C. difficile*. Usually confluent rather than focal mucosal necrosis is found. This appears to be the end result of several types of colonic mucosal injury, not specific to *C. difficile* infection.

The differential diagnosis of pseudomembranous colitis includes other forms of antimicrobial-associated colitis, diarrhoea due to *Salmonella*, *Shigella*, and *Campylobacter* species, intestinal amoebiasis, Crohn's disease, and non-specific ulcerative colitis. These can be differentiated by sigmoidoscopy and rectal biopsy, or by microscopy and culture of the faeces. Two-thirds or more of patients with simple antimicrobial-associated diarrhoea do not have infection with *C. difficile*. Often they complain of sudden abdominal pain and bloody diarrhoea that subsides within a day or two of stopping antimicrobial treatment. Occasionally, patients may be infected with *C. difficile* in addition to another micro-organism capable of causing diarrhoea. Infection with *C. difficile* may exacerbate symptoms in some patients with inflammatory bowel disease.

Treatment

Stopping the associated antimicrobial may allow *C. difficile* colitis to resolve spontaneously. If clinical circumstances dictate active treatment, the antimicrobial of choice is one to which *C. difficile* is susceptible and which is not absorbed following oral administration. Vancomycin is used in a dose of 125 mg every 6 h. Metronidazole, 250 mg four times a day, also appears to be effective, although it is absorbed. Some physicians regard it as less effective than vancomycin. Bacitracin may also be useful. Severe cases usually show improvement after 48 h of treatment and signs and symptoms rapidly return to normal. Failure to respond to vancomycin suggests that the diagnosis is incorrect or that an additional condition or complication may be present.

Patients who are dehydrated need fluid resuscitation. Cholestyramine resins bind *C. difficile* toxin *in vitro*, but have no effect on the clinical course of the colitis. Pseudomembranous colitis has been successfully treated by colectomy. However, the disease is completely reversible by appropriate antimicrobial treatment. In patients who are unable to take vancomycin orally, some physicians have attempted to instil it into the colon via a caecostomy tube; others combine intragastric vancomycin, intermittent clamping of the nasogastric tube, and parenteral metronidazole. *C. difficile* antitoxin is not available in the United Kingdom.

Any of the suggested antimicrobial treatment regimens for pseudomembranous colitis may be followed by relapse. The relapse illness can be clinically more severe than the original. There has never been any evidence that relapse is due to antimicrobial resistance and patients continue to respond to treatment with the original or an alternative drug. Patients relapse both because antimicrobial treatment may not completely clear them of *C. difficile* or because a new exposure to environmental strains has occurred. There is evidence that vancomycin and metronidazole themselves can reduce resistance to the infection; prolonged treatment may produce prolonged susceptibility. On the other hand, patients whose *C. difficile* colitis resolves without antimicrobial treatment usually do not relapse.

Occasional patients may have multiple relapses and many regimens have been suggested for their management. These include tapering doses of vancomycin, a *Lactobacillus* preparation three times a day, or cholestyramine three times a day after a therapeutic course of vancomycin. Cholestyramine can not be combined with vancomycin. In a patient recovering from multiple relapses, tapering vancomycin doses to once daily when diarrhoea stops, then to alternate days, then to progressively longer intervals, can prevent early relapse. Some patients with severe colitis or multiple relapses may continue to have diarrhoea without toxin in their stools. This resembles postdysenteric colitis where continued diarrhoea is due to lingering mucosal injury. Bowel rest with total parenteral nutrition can allow healing and recovery; continued treatment against *C. difficile* is not required. Normal flora may be reconstituted by giving a suspension of normal faeces as an enema.

It may be necessary under certain circumstances to continue an antimicrobial when a patient has developed pseudomembranous colitis. There is no evidence to suggest that concurrent therapy with vancomycin will not be successful, although clinical improvement occurs more slowly. It is reasonable to replace a drug commonly associated with pseudomembranous colitis by one which is not, such as a quinolone, aminoglycoside, tetracycline, or sulphonamide. Repeat treatment with

an inducing antimicrobial at some later time is not contraindicated in a patient who has recovered from pseudomembranous colitis.

Prevention

Clusters of cases of pseudomembranous colitis were reported before its infectious aetiology was understood. Now it is known that *C. difficile* may contaminate the environment of a patient, that patients acquire the organism, and that cross-infection is confirmed by strain typing. The chain of infection for isolated cases may be difficult to trace because spores can persist for months. Since patients receiving antimicrobial treatments are at risk, those with colitis ought to be nursed in barrier isolation. Patients with diarrhoea, especially those who are incontinent, are more important sources of cross-contamination than those with formed stools. Physical cleanliness, enteric precautions, confinement to a single room, and reduced use of the most frequent inducing antimicrobials are the approaches most often used to reduce institutional cross-infection. There is no proven value in retesting patients until they are free of toxin nor in treating asymptomatic toxin excretors.

Necrotizing enterocolitis

Definition

Necrotizing enterocolitis is a fulminating clinical illness characterized by extensive necrosis of the intestinal mucosa and wall. Terms such as darmbrand (Germany), enteritis necroticans, pig bel (Papua New Guinea), or gas gangrene of the bowel describe geographical variants. Cases occur sporadically in adults or as epidemics in all ages. Necrotizing enterocolitis occurs in infants, sometimes in clusters, but is not proven to be due to clostridial infection.

Aetiology

C. perfringens (*C. welchii*) is considered to be the cause. Sporadic cases usually yield *C. perfringens* type A. Gram stain of the necrotic mucosa and the bowel wall shows many Gram-positive bacilli. However, in the German and especially in the Papua New Guinea outbreaks, there is substantial evidence implicating *C. perfringens* type C. Type C produces large amounts of b-toxin, which has lethal and necrotizing effects. Papua New Guinea highlanders have a high prevalence of antibodies to b-toxin; antibodies are rare in people who live where the disease is uncommon. Patients with pig bel have rising levels of antibodies to b-toxin, and specific passive or active immunization has been shown to prevent disease. It is not clear whether exogenous human infection with these organisms occurs or whether the lesions are produced by the overgrowth of endogenous clostridia. Sweet potato, a local dietary staple, contains an inhibitor of trypsin. Combined with a low-protein diet this may impair the ability of the intestine to inactivate endogenously produced b-toxin. However, the methods used for roasting the pigs offer many opportunities for clostridial contamination.

History and physical examination

Sporadic cases, over 50 years of age or recovering from gastric surgery, are regularly reported from Scandinavia, Europe, the United States, Australia, and the Middle East. Alternatively, epidemic outbreaks as described in post-war Germany and among the highlanders of Papua New Guinea follow ingestion of contaminated food or a dramatic change in eating habits. Symptoms develop suddenly in someone who was previously well. There is severe abdominal pain, which is colicky at first and afterwards becomes continuous. Bloody diarrhoea and vomiting may occur. The patient may be extremely toxic and go into shock. On examination there is fever, with abdominal distension, localized or diffuse tenderness, and reduced bowel sounds. A tender mass may be palpated. Later, malabsorption or chronic partial obstruction may develop because of intestinal scarring.

Treatment and prevention

Patients with suspected pig bel should be treated with nasogastic suction and intravenous fluids. Pyrantel is given by mouth and the bowel rested by fasting. One megaunit of benzylpenicillin is given intravenously every 4 h and the patient observed for surgical complications. Mild cases recover without surgical intervention, but if surgical indications are present, the mortality ranges from 35 to 100 per cent. As pig bel continues to be a common disease in Papua New Guinea, consideration should be given to the use of a *C. perfringens* type C toxoid vaccine in local areas. Two doses spaced 3 to 4 months apart have been shown to prevent the disease.

Clostridium perfringens food poisoning

Occurrence and clinical findings

In the United Kingdom and the United States, food poisoning caused by *C. perfringens* is the third most common type of food-borne illness. Meat and poultry are responsible for at least 90 per cent of the outbreaks, which occur where food is prepared in large quantities. Two-thirds of the reported outbreaks are in schools, hospitals, factories, restaurants, or catering establishments, and in a typical outbreak 35 to 40 people are affected. An estimated 12 000 cases were associated with a single out-break in 1969.

The circumstances surrounding an outbreak repeat themselves with monotonous regularity. A meat dish is prepared by stewing, braising, boiling, or steaming and this is allowed to stand at ambient temperatures for a period of 4 to 24 h. The food is served cold or after desultory rewarming. Six to 12 h after eating the meal, the victims complain of crampy abdominal pain and then diarrhoea. Vomiting is unusual and fever inconsequential. Twelve to 24 h later the diarrhoea and pain have subsided. Fatal cases occur rarely; at autopsy they show severe enterocolitis.

Undoubtedly many cases of *C. perfringens* food poisoning occur at home but are not reported. Antibodies to the toxin mediating the symptoms are very common and it is likely that nearly everyone has experienced this disease once or more in their lifetime.

Aetiology

C. perfringens is an ubiquitous, sporulating anaerobe with an unparalleled virtuosity for production of biologically significant toxins. The clinical effects of infection with any particular strain may depend largely on its toxin-producing capacity. Strains associated with food poisoning have a number of special characteristics. They are type A, although their production of a-toxin is variable; they are often heat resistant. Eighty-six per cent of food-poisoning strains produce a specific, heat-labile enterotoxin. Toxin production *in vitro* is closely associated with sporulation rather than with the multiplication of vegetative cells. *In vivo*, toxin probably acts by damaging enterocyte membranes. Free enterotoxin has been detected in diarrhoeal stool after *C. perfringens* food poisoning, antibody to enterotoxin increases after such episodes, and ingestion of 8 to 12 mg of enterotoxin by volunteers produces abdominal pain and diarrhoea.

C. perfringens is a normal human faecal organism, is regularly found in the intestinal tract of domestic animals, often contaminates raw meat, and can be carried by flies. The distribution of enterotoxin-producing strains may be more restricted. However, surface contamination of meat with *C. perfringens* is common and subsequent rolling or grinding will distribute these organisms throughout. Heat-resistant strains survive at maximum temperatures of 100°C. Spores then germinate and multiply to 10^6 to 10^7 cells/g in the highly advantageous, anaerobic environment created when meat cools slowly or stands at ambient temperature. Reheating may not kill these cells; when ingested they multiply still further, sporulate, and release their toxin.

Enterotoxin-producing strains of *C. perfringens* may sometimes cause diarrhoea by means of overgrowth in the gut. Patients, usually elderly, begin to experience diarrhoea without known contact with contaminated food. The diarrhoea may be short lived or persist intermittently for several months. Colony counts of 10^8 to 10^{10}/g of faeces are associated with the presence of high titres of free toxin. Previous antimicrobial treatment may encourage the overgrowth and the same strain has been found to cross infect patients.

Tuberculosis

Richard E. Chaisson and Jean Nachega

Introduction

Tuberculosis is one of the most important diseases in the history of humanity, and remains an extraordinary burden on human health today. Archaeological evidence demonstrates that tuberculosis was present in antiquity, and large epidemics of the disease emerged in Europe in the Middle Ages. While contemporary physicians consider tuberculosis to be one of the classical infectious diseases, recognition of the clinical manifestations of the disease has evolved over the past two millenia. The Greek term *phthisis* was used by Hippocrates to describe the wasting disease later known as tuberculosis. While the Greeks recognized various clinical manifestations of tuberculosis, understanding of the connection between the forms was limited. In the Middle Ages, the study of anatomy and the correlation of pathological findings with clinical syndromes led to a better understanding of the disease. The term 'tuberculosis' was introduced in the early nineteenth century, derived from the tubercles characterized in the study of pathological features of the disease.

The impact of tuberculosis on mankind cannot be overstated, as the disease has killed hundreds of millions of people over the centuries and has had economic and social effects perhaps unparalleled in the history of medicine. Between 1700 and 1950, tuberculosis was a great killer in the developed world, earning the sobriquet 'the captain of the men of death...' from John Bunyan, and 'the White Plague' from René and Jean Dubos. The inspiration that artists have drawn from tuberculosis, portrayed in literature, opera, and art, testifies not only to the importance of the disease within their contemporary societies, but also to the extent to which tuberculosis affected artists themselves. The annals of art are rife with those who succumbed to tuberculosis, including Keats, Chopin, the Brontë sisters, Robert Louis Stevenson, Poe, and many others.

The conquest of tuberculosis through the development of vaccines, drugs, and diagnostics was a principal goal of biomedical research in the nineteenth and twentieth centuries. The first description of the tubercle bacillus as the cause of tuberculosis by Robert Koch in 1882 was a scientific landmark. The postulates established by Koch for determining the microbial aetiology of disease have continuing influence today, and molecular correlates of those derived by Koch further strengthen the ingenuity of his thesis. The discovery of streptomycin by Schatz and Waksman in 1943 was a major triumph; both Koch and Waksman received the Nobel prize for their efforts. The development of additional antimicrobial agents against tuberculosis in the 1950s, 1960s, and 1970s and the evaluation of chemotherapy in elegant studies conducted by the British Medical Research Council, the United States Public Health Service, and the United States Veterans Administration led to a marked apathy about tuberculosis in the closing decades of the twentieth century.

Despite the availability of curative chemotherapy for more than half a century, however, tuberculosis continues to cause an enormous amount of suffering, disability, and mortality. In 1994, the World Health Assembly declared that tuberculosis was a global health crisis, and the situation has only grown more grave since then. Epidemics of HIV-related tuberculosis and multidrug-resistant disease have expanded in the past 5 years, and global control of tuberculosis is a remote possibility at present.

The unique biological properties of the causative organism, *Mycobacterium tuberculosis* complex, allow for a long incubation period between the time of infection and the development of symptoms. Latent tuberculosis infection can persist for decades prior to causing disease, or can persist for the lifetime of an infected person without ever causing clinically evident illness. Because latent infection creates a large reservoir of carriers of the infection, disease elimination is difficult to contemplate.

Aetiology

Tuberculosis is a granulomatous disease caused by organisms of the *M. tuberculosis* complex, including *M. tuberculosis*, *M. bovis*, and *M. africanum*, with *M. tuberculosis* greatly predominating. *M. tuberculosis* and the other mycobacteria are small, rod-shaped or curved bacilli in the Order Actinomycetales, Family Mycobacteriaceae, with a unique, thick cell wall composed of glycolipids and lipids. The lipid-rich coat of the mycobacteria renders these organisms resistant to acid decolorization following carbol-fuschin staining, hence the term 'acid-fast bacilli.' Classification of the mycobacteria was based for many years on the staining and growth properties described by Runyon, but this unwieldy system has been largely replaced with modern techniques that identify mycobacteria by specific DNA sequences and, to a lesser extent, biochemical assays. Mycobacteria are frequently considered according to the diseases they cause rather than their behaviour in the laboratory: *M. tuberculosis* complex causing tuberculosis; *M. leprae* the cause of leprosy; and the non-tuberculous mycobacteria, including rapid growers, associated with a wide range of manifestations, particularly in immunocompromised hosts.

The organisms of the *M. tuberculosis* complex are remarkably slow growing, with a generation time of between 20 and 24 h. The exceedingly slow intrinsic reproductive rate of *M. tuberculosis* contributes both to its behaviour as a pathogen and to difficulties in recovering the organism in culture. Moreover, *M. tuberculosis* is able to persist in a latent form within cells and granulomas for many years, and can reactivate to cause disease decades after infection is acquired. Tubercle bacilli are not known to form pores, but both typical bacilli and non-staining forms of the bacteria persist in cells and tissues, as evidenced by detection of DNA, years after infection is acquired and retain the capacity to replicate and produce clinical illness. These unique biological characteristics make the tubercle bacillus exceedingly difficult to combat and control.

Epidemiology

Despite the widely held belief that tuberculosis was waning during the 1980s, global tuberculosis incidence has been steady or increasing for several decades. In Western Europe and North America, the incidence of tuberculosis peaked in the 1700s and 1800s, then declined over a period of years prior to the development of chemotherapy. Improvements in hygiene and nutrition, along with reductions in household crowding, were credited with these trends. Following the introduction of curative treatment for tuberculosis in the era following Second World War, the incidence of disease fell even further, and tuberculosis deaths were greatly decreased. The success in controlling tuberculosis experienced in the Western nations was not replicated in developing countries, and increasing epidemics of the disease have been occurring in these areas. Ironically, progress in tuberculosis control in the Western nations led to neglect of public health programmes that were responsible for reductions in morbidity. As a consequence of inattention to control, the United States experienced a resurgence of tuberculosis between 1985 and 1992, with a 21 per cent increase in the annual number of reported cases during that time. In the United Kingdom, tuberculosis incidence has plateaued over the past decade, with an annual incidence of 11 cases per 100 000 population since 1991. Worldwide, tuberculosis continues to kill more than 2 million people per year, making it the second leading infectious cause of death after HIV infection. In fact, tuberculosis is a eading cause of death in AIDS, and HIV-related tuberculosis deaths are attributed to AIDS, not tuberculosis. If these deaths were attributed to tuberculosis, it would remain the leading infectious cause of death worldwide.

The World Health Organization estimates that 2 billion people, or one-third of the world's population, are infected with *M. tuberculosis*. From this seedbed of latent infection, about 8 million new cases of active disease arise each year, with a global incidence of approximately 160 cases per 100 000 population. The global

distribution of tuberculosis case rates is shown in Fig. 1. Disease due to *M. tuberculosis* is most common in developing nations, both in absolute numbers and incidence of new cases. Twenty-two countries account for 80 per cent of all tuberculosis, with India and China responsible for 23 and 17 per cent of cases, respectively. In general, the highest incidence of disease is found in the countries of sub-Saharan Africa, where HIV infection has contributed to extraordinary increases in case rates, while the greatest number of cases arise in the populous nations of Asia, which have moderately high rates of disease per capita. The global incidence of tuberculosis is increasing slightly, although population growth is resulting in higher numbers of cases each year. Declines in incidence in the developed world have been offset by increasing rates in the HIV-ravaged countries of Africa and by escalating incidence in Eastern Europe in the aftermath of the collapse of communism and its public health infrastructure.

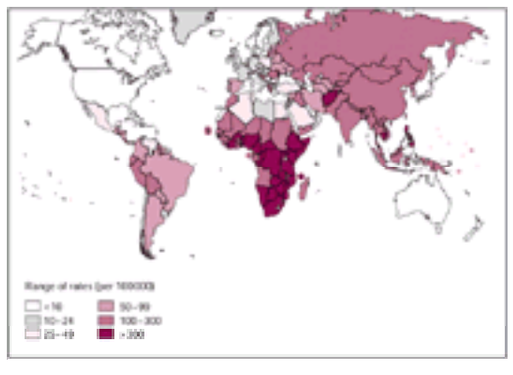

Fig. 1 Global tuberculosis incidence 1999.

Typically tuberculosis affects young adults, with peak incidence in those aged 25 to 44. The dynamics of tuberculosis within a particular country or region, however, reflects both historical trends in tuberculosis transmission and current risk factors and practices of disease control. In Western Europe, for example, tuberculosis is seen in two demographic groups: elderly native Europeans who were presumably infected many years ago and who experience reactivation of latent infections as they age or become immunocompromised, and younger immigrants from high-incidence countries in the developing world. In the United States, tuberculosis is seen in young adults who have immigrated from endemic areas and in those with HIV infection, whereas reactivation tuberculosis in the elderly is increasingly uncommon. In the developing world, tuberculosis most commonly occurs in young adults, with rapidly escalating rates in those with HIV infection. In all countries where tuberculosis is prevalent, young children who acquire tuberculosis from adults account for a small proportion of all cases. It is interesting that children between the ages of 5 and 15 have extremely low rates of tuberculosis, even in areas with a high disease burden.

The epidemiology of tuberculosis is a function of two distinct but related phenomena: the likelihood of becoming infected with *M. tuberculosis* and the probability of developing disease once infection has occurred. Risk factors for becoming infected relate to exposure to infectious individuals. Throughout the world, living with someone who has infectious tuberculosis is the most important risk factor for acquiring infection. The longer the duration of undiagnosed tuberculosis, the greater the severity of disease and probability of transmitting infection. The more intimate the contact, the greater the chance of becoming infected. Exposure to infectious individuals in other environments, including hospitals, prisons, and the workplace, is another important route of infection. In areas of the world where tuberculosis is frequent, exposure in the community is probably unavoidable. In low-prevalence countries community exposure is most likely to occur in distinct pockets of increased incidence, such as poorer areas of large cities or neighbourhoods with high HIV prevalence.

After *M. tuberculosis* infection is acquired, the risk of developing disease is dependent on host immunity. As discussed below, a number of conditions have been identified that increase the risk of active disease in a person with latent tuberculosis infection, most notably HIV infection. Strain differences in *M. tuberculosis* have not been associated with the risk of disease, although inoculum size is associated with the probability of becoming ill. Household contacts who are infected by patients with high sputum levels of acid-fast bacilli have a higher incidence of active disease than contacts of patients who have sputum smears negative for acid-fast bacilli. On the other hand, while there is some evidence that specific strains of *M. tuberculosis* may infect contacts more successfully than other strains, the risk of disease in those infected with these transmissable strains is not elevated.

Tuberculosis is a disease traditionally associated with specific population groups, notably the poor, alcohol and drug abusers, and more recently, those with HIV infection. The increased incidence of tuberculosis in impoverished populations is probably multifactorial, involving increased risk of infection (for example due to crowded living conditions and a higher background prevalence of disease in the community) and increased risk of developing disease after infection (for example due to malnutrition). Similar reasons may explain the higher rates of tuberculosis seen in alcohol and drug abusers, with suppression of host cellular immunity either directly or indirectly from substance abuse. The more recent association of tuberculosis and HIV infection is clearly related to development of cellular immunodeficiency in those with HIV, but in many settings those at highest risk for HIV infection are also more likely to be latently infected with *M. tuberculosis* than others.

The impact of HIV infection on the epidemiology of tuberculosis is striking. As will be discussed below, HIV infection is the most potent known biological risk factor for tuberculosis. The relative risk of tuberculosis in an HIV-infected person is 200- to 1000-fold greater than in someone without HIV infection. As a result of the extraordinary risk conferred by HIV infection, the majority of patients with tuberculosis in many sub-Saharan countries are HIV seropositive. In the United States and the United Kingdom, HIV infection accounts for a substantial proportion of tuberculosis cases in many cities. HIV infection is the unifying theme in many nosocomial outbreaks of tuberculosis, as infection is spread among immunocompromised patients receiving medical care at the same facility. It is increasingly apparent that control of tuberculosis will not be possible globally without control of HIV infection.

Another very important trend in tuberculosis epidemiology is the growing problem of drug-resistant tuberculosis. There are two categories: primary resistance, which is the presence of drug resistance in someone who has never had treatment for tuberculosis, and secondary resistance, the presence of resistance in a patient who has previously been treated for tuberculosis. Primary resistance results from acquiring an infection that is already drug resistant, while acquired resistance is the result of inappropriate therapy that selects for resistant mutants of *M. tuberculosis*. A global survey of resistance performed by the World Health Organization and the International Union Against Tuberculosis and Lung Disease found that the median prevalence of primary drug resistance was 10 per cent, and the median prevalence of acquired resistance was 36 per cent. Moreover, 'hot spots' of drug-resistant tuberculosis were identified on all continents, most notably in the former Soviet nations, where multidrug-resistant tuberculosis is identified in 10 to 20 per cent of all cases. Multidrug-resistant tuberculosis is exceedingly difficult to cure, and so failure to control its spread has ominous implications.

Pathogenesis

The development of active tuberculosis, like all infectious diseases, is a function of the quantity and virulence of the invading organism and the relative resistance or susceptibility of the host to the pathogen. Tubercle bacilli are transmitted between people by aerosols generated by coughing or otherwise expelling infectious pulmonary or laryngeal secretions into the air. *M. tuberculosis* bacilli excreted by this action are contained within droplet nuclei, extremely small particles (less than 1 μm) that remain airborne for long periods and are disseminated by diffusion and convection until they are deposited on surfaces, diluted, or inactivated by ultraviolet radiation. People breathing air into which droplet nuclei have been excreted are at risk of becoming infected if inhaled nuclei are deposited in their alveoli. Transmission of tuberculous infection by other routes, such as inoculation in laboratories and aerosolization of bacilli from tissues in hospitals, has been documented, but these are an insignificant means of spread. *M. bovis* can be acquired from contaminated milk from tuberculous cows, but modern animal husbandry practices and pasteurization of milk have virtually eliminated this mode of infection throughout most of the world.

The natural history of tuberculosis in humans is illustrated in Fig. 2. People who are in contact with someone with infectious tuberculosis may acquire infection, as described above. Factors that affect the likelihood of infection being transmitted include the severity of the disease in the index case (such as extent of radiographic abnormalities, cavitation, frequency of cough), the duration and closeness of exposure, and environmental factors such as humidity, ventilation, and ambient ultraviolet light. A number of studies in diverse locations and circumstances have shown that approximately 20 to 30 per cent of close contacts of a patient with untreated tuberculosis become infected with *M. tuberculosis*, as demonstrated by the development of a reactive tuberculin skin test.

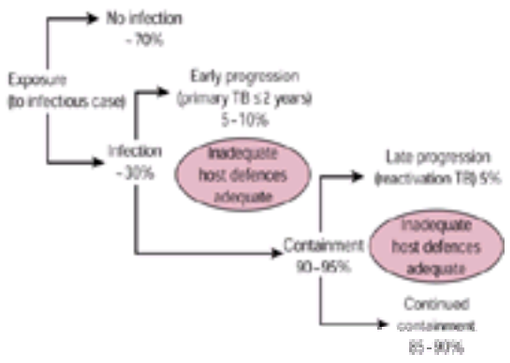

Fig. 2 Natural history of tuberculosis.

Deposition of tubercle bacilli in the alveoli results in a series of protective responses by the cellular immune system that forestall the development of disease in the majority of infected people. Alveolar macrophages ingest tubercle bacilli, which then multiply intracellularly and eventually cause cell lysis with release of organisms. Killing of *M. tuberculosis* within macrophages is prevented by inhibition of phagolysosome formation by the tubercle bacilli through a process that is not understood. Additional alveolar macrophages engulf progeny bacilli, resulting in further intracellular growth and cell death. Over a period of weeks, as tubercle bacilli proliferate within macrophages and are released, infection spreads to regional lymph nodes, elsewhere in the lungs, and systemically. Foci of tubercle bacilli can be established in multiple organs, including the lymph nodes, brain, kidneys, and bones. In most people, after several weeks, specific immunity is developed, with activated T lymphocytes mediating a T_{H1}-type response. Macrophages act as antigen-presenting cells, interacting with CD4 lymphocytes primed for *M. tuberculosis* antigens. Activated CD4 lymphocytes produce both IL-2, which promotes activation of additional T lymphocytes, and interferon-g, which binds with receptors on macrophages and promotes intracellular killing of organisms. Tumour necrosis factor-a production is induced in macrophages, and this too promotes killing of intracellular bacilli. The specific role of CD8 cells in the control of tuberculosis has not been fully elaborated, although there is evidence that cytotoxic T lymphocytes may play a role in containing a tuberculous infection. In addition, CD8 lymphocytes also produce interferon-g and participate in granuloma formation.

The classic immunological response to infection with tubercle bacilli is the walling off of viable bacilli in granulomas, collections of cells surrounding a focus of *M. tuberculosis*, usually within macrophages but sometimes extracellular organisms, that serve to contain the infection. Granulomas consist of macrophages, CD4 and CD8 lymphocytes, fibroblasts, giant cells, and epithelioid cells that produce an extracellular matrix of collagenous and fibrotic materials that are continually remodelled and can become calcified. A calcified granuloma at the initial site of infection in the lung is referred to as a Ghon complex, while the combination of a Ghon complex and a calcified regional lymph node is called a Ranke's complex.

The development of the cellular immune response to *M. tuberculosis* is accompanied by the development of delayed-type hypersensitivity to specific antigens from tubercle bacilli. While delayed-type hypersensitivity is distinct from the cell-mediated immunity that provides protection from disease, this sensitivity to tubercle-derived proteins has proved enormously useful for diagnosing tuberculosis infection. Use of purified protein derivatives (**PPD**) of tuberculin is the basis for estimating the prevalence of latent tuberculosis infection in populations. This is essential in studying the natural history of tuberculosis infection, and is frequently helpful in evaluating patients with suspected tuberculosis disease. The difference between delayed-type hypersensitivity and immunity to tuberculosis is illustrated by the observation that 80 to 90 per cent of patients with active disease, and therefore clearly not immune, have positive tuberculin tests.

For the majority of people acquiring a new tuberculous infection, the development of cell-mediated immunity to the organism is protective and holds the bacilli in check, although viability is usually maintained. A small minority will be unable to contain the infection and progress to active tuberculosis disease, often referred to as primary tuberculosis. Early progression of infection to disease is associated with immunosuppression, particularly with HIV infection, a higher inoculum of organisms, malnutrition, and perhaps, concomitant illness. While rates of active disease in young children who are contacts of infected individuals are no higher than for older contacts, young children with primary tuberculosis do develop more severe forms of tuberculosis than adults, including disseminated disease and tuberculous meningitis.

Those who successfully contain the organisms have a latent tuberculosis infection that may reactivate later in life. Studies of latent tuberculosis infection acquired in childhood or adolescence suggest a lifetime risk of reactivation of *M. tuberculosis* of about 10 per cent. Table 1 lists risk factors for reactivation of latent tuberculosis infection. The most potent is HIV infection, which increases the rate of reactivation by as much as 1000-fold. Immunosuppression from malignancy, cytotoxic therapy, corticosteroids, and other agents that alter cellular immune responses can also reactivate latent tuberculosis infection. Other potentiating factors include diabetes, endstage renal disease, injection drug use (independent of HIV infection), low body weight, gastrointestinal surgery, and silicosis. Cigarette smoking is associated with increased tuberculosis incidence (notably in India), as is alcohol abuse. Inhibitors of tumour necrosis factor-a used to treat rheumatoid arthritis or inflammatory bowel disease increase the risk of tuberculosis. Tuberculosis rates are usually higher in the elderly than in younger adults in developed countries, but this may represent a higher prevalence of latent infection in older cohorts, rather than immunological senescence.

Clinical features

Classification of tuberculosis infection and disease

Infection with *M. tuberculosis* can result in clinical manifestations ranging from asymptomatic carriage of latent bacilli to life-threatening pneumonia. Classification of the different stages of *M. tuberculosis* in humans by the American Thoracic Society (**ATS**) is shown in Table 2. This system is used more for public health purposes than for clinical management, but is useful because it reflects the natural history of *M. tuberculosis* and categorizes patients according to the type of evaluation and treatment they may need.

ATS Category 0 describes people with no history of tuberculosis exposure and a negative tuberculin skin test (if performed). Category 1 includes those people exposed to an infected individual but in whom no evidence of infection is found. This is a temporary category used during the evaluation of contacts of tuberculosis cases; repeat tuberculin testing several months after the exposure would result in these individuals being reclassified to another category. Category 2 is defined as latent tuberculosis infection without evidence of disease, and is based on a positive tuberculin skin test without clinical or radiographic signs of illness. Category 3 is confirmed, active tuberculosis disease requiring treatment. As discussed below, this category is further divided according to the site of disease and laboratory features, including results of acid-fast bacilli smears. Category 4 is defined as inactive tuberculosis. Patients in this category do not have clinical or laboratory evidence of active disease, but are known to have suffered previously from tuberculosis. This category includes those who have been treated and cured of active tuberculosis, as well as individuals who have spontaneously recovered from tuberculosis without treatment. Finally, category 5 refers to patients in whom tuberculosis is suspected, but who are still undergoing evaluation. Depending on the degree of suspicion of the diagnosis, such people might be started on presumptive therapy for tuberculosis pending the outcome of cultures and other laboratory assessments. Like category 1, it is a temporary category for patients undergoing evaluation. All are subsequently reclassified on the basis of diagnostic studies.

The clinical presentation of active tuberculosis is highly variable, depending on the site and extent of disease and the immune status of the host. Historically, active tuberculosis has been classified as 'primary' or 'post-primary' on the basis of both the presumed duration of infection and the clinical features of the disease. However, molecular epidemiological studies suggest that this classification may be unreliable. For example, the 'classic' presentation of reactivation tuberculosis has been seen in patients whose infection is clearly newly acquired, such as in nosocomial outbreaks where DNA fingerprinting confirms recent transmission. For practical purposes, tuberculosis is generally divided into pulmonary and extrapulmonary forms, with considerable clinical heterogeneity within these cate-gories.

Pulmonary tuberculosis

Pulmonary tuberculosis is usually a subacute respiratory infection with prominent constitutional symptoms. The most frequent symptoms of pulmonary tuberculosis are cough, fever, night sweats, and malaise. Cough in pulmonary tuberculosis is initially dry, but often progresses to become productive of sputum and, in some instances, haemoptysis. The sputum is generally yellow in colour, and is neither malodorous nor thick. Haemoptysis may occur acutely in patients with untreated tuberculosis, but is also a feature of treated tuberculosis; damage from prior tuberculosis may result in bronchiectasis or residual cavities that can either become superinfected or erode into blood vessels or airways, producing haemoptysis. Advanced tuberculosis may also present with bloody sputum. Rarely, the bleeding is

massive leading to shock, asphyxia, and death.

Chest pain is not a prominent symptom in pulmonary tuberculosis, although coughing may cause musculoskeletal pain. Patients with tuberculous pleurisy may experience pleuritic pain. Radicular chest pain may be associated with spinal tuberculosis. Dyspnoea alone may be a sign of extensive parenchymal destruction, large pleural effusions, endobronchial obstruction, or pneumothorax.

Patients with tuberculosis also experience loss of appetite and weight loss or cachexia, often out of proportion to their diminished intake of food. Elevations in tumour necrosis factor-a may be responsible. Mild symptoms include emotional lability, irritability, depression, and headache.

Most patients present after feeling unwell for weeks or months. In surveys of populations with high rates of disease and poor access to medical care, a history of cough for more than 3 weeks was strongly associated with a diagnosis of active tuberculosis. Untreated tuberculosis is associated with high mortality, but many patients may have persistent symptoms for years. A study of untreated pulmonary tuberculosis in the pre-therapy era found that after 5 years 50 per cent of patients had died, 25 per cent had spontaneously healed, and 25 per cent were chronically ill with pulmonary disease. A subset of patients have rapidly progressive disease, the so-called 'galloping consumption' of old. This is now most often seen in patients with HIV infection or other forms of severe immunosuppression. These patients have progressively severe pulmonary symptoms over a period of several weeks, often in the setting of disseminated disease. Failure to diagnose and treat these patients promptly may result in death.

Physical findings in pulmonary tuberculosis may be of limited usefulness in making a diagnosis. Fever is an irregular and unreliable feature in tuberculosis. While most patients complain of fevers prior to presentation, only one-half to three-quarters of patients with confirmed tuberculosis have a documented fever. Examination of the chest may reveal dullness to percussion and rales, although these findings are highly variable and non-specific. Signs of consolidation are usually absent. The classic post-tussive rales described in the last century are not often present and are not specific to tuberculosis. Patients with disseminated tuberculosis may have lymphadenopathy, hepatomegaly, or evidence of central nervous system involvement, but these are not generally seen in typical pulmonary tuberculosis. Clubbing and cyanosis are findings associated with prolonged and advanced pulmonary disease. Thus, the diagnosis of tuberculosis almost always rests on the patient's history and epidemiological characteristics, in conjunction with laboratory studies described below. The most important step in making a timely diagnosis of tuberculosis is to think of it in the first place.

Radiological evaluations play a critical role in the diagnosis of pulmonary tuberculosis. Disease due to *M. tuberculosis* can involve any portion of the lungs, and radiographic findings are usually only suggestive, not diagnostic, of tuberculosis. The typical radiological manifestations of pulmonary tuberculosis are upper lobe infiltrates that may show cavitation. *M. tuberculosis* exhibits a unique predilection for the upper zones of the lungs for reasons that are not well understood. Latent infection characteristically reactivates in the apical segments of the upper lobes, or the superior segments of the lower lobes. The infiltrates are often fibronodular and irregular, and may be diffuse and associated with volume loss. Cavities, when present, are rarely symmetrical and do not usually have air–fluid levels, such as those seen in pyogenic lung abscesses. Examples of the radiographic appearance of pulmonary tuberculosis are seen in Fig. 3.

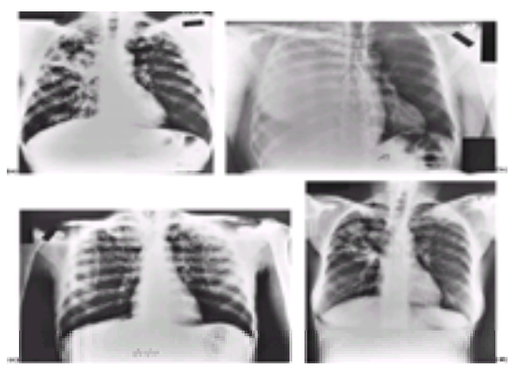

Fig. 3 Radiographic appearance of pulmonary tuberculosis. (a) Extensive tuberculosis with right upper lobe volume loss and multiple small cavities. This patient was the source of at least 14 secondary cases in contacts. (b) A 69-year-old man with right pleural tuberculosis. (c) Diffuse pulmonary nodules in an HIV-infected man with pulmonary tuberculosis. (d) Cavitary upper lobe disease in an HIV-infected woman.

The classic radiographic presentation described above is neither pathognomonic nor highly sensitive for pulmonary tuberculosis. A number of other lung infections, notably the pulmonary mycoses, can present with similar findings. More important, one-third to one-half of patients with pulmonary tuberculosis lack these classic radiographic findings. Lower lung zone infiltrates, mid-lung focal infiltrates, pulmonary nodules, and infiltrates with mediastinal or hilar adenopathy are also seen. In particular, HIV-infected patients with tuberculosis tend to present with 'atypical' findings, and up to 5 per cent of them may have a normal chest radiograph but sputum cultures that yield *M. tuberculosis*. The lack of typical radiographic features is not, therefore, grounds for rejecting the diagnosis in a patient with a history and symptoms compatible with tuberculosis.

Computed tomography (CT) is increasingly used to evaluate radiographic findings that are not readily explained after an initial assessment. They may reveal more extensive involvement than conventional radiographs, including multiple nodules, small cavities, and multilobar infiltrates.

The laboratory diagnosis of pulmonary tuberculosis relies on examination and culture of sputum or other respiratory tract specimens. Definitive diagnosis requires growth of *M. tuberculosis* from respiratory secre-tions, while a probable diagnosis can be based on typical clinical and radiographic findings with either sputum positive for acid-fast bacilli or other specimens, or typical histopathological findings on biopsy material. The specificity of these latter approaches depends on the prevalence of disease due to non-tuberculosis mycobacteria in the population.

Throughout most of the world, acid-fast staining of sputum is the sole test available to confirm the diagnosis of pulmonary tuberculosis. In developing countries, the positive predictive value of the sputum acid-fast smear is very high, as the likelihood of non-tuberculous mycobacterial disease is quite low. In industrialized countries, disease due to the non-tuberculous mycobacteria is relatively more common and reliance on smears without cultures is potentially misleading. Despite the best efforts of clinicians, a confirmed diagnosis of tuberculosis cannot be established in some patients who have the disease, and a response to presumptive therapy forms the basis for establishing the diagnosis.

Extrapulmonary tuberculosis

In the United States, extrapulmonary tuberculosis is defined as disease outside the lung parenchyma, and in the United Kingdom, as disease outside the lungs and pleura. This seemingly subtle distinction has considerable epidemiological significance, however, as pleural tuberculosis is the most common extrapulmonary site of disease in the United States.

During the initial seeding of infection with *M. tuberculosis*, described earlier, haematogenous dissemination of bacilli to a number of organs can occur. These localized infections, as in the lung, can progress into primary tuberculosis or become walled off in small granulomas where bacteria may remain dormant if they are not killed by cell-mediated immune responses. Extrapulmonary tuberculosis, therefore, can either be a presentation of primary or reactivation tuberculosis.

Extrapulmonary tuberculosis may be generalized or confined to a single organ. In otherwise immunocompetent adults, extrapulmonary tuberculosis is found in 15 to 20 per cent of all tuberculosis cases. In young children and immunosuppressed adults, rates of extrapulmonary disease are substantially higher. It is seen in more than half of patients with HIV-related tuberculosis and one-quarter of patients with tuberculosis under 15 years of age. Children less than 2 years old have high rates of miliary and meningeal disease.

The organs most frequently involved are listed in Table 3. To some extent the frequency with which specific organs are involved reflects the pathophysiology of the disease. Infection spreads from the lungs, the primary site of inoculation, by lymphatic and haematogenous routes, to the pleura, lymph nodes, kidneys and other genitourinary organs, bone, and central nervous system. Bacteraemia is transient and rarely detected except in patients with HIV infection and low CD4 lymphocyte

counts.

Both pulmonary and extrapulmonary disease are found in up to 50 per cent of patients with HIV-related tuberculosis, so it is important to consider the possibility of extrapulmonary pathology when pulmonary tuberculosis is diagnosed in an HIV-infected patient (and vice versa). Pulmonary involvement is seen in up to one-quarter of patients with tuberculous meningitis and less frequently with other sites of disease.

Pleural tuberculosis

This is the result of two distinct pathophysiological sequences, which present in strikingly different manners. Most pleural tuberculosis is associated with primary infection, and is the result of seeding of the visceral pleura with relatively small numbers of tubercle bacilli via direct extension from adjacent lung tissue. A large proportion of patients with this form of tuberculous pleurisy will have evident pulmonary disease, although findings may be subtle. The duration of symptoms is generally brief, usually several weeks. Patients complain of fever, chest pain, and non-productive cough. Other constitutional and respiratory symptoms may be present. Unlike pneumococcal pneumonia, which presents abruptly, tuberculous pleurisy has a more insidious onset.

The second form of pleural tuberculosis occurs when larger numbers of bacilli invade the pleural space and multiply, producing frank empyema. Tuberculous empyema is seen in older patients, almost all of whom have extensive pulmonary disease. Patients present with prolonged cough, chest pain, fever, cachexia, and night sweats. Pneumothorax is a common complication that may be associated with a more rapid disease course.

The radiographic picture in tuberculous pleurisy reflects the underlying pathophysiology of the disease. Patients with the primary type of pleurisy tend to have small, unilateral effusions, and up to half have visible parenchymal lesions on plain radiographs. In patients with tuberculous empyema, the effusions are larger, more likely to be loculated, and adjacent pulmonary involvement is often evident.

When pulmonary parenchymal involvement is manifest, sputum smears and cultures are likely to be diagnostic and pleural disease can be inferred from the pulmonary findings. When pulmonary findings are minimal, or the initial test results unrevealing, analysis of pleural fluid is essential. Acid-fast stains of pleural fluid are most often negative in patients with primary tuberculous pleurisy, as few organisms are present. Repeated sampling will show organisms in less than half of cases. Similarly, cultures may be negative. The pleural fluid is usually serous and exudative, with a protein concentration that is more than 50 per cent of the serum level, normal or low glucose, and a slightly acidic pH. The white blood cell count of the pleural fluid is usually in the range of 1000 to 10 000/µl, with a lymphocytic predominance. Lactate dehyrogenase and adenosine deaminase levels are generally elevated. These tests are non-specific and cannot reliably distinguish tuberculous pleurisy from other pleural diseases.

Percutaneous biopsy of the pleura reveals granulomatous inflammation in up to 80 per cent of cases, and cultures obtained at the time of biopsy are positive in over half of patients. If a first attempt fails to provide a diagnosis, a second biopsy may be successful. Compared with blind sampling with a percutaneous pleural needle, viewing biopsy targets by thorascopy improves the diagnostic yield.

Lymphatic tuberculosis

This can occur in any location, but classic scrofula, involving the cervical or supraclavicular chains, is the most common presentation. Mediastinal and hilar lymphatic tuberculosis is a feature both of primary and disseminated disease, but discovery of these lesions is usually incidental. Lymphatic tuberculosis is thought to result from drainage of bacilli in the lungs into supraclavicular and posterior cervical lymph node chains. In contrast, lymphatic disease caused by non-tuberculous mycobacteria more often involves anterior cervical, preauricular, or submandibular lymph nodes, suggesting acquisition through the oropharynx. In patients with HIV infection, many groups of lymph nodes may be involved, including axillary, inguinal, mesenteric, and retroperitoneal.

Symptoms in lymphatic tuberculosis are generally limited, unless the disease is disseminated. Painless swelling of a lymph node is the most common presentation. Constitutional symptoms are not prominent in most cases. Examination of the area may reveal several enlarged lymph nodes, as only about 20 per cent of patients have disease of a solitary node.

The diagnosis of lymphatic tuberculosis usually depends on cultures from affected nodes. Biopsies may show granulomatous changes and acid-fast bacilli. Such findings are non-specific, however, and cannot distinguish tuberculous from non-tuberculous lymphadenitis. As discussed elsewhere, the presence of a positive tuberculin skin test with typical biopsy findings is strongly suggestive of tuberculosis. If lymphatic tuberculosis is suspected, these findings warrant presumptive therapy.

Genitourinary tuberculosis

This encompasses a broad array of clinical entities, ranging from disease of the kidneys to endometrial, prostatic, and epididymal disease. The most common of these is renal tuberculosis, which results from haematogenous seeding of the renal cortex during the primary infection. The pathogenesis of other genitourinary sites is either from downstream extension of renal infection over time or from haematogenous seeding at the time of the initial acquisition of *M. tuberculosis*.

Renal tuberculosis is probably underdiagnosed because it is frequently asymptomatic. Many cases are diagnosed as a result of routine detection of sterile pyuria. The development of symptoms reflects a more advanced stage of disease, associated with considerable tissue destruction. When genitourinary tuberculosis is symptomatic, the most common complaints are localized, including urinary symptoms and flank pain. In men, tuberculosis can cause prostatitis and epididymitis, both of which can present with pain resulting from swelling. In women, genital tract tuberculosis may be symptomatic when it involves the ovaries and fallopian tubes; pelvic pain is also a feature of endometrial tuberculosis. However, menstrual abnormalities and infertility may be the only signs of genital disease.

The diagnosis of genitourinary tuberculosis depends on the anatomical site of the disease. Renal tuberculosis, suggested by sterile pyuria, is diagnosed by isolation of organisms in the urine. Early morning urine is more likely to grow *M. tuberculosis* than spot samples obtained at other times. In patients with symptoms of upper urinary tract illness, radiological studies are often helpful. The kidneys may appear calcified on abdominal radiographs. Intravenous pyelography may show distorted or dilated calyces or renal pelvis, papillary necrosis, cavitation or abscesses of the renal parenchyma, or intrarenal or ureteric obstructions. Use of renal ultrasound or CT scanning may be more sensitive for identifying the abnormalities of renal tuberculosis, but there is the greatest experience with contrast radiography. When tuberculosis of the bladder is suspected, cystoscopy with biopsy may lead to the identification of granulomas prior to identification of organisms by culture. Diagnosis of prostatic, testicular, or epididymal tuberculosis is usually accomplished with cultures obtained by fine needle aspiration or transurethral resection of the prostate. Cervical and endometrial tuberculosis can be diagnosed by biopsy with culture.

Tuberculous meningitis (see also Chapter 24.14.1)

This is the most common central nervous system manifestation of tuberculosis. It is much more likely to occur in children under the age of 5 and HIV-infected patients than in immunocompetent adults. Although meningitis accounts for only a small fraction of all cases of tuberculosis, it is a devastating form of the disease that is uniformly fatal if left untreated.

The pathogenesis of meningeal tuberculosis varies with the age and immunological status of the patient. Reactivation of microscopic granulomas in the meninges was found by Rich to cause diffuse meningeal infection. These foci of infection are probably implanted at the time of primary bacillaemia. When they rupture into the subarachnoid space they invoke an inflammatory response leading to tuberculous meningitis. Meningeal disease can also occur in conjunction with miliary disease, especially in children. Adults can acquire meningeal disease during bacillaemia of miliary disease, but this is not the usual pathogenesis of meningeal infection. Rarely, invasion into the spinal canal from a paraspinous or vertebral focus can be the source of central nervous system involvement.

Historically, the clinical spectrum of tuberculous meningitis has been categorized in three stages, defined by the British Medical Research Council in 1948. Stage 1 consists of a prodrome lasting for 1 to 3 months. Non-specific symptoms such as fever, malaise, and headache predominate. In this stage, patients are conscious and rational, but may have meningism. Focal neurological signs are absent and there are no signs of hydrocephalus. In stage 2 disease, single cranial nerve abnormalities, such as ptosis or facial paralysis appear, and paresis and focal seizures may occur. Kernig's and Brudzinski's signs and hyperactive deep tendon reflexes may be found. Prominent signs include altered cerebration, behavioural change, impaired cognitive ability, and increasing stupor. Headache and fever are common.

In stage 3, patients are comatose (Glasgow coma scale less than 8) or stuporous and often have multiple cranial nerve palsies and hemiplegia or paraplegia. By this stage, hydrocephalus is common and chronic inflammation in the enclosed space of the skull may result in intracranial hypertension. Seizures may be a prominent feature.

Fever, headache, changes in cerebration, and meningism are present in the majority of patients in most large studies, although no one single sign or symptom is reliably sensitive or specific. Children can be especially difficult to diagnose as symptoms such as fever, vomiting, drowsiness, or irritablity are commonly seen in many minor viral illnesses.

Transient tuberculous meningitis that presents as an aseptic meningitis and resolves without treatment has been described. Benign presentations of meningeal tuberculosis are exceedingly uncommon in clinical practice, and when the diagnosis is made, treatment is mandatory, even in the patient with seemingly trivial symptoms.

Diagnosis is often difficult and requires a high degree of suspicion. In disseminated disease, signs of tuberculosis in other organs, particularly the lungs, are often present. Between 25 and 50 per cent of patients with meningitis in most series also have radiographic evidence of pulmonary tuberculosis, either active or healed. The critical features of tuberculous meningitis, however, are found in the cerebrospinal fluid. Patients with tuberculous meningitis usually have elevated cerebrospinal fluid pressure. An exudative fluid with a mononuclear cell pleocytosis is characteristic. Cerebrospinal fluid is usually clear and the protein is generally in the range of 100 to 500 mg/dl. Hypoglycorrhachia is typical, with cerebrospinal fluid glucose less than 50 per cent of the serum value. The white blood cell count is rarely above1000/µl, and cell counts of below 500/µl are typical. In early meningitis the cells may be predominantly neutrophils, but mononuclear cells predominate in most instances. Acid-fast stains of concentrated cerebrospinal fluid are only positive in one-third or fewer of patients, and cultures are positive in only one-half, although repeated sampling increases the yield.

The disastrous consequences of failing to diagnose tuberculous meningitis, coupled with the low yield of acid-fast stains and cultures from cerebrospinal fluid, has prompted the development of additional tests for establishing a diagnosis. Adenosine deaminase was initially reported to be exceptionally accurate for tuberculous meningitis. Subsequent experience, however, has found it to be insufficiently specific to distinguish tuberculosis from a variety of other acute and chronic meningitides. A number of other tests based on identification of mycobacterial antigens or specific antibodies have been evaluated, but none has been found to be reliable. Nucleic acid amplification tests such as the polymerase chain reaction (**PCR**) have great appeal, but the sensitivity and specificity of available assays are only moderately good. Thus, the diagnosis of tuberculous meningitis often rests upon the astute judgment of a clinician with a high degree of suspicion based on epidemiological and clinical clues. Presumptive therapy is frequently necessary.

Central nervous system tuberculomas are an unusual manifestation and are seen in a small proportion of patients with tuberculous meningitis. Tuberculomas are the result of enlarging tubercles that extend into brain parenchyma rather than into the subarachnoid space. Patients with HIV infection appear to have an increased risk of tuberculomas of the central nervous system, but the disease is far less common than toxoplasmosis, even in areas where tuberculosis is highly prevalent. Tuberculomas of the central nervous system may appear with clinical features of meningitis or of intracranial mass lesions. In the absence of meningeal involvement, seizures or headaches may be the only symptoms. The diagnosis is suggested by brain imaging; MRI is more sensitive than CT scanning. Biopsy of the lesion is required for diagnosis, and material should be submitted for histopathological staining and culture.

Bone and joint tuberculosis

This may affect a number of areas, but vertebral tuberculosis (Pott's disease) is the most common form, accounting for almost one-half of cases. Haematogenous seeding of the anterior portion of vertebral bone during initial infection sets the stage for later development of Pott's disease. Infection grows initially within the anterior vertebral body, then may spread to the disc space and to paraspinous tissues. Destruction of the vertebral body causes wedging and eventual collapse. Patients usually complain of back pain, with constitutional symptoms less prominent. Neurological impairment is a late complication, but delays in diagnosis are common and many patients experience neurological sequelae. Imaging studies of the spine most often reveal anterior wedging, collapse of vertebrae, and paraspinous abscesses. The diagnosis is established with bone biopsy or curettage, or by culture of the drainage from a paraspinous abscess.

Miliary tuberculosis and disseminated tuberculosis

These terms are used interchangeably to describe widespread infection and absent or minimal host immune responses. The term 'miliary tuberculosis' is derived from the classic radiographic appearance of haematogenous tuberculosis, in which tiny pulmonary infiltrates with the appearance of millet seeds are distributed throughout the lungs. Miliary tuberculosis is a more common consequence of primary tuberculosis infection than reactivation, and is seen more frequently in children and immunocompromised adults. Primary miliary tuberculosis presents with fever and other constitutional symptoms over a period of several weeks. Clinical evaluation may reveal lymphadenopathy or splenomegaly, and laboratory tests may show only anaemia. The chest radiograph is initially normal but later develops the typical miliary pattern. Involvement of multiple organ systems is the rule, most often the liver, spleen, lymph nodes, central nervous system, and urinary tract. Patients with reactivation of latent infection who present with miliary disease may have a more fulminant course although, without treatment, progression to severe disease is the rule in all patients. The diagnosis is made on tissue biopsy and culture, as sputum smears are often negative, reflecting the small numbers of bacilli typically present in respiratory secretions.

Other forms of extrapulmonary tuberculosis

These less common sites of infection are diagnosed by a combination of clinical suspicion and the results of biopsies and cultures. Abdominal, ocular, adrenal, and cutaneous tuberculosis are rarely encountered in the modern era, even in immunocompromised patients.

Laboratory diagnosis

Evaluation of patients for *M. tuberculosis* infection or disease relies on both non-specific and specific tests. Imaging studies, body fluid chemistry and cell counts, and histochemical staining, as described above, are useful and important tests for the diagnosis of tuberculosis. Specific studies for identifying mycobacterial infections include the tuberculin skin test, acid-fast microscopy, and mycobacterial culture.

Tuberculin skin testing

Tuberculin skin testing involves the intradermal injection of purified proteins of *M. tuberculosis* (purified protein derivative, or PPD tuberculin) that provokes a cell-mediated delayed-type hypersensitivity reaction, which produces a zone of induration. Tuberculin originated with Robert Koch, who prepared a tubercle sensitin that he thought would cure tuberculosis. Administration of Koch's tuberculin, of course, did not cure the disease, and hypersensitivity reactions to the agent were sometimes severe or fatal, bringing Koch great discredit.

Fortunately, it was recognized that because tuberculin induced reactions in people who were infected with tuberculosis, the substance might prove a better diagnostic test than treatment. Over a period of years, refinements were made in the preparation of tuberculins, and in 1939 Seibert and Glenn produced the reference lot of tuberculin, called PPD-S, which has served as the international standard. Current tuberculin preparations are composed of a variety of small tuberculous proteins derived from culture filtrates and stabilized with a detergent (Tween) to prevent precipitation. The standard dose of tuberculin is 5 tuberculin units (**TU**) of PPD-S, equivalent to 0.1 mg of tuberculin in a volume of 0.1 ml. Commercial and other tuberculin products are standarized against PPD-S to ensure bioequivalence.

Tuberculin testing is used to identify individuals with *M. tuberculosis* infection, and the test cannot distinguish those who have disease from those with latent infection. Intradermal injection of tuberculin into an infected individual invokes a delayed-type hypersensitivity response. Specific T lymphocytes sensitized to tuberculous antigens from prior *M. tuberculosis* infection cause a local reaction at the site of injection. Inflammation, vasodilatation, and fibrin deposition at the site result in both erythema and induration of the skin, the key feature of a tuberculin response. The result of tuberculin testing is categorized according to the amount of induration measured.

Tuberculin skin testing should be done by the Mantoux method, as this is the only technique that has been standardized and extensively validated. An injection of 0.1 ml of PPD-S is given intradermally in the volar surface of the forearm using a tuberculin syringe and small-gauge needle, causing a small wheal. Injection subcutaneously will result in uninterpretable results. Multipuncture devices should not be used. The amount of induration should be measured 2 to 5 days after the

injection; measurements performed precisely 48 to 72 h later are not essential. The transverse diameter of induration should be measured in millimetres using a ruler. The edge of the induration can be seen and marked, or the margins can be detected using the ballpoint pen method, in which the pen is rolled over the skin with light pressure and its progress is stopped at the demarcation of the indurated area.

Criteria for the interpretation of tuberculin skin tests vary according to clinical and epidemiological circumstances. Cut-offs for positive tests developed by the American Thoracic Society and the Centers for Disease Control and Prevention are listed in Table 4. A cut-off of 5-mm induration is used for those at high risk of tuberculosis infection, or at high risk of disease if infected. This category includes close contacts of infectious individuals and patients with radiographic abnormalities consistent with tuberculosis. The rationale for the 5-mm cut-off in these patients is their high pretest probability of being infected. A 5-mm cut-off is also used for HIV-infected patients and those immunocompromised by corticosteroids or other agents. Failure to diagnose tuberculosis infection in these people could be calamitous, so a lower threshhold is used to maximize sensitivity. The use of control antigens such as *Candida* or tetanus toxoid to aid the interpretation of tuberculin tests in HIV-infected patients has been shown to be of no value and is not recommended.

A cut-off of 10-mm induration is used for people from populations with a high prevalence of tuberculosis or for people with conditions that increase the risk of developing active disease if infected. This would include immigrants from endemic areas, residents of some inner cities, and health care workers, as well as patients with diabetes, renal disease, silicosis, and other medical onditions associated with an elevated risk of reactivation of latent tuberculosis. Finally, a cut-off of 15 mm is used in people who have no risk factors for tuberculosis infection or disease. These people are unlikely to be tested.

Tuberculin skin testing is frustratingly crude and somewhat cumbersome, but has proved superior to numerous more 'modern' assays, including antibody tests, quantitative interferon-g detection assays, and other *in vitro* immunodiagnostics. Recently, the use of Elispot assays to detect antigen-recognizing T cells has shown promise as an alternative to tuberculin testing, although further validation is required.

The test does suffer, however, from limitations in both sensitivity and specificity. The 5-TU dose of tuberculin used diagnostically is based on studies in the 1940s that showed that 99 per cent of patients with chronic tuberculosis responded to this dose, while less than 20 per cent of persons without disease and no history of tuberculosis exposure had a response. Subsequent research suggested that the lack of specificity of tuberculin testing may be the result of cross-reactions due to exposure to non-tuberculous mycobacteria. Use of tuberculin derived from *M. avium intracellulare* (PPD-B), for example, induces larger reactions than PPD-S in healthy people from areas where this organism is widespread in the environment. Another important cause of non-specific reactions to tuberculin is vaccination with BCG (bacille Calmette–Guérin). While the reactogenicity of BCG vaccine differs according to the strain, immunization with BCG can produce falsely positive skin test results. Reactions induced by BCG tend to be smaller than true positive reactions, and wane over a period of several years. Studies in populations with high rates of BCG coverage indicate that tuberculin testing can still be used to predict those who are most likely to be infected with *M. tuberculosis*, even though precision is reduced because of cross-reactions.

False-negative tuberculin tests result from both errors in applying and interpreting the test and from anergy. Errors in injection of tuberculin are common, and inter-reader variability in measuring results is high. Fortunately, if there is doubt about the interpretation of a skin test, multiple readers can measure the result over a period of days, or the test can be repeated and reinterpreted. Specific anergy to tuberculin is seen in several situations. Approximately 10 to 20 per cent of patients with culture-confirmed pulmonary tuberculosis fail to respond to tuberculin as a result of anergy. These patients will often mount a response after their disease has been treated. HIV-infected patients have a high prevalence of anergy, both to tuberculin and other antigens. Only 10 to 40 per cent of patients with low CD4 counts and confirmed tuberculosis respond to tuberculin. Transient anergy is associated with acute viral infections such as measles, or live virus vaccinations, and other acute medical illnesses.

Microscopic staining

Microscopic staining of acid-fast bacilli is the method most widely used to diagnose tuberculosis throughout the world. Acid-fast staining is inexpensive, rapid, and technologically undemanding, making it an attractive technique for identifying mycobacterial infections. The waxy glycolipid matrix of the mycobacterial cell wall is resistant to acid-alcohol decolorization after staining with carbolfuchsin dyes, and red bacilli are visible after counterstaining. Both the Ziehl–Neelsen method (which requires heat fixation) and the Kinyoun method utilize methylene blue or malachite green counterstains, and have similar sensitivities for identifying acid-fast bacilli in clinical specimens.

The major limitation of acid-fast staining is that a relatively large number of bacilli must be present to be seen microscopically. Acid-fast smears are generally negative when there are fewer than 10 000 bacilli/ml of sputum, and many microscope fields need to be examined to identify bacilli even when there are 10 000 to 50 000 bacilli/ml. Thus, up to 50 per cent of patients with sputum cultures positive for *M. tuberculosis* have negative acid-fast smears. Where the sputum smear is the only test performed to confirm tuberculosis, a large number of smear-negative cases go unde-tected. This is a serious problem for patients without cavitary tuberculosis, who tend to have fewer bacilli in their sputum, including many HIV-infected patients with tuberculosis in developing countries.

Several techniques can be used to improve the yield of sputum smears. The most important method is enrichment of the specimen through concentration of the sputum. Centrifugation of sputum allows examination of the bacilli-rich pellet, which improves the sensitivity of smears substantially. Treatment of sputum with mucolytic agents is also helpful in identifying organisms by both smear and culture. Use of fluorochrome procedures to identify mycobacteria is more sensitive, but less specific, than acid-fast stains. Auramine O or auramine-rhodamine dyes are used on concentrated smears and examined under a fluorescence microscope. This technique allows much more rapid screening of slides that the traditional methods, but confirmation of positive results with Ziehl–Neelsen or Kinyoun staining is essential, as false-positive fluorochrome results are not uncommon.

The proper collection of specimens is also important for optimizing the results of microscopy and culture. Early morning sputum specimens tend to have a higher yield than specimens collected at other times, and overnight sputum collections provide even greater sensitivity. Morning gastric aspirates have a moderate yield for acid-fast bacilli in children, who generally have a difficult time producing sputum. Sputum induction with hypertonic saline is useful in evaluating patients with minimal or no sputum production, and the use of fibreptic bronchoscopy is often advocated for patients with negative sputum smears. In several series, however, the yield of post-bronchoscopy spontaneous sputum samples was higher than the bronchoalveolar lavage fluid. While the goal of sputum collection is to collect a pure lower respiratory tract sample, specimens that appear to consist primarily of upper respiratory tract or oral secretions often are smear or culture positive in patients with pulmonary tuberculosis.

Examination of multiple specimens increases the sensitivity of sputum microscopy for acid-fast bacilli. The first smear identifies 70 to 80 per cent of patients, the second another 10 to 15 per cent, and the third another 5 to 10 per cent. Review of additional specimens has little value.

In addition to the modest sensitivity of acid-fast staining, the specificity of this technique can also present problems. The morphological properties of the mycobacteria are sufficiently similar to make distinguishing *M. tuberculosis* from non-tuberculous mycobacteria impossible on the basis of acid-fast smears. This is not a serious concern where tuberculosis is common and non-tuberculous mycobacterial infections are unusual. However, in many industrialized countries, disease due to the non-tuberculous mycobacteria is relatively common compared with tuberculosis, and distinguishing these types of infections has important therapeutic and public health implications. Thus, while sputum microscopy is useful because of its rapidity and low cost, it should be supplemented with culture or other more sensitive and specific tests whenever feasible.

Culture, nucleic acid amplification, and susceptibility testing

Cultivation of *M. tuberculosis* in the laboratory is the gold standard for confirming the diagnosis of tuberculosis. A variety of media are available that support the growth of mycobacteria, including egg- and potato-based solid media and several broth-based media. The intrinsic growth rate of *M. tuberculosis* makes the recovery of the organism in culture a slow process. In traditional egg-based media such as Lowenstein–Jensen, growth of colonies of *M. tuberculosis* takes between 3 and 6 weeks, and 7H11 agar requires an average of 3 to 4 weeks to show colonies. Obviously, the glacial pace of these traditional culture systems interferes with optimal patient management, and more rapid techniques are required.

Several faster (not rapid) systems for detection of mycobacteria in culture have been commercially developed. The radiometric BACTEC system (BD Biosciences) utilizes ^{14}C palmitate in 7H12 broth to detect mycobacterial growth more quickly. Uptake and metabolism of the palmitate by mycobacteria releases $^{14}CO_2$ which is detected radiometrically. The relative amount of $^{14}CO_2$ produced is used to calculate a growth index, which is considerably more sensitive than visual inspection of colonies on agar. The average time to positive culture by BACTEC is 8 to 12 days, rather than the 3 to 4 weeks required with conventional media. The technology is

automated so that regular visual inspection of culture bottles is not required, but BACTEC systems are expensive and require radioisotopes.

The Septi-Chek system combines solid and broth media. The Mycobacterial Growth Indicator Tube (MGIT) is a broth-based system that uses automated fluorescence detection to monitor growth. Both systems are more rapid than conventional culture.

Many clinical laboratories use more than one culture system for mycobacteria, both to increase the overall recovery rate and to provide quality control. In addition, if one culture becomes contaminated, alternative cultures can still be utilized.

Preparation of specimens for mycobacterial culture follows the same steps as outlined for acid-fast smears. In addition, specimens being submitted for culture also require decontamination to prevent overgrowth by more rapidly multiplying bacteria. Sodium hydroxide and *N*-acetyl-L-cysteine are commonly used together for mucolysis and decontamination. By necessity, decontamination also inactivates more than 50 per cent of mycobacteria in a specimen, thereby reducing the potential yield of the culture. Failure to decontaminate, however, leads to bacterial overgrowth and uninterpretable results. Lack of growth as a result of over-decontamination and bacterial overgrowth resulting from under-decontamination emphasize the importance and utility of obtaining multiple specimens for culture, when possible. As with sputum smears, the yield of mycobacterial culture increases with evaluation of additional specimens.

After mycobacterial growth has been identified, speciation of the organism is required. Conventional techniques for identification involve characterization of colony morphology, pigmentation, rate of growth, and biochemical tests. Niacin reduction, nitrate reduction, and lack of catalase activity at elevated temperatures are all characteristic of *M. tuberculosis*. Species identification using these methods is time consuming and tedious, and further delays the diagnosis of tuberculosis.

The use of nucleic acid probes has dramatically simplified species identification of mycobacteria over the past decade. DNA probes that react with specific mycobacterial rRNA sequences to form DNA–RNA hybrids that can readily be detected by chemoluminescence are commercially available for *M. tuberculosis*, *M. avium* complex, *M. kansasii*, and *M. gordonae*. These tests can be performed within hours of detection of mycobacterial growth, and accelerate the diagnosis of specific pathogens. The sensitivity of these probes is approximately 90 to 95 per cent, depending on the species, with specificities approaching 100 per cent. Cultures that fail to respond to any of the DNA–RNA probes are almost always due to another mycobacterial species, but final identification depends on the traditional laborious biochemical techniques.

The difficulties of identifying mycobacteria in patient specimens accentuate the need for rapid and sensitive diagnostic methods for tuberculosis. If any infection seems suited to diagnosis by nucleic acid amplification assays, it would appear to be tuberculosis. Multiple studies of 'in-house' PCR assays for *M. tuberculosis* have shown modest sensitivity and specificity. PCR inhibitors in sputum have been a knotty problem in the molecular diagnosis of pulmonary tuberculosis, although the sensitivity has been lower than that of culture in non-respiratory specimens as well. Recently, several commercial nucleic acid amplification tests have been introduced or are nearing approval, including assays based on RT-PCR, transcription-mediated amplification, ligase chain reaction, and strand displacement amplification. All of these techniques use specific *M. tuberculosis* DNA sequences (most use the *M. tuberculosis* transposon *IS*6110) as targets for nucleic acid amplification. The great advantage of these assays is that they can provide results within 1 day of the collection of specimens. Their disadvantage is that they are uniformly less sensitive than culture, particularly in patients who have negative sputum smears. Early studies of these techniques have suggested that specificity was excellent overall but was reduced in smear-positive samples; further refinement in these assays has resulted in improved sensitivity and specificity.

Evaluation of nucleic acid amplification assays under field conditions has generally shown favourable results. When using these tests, however, clinicians must not forget fundamental clinical and epidemiological principles governing the diagnosis of tuberculosis: a negative test in a patient suspected of having tuberculosis should not exclude the diagnosis, nor should a positive test confirm it if clinical circumstances do not support the diagnosis. While both the positive and negative predictive values of nucleic acid amplification tests are high (70 to 90 per cent and over 90 per cent, respectively), misclassification of patients does occur, and it is important to use mycobacterial culture to validate the results of these rapid assays.

Drug susceptibility testing of *M. tuberculosis* isolates is essential for both clinical management and public health purposes. Susceptibility tests for the first-line antituberculosis drugs should be performed on at least one culture at the time of diagnosis for all patients. If the initial isolate is susceptible to the first-line agents, and treatment proceeds without incident, additional susceptibility tests are not required. Susceptibility testing should be performed for patients who relapse with tuberculosis and for patients whose treatment is a failure after 3 to 4 months of therapy.

Susceptibility testing for *M. tuberculosis* uses standard concentrations of antituberculosis drugs to measure inhibition of bacterial growth in culture. Drugs tested routinely include isoniazid, rifampicin, pyrazinamide, ethambutol and streptomycin. Testing of second-line antituberculosis drugs is only done when resistance to the first-line agents is documented or strongly suspected.

Susceptibility testing is generally performed on subcultures of the primary isolate, although direct inoculation of sputum or other specimens can be performed in the case of a strongly positive acid-fast bacilli smear. The standard method for measuring susceptibility to antituberculosis drugs is the proportions method. The organism is grown on agar plates in the presence of known concentrations of specific drugs. Growth on the plates is then compared with growth on control plates. By convention, if the test plate shows a colony count that is more than 1 per cent of the control value, the isolate is resistant. Laboratories will report the isolate as being susceptible or resistant to the concentration of the drug used in the assay.

An alternative method for susceptibility testing is the BACTEC system, in which culture bottles contain antituberculosis drugs. Growth indices are compared with control cultures to determine susceptibility. The BACTEC system provides results more quickly than the proportions method, is automated, but is more expensive. Other automated commercial culture systems have also been developed for determining drug susceptiblity.

The use of molecular methods to determine drug susceptibility is promising but not currently in routine use. Specific mutations in *M. tuberculosis* have been identified which confer resistance to antituberculosis drugs. For example, mutations in a small region of the *rpo*B gene of *M. tuberculosis* are responsible for more than 90 per cent of all rifampicin resistance. Sequencing of this portion of the genome using a variety of techniques has been shown to be feasible in research laboratories. Rapid identification of rifamicin resistance would be of enormous clinical benefit, as almost all rifampicin-resistant *M. tuberculosis* isolates are also resistant to isoniazid and, by definition, multidrug resistant. Molecular diagnosis of other types of resistance is more difficult, as the genetic basis of resistance to other drugs is either heterogenous or not completely understood.

Treatment of active tuberculosis

The treatment of tuberculosis requires the use of a combination of antimycobacterial drugs active against the strain of *M. tuberculosis* causing the patient's disease. The use of multiple agents is necessitated by the emergence of drug resistance when single agents are used. Mutations that confer resistance to antimycobacterial drugs arise spontaneously in wild-type populations of *M. tuberculosis* in frequencies ranging from 1 in 10^5 to 1 in 10^8 bacilli. When there are large numbers of organisms, such as are present during active pulmonary disease, a single agent will kill susceptible bacilli, but naturally drug-resistant mutants will survive and eventually emerge to cause drug-resistant disease. Since the mechanisms of resistance are genetically distinct and arise independently, multiple drug resistance within a single organism is exceedingly rare in nature. The use of two or more agents with different mechanisms of action assures that populations of drug-resistant bacilli are not selected for during therapy.

Drugs for tuberculosis are divided into first-line and second-line agents. First-line agents are widely available and used routinely in the treatment of tuberculosis, while second-line agents are generally less potent, more toxic, and less readily available. An exception to this is the fluoroquinolones, which appear to have moderately good antituberculosis activity and are widely available; their utility in tuberculosis, however, remains unstudied. Second-line drugs are reserved for the treatment of drug-resistant tuberculosis. Table 5 lists the first-line antituberculosis drugs, their activity in the treatment of tuberculosis, and common toxicities.

Regimens currently used for the treatment of tuberculosis are based in part on trials conducted by the British Medical Research Council over the past 30 years. By combining drugs that target both rapidly growing bacillary populations and slow-growing or semi-dormant organisms within cells, modern short-course chemotherapy can successfully cure drug-susceptible pulmonary tuberculosis in 6 months. The regimens recommended for treatment of drug-susceptible tuberculosis are shown in Table 6. Treatment of extrapulmonary tuberculosis is generally for the same duration as for pulmonary disease, with the exceptions of bone and joint and central nervous system tuberculosis, which are treated for 12 months. HIV-related tuberculosis is also treated for 6 months.

The dynamics of mycobacterial growth are such that treatment needs to be administered only once daily, and can be given as infrequently as twice per week. The long generation time of *M. tuberculosis* and a postantibiotic effect of antituberculosis drugs renders more frequent drug dosing unnecessary. The dosages for drugs

are listed in Table 7 according to the frequency with which they are administered.

Isoniazid is a key component of treatment because of its high bactericidal activity. Rifampicin is essential for short-course therapy because it is active against all populations of bacilli, both within and outside cells. Pyrazinamide is uniquely active during the first 2 months of therapy, but appears to have no activity thereafter. The addition of pyrazinamide to the treatment regimen allows the duration of therapy to be reduced from 9 to 6 months, however. Streptomycin has bactericidal activity against *M. tuberculosis*, and ethambutol has bacteriostatic activity at lower doses and bactericidal activity at high doses. These latter agents are given primarily to prevent the emergence of drug resistance, as they appear to add little activity to combination regimens against drug-susceptible tuberculosis.

Although antituberculosis therapy is remarkably well tolerated and almost always given to ambulant patients, important drug toxicities do exist. The most serious adverse drug reaction during tuberculosis treatment is liver toxicity, which may occur in up to 5 to 10 per cent of treated patients. Isoniazid, rifampicin, and pyrazinamide are all associated with liver toxicity. Use of these agents together increases the risk of a reaction. Isoniazid causes more hepatotoxicity than rifampicin or pyrazinamide, and is the agent most frequently implicated when reactions occur. Isoniazid can produce an idiosyncratic hepatocellular injury, manifested by elevated liver enzymes and clinical hepatitis. Elevation of transaminases does not always portend the development of hepatitis, but may serve as an important signal to anticipate clinical toxicity. The development of signs and symptoms of hepatitis, such as abdominal pain, nausea, vomiting, or jaundice, requires immediate discontinuation of isoniazid, as continuing treatment may result in death from hepatic failure. Risk factors for developing isoniazid hepatotoxicity include increasing age, chronic liver disease, alcohol abuse, daily dosing of isoniazid, and use of other hepatotoxic drugs, including rifampicin. In addition, people with a slow isoniazid-acetylation genotype are significantly more likely to develop hepatoxicity from the drug than intermediate or rapid acetylators.

Isoniazid interferes with metabolism of pyridoxine (vitamin B_6), which can result in a sensory neuropathy. Co-administration of pyridoxine with isoniazid abrogates this effect without compromising the antimicrobial activity.

Rifampicin also causes hepatotoxicity, although the characteristic picture of liver disturbances due to rifampicin is cholestasis. However, the incidence of hepatotoxicity when rifampicin is given with isoniazid is substantially greater than when isoniazid is given alone. Rifampicin predictably causes a discoloration of body fluids, resulting in orange-tinted tears, sweat, and urine. Haematological toxicity from rifampicin includes thrombocytopenia and anaemia. Higher doses of rifampicin may produce a hypersensitivity reaction, with fever, rash, and joint swelling. For this reason, doses of rifampicin are not escalated during intermittent therapy, whereas the intermittent dosages of the other drugs are increased to deliver weekly doses that are equivalent to daily dosing.

Pyrazinamide is often associated with arthralgias, and may precipitate gout. Pyrazinamide inhibits renal tubular excretion of uric acid, resulting in increased serum levels of uric acid. Frank gouty arthritis is relatively uncommon with pyrazinamide use, and its frequency is reduced with intermittent dosing. Routine use of allopurinol to prevent gout is not recommended.

The major toxicity of ethambutol is optic neuritis, which is common at doses above 30 mg/kg daily and unusual at doses below 25 mg/kg daily. Patients receiving ethambutol should have baseline tests of visual acuity and colour discrimination, with monthly monitoring while on treatment. Ethambutol use is discouraged in children under 7 years old because of their inability to report visual disturbances reliably. The incidence of optic neuritis with the doses of ethambutol typically used is so low that use in young children is only relatively contraindicated.

Streptomycin was a staple of antituberculosis therapy for many years, but its use has been greatly curbed in recent years. A number of studies have demonstrated that regimens containing isoniazid, rifampicin, and pyrazinamide are equally efficacious with or without streptomycin. Streptomycin is given by intramuscular injection, causing discomfort to patients and creating an infection risk for patients and health care workers. In addition, streptomycin can be ototoxic and nephrotoxic. Consequently, ethambutol has replaced streptomycin in many parts of the world.

Patients receiving therapy for tuberculosis require regular monitoring to assess compliance, clinical response, and adverse reactions. In the initial phase of therapy, monitoring by a nurse or other trained clinician at least weekly is recommended, and supervision of every dose of medication is suggested by the World Health Organization and other authorities (see below). Patients should be observed for clinical responses, including defervescence, improvement in cough and appetite, and weight gain. Improvement in these symptoms and signs may take several weeks, but usually occurs within 3 weeks after starting treatment. Failure to improve suggests that the patient is not adhering to treatment, has drug-resistant tuberculosis, or has another illness in addition to or instead of tuberculosis.

Treatment response should also be documented with repeated sputum smears and cultures and a follow-up chest radiograph after 2 to 3 months (for pulmonary tuberculosis). All patients should have a repeat sputum smear and culture after 2 months of therapy; those who are smear or culture positive at 2 months should have another at 3 months. Failure to convert sputum smears and cultures to negative with 3 months of therapy is associated with a high risk of treatment failure; patients who are still smear or culture positive at 4 months of treatment are considered to have experienced treatment failure and should be evaluated for drug-resistant disease. A culture at the end of therapy is recommended to document cure, while a radiograph at this time is not necessary.

Monitoring for drug toxicity is also required throughout therapy. At least monthly monitoring for symptoms and signs of liver toxicity is essential, and patients should be advised to stop therapy and seek care if evidence of hepatitis is noted. Routine liver enzyme monitoring is recommended primarily for patients with underlying liver disease or baseline abnormalities in liver enzymes. Patients with symptoms of hepatitis, of course, should have liver studies obtained. As noted above, monthly visual assessment is also recommended when ethambutol is given.

For more than 40 years, experts in tuberculosis have noted that the success of treatment depends largely on adherence to therapy. Poor adherence to therapy is responsible for treatment failures, early relapses, and the emergence of drug-resistant disease. Two major interventions to improve adherence and prevent bad outcomes are directly observed therapy (**DOT**) and the use of fixed-dose combination tablets. DOT was first promoted in the 1950s in India, and experience with DOT grew over the ensuing years. Intermittent dosing of tuberculosis therapy, along with the relatively short course of treatment, make supervision of treatment feasible in many situations. Ecological and programmatic studies of DOT programmes have shown that their introduction improves cure rates for tuberculosis, reduces non-compliance, and reduces the emergence of drug-resistant disease. Two observational studies have shown better survival of HIV-infected patients with tuberculosis who receive DOT.

On the other hand, two randomized trials of DOT in developing countries have not found improved treatment completion rates compared with self-administered treatment. These trials have been criticized for demonstrating only that even DOT can be carried out badly, but the lack of randomized studies documenting that DOT *per se* leads to improved outcomes is of some concern. The data from observational studies are compelling, however, and DOT is strongly encouraged by many experts and professional organizations.

The use of fixed-dose combination tablets is intended to reduce the risk of selecting for drug resistance, as opposed to improving adherence generally. By combining two, three, or four medications in the same tablet, depending on the regimen being used, the opportunity for patients to receive partial treatment that would select for drug resistance is avoided. The bioequivalence of fixed-dose combinations to individual medications has been established for some, but not all, of the combination products on the market.

The catastrophic state of global tuberculosis control led the World Health Organization (**WHO**) to develop the **DOTS** strategy (or directly observed therapy, short-course). This strategy is a series of policies related to national tuberculosis control practices. The five elements of the DOTS strategy are:

1. governmental commitment to tuberculosis control;
2. a reliable supply of tuberculosis drugs;
3. diagnosis of tuberculosis cases microscopically;
4. a registration system for tracking the outcomes of treatment; and
5. supervision (DOT) of at least the first 8 weeks of treatment.

The DOTS strategy has been extremely successful in focusing attention on serious problems in tuberculosis treatment and control, and implementation of the programme in a number of countries has produced remarkable improvements in clinical outcomes for patients with tuberculosis. There is strong evidence that the use of the DOTS strategy results in lower rates of drug-resistant tuberculosis. None the less, the WHO estimates that in 2000 only 25 per cent of patients with tuberculosis in the world were treated within a DOTS programme. Further expansion of the DOTS strategy and improvements in tuberculosis treatment programmes are clearly needed.

The treatment of drug-resistant tuberculosis is beyond the scope of this chapter. Patients with drug-resistant tuberculosis should be managed by a physician who is a tuberculosis expert. Supervised therapy is considered mandatory for patients with resistant tuberculosis. Physician mistakes remain one of the leading causes of the emergence of drug resistance, and the identification of a drug-resistant isolate of *M. tuberculosis* should result in immediate expert consultation.

Treatment of latent tuberculosis infection

Prevention of tuberculosis with isoniazid therapy was first documented in children in the mid-1950s. Subsequently, a number of controlled trials of isoniazid chemoprophylaxis were undertaken, and its efficacy firmly established. A meta-analysis of 11 placebo-controlled trials of isoniazid, involving more than 70 000 persons, found that treatment reduced tuberculosis incidence by 63 per cent. Among patients who adhered to more than 80 per cent of the isoniazid regimen, protection was 81 per cent. These studies also showed that isoniazid chemoprophylaxis reduced tuberculosis deaths by 72 per cent. The efficacy of isoniazid therapy in preventing tuberculosis in high-risk persons is incontrovertible.

Enthusiasm for isoniazid chemoprophylaxis was considerably dampened in the late 1960s and early 1970s when drug-related hepatotoxicity, including deaths, was observed. A number of studies based on decision analysis or modelling suggested that the risks of chemoprophylaxis might outweigh the benefits, and use of preventive therapy was curtailed or ignored in many settings. Because the risk of isoniazid-related hepatotoxicity increases with age, use of chemoprophylaxis in people over 35 years old was particularly discouraged. The resurgence of tuberculosis in the developed world, particularly HIV-related tuberculosis, and the uncontrolled global epidemic have renewed interest in the use of preventive therapy in high-risk individuals.

The use of preventive therapy for tuberculosis now focuses on high-risk groups of individuals who are either known or strongly suspected to be latently infected with *M. tuberuclosis*. The term 'treatment of latent tuberculosis infection' is now preferred, emphasizing that preventive treatment is really targeted at an established infection. The American Thoracic Society and the Centers for Disease Control and Prevention published guidelines in 2000 on screening for latent tuberculosis that stress the importance of targeting efforts on populations and patients who would benefit from treatment to prevent active disease. In the past, screening for tuberculosis infection has been unfocused and often directed at patients who, if found to be infected, would have little risk of progressing to active disease. The new guidelines propose that only people with a high risk of disease or high prior probability of latent tuberculosis be tested, and that treatment be offered to infected individuals regardless of age. Individuals who should be targeted for tuberculin testing are those listed in the first two columns of Table 4, that is, those in whom a positive test is considered as 5- or 10-mm or more induration. People without risk factors for tuberculosis (those in whom a positive test is 15 mm or more) should not be tested.

Treatment regimens for latent tuberculosis are listed in Table 8, along with the rating given to the regimen by the American Thoracic Society (ATS) and Centers for Disease Control and Prevention (CDC). Isoniazid remains a favoured drug for tuberculosis preventive therapy because of its well-documented efficacy, low cost, and relatively low toxicity. The optimal duration of isoniazid therapy for latent tuberculosis has been the subject of extensive debate in the past 20 years. The International Union Against Tuberculosis and Lung Disease conducted a landmark trial in Eastern Europe in the 1970s and 1980s that compared no treatment with 3, 6, or 12 months of isoniazid in adults with fibrotic changes on radiography. The results showed that, compared with placebo, 12 months of isoniazid reduced the incidence of tuberculosis by 75 per cent, compared with 66 per cent for 6 months and 20 per cent for 3 months. In addition, patients who completed the 12 months of therapy and were judged to be compliant experienced a 92 per cent reduction in tuberculosis risk, compared with a 69 per cent decrease for compliant patients completing a 6-month regimen. A meta-analysis by the Cochrane Collaborative found that 12 months of isoniazid was more effective than 6 months for prevention of tuberculosis. A recent analysis of varying durations of isoniazid therapy in Alaskan natives revealed that the effectiveness of isoniazid therapy was optimal after 9 months, and that further treatment conferred no additional benefit. The new ATS/CDC statement, therefore, recommends 9 months of isoniazid as the preferred regimen, with 6 months considered an alternative, but less effective, course of treatment.

Although isoniazid is a well tolerated drug, serious hepatotoxicity can occur in a small proportion of patients. Isoniazid may result in asymptomatic elevations in hepatic transaminase levels, but this does not always signal impending clinical toxicity. Hepatotoxicity is of concern when symptoms of hepatitis, including pain, nausea, vomiting, and jaundice, develop. Continuing isoniazid in the presence of symptoms may lead to death from fulminant hepatic necrosis and liver failure, with a case–fatality rate of 10 to15 per cent. Studies in the 1960s and 1970s found evidence of hepatotoxicity in 1 to 5 per cent of isoniazid recipients, with higher rates among older patients. More recent experience with isoniazid therapy that is closely monitored shows a risk of hepatotoxicity in the range of 0.1 to 0.3 per cent. Thus, appropriate patient screening and follow-up makes the use of isoniazid for treating latent infection markedly safer.

One of the most important new developments in the treatment of latent tuberculosis is the development of alternative regimens that shorten the duration of treatment. Based on studies in animal models of latent tuberculosis, rifampicin alone given for 3 to 4 months, or rifampicin and pyrazinamide given for 2 to 3 months, were felt to be potentially active regimens and were tested in clinical trials. A 3-month regimen of rifampicin alone was found to reduce the incidence of tuberculosis by about 65 per cent in men with silicosis, and was more effective than 6 months of isoniazid. Three studies of rifampicin and pyrazinamide for latent tuberculosis in HIV-infected, tuberculin-positive patients have been carried out. In each of these studies, the combination of rifampicin and pyrazinamide was as effective as 6 or 12 months of isoniazid. A meta-analysis of the studies found rifampicin with pyrazinamide was equivalent to isoniazid for preventing active tuberculosis, with an odds ratio of 1.0.

Rifampicin with pyrazinamide is generally well tolerated, but can be associated with serious hepatotoxicity. However, the use of rifampicin does pose the risk of important drug interactions. For example, reduction in methadone concentrations caused by rifampicin can precipitate narcotic withdrawal. Moreover, rifampicin can lower levels of protease inhibitors and non-nucleoside reverse transcriptase inhibitors used to treat HIV infection. Substitution of rifabutin for rifampicin in patients receiving anti-HIV drugs is based on the observation that rifabutin is equally as efficacious as rifampicin in the treatment of active tuberculosis.

Candidates for treatment of latent tuberculosis are listed in Table 4. Criteria for treatment include a positive tuberculin test according to the categories in Table 4, elevated risk for developing active tuberculosis if untreated, and exclusion of active tuberculosis by clinical evaluation and chest radiography. In addition, HIV-infected and other severely immunocompromised persons who are contacts of a patient with infectious tuberculosis should be treated for latent tuberculosis regardless of tuberculin skin test results.

Patients receiving treatment for latent tuberculosis should be monitored for drug toxicity, as well as to promote adherence to therapy. As in the treatment of active tuberculosis, patients receiving isoniazid should be warned about signs and symptoms of hepatotoxicity and advised to discontinue therapy and seek care if any of these occur. Patients with or at risk for chronic liver disease should have baseline liver enzymes obtained, with monthly monitoring if the results are abnormal. All patients should be clinically evaluated at least monthly to assess toxicity and those receiving rifampicin and pyrazinamide more often. Treatment of patients with mild transaminase elevations (3 times upper limits of normal or less) can proceed with regular clinical and laboratory monitoring. Higher elevations of transaminases, or the development of symptoms or signs of hepatitis, should be managed with discontinuation of therapy at least temporarily. Patients who complete therapy for latent tuberculosis do not require any periodic monitoring for tuberculosis subsequently.

Prevention of tuberculosis

Strategies to control tuberculosis are aimed at the prevention of the spread of *M. tuberculosis* infection and the development of clinical tuberculosis. The principal approaches employed toward this end are:

1. identification and treatment of infectious tuberculosis cases;
2. treatment of latent tuberculosis infection;
3. prevention of exposure to infectious particles in air, especially in hospitals and other institutions; and
4. vaccination.

Case identification and treatment reduces transmission by rendering patients with communicable tuberculosis non-infectious. Patients with pulmonary tuberculosis produce infectious aerosols that may transmit tubercle bacilli to contacts breathing the same air. When cases are identified and treated, infectiousness is rapidly eliminated. The duration of treatment required to prevent further transmission of infection is not known precisely, but experimental, clinical, and microbiological data suggest that the level of infectiousness is reduced enormously within several days of beginning effective treatment. The number of secondary infections generated by a patient with infectious tuberculosis varies greatly, depending on the duration of illness, the extent of pulmonary pathology, the amount of patient coughing, and the environment into which the patient expels infectious aerosols. Early diagnosis and treatment reduces the number of secondary infections, while delays can result in ongoing transmission to large numbers of contacts. Failure to retain patients in treatment until they are cured also contributes to spread of infection.

Treatment of latent tuberculosis infection has been discussed above (Table 8). The benefit of treating latent infection is not only to the individual patient, who does not fall ill with tuberculosis, but also accrues to the potential contacts of that patient, who might become secondarily infected were disease to develop. Targeting of high-risk groups for screening and treatment of latent tuberculosis thereby reduces tuberculosis incidence within communities. Groups that should be targeted for screening are listed in the first two columns of Table 4.

Control of exposure to infectious aerosols can have a major impact on the spread of tuberculosis. In the late 1980s and early 1990s, transmission of tuberculosis, including multidrug-resistant tuberculosis, was widespread in hospitals, shelters for the homeless, and correctional facilities in New York City. The congregation of large numbers of highly susceptible people, especially HIV-infected persons, in closed environments with individuals with untreated tuberculosis resulted in numerous microepidemics of both drug-susceptible and drug-resistant tuberculosis. Reversal of the resurgence of tuberculosis in New York at that time was attributable in large part to strengthening of infection control practices.

Tuberculosis infection control involves prompt identification and isolation of patients with suspected tuberculosis. The decision to isolate a patient in a hospital setting is a function of epidemiological and clinical factors. Patients with known risk factors for tuberculosis who present with symptoms and signs characteristic of pulmonary tuberculosis should be placed in respiratory isolation. Local epidemiological data should influence isolation practices. Where tuberculosis is prevalent, all HIV-infected patients with pneumonia may require isolation, whereas isolation is more selective and based on individual patient features in low-prevalence settings.

Respiratory isolation requires nursing the patient in a room with negative air pressure relative to adjoining areas. Ventilation to the room should provide at least six complete air changes per hour, and air should not be recirculated without filtering or irradiation. Patients should be instructed always to cover their mouths when coughing, and should wear surgical face masks when outside the room to reduce aerosol generation. Anyone entering the patient's room should wear an appropriate face mask or respirator to prevent inhalation of droplet nuclei with tubercle bacilli. Much debate has occurred in recent years in the United States about what constitutes appropriate protection for health care workers exposed to infectious tuberculosis. This debate is influenced as much by philosophy as by science, and will not be detailed here. Use of surgical masks for protection against tuberculosis is clearly inappropriate, even though these masks are useful when placed on patients to prevent creation of infectious aerosols. Tightly fitting face masks that filter out more than 99.7 per cent of particles greater than 0.5 µm in size (high efficiency particle air—HEPA—filters) are effective. Other devices, including positive air pressure respirators (PAPRs), are also effective.

Ultraviolet germicidal irradiation can be useful for reducing the number of infectious particles in ambient air in settings where ventilation alone is not sufficient. Ultraviolet light must be concentrated in areas of rooms where exposure to people will not occur, such as upper air zones, in order to prevent skin and ocular toxicity. Areas where ultraviolet lights are often used include bronchoscopy suites, inside air circulation ducts, in emergency rooms, and in shelters for the homeless.

Criteria for discontinuation of respiratory isolation are listed in Table 9. Guidelines for taking patients out of isolation in the hospital are strict and are intended to protect other vulnerable patients and hospital staff from any exposure to the disease. Respiratory isolation is not usually required or practical in the home setting, and patients with infectious tuberculosis do not need to be admitted to hospital solely for respiratory isolation. It is assumed that contacts in the home environment will already have significant exposure to tuberculosis by the time a diagnosis is made, and isolation of the patient affords no measurable benefit. Exceptions to this may include patients living in congregate living facilities or other special situations. The primary protective measures for contacts of infected individuals are a clinical evaluation to identify and evaluate symptoms of tuberculosis and tuberculin skin testing, with treatment of latent infection if present.

Vaccination against tuberculosis with BCG vaccine is widely administered throughout the world, but remains controversial. BCG is an attenuated live bacterial vaccine developed in the early twentieth century by Calmette and Guérin at the Institut Pasteur. After a series of uncontrolled and anecdotal assessments of the vaccine, a series of controlled trials of BCG was begun in the 1930s and continued through the 1990s. The efficacy of BCG has varied greatly in these studies, ranging from more than 80 per cent protection to complete lack of protection, with possibly increased risk in vaccine recipients. A meta-analysis of BCG trials performed in the early 1990s found that the weighted protective benefit of BCG was about 50 per cent for both the prevention of active tuberculosis disease and death.

In addition to the protective efficacy observed in trials of BCG, there is evidence that BCG diminishes haematogenous dissemination of primary tuberculosis infection and thereby reduces the incidence of miliary tuberculosis and tuberculous meningitis in children. It is primarily for this reason that BCG is included in the Expanded Program on Immunization of the WHO.

The current efficacy of BCG for preventing pulmonary tuberculosis is debated on the basis of several recent trials which have failed to show protection. A number of hypotheses have been proposed for the variation in efficacy reported in various studies, including differences in susceptibility within populations, environmental exposure to mycobacteria which masks vaccine effect, and attenuation of vaccine immunogenicity. The last explanation is very compelling and fits well with clinical trials data. Unlike most vaccines, BCG is not standardized and there is no seedlot of vaccine from which new batches are derived. BCG is grown in a number of laboratories around the world and has not been re-passaged in animals since it was derived from cattle a century ago. Multiple commercial and non-commercial BCG products are in use at present, and comparative genomic analysis demonstrates considerable genetic heterogeneity in these strains, with many gene deletions and polymorphisms. One analysis of BCG trials found that protective efficacy was reduced in studies using multiply-passaged vaccine strains. The evidence supports the hypothesis that BCG has become further attenuated over time and no longer promotes immunity to *M. tuberculosis* infection and disease in adults. This position has not been universally accepted, however, and BCG remains one of the most widely administered vaccines in the world, largely for its perceived effects on paediatric tuberculosis.

Areas for further research

Effective global tuberculosis control will require a co-ordinated set of clinical and public health strategies based on a thorough understanding of the epidemiology, pathogenesis, and therapy of infection with *M. tuberculosis*. It appears that the WHO DOTS strategy, which focuses on finding and effectively treating cases, is not sufficient to control or eliminate tuberculosis, particularly in countries with large HIV epidemics. Improved methods for the diagnosis and treatment of tuberculosis infection and disease, particularly drug-resistant tuberculosis, are urgently needed. Effective regimens for the treatment of multidrug-resistant tuberculosis, with both existing and new agents, need to be developed. A better understanding of the pathogenesis of and natural immunity to tuberculosis may contribute to the development of a more effective vaccine. The sequencing of the genome of *M. tuberculosis* promises to open the door to a new generation of research on tuberculosis and its control. Scientific progress alone, however, will be insufficient to combat tuberculosis worldwide. The willingness of societies and nations to pay for the deployment of the fruits of biomedical research, both past and future, to combat the disease where it is prevalent will be required for the conquest of tuberculosis.

7.11.23 Disease caused by environmental mycobacteria

J. M. Grange and P. D. O. Davies

Introduction

In addition to the tubercle and leprosy bacilli, the genus *Mycobacterium* contains at least 60 species that exist naturally as environmental saprophytes and some of these occasionally cause opportunist disease in humans and animals. The environmental mycobacteria are divisible into two main groups, the slow and rapid growers, according to their rate of growth on subculture. Originally allocated to broad groups according to pigmentation and other cultural characteristics, almost all environmental mycobacteria are now readily identifiable at species level.

Most of the slow growers are able to cause human disease and the commonest pathogens are the closely related species *M. avium* and *M. intracellulare*, which are usually grouped together as the *M. avium* complex. With rare exceptions, the only pathogenic rapid growers are *M. chelonae* (including *M. abscessus*) and *M. fortuitum*. The principal pathogenic environmental mycobacteria are listed in Table 1.

The environmental mycobacteria cause two named diseases with characteristic features: swimming pool granuloma caused by *M. marinum* and Buruli ulcer caused by *M. ulcerans*. The other mycobacterioses are much less specific, often resembling tuberculosis, and require identification of the causative organism for diagnosis.

Ecology and epidemiology

The environmental mycobacteria are particularly associated with water and are found in swamps, ponds, rivers, and also colonize piped water supplies. They are readily transmissible to humans by drinking water, by inhalation of aerosols, or by traumatic inoculation. Infection of humans by environmental mycobacteria is widespread and common but overt disease is rare. In some regions such infection may be sufficient to cause cross-reactions on tuberculin testing and to modify the protective efficacy of subsequent BCG vaccination, thereby possibly explaining the diversity of protection seen in major BCG trials.

The incidence of overt disease due to environmental mycobacteria is related to the species and numbers of mycobacteria in the environment, the opportunities for infection, and the susceptibility of the human population. Person-to-person transmission of overt disease very rarely, if ever, occurs and the prevalence of such disease is unaffected by tuberculosis control measures designed to break the cycle of person-to-person transmission. In recent years there has been an increase in the incidence of disease due to environmental mycobacteria in many countries because of immunosuppression, notably due to HIV infection.

The types of environmental mycobacterial disease in humans

The environmental mycobacteria cause four main types of disease: chronic pulmonary, lymphadenitis, postinoculation, and disseminated.

Chronic pulmonary disease

This form of environmental mycobacterial disease usually occurs in patients with predisposing local lung lesions, including industrial dust disease, old tuberculous cavities, chronic obstructive pulmonary disease, cancer, cystic fibrosis, and bronchiectasis, or generalized autoimmune or immunosuppressive disorders. However, a substantial minority of cases occur in people who otherwise appear healthy. Most patients are middle aged or elderly and men are usually more frequently affected than women. Environmental mycobacterial infection is also commoner in people who smoke. In some areas of the United Kingdom the incidence of environmental mycobacterial disease in the middle aged and elderly white population exceeds that of tuberculosis.

The most frequent causes worldwide are the *M. avium* complex and *M. kansasii*. *M. xenopi* is more restricted geographically but frequently occurs in southern England while, for unknown reasons, *M. malmoense* is encountered as a pathogen with increasing frequency in many parts of Europe including northern England. Rarer causes include *M. scrofulaceum*, *M. szulgai*, and *M. chelonae*.

Clinical presentation

Symptoms develop insidiously over weeks or months and include cough, malaise, weight loss, and sweats, in a pattern similar to tuberculosis but more chronic.

There are no diagnostically reliable clinical and radiological differences between pulmonary environmental mycobacterial disease and tuberculosis and diagnosis therefore depends on the isolation and identification of the causative organism. In contrast to *M. tuberculosis*, environmental mycobacteria isolated from sputum may not be the primary cause of disease; they may be transitory contaminants of the pharynx or secondary saprophytes of diseased tissue. There are no absolute criteria for distinguishing between these possibilities, but at least two pure cultures from specimens taken at least 1 week apart from patients with compatible symptoms and radiological signs in whom other causes, including tuberculosis, have been rigorously excluded render the diagnosis very likely. In some cases, a diagnosis is made or confirmed by microbiological examination of washings, brushings, or biopsies obtained by fibre-optic bronchoscopy.

Lymphadenitis

This is principally a disease of young children, occurring most frequently in the second year of life and then declining in frequency up to the fifth year, after which it is seldom encountered. The risk is reduced by neonatal BCG vaccination. The disease usually affects the cervical lymph nodes but other nodes, such as axillary and inguinal, may be involved, especially in older patients. Lymphadenitis is caused by many mycobacterial species, the commonest cause being the *M. avium* complex and *M. scrofulaceum*. Most cases occur in otherwise healthy children with no obvious predisposing cause but some cases, particularly in older age groups, are associated with human immunodeficiency virus (**HIV**) infection.

In most cases without predisposing causes, a single node is involved and surgical excision, if technically possible, is curative. More limited treatment, such as incision and drainage, may lead to sinus formation and should be avoided. Disseminated disease may develop in a few children, particularly those with some form of congenital immune deficiency, and in HIV-positive people.

Postinoculation mycobacterioses

Buruli ulcer is thought to result from inoculation of the causative organism, *M. ulcerans*, into the skin, principally by spiky vegetation. This disease is described elsewhere.

The natural habitat of *M. marinum*, the cause of swimming pool granuloma or fish tank granuloma, is water: it enters cuts and abrasions acquired whilst indulging in aquatic activities such as swimming and tending to tropical fish-tanks. The cutaneous lesions are usually warty, although pustules and ulcers may develop. There may be 'sporotrichoid' spread of lesions along the draining lymphatics (Fig. 1). The lesions usually heal spontaneously after a few months, but chemotherapy (see below)

accelerates resolution. There have been occasional reports of tenosynovitis, carpal tunnel syndrome, osteomyelitis, and disseminated disease due to *M. marinum*.

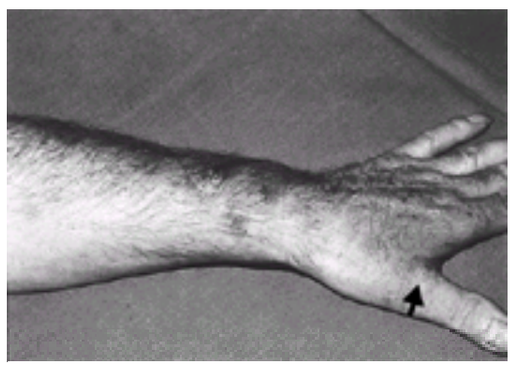

Fig. 1 *Mycobacterium marinum* infection. A small lesion at the base of the thumb (arrowed) and secondary lesions on the wrist and forearm due to 'sporotrichoid' spread (by courtesy of Dr G. Haase).

Most other cases of postinoculation disease are caused by the rapid growers *M. chelonae* and *M. fortuitum*. The most common lesions are postinjection abscesses, which may occur sporadically or in mini-epidemics due to the use of contaminated multidose vaccines or other injectable materials. Abscesses develop from 1 to 12 months after injection and may enlarge to 7 cm or more in diameter. They tend to be chronic and localized, but multiple abscesses with spreading cellulitis may develop in people with insulin-dependent diabetes. Localized abscesses usually respond well to excision or curretage, but chemotherapy (see below) may be required for multiple or spreading lesions.

Trauma to the cornea predisposes to infection by rapid growers *M. chelonae* and *M. fortuitum*. Treatment with topical amikacin and eythromycin may lead to temporary resolution but relapse is common, especially in cases due to *M. chelonae*, and corneal grafting is usually required.

More serious infections have followed accidental inoculation during surgical operations, especially when contaminated materials, including heart valve xenografts, have been inserted. Contamination during cardiac valve surgery has resulted in mycobacterial endocarditis with septicaemia and osteomyelitis of the sternum requiring extensive debridement.

Disseminated disease

Before HIV, disseminated disease due to environmental mycobacteria was very rare. Some cases, usually due to the *M. avium* complex or *M. chelonae*, occur in young people with congenital immune deficiencies (Fig. 2) and others, due principally to *M. chelonae*, occur in renal transplant recipients. *M. haemophilum* is a cause of multiple skin lesions in transplant recipients. As suggested by the name, this mycobacterium requires the addition of blood or other sources of iron in the medium for its *in vitro* cultivation.

Fig. 2 Ulcers of the lower lip as the initial manifestation of disseminated *Mycobacterium chelonae* infection in a 4-year-old girl with autosomal IgA deficiency (by courtesy of Dr K. Schopfer).

The situation changed dramatically after the advent of the HIV pandemic and disseminated environmental mycobacterial disease was reported in 30 to 50 per cent of patients with AIDS, particularly in the United States. For reasons that are not clear, the great majority of such cases, 90 per cent or more, are caused by the *M. avium* complex, usually those identifiable by DNA homology as *M. avium* rather than *M. intracellulare*. Some cases are due to *M. genevense*, a very slowly growing species which, like *M. avium*, has been isolated from diseased birds. The number of cases of disseminated AIDS-related environmental mycobacterial disease has declined in the wealthier nations following the introduction of highly active antiretroviral therapy (HAART). Although HIV infection is common in Africa, and *M. avium* is present in the environment, AIDS-related disease due to this species is, for unknown reasons, rare in that continent.

The mechanism of the establishment of this disease in humans is poorly understood. Some workers consider it to be the result of recent infection while others postulate that the disease emerges from dormant foci of infection in the lymphatic tissues of the alimentary or respiratory tracts acquired many years previously.

The symptoms—fever, night sweats, weight loss, those of anaemia and general malaise—are rather non-specific and may be caused by other AIDS-related infections. Involvement of the intestine may lead to malabsorption and chronic diarrhoea. The diagnosis of AIDS-related *M. avium* complex disease is made by culture of blood or of biopsies of liver, lymph nodes, or bone marrow. The bacilli may be isolated from faeces in disseminated disease, but they may also be present in the intestinal tract of healthy persons.

Treatment of established disease improves the quality of the remainder of the patient's life. Opinions differ as to the place for prophylactic therapy, but the introduction of highly active antiretroviral therapy makes this less relevant.

Therapy

This depends on the site and severity of the infection, the presence of predisposing conditions such as congenital or acquired immunosuppression, the species of mycobacterium, and the result of *in vitro* drug-susceptibility tests.

As indicated above, skin lesions may be cured by excision, curettage, or drainage. Surgical excision, when technically possible, is used to treat lymphadenitis and should be considered in cases of localized pulmonary lesions.

Most cases of pulmonary disease due to the *M. avium* complex and other slow-growing environmental mycobacteria respond to regimens containing rifampicin, ethambutol, and isoniazid. In contrast to tuberculosis, ethambutol appears to be more effective than isoniazid and should be continued for the full duration of therapy, provided that ocular toxicity does not occur. Treatment for 18 or 24 months produces up to 80 per cent cure rate in disease due to the *M. avium* complex, *M. xenopi*, and *M. malmoense*. Shorter regimens are effective for treatment of *M. kansasii* infections. Recommended regimens are summarized in Table 2. Surgery may be considered in certain cases where chemotherapy is ineffective.

There is evidence that the regimens based on the newer macrolides, as used to treat disseminated AIDS-related *M. avium* disease (see below), are effective in the treatment of pulmonary disease due to this complex in HIV-negative patients, but their suitability for the treatment of such diseases caused by other slow-growing species has not been established.

There have been no comparative trials of drug regimens for disease due to the rapidly growing species *M. chelonae* and *M. fortuitum*. Therapy is therefore based on anecdotal experience and the results of *in vitro* susceptibility tests. The duration of therapy depends on clinical response. Localized disease often responds to erythromycin with trimethoprim, while spreading or disseminated disease may require the addition of amikacin or a cephalosporin such as ceftriaxone. Limited experience indicates that the fluoroquinolones are effective against *M. fortuitum* and imipenem or meropenem against *M. chelonae*.

Skin lesions due to *M. marinum* respond to doxycycline or minocycline, or a combination of rifampicin and ethambutol.

The newer macrolides, clarithromycin and azithromycin, form the basis of therapy of disseminated infection, usually due to the *M. avium* complex in patients with AIDS. Commonly used regimens contain one of these together with rifabutin and ethambutol, but revision on the basis of *in vitro* drug susceptibility testing may be required. The duration of therapy depends on clinical and bacteriological response. At one time merely palliative, such regimens may be curative when combined with antiretroviral therapy. The place for prophylaxis, usually clarithromycin, is controversial and rendered less relevant by the advent of antiretroviral therapy.

7.11.24 Leprosy (Hansen's disease)

Diana N. J. Lockwood

Definition

Leprosy is a chronic granulomatous disease caused by *Mycobacterium leprae*. Its principal manifestations are anaesthetic skin lesions and peripheral neuropathy with peripheral nerve thickening. The clinical form is determined by the degree of cell-mediated immunity towards *M. leprae*. High levels of cell-mediated immunity with elimination of leprosy bacilli produces tuberculoid leprosy, whereas absent cell-mediated immunity results in lepromatous leprosy. Complications of leprosy result from nerve damage, immunological reactions, and bacillary infiltration. Nerve damage accompanying leprosy is a serious complication because it causes lifelong morbidity. Current antileprosy drugs are highly effective in killing bacilli but may not halt nerve damage. Patients with leprosy the world over are frequently stigmatized. Words such as 'leper' should be avoided and the disease should be referred to as Hansen's disease.

Aetiology

Leprosy is caused by *M. leprae*, an acid-fast intracellular organism not yet cultivated *in vitro*. It was first identified in the nodules of patients with lepromatous leprosy by Hansen in 1873. *M. leprae* preferentially parasitizes skin macrophages and peripheral nerve Schwann cells.

In vivo cultivation of *M. leprae*

M. leprae can be grown in the mouse footpad, but growth is slow, taking over 6 months to produce significant yields. The nine-banded armadillo is susceptible to *M. leprae* infection, and develops lepromatous disease. The armadillo and mouse models of *M. leprae* infection have been useful for producing *M. leprae* for biological studies and studying drug sensitivity patterns, respectively.

Biological characteristics

M. leprae is a stable, hardy organism, withstanding drying for up to 5 months. It has a doubling time of 12 days (compared with 20 min for *Escherichia coli*). The optimum growth temperature is 27°C to 30°C, consistent with the clinical observation of maximal *M. leprae* growth at cool superficial sites (skin, nasal mucosa, and peripheral nerves). *M. leprae* is a single species with isolates having similar biological characteristics and identical genotypes (using restriction fragment polymorphism analysis) irrespective of the type of leprosy, race, or geographical origin of the isolate.

Mycobacterial structure and metabolism

M. leprae possesses a complex cell wall comprising lipids and carbohydrates. It synthesizes a species-specific phenolic glycolipid and lipoarabinomannan. Antibody and T-cell screening has identified numerous protein antigens that are important immune targets.

M. leprae genome

M. leprae has a 3.27 Mb genome that displays extreme reductive evolution. Less than half the genome contains functional genes and many pseudogenes are present. One hundred and sixty-five genes are unique to *M. leprae* and functions can be attributed to 29 of them. Analysis of these unique proteins will be critical for developing new diagnostic tests. Comparison of biosynthetic pathways with *M. tuberculosis* is giving new insights into *M. leprae* metabolism. For lipolysis *M. leprae* has only two genes (*M. tuberculosis* has 22); *M. leprae* has also lost many genes for carbon catabolism and many carbon sources (e.g. acetate and galactose) are unavailable to it. This gene loss leaves *M. leprae* unable to respond to different environments and underlies the impossibility of growing the organism *in vitro*.

Epidemiology

Today, about 4 million people are disabled by leprosy. The much quoted figures of a fall in registered patients on treatment from 12 million in 1988 to 0.82 million in 1999 are misleading. Prevalence has fallen by means of effective antibiotic therapy and altered case definition. However, incidence remains stable at around 800 000 new cases annually with high rates of childhood cases. Intensive leprosy elimination campaigns held in 1998 and 1999 detected large numbers of new cases. A week-long campaign in Nepal found 11 696 new cases, doubling the national case load.

Geographical distribution

Seventy-seven per cent of patients with leprosy live in South-East Asia, 8.3 per cent in Africa, and 10 per cent in the Americas. India dominates the picture with 70 per cent of the world's leprosy cases; 86 per cent reside in six countries (India, Brazil, Indonesia, Myanmar, Madagascar, and Nepal). Leprosy has not always been a tropical disease; it was widespread in medieval Europe and was endemic in Norway until the early twentieth century. In North America, small foci of infection are still found in Texas and Louisiana. Nearly all new patients now seen in Europe and North America have acquired their infection abroad.

Risk factors

Leprosy is a chronic disease with a long incubation period. An average incubation time of 2 to 5 years has been calculated for tuberculoid cases and 8 to 12 years for lepromatous cases. American servicemen who developed leprosy after serving in the tropics presented up to 20 years after their presumed exposure. Age, sex, and household contact are important determinants of leprosy risk; incidence reaches a peak at 10 to 14 years; the excess of male cases is attributed to women's reluctance to present to health workers with skin lesions. Poor nutritional status is cited as predisposing to leprosy but no good evidence substantiates this. Improved socio-economic conditions, extended schooling, and good housing conditions reduce the risk of leprosy. Subclinical infection with *M. leprae* is probably common but the development of established disease is rare. Little work has been done on the early events in infection with *M. leprae* because there is no simple test that can establish whether an individual has encountered *M. leprae* and mounted a protective immune response.

HIV and leprosy

Studies from Malawi, Uganda, Mali, and South India have not found HIV infection to be a risk factor for leprosy. HIV/leprosy coinfected patients have typical skin lesions and typical leprosy histology and granuloma formation despite low circulating CD4 counts.

Transmission

The transmission of *M. leprae* is only partially understood. Untreated lepromatous patients discharge abundant organisms from their nasal mucosa into the environment. Studies in Indonesia and Ethiopia using polymerase chain reaction (PCR) primers to detect *M. leprae* DNA in nasal swabs have shown that up to 5 per cent of the population in leprosy endemic areas carry *M. leprae* DNA in their noses. The organism is then inhaled, multiplies on the inferior turbinates, and has a brief bacteraemic phase before binding to and entering Schwann cells and macrophages. The combination of an environmentally well-adapted organism, high carriage rates, and a long incubation period means that, even with effective antibiotics, transmission will continue for a long time.

Pathogenesis

Leprosy is a bacterial infection in which clinical features are determined by the host's immune response (Table 1).

The immune response to *M. leprae* and the leprosy spectrum

The Ridley–Jopling classification (Fig. 1) places patients on a spectrum of disease according to their clinical features, bacterial load, and histological and immunological responses. The two poles of the spectrum are tuberculoid (**TT**; paucibacillary) and lepromatous leprosy (**LL**; multibacillary). At the tuberculoid pole, well-expressed cell-mediated immunity effectively controls bacillary multiplication with the formation of organized epithelioid-cell granulomas; at the lepromatous pole there is cellular anergy towards *M. leprae* with abundant bacillary multiplication. Between these two poles is a continuum, varying from the patient with moderate cell-mediated immunity (borderline tuberculoid, **BT**) through borderline (**BB**) to the patient with little cellular response, borderline lepromatous (**BL**). The polar groups (TT, LL) are stable, but within the central groups (BT, BB, BL) the disease tends to downgrade to the lepromatous pole in the absence of treatment and upgrading towards the tuberculoid pole may occur during or after treatment.

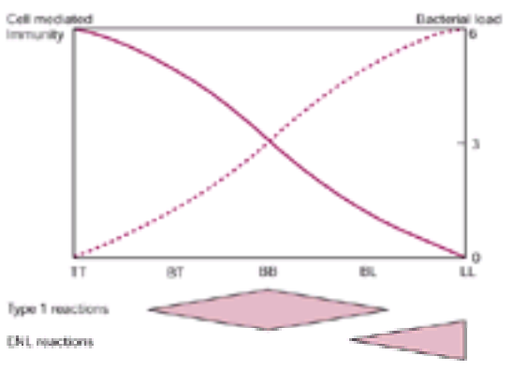

Fig. 1 The Ridley–Jopling spectrum of bacterial load, cell-mediated immunity, and reactions.

Both T cells and macrophages play important roles in the processing, recognition, and response to *M. leprae* antigens. In tuberculoid leprosy, *in vitro* tests of T-cell function such as lymphocyte transformation tests show a strong response to *M. leprae* protein antigens with the production of T_{H1}-type cytokines (interferon-g and interleukin 2, **IL-2**). Skin tests with lepromin, a heat-killed *M. leprae* preparation, are strongly positive. Staining of skin biopsies from tuberculoid lesions with T-cell markers shows highly organized granulomas composed predominantly of CD4 cells and macrophages with a peripheral mantle of CD8 cells. This strong cell-mediated immune response clears bacilli but with concomitant local tissue destruction, especially in nerves.

Patients with lepromatous leprosy have no cell-mediated immunity to *M. leprae* with a failure of the T-cell and macrophage response. Tests for lepromin are negative. This anergy is specific for *M. leprae*. Patients with LL disease respond to other mycobacteria such as *M. tuberculosis*, both *in vitro* and in skin tests. Identification of cell types in LL granulomas shows a disorganized mixture of macrophages and T cells, mainly CD8 cells. The T-cell failure may be due to clonal anergy or active suppression. Defects in cytokine production have been demonstrated; intralesional injections of recombinant IL-2 reconstitute the local immune response with elimination of *M. leprae* from macrophages. The T-cell cytokines that are produced are of the T_{H2} type. Macrophage defects described in LL disease include: defective antigen presentation and recognition, defective IL-1 production, a failure of macrophages to kill *M. leprae*, and a macrophage suppression of the T-cell response. Patients with lepromatous leprosy produce a range of autoantibodies that are both organ specific (against thyroid, nerve, testis, and gastric mucosa) and non-specific, such as rheumatoid factors, anti-DNA, cryoglobulins, and cardiolipin.

Bacterial load

In lepromatous leprosy, bacilli spread haematogenously to cool, superficial sites including eyes, upper respiratory mucosa, testes, small muscles, and bones of the hands, feet, and face as well as to peripheral nerves and skin. The heavy bacterial load causes structural damage at all these sites. In tuberculoid leprosy, bacilli are not readily found.

Leprosy reactions

Leprosy reactions are events superimposed on the Ridley–Jopling spectrum. Type 1 (reversal reactions) occur in borderline patients (BT, BB, BL) and are delayed hypersensitivity reactions caused by increased recognition of *M. leprae* antigens in skin and nerve sites. They are characterized by an increase in lymphocytes (CD4 and IL-2-producing cells) within lesions, severe oedema with disruption of the granuloma, and giant cell formation. There is local production of cytokines such as interferon-g and tumour necrosis factor-a. Type 1 reactions are probably associated with a switch from production of T_{H1}- to T_{H2}-type cytokines.

Type 2 reactions, erythema nodosum leprosum (**ENL**), are partly due to immune complex deposition and occur in BL and LL patients who produce antibodies and have a large antigen load. There is vasculitis with lesional immunoglobulin, complement, and polymorphs and circulating immune complexes. There is also enhanced T-cell activity with increased CD8 cells, increased circulating IL-2 receptors, and high levels of circulating tumour necrosis factor-a. After reaction, lepromatous patients revert to a state of immunological unresponsiveness.

Nerve damage

Nerve damage occurs in skin lesions and in peripheral nerve trunks. Myelinated and unmyelinated sensory fibres are affected early. In tuberculoid disease, epithelioid granulomas and perineural inflammation occur. In established lepromatous infection, almost all the cutaneous nerves and peripheral nerve trunks are involved. Bacilli are found in Schwann, perineurial, and endothelial cells. Extensive demyelination occurs and later wallerian degeneration. Despite large numbers of organisms in the nerve there is only a small inflammatory response, but ultimately the nerve becomes fibrotic and is hyalinized. The formation of small granulomas is characteristic of borderline leprosy; granulomatous regions may abut strands of normal looking but heavily bacillated Schwann cells. The combination of lepromatous bacillation and cell-mediated immunity produces widespread nerve damage in borderline leprosy.

Clinical features of leprosy

Patients commonly present with skin lesions, weakness or numbness due to a peripheral nerve lesion, or a burn or ulcer in an anaesthetic hand or foot. Borderline patients may present in reaction with nerve pain, sudden palsy, multiple new skin lesions, pain in the eye, or a systemic febrile illness.

The cardinal signs are:

1. typical skin lesions, anaesthetic at the tuberculoid end of the spectrum;
2. thickened peripheral nerves; and
3. acid-fast bacilli on skin smears or biopsy.

Presenting symptoms

Early lesions

The commonest early lesion is an area of numbness on the skin or a visible skin lesion. The classic early skin lesion, especially in surveys, is indeterminate leprosy, which is commonly found on the face, extensor surface of the limbs, buttocks, or trunk. Indeterminate lesions consist of one or more slightly hypopigmented or erythematous macules, a few centimetres in diameter, with poorly defined margins. Hair growth and nerve function are unimpaired. A biopsy may show the perineurovascular infiltrate and only scanty acid-fast bacilli. The indeterminate phase may last for months or years before resolving or developing into one of the determinate types of leprosy.

Skin

The commonest skin lesions are macules or plaques; papules and nodules are more rare. In lepromatous leprosy a diffuse infiltration of the skin often occurs. Lesions may be found anywhere although rarely in the axillas, perineum, or hairy scalp. Tuberculoid patients have few, hypopigmented lesions while lepromatous patients have numerous, sometimes confluent lesions. The few tuberculoid lesions are usually asymmetrical, more numerous lesions are likely to be distributed symmetrically.

Anaesthesia

Anaesthesia may occur in skin lesions when dermal nerves are involved or in the distribution of a large peripheral nerve. In skin lesions the small dermal sensory and autonomic nerve fibres supplying dermal and subcutaneous structures are damaged causing local sensory loss and loss of sweating within that area.

Peripheral neuropathy

Peripheral nerve trunks are vulnerable at sites where they are superficial or are in fibro-osseous tunnels. At these points a small increase in nerve diameter raises intraneural pressure causing neural compression and ischaemia. Damage to peripheral nerve trunks produces characteristic signs with dermatomal sensory loss and dysfunction of muscles supplied by that peripheral nerve. The sites of predilection for peripheral nerve involvement are ulnar (at the elbow), median (at the wrist), radial, radial cutaneous (at the wrist), common peroneal (at the knee), posterior tibial and sural nerves at the ankle, facial nerve as it crosses the zygomatic arch, and great auricular in the posterior triangle of the neck. All these nerves should be examined for enlargement and tenderness.

Tuberculoid leprosy (TT)

Infection is localized and asymmetrical. A typical tuberculoid skin lesion is a macule or plaque, single, erythematous or purple with raised and clear-cut edges sloping towards a flattened hypopigmented centre. The surface is anaesthetized, dry, and hairless. Sensory impairment may be difficult to demonstrate on the face, where there are abundant nerve endings. If one palpates the edge of the lesions, a thickened cutaneous nerve may be found. If peripheral nerve trunk involvement is present, only one nerve trunk is enlarged. No *M. leprae* are found in skin smears. True tuberculoid leprosy has a good prognosis, many infections resolve without treatment and peripheral nerve trunk damage is limited.

Borderline tuberculoid (BT) (Plate 1)

The skin lesions are similar to TT leprosy and there may be few or many lesions (Fig. 2). The margins are less well defined and there may be satellite lesions. Damage to peripheral nerves is widespread and severe, usually with several thickened nerve trunks. It is important to recognize BT leprosy because these patients are at risk of reversal reactions leading to rapid deterioration in nerve function with consequent deformities.

Fig. 2 Active tuberculoid annular lesions showing the sharp outer edge, thin, raised, erythematous, dry rim, and the broad, hypopigmented, dry centre with slight hair loss. The 'satellite' lesion at the lower outer edge indicates that this is borderline tuberculoid leprosy. As shown, biopsies and smears should be taken from the raised, active rim.

Borderline leprosy (BB)

BB disease is the most unstable part of the spectrum and patients usually downgrade towards lepromatous leprosy if they are not treated or upgrade towards tuberculoid leprosy as part of a reversal reaction. There are numerous skin lesions which may be macules, papules, or plaques and vary in size, shape, and distribution. The edges of the lesions may have streaming, irregular borders. Annular lesions with a broad, irregular edge and a sharply defined punched-out centre are characteristic of BB disease (Fig. 3). Nerve damage is variable.

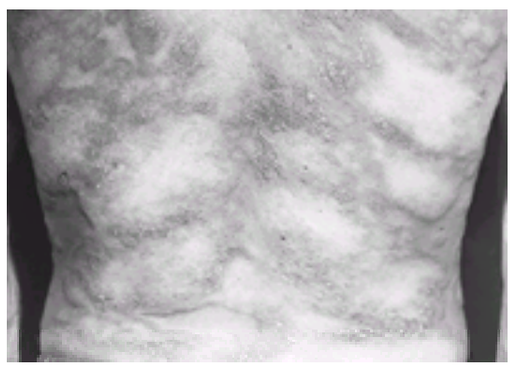

Fig. 3 Borderline annular lesions on the shoulder and back: the rim is broad, the edge irregular, and the 'punched-out' centre is hypopigmented and anaesthetized.

Borderline lepromatous leprosy (BL)

This is characterized by widespread, variable, asymmetrical skin lesions. There may be erythematous or hyperpigmented papules, succulent nodules or plaques, and sensation in the lesions may be normal. Peripheral nerve involvement is widespread. While patients with BL leprosy do not suffer the extreme consequences of bacillary multiplication that are seen in LL disease, they may experience either or both reversal and ENL reactions.

Lepromatous leprosy (LL) (Plate 2)

The patient with untreated polar lepromatous leprosy may be carrying 10^{11} leprosy bacilli. The onset of disease is frequently insidious, the earliest lesions being ill defined, shiny, hypopigmented or erythematous macules. Gradually the skin becomes infiltrated and thickened and nodules develop (Fig. 4); facial skin thickening causes the characteristic leonine facies (Fig. 5). Hair is lost, especially the lateral third of the eye brows (madarosis). Dermal nerves are destroyed leading to a progressive glove and stocking anaesthesia and sensory loss (light touch, pain, and temperature) which begins at the hands and feet and gradually extends to the whole body except for the axillas, groins, and scalp. Position sense is preserved. Sweating is lost, which is uncomfortable in the tropics as compensatory sweating occurs in the remaining intact areas. Damage to peripheral nerves is symmetrical and occurs late in disease. Infiltration of the corneal nerves causes anaesthesia, which predisposes to injury, secondary infection, and blindness.

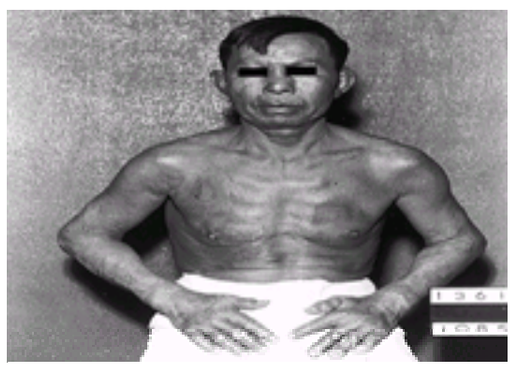

Fig. 4 Active, untreated lepromatous leprosy, showing generalized infiltration of the skin, swelling of fingers and lips, and thinning of eyebrows and eyelashes. The residual annular lesions visible in both pectoral regions indicate that this patient has 'downgraded' from borderline.

Fig. 5 Leonine facies in advanced untreated lepromatous leprosy, with gross thickening of the ear lobes. The skin of the trunk and limbs is infiltrated and mildly erythematous, and small papules are present on some knuckles.

Nasal symptoms can often be elicited early in the disease, and 80 per cent of patients with newly diagnosed lepromatous leprosy have hyperaemic or ulcerated nasal mucosa. Septal perforation may occur. There may be papules on the lips and nodules on the palate, uvula, tongue, and gums. Bone involvement is common, with absorption of the terminal phalanges and pencilling of the heads and shafts of the metatarsals. Testicular atrophy results from diffuse infiltration and the acute orchitis that occurs during ENL reactions. The consequent loss of testosterone leads to azoospermia and gynaecomastia. The extremities become oedematous. The skin of the legs becomes icthyotic and ulcerates easily.

Other forms of leprosy

There are several variant forms of leprosy. Pure neural leprosy occurs principally in India, where it is the presenting form for 10 per cent of patients. There is asymmetrical involvement of peripheral nerve trunks and no visible skin lesions. On nerve biopsy all types of leprosy have been found.

Histoid lesions are distinctive nodules occurring in lepromatous cases which have relapsed due to dapsone resistance or non-compliance with chemotherapy.

Lucio's leprosy is a form of lepromatous leprosy found only in Latin Americans, with a uniform, diffuse, shiny skin infiltration.

Eye disease in leprosy

Blindness due to leprosy, which occurs in at least 2.5 per cent of patients, is a devastating complication for a patient with anaesthesia of the hands and feet. Eye damage results from both nerve damage and bacillary invasion. Lagophthalmos results from paresis of the orbicularis oculi due to involvement of the zygomatic and temporal branches of the facial (VIIth) nerve. These superficial branches are frequently involved in borderline tuberculoid cases, particularly if there are facial skin lesions. In lepromatous disease, lagophthalmos occurs later and is usually bilateral. Damage to the ophthalmic branch of the trigeminal (Vth) nerve causes anaesthesia of the cornea and conjunctiva resulting in drying of the cornea and makes the cornea susceptible to trauma and ulceration. Lepromatous infiltration in corneal nerves produces punctate keratitis and corneal lepromas. Invasion of the iris and ciliary body makes them extremely susceptible to reactions.

Leprosy reactions

Type 1 (reversal reactions) (Plate 3, Plate 4)

These are characterized by acute neuritis and/or acutely inflamed skin lesions (Fig. 6). Nerves become tender with new loss of sensation or motor weakness. Existing skin lesions become erythematous or oedematous; new lesions may appear (Fig. 7). Occasionally oedema of the hands, face, or feet is the presenting symptom, but constitutional symptoms are unusual. Type 1 reactions occur in borderline patients—35 per cent of BL patients will experience a type 1 reaction. The commonest time for reactions is in the first 2 months after starting treatment and in the puerperium.

Fig. 6 Type 1 (reversal) reaction: this BL patient developed new, sharp-edged, well-defined, erythematous plaques with desquamating surfaces about 6 months after starting chemotherapy.

Fig. 7 Reversal-reaction plaque on the left cheek and ear: the edge of this BT lesion has become very sharply defined, more raised, and erythematous, dry, and scaly. Treatment with corticosteroids is imperative, as the patient is at grave risk of rapidly developing lagophthalmos due to associated involvement of branches of the facial nerve.

Type 2 (ENL reactions)

These occur in LL and BL patients. Before multidrug therapy some 50 per cent of LL patients experienced erythema nodosum leprosum (ENL) reactions, the clofazimine component of multidrug therapy has reduced this to 15 per cent. Attacks are acute and may recur over several years. ENL manifests most commonly as painful red nodules on the face and extensor surfaces of limbs (Fig. 8). The lesions may be superficial or deep, with suppuration or brawny induration when chronic. Acute lesions crop and desquamate, fading over several days. ENL is a systemic disorder producing fever and malaise and may be accompanied by uveitis, dactylitis, arthritis, neuritis, lymphadenitis, and orchitis.

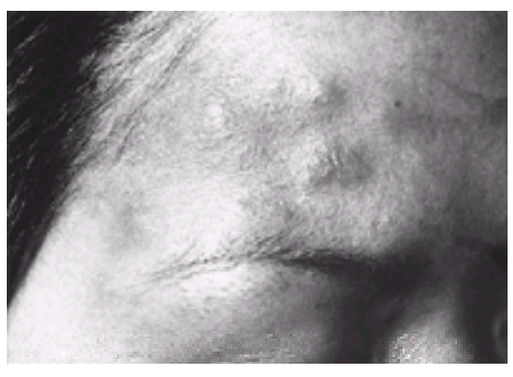

Fig. 8 Erythema nodosum leprosum (ENL) on the forehead of a patient with early lepromatous leprosy. The papules (and nodules) are firm and tender, with rather indefinite edges. In dark-skinned patients the ENL lesions are often easier to feel than to see, especially over the extensor surfaces of the arms and thighs.

Neuritis (Plate 5, Plate 6)

Silent neuropathy is an important form of nerve damage and presents as a functional neural deficit without a manifest acute or subacute neuritis. An Indian study following a cohort of 2608 patients found that 75 per cent of those developing deformity had no history of reactions. In Ethiopian and Bangladeshi cohort studies,

silent neuritis accounted for most neuritis. This emphasizes the importance of regular nerve function testing so that new deficits can be detected.

Diagnosis

The diagnosis is made on the clinical findings of one or more of the cardinal signs of leprosy and supported by the finding of acid-fast bacilli on slit skin smears. The whole body should be inspected in a good light otherwise lesions may be missed, particularly on the buttocks. Skin lesions should be tested for anaesthesia to light touch, pin prick, and temperature. The peripheral nerves should be palpated systematically examining for thickening and tenderness. Wherever possible the diagnosis should be supported by a skin biopsy, which is essential for accurate classification. Serology is not usually helpful diagnostically because antibodies to the species-specific glycolipid PGL-1 are present in 90 per cent of untreated lepromatous patients but only 40 to 50 per cent of paucibacillary patients and 5 to 10 per cent of healthy controls. Polymerase chain reaction for detecting *M.leprae* DNA has not proved sensitive or specific enough for diagnosis.

Outside leprosy endemic areas doctors frequently fail to consider the diagnosis of leprosy. Of new patients seen from 1995 to 1999 at The Hospital for Tropical Diseases, London, diagnosis had been delayed in over 80 per cent of cases. Patients had been misdiagnosed by dermatologists, neurologists, orthopaedic surgeons, and rheumatologists. A common problem was failure to consider leprosy as a cause of peripheral neuropathy in patients from leprosy endemic countries. These delays had serious consequences for patients; over half of them had nerve damage and disability.

Slit skin smears

The bacterial load is assessed by making a small incision through the epidermis, scraping dermal material, and smearing evenly on to a glass slide. At least six sites should be sampled (earlobes, eyebrows, edges of active lesions). The smears are then stained and acid-fast bacilli are counted. Scoring is done on a logarithmic scale per high-power field. A score of 1+ indicates 1 to 10 bacilli in 100 fields, 6+ over 1000 per field. Smears are useful for confirming the diagnosis and should be done annually to monitor response to treatment.

Differential diagnosis

Doctors should be aware of the normal range of skin colour and texture in their local population, and also of the common endemic skin diseases, such as onchocerciasis, that may coexist or mimic leprosy.

Skin

The variety of leprosy skin lesions means that a potentially wide range of skin conditions are in the differential diagnosis. At the tuberculoid end of the spectrum, anaesthesia differentiates leprosy from fungal infections, vitiligo, and eczema. At the lepromatous end the presence of acid-fast bacilli in smears differentiates leprosy nodules from onchocerciasis, Kaposi's sarcoma, and post-kala-azar dermal leishmaniasis.

Nerves

Peripheral nerve thickening is rarely seen except in leprosy. Hereditary sensory motor neuropathy type III is associated with palpable peripheral nerve hypertrophy. Amyloidosis, which can also complicate leprosy, causes thickening of peripheral nerves. Charcot–Marie–Tooth disease is an inherited neuropathy that causes distal atrophy and weakness. The causes of other polyneuropathies such as HIV, diabetes, alcoholism, vasculitides, and heavy metal poisoning should all be considered where appropriate.

Treatment

There are five main principles of treatment:

1. stop the infection with chemotherapy;
2. treat reactions;
3. educate the patient about leprosy;
4. prevent disability; and
5. support the patient socially and psychologically.

These objectives need the patient's co-operation and confidence. In endemic countries, this will usually be achieved through the leprosy outpatient clinic. In countries where leprosy is uncommon, or when the clinical or social situation is complicated, it is often best to admit the patient to an experienced unit. This permits careful assessment together with accurate evaluation of nerve and eye involvement, patient education, and initiation of treatment.

Chemotherapy

All patients with leprosy should be given an appropriate multidrug combination. In the hospital setting, where skin smears and skin biopsies can be combined with clinical data, patients can be classified into paucibacillary (skin smear-negative tuberculoid and BT) and multibacillary (skin smear-positive BT, all BB, BL, and LL). The first-line antileprosy drugs are rifampicin, clofazimine, and dapsone. Table 2 gives the drug combinations, doses, and duration of treatment. Patients with multibacillary disease and an initial bacterial index greater than 4 will need longer treatment and the duration should be guided by their clinical status and bacterial index.

Rifampicin is a potent bactericide for *M. leprae*. Four days after a single 600 mg dose, bacilli from a previously untreated patient with multibacillary disease were no longer viable in a mouse foot-pad test. It acts by inhibiting DNA-dependent RNA polymerase. Because *M. leprae* can develop resistance to rifampicin as a one-step process, this drug should always be given in combination with other antileprotics.

Dapsone (**DDS**, 4,4-diaminodiphenylsulphone) is weakly bactericidal. Oral absorption is good and it has a long half-life, averaging 28 h. It commonly causes mild haemolysis, but rarely anaemia. Glucose-6-phosphate dehydrogenase deficiency is seldom a problem. The 'DDS syndrome', which is occasionally seen in leprosy, begins 6 weeks after starting dapsone and manifests as exfoliative dermatitis associated with lymphadenopathy, hepatosplenomegaly, fever, and hepatitis.

Clofazimine is a red, fat-soluble, crystalline dye. The mechanism of its weakly bactericidal action against *M. leprae* remains unknown. The most troublesome side-effect is skin discoloration, ranging from red to purple-black, the degree depending on the drug dose and extent of leprous infiltration. The pigmentation usually fades within 6 to 12 months of stopping clofazimine, although traces of discoloration may remain for up to 4 years. Urine, sputum, and sweat may become pink. Clofazimine also produces a characteristic icthyosis on the shins and forearms.

New drugs bactericidal for *M. leprae* have been identified, notably the fluoroquinolones pefloxacin and ofloxacin, minocycline, and clarithromycin. These agents are now established second-line drugs and may replace dapsone and clofazimine. Minocycline causes a black pigmentation of skin lesions and so may not be an appropriate substitute for clofazimine if pigmentation is to be avoided.

Since the introduction of multidrug therapy more than 10 million patients have been treated successfully. Clinical improvement has been rapid and toxicity rare. The treatment duration has been shortened. Monthly supervision of the rifampicin component has been crucial to success. Other benefits are reduced deformity rates, increased compliance in control schemes, a halving of the annual case load, and reduction of the long-term (though not short-term) cost of control schemes. At the end of a 6-month treatment of borderline disease there may still be signs of inflammation, which should not be mistaken for active infection. The distinction between relapse and reaction may be difficult. World Health Organization (**WHO**) studies have reported a cumulative relapse rate of 1.07 per cent for paucibacillary leprosy and 0.77 per cent for multibacillary leprosy at 9 years after completion of multidrug therapy. *M. leprae* is such a slow-growing organism that relapse only occurs after many years. *M. leprae* isolates from relapsed patients who have received multidrug therapy are fully drug sensitive and patients can be retreated with the same regimen.

A single-dose triple-drug combination (rifampicin, ofloxacin, and minocycline) has been tested in India for patients with single skin lesions and improved 98 per cent of

patients. Although the study had major flaws and single-dose treatment is less effective than the conventional 6-month treatment for paucibacillary leprosy, it is an operationally attractive field regimen and has been recommended for use by the WHO.

Reactions may develop months or years after stopping chemotherapy, especially in BL or LL patients. It is therefore vital when discharging patients to warn them to return should new symptoms appear, especially in hands, feet, or eyes. Patients with reactions or physical or psychological complications will need long-term care.

Management of reactions

Awareness of the early symptoms of reversal reactions by both patient and physician is important because, if left untreated, severe nerve damage may develop. The peak time for reversal reactions is in the first 2 months of treatment. Patients should be warned about reactions because the sudden appearance of reactional lesions after starting treatment is distressing and undermines confidence. The treatment of reactions is aimed at controlling acute inflammation, easing pain, reversing nerve and eye damage, and reassuring the patient. Multidrug therapy should be continued.

Type 1 (reversal) reactions

Simple anti-inflammatory drugs are rarely sufficient to control symptoms. If there is any evidence of neuritis (nerve tenderness, new anaesthesia, and/or motor loss), corticosteroid treatment should be started. Prednisolone should be given, starting at 40 to 60 mg daily, reducing to 40 mg after a few days, and then by 5 mg every 2 to 4 weeks. Patients with BT leprosy in reaction commonly need 2 to 4 months of steroids while BL reactions may need 6 months.

Type 2 (ENL) reactions (Plate 7)

This is a difficult condition to treat and frequently requires treatment with high-dose steroids (80 mg daily, tapered down rapidly) or thalidomide. Since ENL frequently recurs, steroid dependency can easily develop. Thalidomide (400 mg daily) is superior to steroids in controlling ENL and is the drug of choice for young men with severe ENL. Women with severe ENL may benefit from thalidomide treatment. This is a difficult decision for the woman and her physician and needs careful discussion of the benefits and risks (phocomelia when thalidomide is taken in the first trimester). Women should use double contraception and report immediately if menstruation is delayed. Unfortunately, the problems with thalidomide mean that it is unavailable in several leprosy endemic countries despite its undoubted value. Clofazimine has a useful anti-inflammatory effect in ENL and can be used at 300 mg per day for several months. Low-grade chronic erythema nodosum, with iritis or neuritis, will require long-term suppression, preferably with thalidomide or clofazimine. Acute iridocyclitis is treated with 4-hourly instillation of 1 per cent hydrocortisone eye drops and 1 per cent atropine drops twice daily.

Neuritis

Silent neuritis should be treated similarly to reversal reactions—prednisolone in a dose of 40 mg daily and reducing slowly over a period of months.

Education of the patient

Stigmatization due to leprosy occurs worldwide. Patients are frightened of social ostracization, physical rejection, and the development of deformities. It is often useful to ask them about their fears so that these can be addressed. They should be reassured that having started treatment they are not infectious to family or friends. The importance of compliance with antibiotic therapy needs to be emphasized. The patient needs a careful explanation of the diagnosis, aetiology, and prognosis.

Prevention of disability

The morbidity and disability associated with leprosy is secondary to nerve damage. A major goal in prevention of disability is to create patient self-awareness so that damage is minimized. Monitoring sensation and muscle power in patient's hands, feet, and eyes should be part of the routine follow-up so that new nerve damage is detected early. The patient with an anaesthetized hand or foot needs to understand the importance of daily self-care, especially protection when doing potentially dangerous tasks and inspection for trauma. It is helpful to identify for each patient potentially dangerous situations, such as cooking, car repairs, or smoking. Soaking dry hands and feet followed by rubbing with oil keeps the skin moist and supple.

An anaesthetized foot needs the protection of an appropriate shoe. For anaesthesia alone, a well-fitting 'trainer' with firm soles and shock-absorbing inners will provide adequate protection. Once there is deformity, such as clawing, shoes must be made specially to ensure protection of pressure points and even weight distribution.

The patient should be taught to question the cause of an injury so that the risk can be avoided in the future. Plantar ulceration occurs secondary to increased pressure over bony prominences. Ulceration is treated by rest. Unlike ulcers in the feet of patients with diabetes or ischaemia, ulcers in leprosy heal if they are protected from weight-bearing. No weight-bearing is permitted until the ulcer has healed. Appropriate footwear should be provided to prevent recurrence.

Physiotherapy exercises should be taught to maximize function of weak muscles and prevent contracture. Contractures of hands and feet, foot drop, lagophthalmos, entropion, and ectropion are amenable to surgery.

Social, psychological, and economic rehabilitation

The social and cultural background of the patient determine the nature of many of the problems that may be encountered. The patient may have difficulty in coming to terms with leprosy. The community may reject the patient. Education, gainful employment, confidence from family, friends, and doctor, and plastic surgery to correct stigmatizing deformity all have a role to play.

Prognosis

The majority of patients—especially those who have no nerve damage at the time of diagnosis—do well on multidrug treatment with resolution of skin lesions. Left untreated, borderline patients will downgrade towards the lepromatous end of the spectrum and lepromatous patients will suffer the consequences of bacillary invasion. Borderline patients are at risk of developing type 1 reactions, which may result in devastating nerve damage. Treatment of the neuritis is currently unsatisfactory and patients with neuritis may develop permanent nerve damage despite corticosteroid treatment. It is not possible to predict which patients will develop reactions or nerve damage. Nerve damage and its complications may be severely disabling, especially when all four limbs and both eyes are affected.

Leprosy in women

Women with leprosy are in double jeopardy, not only may they develop postpartum nerve damage but they are at particular risk of social ostracization with rejection by spouses and family.

Pregnancy and leprosy

There is little good evidence that pregnancy causes new disease or relapse. However, there is a clear temporal association between parturition and the development of type 1 reactions and neuritis when cell-mediated immunity returns to prepregnancy levels. In an Ethiopian study, 42 per cent of pregnancies in BL patients were complicated by a type 1 reaction in the postpartum period. In the same cohort, LL patients experienced ENL reactions throughout pregnancy and lactation. ENL in pregnancy is associated with early loss of nerve function compared with non-pregnant individuals. Pregnant and newly delivered women should have regular neurological examination and steroid treatment instituted for neuritis. Rifampicin, dapsone, and clofazimine are safe during pregnancy. Clofazimine crosses the placenta and babies may be born with mild clofazimine pigmentation. Lepra reactions can be managed with the steroid regimens given above but with a more rapid reduction in dose. Women should be warned before becoming pregnant of the risk that their condition will deteriorate after delivery. Ideally pregnancies should be planned when leprosy is well controlled.

Prevention and control

The current strategy of leprosy control in endemic countries through vertical programmes providing case detection, treatment with WHO multidrug therapy, and contact examination and supported by case-finding campaigns, especially in schools, has been very successful. Effective treatment is not merely restricted to chemotherapy but also involves good case management with effective monitoring and supervision. An important secondary role of leprosy control programmes is the prevention of disabilities.

Vaccines against leprosy

The substantial cross-reactivity between bacille Calmette–Guérin (**BCG**) and *M. leprae* has been exploited in attempts to develop a vaccine against leprosy. Trials of BCG as a vaccine against leprosy in Uganda, New Guinea, Burma, and South India showed it to confer statistically significant but variable protection, ranging from 80 per cent in Uganda to 20 per cent in Burma. A case–control study in Venezuela showed BCG vaccination to give 56 per cent protection to the household contacts of patients with leprosy. Combining BCG and killed *M. leprae* has been tried, but in both a large population-based trial in Malawi and an immunoprophylactic trial in Venezuela there was no advantage for BCG plus *M. leprae* over BCG alone.

Areas of uncertainty/controversy

The optimum duration of treatment is a controversial area. The last WHO expert committee recommended that treatment for multibacillary cases could be reduced from 24 to 12 months. The classification of leprosy cases has been simplified. Cases are now classified by the number of lesions; slit skin smears are not mandatory. The decision to stop recommending slit skin smears was made because of the poor standard of smears in the field. A WHO sponsored trial comparing 12 months with 24 months treatment is in progress, but intake only started in 1992 and a 10-year follow-up is needed to assess relapse rates. Data from India show that patients with a high initial bacterial load (bacterial index greater than 4) treated with 2 years of rifampicin, clofazimine, and dapsone had a relapse rate of 8/100 person years, whereas patients treated to smear negativity had a relapse rate of 2/100 person years. The dilemma is that if skin smears are abandoned then those patients in need of longer treatment courses cannot be identified. These arguments illustrate the difficulty in providing sound evidence for policy decisions when a decade-long wait is needed.

The shortening of drug treatment for leprosy means that the vertical leprosy programmes are now treating far fewer patients. There is considerable discussion about how best to detect, treat, and prevent leprosy disability in the future. There are several possibilities—integration with tuberculosis programmes, dermatology programmes, or at health centre level. Whichever model is chosen as being locally appropriate, it should be remembered that treating patients with leprosy is a long-term enterprise involving patients, their families, and health workers.

Areas where further research is needed

The epidemiology of leprosy still poses unanswered questions. Why are 70 per cent of all patients with leprosy in India? Is this due to living conditions, genetic susceptibilty, or particular environmental conditions in India?

Early detection of cases is vital both at an individual and population level. It is now recognized that substantial nerve damage occurs before diagnosis. A test for early infection might help detect individual cases before nerve damage is established and before the spread of infection. Leprosy-specific peptides for skin tests have been generated and are being evaluated.

The medical management of reactions and nerve damage is currently limited to steroids. These are not effective for about 30 per cent cases. Thus trials of new immunosuppressants are urgently needed.

The WHO started the 1990s with the bold slogan of 'Eliminating leprosy as a public health problem by 2000'. This initiative galvanized leprosy control programmes worldwide, but the unique biology of *M. leprae* and its interaction with the human host meant that the target was unattainable. As the millennium approached the slogan was quietly dropped to the disappointment of many leprosy workers and governments. Leprosy is a bacterial disease with challenging immunological complications and will be a global and individual problem for many decades. It is unlikely to be eradicated until there is considerable improvement in general health, wealth, living conditions, and education.

7.11.25 Buruli ulcer: *Mycobacterium ulcerans* infection

Wayne M. Meyers and Françoise Portaels

Introduction

Buruli ulcer, also known as Bairnsdale or Searles' ulcer (Australia), and Kakerifu or Toro ulcer (Congo), is an indolent, necrotizing infection of the skin, subcutaneous tissue, and bone, caused by *Mycobacterium ulcerans*. After tuberculosis and leprosy, Buruli ulcer is the third most common mycobacterial disease, and is recognized by the WHO as a re-emerging infection.

Aetiology

In 1948 MacCallum and colleagues first isolated the causative agent from patients in Australia. *M. ulcerans* is a slow-growing, acid-fast bacillus which grows optimally at 32°C, and elaborates mycolactone, a cytotoxic and immunosuppressive polyketide. Putatively, this toxin is the primary virulence factor of *M. ulcerans*. Data from 16S rRNA sequences define four groups of *M. ulcerans*: African, American, Asian, and Australian strains.

Epidemiology and transmission

All endemic foci of Buruli ulcer are near rural freshwater wetlands, especially still or slow-moving water (ponds and swamps). All foci except those in southern Australia and northern Asia are tropical. Major endemic areas are Benin, Ghana, Ivory Coast, Nigeria, Congo, Gabon, Uganda, and adjacent countries. There are minor foci in South and Central America and south-east and northern Asia.

Documented environmental sources of *M. ulcerans* include water in irrigation systems and water bugs that dwell in the roots of aquatic plants in the bottom mud of swamps. In Australia, koala, possum, and naturalized alpaca contract the infection naturally.

Outbreaks of disease often follow environmental changes that promote flooding or alter water courses, such as deforestation or construction of dams and irrigation systems. Increases in farming populations near wetlands may contribute to the rapid re-emergence of Buruli ulcer in Africa. Approximately 75 per cent of all new infections are in children, who often play semi-naked in swampy terrain.

We postulate that humans become infected by traumatic introduction of the bacillus into the dermis or subcutis from the overlying *M. ulcerans*-contaminated skin surface. The trauma may be as slight as a hypodermic injection or as severe as a land-mine wound or snakebite. Biting insects (e.g. water bugs) may serve as mechanical vectors. Aerosols arising from the surface of ponds and swamps may disseminate *M. ulcerans*. Patient-to-patient transmission is rare.

Pathogenesis

No predisposing host factors are known. Once introduced, the small amount of mycolactone produced by a few *M. ulcerans* bacilli causes tissue necrosis and suppresses local immune responses ensuring survival of the bacillus in a nidus of nutrient necrotic tissue. The toxin targets subcutaneous fat cells so that necrosis can spread in and just superficial to fascial planes. *M. ulcerans* invades lymphatics and probably blood vessels, causing metastatic spread.

Clinical features

Clinical effects may be localized or disseminated. Except for those with massive lesions, patients are usually surprisingly well without specific systemic symptoms or abnormal laboratory findings.

Localized disease

Typically the initial cutaneous lesion is a single, firm, painless, non-tender, movable subcutaneous nodule up to 3 cm in diameter. Limbs are most frequently affected, often around joints. There is marked variation in the natural history of the disease, but nodules usually ulcerate within 1 to 3 months of inoculation. A whitish necrotic slough develops in the base of the ulcer and the surrounding skin is indurated and hyperpigmented. Ulcer borders are undermined, sometimes extending 15 to 20 cm or more (major ulcerative disease) (Fig. 1 and Plate 1). Some small (1 to 2 cm in diameter) ulcerated lesions with shallow undermining self-heal early without sequelae (minor ulcerative disease). Without treatment, major ulcerative lesions tend to become inactive, usually after months or years, and heal by scarring. Typically the scars are depressed and stellate, often causing disfiguring and crippling cicatricial contractions.

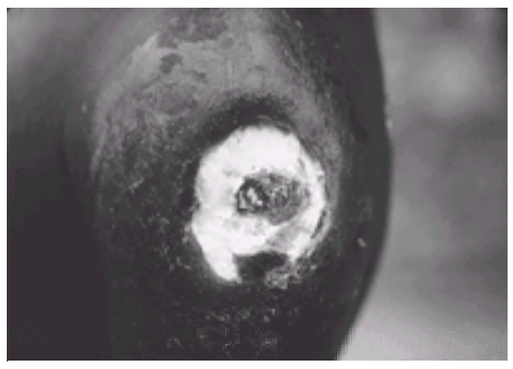

Fig. 1 Buruli ulcer on the left deltoid area in a 12-year-old Congolese boy who had received a hypodermic injection at this site 3 months previously. Note central necrotic slough in the base of the ulcer, and undermined edges. (See also Plate 1.)

Disseminated disease

Disseminated disease may pass only through the nodular stage or arise from localized major ulcerative lesions; however, following inoculation, the disease

sometimes disseminates directly and rapidly. These patients present with indurated plaques of varying size, sometimes covering an entire limb or vast areas of the trunk. Without treatment, such lesions will eventually slough, leaving a large ulcer with continuing extension of disease at the borders. Structures such as eyes, breasts, and genitalia may be damaged or lost.

While metastatic spread may arise from localized disease, patients with the highly bacilliferous disseminated cutaneous form are more prone to develop metastatic lesions. Spread may be to distant skin sites or to bone. Bones of the limbs are affected most frequently. *M. ulcerans* osteomyelitis is an increasing problem in many endemic areas, and often leads to amputations and other disabilities.

Differential clinical diagnosis

Diagnosis of the nodular stage is often perplexing. Differential diagnoses include bacterial, mycotic, and parasitic infections, inflammatory lesions, and tumours. Ulcers resembling Buruli ulcer include tropical phagedenic ulcer (malodorous and not undermined), venous stasis ulcer (not undermined), and bites by venomous snakes or spiders (history helpful).

Pathology

Optimal biopsy specimens contain the necrotic base of ulcers and undermined edge of lesions and subcutaneous tissue and fascia. Histopathological sections reveal a contiguous coagulation necrosis (non-caseating) of the deep dermis, panniculus, and fascia. Vasculitis and mineralization in these areas are common. Clumps of extracellular acid-fast bacilli are most plentiful in the base of the ulcer. Necrosis extends well beyond the location of the bacilli. Local and regional lymph nodes are often invaded and sometimes necrotic. In bone, the marrow is necrotic and contains acid-fast bacilli, and trabeculas are eroded. Development of delayed-type hypersensitivity granulomas heralds healing and eventual fibrosis.

Laboratory diagnosis

Smears stained by the Ziehl–Neelsen method from the ulcer base often reveal acid-fast bacilli in clumps. Cultures for *M. ulcerans* are often positive. Polymerase chain reaction is available for specific identification of *M. ulcerans*. Histopathological changes are characteristic.

Treatment

Wide surgical excision and skin grafting is the recommended treatment. Antimicrobial agents (e.g. rifampin and clarithromycin) should be administered before and after surgery to limit bacterial dissemination. Heating the lesion to 40°C is a useful adjunct. Oral antimycobacterial therapy without surgery may heal nodules and minor ulcerative lesions, but controlled trials are needed to establish efficacy. Physiotherapy is essential to prevent contraction deformities.

Prevention and control

Bacille Calmette-Guérin (BCG) vaccination provides short-lived protection. There are no practicable effective control measures for inhabitants of endemic areas. Tourists can avoid the wetlands in endemic countries.

Socio-economic impact

Patients are often disabled for life and require welfare services, often locally limited or unavailable. They require hospital stays of many months, taxing overburdened services.

7.11.26

Actinomycoses

K. P. Schaal

Definition

Actinomycoses are subacute to chronic, granulomatous as well as suppurative inflammatory diseases that tend to progress slowly and usually give rise to multiple abscesses and draining sinus tracts. Various fermentative (facultatively anaerobic or capnophilic) actinomycetes of the genera *Actinomyces* and *Propionibacterium*, but rarely also *Bifidobacterium*, may act as the principal causative agents of the disease. Because the term 'actinomycoses' denotes a polyaetiological inflammatory syndrome rather than a condition attributable to a single pathogenic actinomycete species, it should only be used in the plural.

Aetiology of human actinomycoses

Actinomyces israelii and *A. gerencseriae* are by far the most frequent and most characteristic pathogens aetiologically involved in the human form of the disease. *Propionibacterium propionicum*, *Actinomyces naeslundii*, *A. odontolyticus*, *A. viscosus*, *A. meyeri*, and *Bifidobacterium dentium* (formerly '*Actinomyces eriksonii*') are further potential but less common causes of actinomycotic infections, while *Actinomyces bovis* has been recovered solely from animals (Table 1).

Pathogenesis and pathology

Most of the fermentative actinomycetes pathogenic to man are found regularly and abundantly in the mouths of healthy adults. However, these microbes occur only sporadically or in low numbers in the digestive, respiratory, and genital tracts, as well as in the mouths of babies before teething and of adults without any natural teeth or tooth implants. Therefore, these actinomycetes may be considered facultatively pathogenic commensals of the human mucous membranes, which, apart from the very rare actinomycotic wound infections after human bites or fist fights, produce disease exclusively as endogenous pathogens.

For active invasion of the tissue, the classical pathogenic fermentative actinomycetes apparently require a negative redox potential, which may result either from insufficient blood supply (caused by circulatory or vascular diseases, crush injuries, or foreign bodies) or from the reducing and necrotizing capacity of other microbes in the lesion. Defective functions of the immune system do not specifically predispose to actinomycotic infections.

Synergistic polymicrobial infection

True actinomycoses are essentially always synergistic mixed infections, in which the actinomycetes act as the specific component, the so-called 'guiding organisms', which decide on the characteristic course and the late symptoms of the disease. The so-called concomitant microbes (Table 2), which may vary considerably in composition (about 100 aerobic and anaerobic species) and number (up to 10 per case) of species from case to case, are often responsible for the clinical picture at the beginning of the infection and for certain complications; they are also part of the resident or transient surface microflora of the mucous membranes of man.

Particularly pronounced synergistic interactions appear to exist between pathogenic fermentative actinomycetes, especially *Actinomyces israelii* and *A. gerencseriae*, and *Actinobacillus actinomycetemcomitans*. The latter organism, the name of which refers to its characteristic association with actinomycetes, may even sustain the inflammatory process under similar clinical symptoms after chemotherapeutic elimination of the causative actinomycete.

Histopathology

Initially, an inflammatory granulation tissue develops, which usually breaks down to form either an acute abscess or chronic multiple abscesses with proliferation of connective tissue. The pathognomonic sulphur granules are formed primarily in the infected tissue, but may also appear as free structures in abscess content or sinus discharge. They are then of the highest diagnostic importance.

Sulphur granules, which were originally designated 'Drusen' in Harz's first description of *Actinomyces bovis* in 1877, are macroscopically visible (up to 1 mm in diameter), yellowish, reddish to brownish particles, which exhibit a cauliflower-like appearance under the microscope at low magnifications (Fig. 1). They consist of a conglomerate of filamentous actinomycete microcolonies formed *in vivo* and surrounded by tissue reaction material, especially polymorphonuclear granulocytes. At high magnification, a Gram-stained smear of the completely crushed granule reveals the presence of clusters of Gram-positive interwoven branching filaments with radially arranged peripheral hyphae and of a variety of other Gram-positive and Gram-negative rods and cocci, which represent the concomitant flora. A club-shaped layer of hyaline material may be seen on the tips of peripheral filaments, which can aid in the differentiation of actinomycotic sulphur granules from macroscopically similar particles of various other microbial and non-microbial origins.

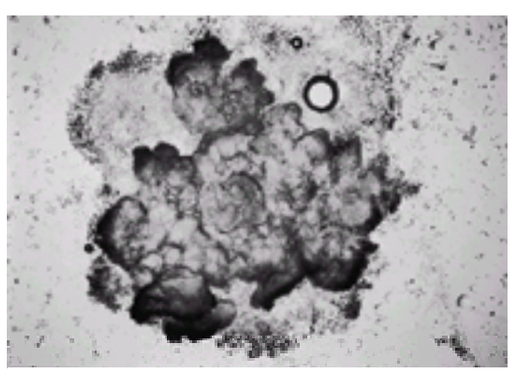

Fig. 1 Actinomycotic sulphur granule. Micrograph of a particle embedded in 1 per cent methylene-blue solution, original diameter 0.8 mm. Note the cauliflower-like structure in the centre of the particle and the partially dark-stained granulocytes in the periphery.

Clinical manifestations

The primary actinomycotic lesion usually develops in tissue adjacent to a mucous membrane at sites such as the cervicofacial, thoracic, and abdominal areas. The infection tends to progress slowly and to penetrate without regard to natural organ borders, or to spread haematogenously even to distant sites. Remission and exacerbation of symptoms with and without antimicrobial treatment is characteristic. As in other endogenous microbial diseases, the incubation period of actinomycoses is not defined.

Cervicofacial actinomycoses

In the vast majority of cases, actinomycotic lesions primarily involve the face or neck. Conditions predisposing to these cervicofacial infections include tooth extractions, fractures of the jaw, periodontal abscesses, foreign bodies penetrating the mucosal barrier (bone splinters, fish bones, awns of cereals), or suppurating tonsillar crypts.

Initially, the cervicofacial actinomycoses present either as an acute, usually odontogenic, abscess or cellulitis of the floor of the mouth, or as a slowly developing, chronic, hard, painless, reddish or livid swelling. Small acute actinomycotic abscesses may heal after surgical drainage alone. More often, however, the acute initial stage is followed by a subacute to chronic course if no specific antimicrobial treatment is given, thereby imitating the primarily chronic form, which is characterized by regression and cicatrization of central suppurative foci while the infection progresses peripherally producing hard, painless, livid infiltrations. These may lead to multiple, new areas of liquefaction, fistulae (Fig. 2), which often discharge pus containing sulphur granules, and multilocular cavities with poor healing and a tendency to recur after temporary regressions of the inflammatory symptoms.

Fig. 2 Primarily chronic cervicofacial actinomycosis with several draining sinus tracts and livid discoloration of the skin in a 42-year-old man.

With inappropriate or no treatment, cervicofacial actinomycoses extend slowly, even across organ borders, and may become life-threatening by invasion of the cranial cavity, the mediastinum, or the bloodstream.

Thoracic actinomycoses

Thoracic manifestations, which are much less common than the cervicofacial form (Table 3), usually develop after aspiration or inhalation of material from the mouth (dental plaque or calculus, tonsillar crypt contents) or a foreign body that contains or is contaminated with the causative agents. Occasionally, this form of disease may result from extension of an actinomycotic process of the neck, from an abdominal infection perforating the diaphragm, or from a distant focus by haematogenous spread.

Primary pulmonary actinomycoses present as bronchopneumonic infiltrations that may imitate tuberculosis or bronchial carcinoma radiographically, appearing as single dense or multiple spotted shadows in which cavitations may develop (Fig. 3). If not diagnosed and treated properly, pulmonary infections may extend through to the pleural cavity producing empyema, to the pericardium, or to the chest wall; they may even appear as a paravertebral (psoas) abscess tracking down to the groin.

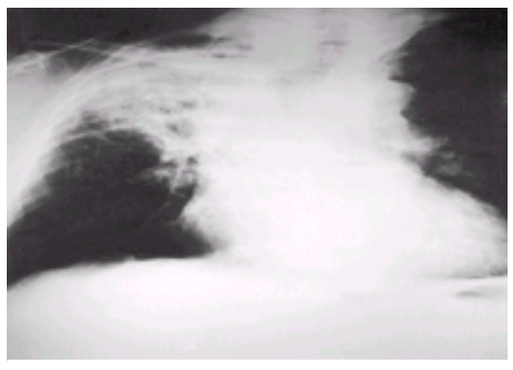

Fig. 3 Chest radiograph of pulmonary actinomycosis of the right upper lobe in a 62-year-old man. The disease was only diagnosed after a huge subcutaneous abscess had developed covering the whole right shoulder blade.

Abdominal actinomycoses

Actinomycoses of the abdomen and pelvis are rare (Table 3). They originate either from acute perforating gastrointestinal diseases (appendicitis, diverticulitis, various ulcerative diseases), from surgical or accidental trauma including injuries caused by ingested bone splinters or fish bones, or from inflammations of the female internal genital organs.

Women who wear intrauterine contraceptive devices or vaginal pessaries for long periods often show a characteristic colonization of the cervical canal and the uterine cavity by various fermentative actinomycetes and other anaerobes resembling the synergistic actinomycotic flora. However, this colonization only rarely results in an invasive actinomycotic process.

Most abdominal actinomycoses present as slowly growing tumours, which, in the absence of sinus tracts discharging pus with sulphur granules, are difficult to differentiate from malignant neoplasms such as colonic, rectal, ovarian, or cervical carcinomas. By direct extension, any abdominal tissue or organ may be involved including muscle, liver, spleen, kidney, fallopian tubes, ovaries, testes, bladder, or rectum. Haematogenous liver abscesses have been seen, especially associated with genital actinomycoses.

Actinomycotic infections of the central nervous system

Actinomycoses of the brain and the spinal cord are very rare. They may arise from direct extension of cervicofacial infections. Haematogenous spread is also

possible, particularly from primary lesions in the lungs or abdomen. The spinal canal may be directly involved from these sites. Brain abscess is much more common than meningitis.

Actinomycoses of the bone

Bone involvement is also very rare. It usually develops by direct extension from soft tissue infection resulting in a periostitis with new bone formation visible by radiography. If the bone itself is invaded, localized areas of bone destruction surrounded by increased bone density usually develop. Mandible, ribs, and spine are most frequently involved.

Cutaneous actinomycoses

Actinomycotic lesions of the skin are extremely rare. Usually, they originate from wounds that were contaminated with saliva or dental plaque following human bites or fist fights, but they may also result from haematogenous spread. Symptoms are similar to those of cervicofacial actinomycoses.

Diagnosis

Clinical symptoms are often misleading, especially in the early stages of the disease, histopathological appearances are unreliable, and diagnosis chiefly rests on bacteriological methods.

Radiography

In cervicofacial cases, radiography is useful only for detecting bone involvement. A pulmonary infiltrate associated with a proliferative lesion or destruction of ribs is highly suggestive of either actinomycosis or a tumour. Radiography may also help to locate the abdominal processes and to identify the involvement of organs such as liver, kidney, urinary bladder, or ureter. In general, however, radiographic changes are not diagnostic.

Laboratory diagnosis

Clinical chemistry and haematology

Small, localized actinomycotic lesions are not usually associated with abnormalities. In advanced cases, however, especially those in the thoracic or the abdominal area, a raised erythrocyte sedimentation rate and pronounced leucocytosis may be found. When the central nervous system is involved, a polymorphonuclear or mononuclear pleocytosis is commonly found. The protein content of the cerebrospinal fluid is frequently elevated and the sugar content moderately depressed.

Bacteriology

Pus specimens containing sulphur granules and occasionally looking like semolina should prompt the clinician to ask and the bacteriologist to look specifically for actinomycetes using suitable cultural techniques and other methods.

Pus, sinus discharge, bronchial secretions, granulation tissue, or biopsy materials are suitable specimens. Precautions must be taken to prevent contamination of the specimen by the indigenous mucosal flora. In cases of cervicofacial actinomycoses, pus should therefore be obtained only by transcutaneous puncture of the abscesses or by transcutaneous needle biopsy. When abscesses have already been incised, a sufficient amount of pus should be collected instead of using only a swab. Because sputum always contains oral actinomycetes, bronchial secretions should be obtained by transtracheal aspiration, or material should be collected by transthoracic percutaneous needle biopsy. Percutaneous puncture of suspected abscesses is often the only way of obtaining suitable specimens for diagnosing abdominal actinomycoses.

The transport of specimens to the bacteriological laboratory should be as fast as possible, preferably by messenger. Alternatively, a reducing transport medium such as one of the modifications of Stuart's medium should be used. The specimen should arrive in the laboratory within 24 h, although it has occasionally proved possible to isolate actinomycetes from samples that took 7 days or more to get to the diagnostic laboratory by post.

A quick and comparatively reliable tentative diagnosis is possible microscopically when sulphur granules are present (Fig. 1). The demonstration of concomitant bacteria in Gram-stained smears prepared from crushed granule material allows the differentiation of actinomycotic granules from similar particles produced by *Nocardia*, *Actinomadura*, or *Streptomyces* species.

Use of transparent culture media and careful microscopic examination of the cultures, preferably on Fortner plates, after at least 2, 7, and 14 days of incubation, enables a specialized laboratory to detect possible actinomycete colonies and to subculture them for identification. Isolation and definite identification to the species level may require a further 1 to 2 weeks. Techniques such as the application of gene probes or the polymerase chain reaction for detecting and identifying fermentative actinomycetes are not yet widely used.

Serological diagnosis

None of the routine serological methods has yet provided satisfactory results because sensitivity and specificity have been found to be too low.

Treatment

As the aetiology of human actinomycoses is always polymicrobial, the antibacterial drugs used for treatment should in principle cover both the causative actinomycetes and all of the concomitant bacteria. This usually requires the administration of drug combinations, in which aminopenicillins currently represent the therapeutic basis because they are slightly more active against the pathogenic actinomycetes than is penicillin G and because they are able to inhibit *Actinobacillus actinomycetemcomitans* which is usually resistant to narrow-spectrum penicillins. However, the presence of concomitant b-lactamase producers such as *Bacteroides fragilis*, *B. thetaiotaomicron*, or *Staphylococcus aureus* (b-lactamase producing) may impair the therapeutic efficacy of aminopenicillins and that of many other b-lactams so that the combination with a b-lactamase inhibitor is advisable or even necessary.

For cervicofacial actinomycoses, amoxicillin plus clavulanic acid has proved to be the treatment of choice. Three doses of 2.0 g amoxicillin plus 0.2 g clavulanic acid per day for 1 week and three doses of 1.1 g of the combination for an additional 7 days usually result in complete cure. Thoracic actinomycoses mostly respond to the same regimen. However, it is advisable to maintain doses of 2.2 g, three times per day, for 2 weeks, and to continue treatment for 3 to 4 weeks. Advanced pulmonary cases may require the addition of 2 g ampicillin, three times a day, in order to increase the tissue concentration of aminopenicillin and, depending on the composition of the concomitant flora, the use of an antimicrobial specifically active against resistant enterobacteriaceae; the application of drugs such as metronidazole or clindamycin against strict anaerobes is only necessary, as an adjunct to the aminopenicillins, in chronic cases with reduced blood supply.

Since in abdominal actinomycoses enterobacteriaceae and b-lactamase producing *Bacteroides* species are usually present and the correct diagnosis is mostly established late, suitable antimicrobial combinations for these cases are amoxicillin plus clavulanic acid plus metronidazole plus tobramycin (gentamicin) or ampicillin plus clindamycin plus an aminoglycoside. Imipenem might also be a good choice, but this drug has not yet been widely used for treating actinomycotic infections.

Neither clindamycin nor metronidazole should be used alone. Clindamycin is almost completely ineffective against *Actinobacillus actinomycetemcomitans* and metronidazole shows no activity at all against pathogenic actinomycetes. The use of further combinations, including additional aminoglycosides, cephalosporins, or b-lactamase-stable penicillins, may be necessary depending on the presence of unusual aerobic organisms. In patients allergic to penicillins, tetracyclines or possibly cephalosporins may be tried instead of aminopenicillins. Incision of abscesses and drainage of pus may still be necessary as an adjunct to the antimicrobial chemotherapy and may help to accelerate recovery and to decrease the risk of relapses.

Prognosis

The prognosis of cervicofacial and cutaneous actinomycotic infections is good provided that the diagnosis is established early and antimicrobial treatment is adequate. However, thoracic, abdominal, and systemic manifestations remain serious conditions that require all possible diagnostic and therapeutic efforts. Without proper treatment, the prognosis is grave.

Epidemiology

Actinomycoses are not transmissible and cannot be brought under control by vaccination or by measures that prevent spread. Sporadically, they occur worldwide. In Germany, the incidence of the disease was estimated to range from 1 in 40 000 (acute and chronic cases together) to 1 in 80 000 (chronic cases alone) per year, but appears to be decreasing in recent years.

Adult males are affected two to four times more frequently than are females by cervicofacial actinomycoses. Although actinomycoses may be found in patients of any age, men are predominantly affected between their 20th and 40th years and women in the second and third decade of their lives. Before puberty and in old age, actinomycoses occur sporadically in patients of both sexes.

Other diseases caused by fermentative actinomycetes

Fermentative actinomycetes play some part in dental caries and periodontal disease, but are clearly not the most important microbes contributing to these important health problems. Lacrimal canaliculitis with and without conjunctivitis is commonly caused by fermentative actinomycetes, in particular *Propionibacterium propionicum*, *Actinomyces viscosus*, or *A. israelii* and rarely by other actinomycete species. The concomitant flora, when present, is usually less complex than that of typical actinomycoses. Removal of the lacrimal concretions that are usually present and local application of antimicrobials always result in prompt cure.

Arcanobacterium pyogenes and *A. haemolyticum* (formerly '*Corynebacterium* (*Actinomyces*) *pyogenes*' and '*C. haemolyticum*') cause acute pharyngitis, urethritis, or cutaneous or subcutaneous suppurations. The recently described species *Actinomyces neuii* subspecies *neuii* and subspecies *anitratus*, *A. graevenitzii*, *A. europaeus*, *A. radingae*, *A. turicensis*, *A. funkei*, *A. radicidentis*, and *A. urogenitalis*, as well as *Arcanobacterium* (*Actinomyces*) *bernardiae* and *Actinobaculum schaalii* have been isolated from various clinical sources including abscesses and blood cultures, and may also be associated with mixed bacterial flora. *A. turicensis* and possibly *A. urogenitalis* seem to be particularly common in genital infections while *A. radingae* was found only in patients with skin-related pathologies, *A. europaeus* was detected in patients with urinary tract infections, and *A. radicidentis* was isolated from infected root canals of teeth.

7.11.27 Nocardiosis

R. J. Hay

Nocardiosis (nocardiasis) is the infection caused by *Nocardia* species, usually *Nocardia asteroides* but, less commonly, *N. brasiliensis*, *N. otitidiscaviarum*, and *N. transvaliensis*. The term is most commonly applied to systemic infection due to these organisms but can also be used to describe cutaneous disease that follows the implantation of infection. These organisms are also important causes of actinomycetoma, particularly in Mexico and Central America.

The nocardias are Gram-positive, filamentous, branching bacteria that ramify in infected tissues. They can also break up into bacillary forms and, in some conditions, aggregate into grains typical of mycetomas. These organisms are aerobic and partially acid fast. They grow readily on ordinary laboratory media.

Pathogenesis

Nocardia species are found in soil, particularly where there is decaying vegetation. They can also be isolated from the air and, in most cases, systemic infection is by the airborne route; rarely nocardiosis can be acquired after inoculation into the skin. The characteristic histopathological response to infection is the production of polymorphonuclear leucocyte abscesses without extensive fibrosis. Caseation and palisading granulomas are not generally seen. Metastases can occur in other organs. Dissemination of infection to the skin can occur in such systemic infections. By contrast, in primary cutaneous infections the lesion is usually localized to an abscess containing filaments at the site of inoculation and is accompanied by local lymphadenopathy. Mycetoma grain formation may occur in some of these infections that follow inoculation. It is not known why, in some patients, transcutaneous infection with nocardia results in the development of a mycetoma whereas in others a subcutaneous abscess containing filaments is formed. The tendency to develop into mycetomas appears to be more common with *N. brasiliensis* infections.

Epidemiology

Otherwise healthy patients may be infected by nocardia, although the frequency of subclinical exposure and sensitization in normal populations is unknown. However, the majority of patients with systemic nocardiosis are immunocompromised, most commonly with a condition that affects the expression of T-lymphocyte-mediated immune responses. The list of underlying conditions includes:

1. malignancies, including cancer and lymphoma;
2. AIDS and other immunodeficiency states such as chronic granulomatous disease;
3. solid-organ transplantation;
4. other conditions that require high doses of corticosteroids, such as collagen-vascular disease and rheumatoid arthritis; and
5. pre-existing pulmonary disease—alveolar proteinosis, in particular, seems to predispose to nocardiosis.

The usual site of primary infection is the lung and the disease may remain restricted to this site. It may also be disseminated to other organs, particularly to the brain and skin. Nocardiosis can occur at any age, although it is rare, particularly in childhood.

Clinical features

Primary cutaneous nocardiosis

This is an uncommon infection that appears to follow traumatic inoculation of organisms in a superficial abrasion. The usual primary lesion is a small nodule, ulcer, or abscess at the site of inoculation. There may be a small chain of secondary nodules (cf. sporotrichosis) along the course of a lymphatic and local lymphadenopathy is common. Some such cases resolve spontaneously. This form of disease is usually caused by *N. asteroides*.

Nocardia mycetoma

This is discussed in Chapter 7.12.1. *N. brasiliensis* is the usual cause.

Pulmonary nocardiosis

Pulmonary infection is seen in about 75 per cent of cases of systemic nocardiosis, even where there are disseminated lesions elsewhere. Symptoms of pulmonary nocardiosis are variable, with cough, fever, and leucocytosis. In otherwise healthy individuals the changes and signs may be very similar to pulmonary tuberculosis, whereas in the immunocompromised patient the lesions present as rapidly developing, single or multiple lung lesions. In patients with AIDS, symptoms are often minimal, even in the presence of extensive disease. These changes are reflected by the course of the disease. In some patients, progression is rapid, in others chronic.

Chest radiographs may show segmental or lobar infiltrates, cavitation, nodules, or diffuse miliary infiltrates. Calcification is not common. The infection may spread locally to involve adjacent structures such as the pleural space and diaphragm or may spread to other sites. Very occasionally, nocardias can be isolated from sputum of otherwise healthy patients. Whether this reflects the process of asymptomatic sensitization is not known. Most cases of pulmonary nocardiosis are caused by *N. asteroides*.

Disseminated nocardiosis

Haematogenous spread is common in the immunocompromised patient and may occur without evidence of pulmonary infection. The most common site for dissemination is the brain, where it presents with localized abscesses without meningeal involvement. The signs are those due to an intracerebral space-occupying lesion. Spread to other sites is less common, although dissemination to skin, liver, kidneys, and bone may occur.

The acute disseminated forms and those with involvement of the central nervous system have the worst prognosis. Continued therapy with corticosteroids also appears to have bad prognostic significance. Infection in patients with AIDS may not be recognized before death. Rapid diagnosis is therefore a key to successful management. By contrast, pulmonary infection in otherwise healthy patients is usually a chronic process and has to be distinguished from tuberculosis.

Laboratory diagnosis

The infection is often recognized initially by direct microscopy of pus, bronchial washings, or tissue. In Gram stains the organisms can be shown as fine, branching filaments, although distinction from other bacteria may be difficult if short, rod-like forms predominate. A modified acid-fast stain using weak acid can be used to

demonstrate filaments.

Nocardia species grow on ordinary media aerobically. Colonies may take 2 to 3 weeks to appear and cultures need prolonged incubation. Growth is generally more rapid on Lowenstein–Jensen medium.

Histopathological examination is useful in some cases. Filaments stain with modified acid-fast stains using an aqueous solution of a weak acid for decolorization, but can also be highlighted with the methenamine–silver stain (Grocott modification). The branching nature of the organism is best appreciated in histopathological material. Other pathogens such as *Pneumocystis* species may also be present in histopathological material.

Serological tests (usually counterimmunoelectrophoresis or enzyme immunoassay) can be obtained in reference centres and are generally used to monitor the progress of therapy rather than establish the diagnosis.

Therapy

The mainstays of therapy are sulphonamides such as sulphadiazine and sulphafurazole, given in doses of 4 to 6 g daily. Co-trimoxazole is also effective, particularly in pulmonary forms, although the ratio of the trimethoprim to sulphonamide components is not ideal for intracerebral infections. In many cases, drainage of abscesses may hasten recovery. Unfortunately, there have been no multicentre clinical studies aimed at reaching a consensus on the most appropriate therapy for this uncommon infection. Thus, much of the recommended drug therapy is derived from the personal experiences of few cases. It is, for instance, the general practice to use two antibiotics.

Other drugs that have been used include amikacin, ampicillin, and minocycline—although testing is necessary before using these. Experience of other drugs is similarly limited. For instance, ciprofloxacin, cefotaxime, and imipenem are all active *in vitro* but clinical experience with them is limited at present.

Clustering of cases may occur occasionally, suggesting exposure to a common source of infection. In two such episodes there had been extensive construction work in the vicinity of the hospital involved. At present, no methods of prevention are known, although the existence of more than two cases in a single or adjacent wards should alert clinicians to the possibility of environmentally acquired infection.

7.11.28 Rat-bite fevers

D. A. Warrell

Introduction

Rat bites are not uncommon, even in cities. Young children are often bitten while asleep. Patients with diabetic or leprous neuropathy are particularly vulnerable. Rodent bites can transmit lymphocytic choriomeningitis and other arenaviruses, rabies, leptospirosis, melioidosis, tularaemia, plague, murine typhus, trench fever, *Pasteurella multocida*, and the two rat-bite fevers caused by *Streptobacillus moniliformis* and *Spirillum minus*.

Streptobacillus moniliformis infection (streptobacillary rat-bite fever and Haverhill fever)

This organism is part of the normal pharyngeal flora of up to 50 per cent of wild and laboratory rats and can be recovered from the nasopharynx, middle ear, saliva, and urine. It can also cause severe disease in rodents: septicaemia, pneumonia, conjunctivitis, polyarthritis, and abortion. It has been isolated from rats, mice, guinea-pigs, gerbils, squirrels, and turkeys as well as animals that feed on rodents such as cats, dogs, pigs, ferrets, and weasels.

S. moniliformis derives its name from the filaments and chains with yeast-like swellings seen in mature cultures on solid media. It is a non-motile, pleomorphic, filamentous, Gram-negative rod, 1 to 5 µm long, and is microaerophilic. It can be grown in ordinary blood culture media, but thrives only when blood, serum, or ascitic fluid are added (for example, trypticase soy agar with 20 per cent horse or rabbit serum added under 8 per cent CO_2). In liquid media, 'puff ball' colonies appear in 1 to 6 days. In concentrations exceeding 0.0125 per cent, sodium polyanethol sulphonate ('Liquoid'), a laboratory anticoagulant often added to blood culture broths for isolating aerobic bacteria, inhibits the growth of *S. moniliformis*. In culture, L-phase variants occur spontaneously. These lack a cell wall and are therefore resistant to penicillin. The organism has been cultured from patients' bite wounds, blood, synovial and pericardial fluid, and from abscesses.

Epidemiology

The infection occurs worldwide in two forms. Rat-bite fever is caused by bites or scratches by rodents or their predators or mere contact with these mammals whether living or dead. In some countries, 10 per cent of those bitten by wild rats will be infected. Most rat-bite victims are children of poor families living in urban areas. The bite may not be suspected since many are inflicted while the patient is asleep. Laboratory staff who work with rats are also at special risk. Haverhill fever, named after a town in Massachusetts, follows ingestion of raw milk, food, or water contaminated by rats. An outbreak in a boarding school in England in 1983 affected 304 people, 43 per cent of the school's population, and was attributed to contamination of the water supply by rats.

Clinical features

After an incubation period, which is usually less than 10 days and often as short as 1 to 3 days, there is a sudden high fever with rigors, vomiting, severe headache, myalgia, and muscle tenderness. Evidence of the bite has usually disappeared by this stage. About 75 per cent of patients develop a rash between 1 and 8 days later. Discrete erythematous macules, 1 to 4 mm in diameter, appear symmetrically on the lateral and extensor surfaces and over the joints. They are often most marked on the hands and feet (palms and soles) with associated petechiae, but they also occur on the face. Papules, vesicles, and pustules with scabs have also been described. About half the patients develop an asymmetrical migratory polyarthralgia or arthritis, usually involving the knees, ankles, elbows, shoulders, and hips and often associated with effusions. Joint pains may be the dominant symptom in patients with rat-bite fever. Diarrhoea and loss of weight are described in young children. Fever and other symptoms subside in a few days in treated cases, but fever may persist for 1 to 2 weeks (or relapse over several months) and arthritis for many months in those untreated. Severe infections can lead to bronchitis, pneumonia, metastatic abscess formation (including cerebral abscess), myocarditis, pericarditis with effusion, subacute glomerulonephritis, interstitial nephritis, splenitis or splenic abscess, amnionitis, and anaemia. Infective endocarditis, usually with underlying rheumatic or other valve disease, has been described in 18 cases, one with human immunodeficiency virus (**HIV**) infection.

Haverhill fever (erythema arthriticum epidemicum) follows a similar clinical course after the patient has drunk unpasteurized milk or contaminated water. Vomiting, stomatitis, and upper respiratory tract symptoms such as sore throat are said to be more prominent than in rat-bite fever.

Diagnosis

Unlike *Spirillum minus* infection (sodoku), the incubation period is short, the bite wound heals permanently with little local lymphadenopathy, the rash is morbilliform or petechial, and arthritis is common.

The diagnosis can be confirmed by culturing the organism from blood, joint fluid, or pus. In patients with infective endocarditis the differential diagnosis of the slow-growing, microaerophilic organism will include *Haemophilus aphrophilus*, *Cardiobacterium hominis, Actinomyces actinomycetencomitans*, and *Eikenella corrodens*. A high or rising titre of agglutinins, complement-fixing or fluorescent antibodies, may be detected between 2 and 3 weeks. A peripheral leucocytosis of 10 000 to 30 000/µl is usual and false-positive serological tests for syphilis are found in 15 to 25 per cent of cases.

Treatment

Streptobacillus moniliformis is sensitive to penicillin and can be treated with procaine benzylpenicillin (adult dose 600 mg or 600 000 units) by intramuscular injection every 12 hours for 7 to 14 days, or by penicillin-V 2 g a day by mouth. Penicillin-resistant L-variants are susceptible to streptomycin, tetracycline, and probably erythromycin. For patients hypersensitive to penicillin, erythromycin, chloramphenicol, tetracycline, or cephalosporins can be used. Erythromycin was used successfully in the boarding-school outbreak of Haverhill fever in England in 1983.

Patients with endocarditis should be treated with intravenous benzylpenicillin, 4.8 to 14.4 g (8–24 000 000 units) each day for between 4 and 6 weeks, or 4.8 mega units of procaine benzylpenicillin daily by intramuscular injection for 4 weeks if the cultured organism has a sensitivity of 0.1 µg/ml. The addition of streptomycin improves bactericidal activity and eliminates L-forms.

Prognosis

The untreated case fatality was reported to be 10 to 13 per cent. However, the overall mortality in patients with endocarditis is about 50 per cent. Residual arthralgia,

persisting for as long as 10 years, has been described.

Spirillum minus infection (sodoku, sokosha)

Spirillum minus may be found in the blood of up to 25 per cent of apparently healthy rodents and in the eye discharge and mouths of rats with interstitial keratitis and conjunctivitis. *S. minus* is a relatively thick, tightly coiled, Gram-negative spirillum (**not** a spirochaete), between 2.5 and 5.0 µm long, with 2 to 6 (commonly 3) spirals, resembling campylobacters. It darts about under the power of its terminal flagella. Continuous culture on artificial media has not been achieved, but the organism can be demonstrated by inoculating material from the bite wound, regional lymph nodes, or blood intraperitoneally into mice or guinea-pigs. Organisms usually appear in the rodent's blood within 5 to 15 days of inoculation.

Epidemiology

Sodoku is found worldwide but is particularly common in Japan. It results from bites, scratches, or mere contact with rodents or their predators including dogs, cats, and pigs.

Clinical features

The initial bite wound usually heals without signs of local inflammation. After an incubation period of between 5 and 30 days, usually 7 days or more, there is sudden fever which, in untreated cases, reaches its height in 3 days and resolves by crisis after a further 3 days. Other acute symptoms include rigors, myalgia, and prostration. At the start of the illness the healed bite wound becomes inflamed and swollen; it may break down to become necrotic or suppurative. Regional lymph nodes are usually enlarged and tender. The exanthem often starts at the site of the bite and spreads from there. It consists of angry purplish or reddish-brown indurated papules, plaques, or macules with urticarial lesions. Arthralgia may be severe but there are no joint effusions. Severe manifestations including meningitis, cerebral abscess, encephalitis, endocarditis, myocarditis, myocardial abscess, pleural effusion, chorioamnionitis, subcutaneous abscesses, and involvement of liver, kidney, and other organs are seen in about 10 per cent of cases. Relapses of fever, rash, and other symptoms lasting 3 to 6 days may occur between remissions of a week or so for 2 to months and occasionally up to a year in untreated patients.

Diagnosis

Clinically, sodoku is distinguishable from streptobacillary rat-bite fever by its longer incubation period, by the marked reaction at the bite site with local lymphadenopathy at the start of symptoms, by the different rash (dark papular rather than morbilliform and petechial), and by the rarity of arthritis. The diagnosis can be confirmed by examining an aspirate from the bite wound, lymph nodes, exanthem, or blood (thick and thin films) by dark-field microscopy or by staining with Wright's or Giemsa stain. Spirochaetes can be detected in the blood, peritoneal fluid, or heart muscle of inoculated rodents but cannot be cultured on artificial media. No specific serological tests are available. False-positive serological tests for syphilis are found in 50 to 60 per cent of cases, and reactions with Proteus OXK are also common.

Differential diagnosis of rat-bite fevers

An acute, severe, febrile illness following a rat bite, or other contact with rodents or their predators, should raise the possibility of other rodent-related infections. These include: *Pasteurella multocida*, which produces local pain and erythema within a few hours of the bite; plague; tularaemia; leptospirosis; murine typhus; and arenaviruses such as lymphocytic choriomeningitis, Lassa fever (Africa), or Argentine, Bolivian, or Venezuelan haemorrhagic fevers (South America). Ingestion of raw milk should also raise the possibility of brucellosis.

Treatment

Penicillin is the drug of choice. For adults, procaine benzylpenicillin 600 mg (600 000 units) should be given every 12 hours for 7 to 14 days. Penicillin-V, 2 g/day by mouth, is also said to be effective. A Jarisch–Herxheimer reaction may complicate penicillin treatment.

Prognosis

Untreated case fatality is about 2 to 10 per cent.

Prevention of rat-bite fevers

These infections can be prevented by rodent control, by encouraging laboratory workers to wear gloves and use correct techniques when handling rodents, to clean all rodent bite wounds, and to take prophylactic penicillin when bitten. Haverhill fever is prevented by avoiding the con-sumption of raw milk, by monitoring water supplies (especially those not derived from the mains), and by controlling rat populations.

7.11.29 Lyme borreliosis

John Nowakowski, Robert B. Nadelman, and Gary P. Wormser

Lyme borreliosis (also called Lyme disease) is an infection caused by the spirochaete, *Borrelia burgdorferi*, which is transmitted to humans by the usually asymptomatic bite of certain ticks of the genus *Ixodes* (Plate 1). The entire chromosome of *Borrelia burgdorferi* and 11 of its plasmids have been sequenced. Ticks acquire this borrelial infection in a complex tick–vertebrate transmission cycle. The white-footed mouse is the most important reservoir for *B. burgdorferi* in North America, but in Europe a variety of small mammals and birds are involved, possibly reflecting the much more varied and complex ecology of the *Ixodes* ticks in Eurasia. White-tailed deer, an important host for adult *Ixodes* ticks, are not a reservoir for *B. burgdorferi*.

Lyme borreliosis occurs in north-eastern, mid-Atlantic, north-central, and far western regions of the United States, limited foci in Canada (mainly in eastern Ontario), and much of Europe and northern Asia. Migrating birds may play a role in the spread of ticks and *B. burgdorferi* to new geographical locations.

Lyme borreliosis occurs equally in males and females, and affects people of all ages. There is a bimodal age distribution with the highest rates in children 5 to 9 years old and adults more than 30 years old.

Clinical manifestations

The somewhat different manifestations of Lyme borreliosis in Eurasia compared with North America (Table 1) may be explained by the wider variety of genospecies of *B. burgdorferi*. Clinical features are similar in adults and children.

Erythema migrans (Plate 2)

Erythema migrans, the clinical hallmark of Lyme borreliosis, is recognized in approximately 90 per cent of patients with objective evidence of *B. burgdorferi* infection. Typically, erythema migrans begins as a red macule or papule at the site of a tick bite that occurred 7 to 10 days earlier. The rash expands over days to weeks. Central clearing may or may not be present. Secondary cutaneous lesions may develop after haematogenous spread of spirochaetes. Erythema migrans must be distinguished from local tick bite reactions **,**tinea, insect and spider bites, bacterial cellulitis, and plant dermatitis.

Systemic complaints in patients with erythema migrans are more common in the United States than in Europe, perhaps as a result of illness caused by a more virulent genospecies (*B. burgdorferi sensu stricto* rather than *B. afzelii*) or more frequent coinfection with other tickborne pathogens. Symptoms include fatigue, myalgia, arthralgia, headache, fever and/or chills, and stiff neck. Prominent respiratory and/or gastrointestinal complaints are so infrequent that their presence should suggest an alternative diagnosis or coinfection. The most common objective physical findings are regional lymphadenopathy and fever. Occasional cases of febrile viral-like illness without erythema migrans have been attributed to Lyme borreliosis.

Carditis

Typically cardiac disease develops within weeks to months after infection. It is usually manifested by fluctuating degrees of atrioventricular block which may cause the patient to complain of dizziness, palpitations, dyspnoea, chest pain, or syncope. Pericarditis with effusion is rarely observed. The incidence (as measured by ECG-confirmed heart block) has been observed to be low in both the United States (< 1 per cent) and Europe (< 4 per cent). *B. burgdorferi* has been recovered in culture from the myocardium of several European patients with congestive heart failure including two with acute myocarditis and one with chronic cardiomyopathy.

Neurological disease

The incidence of neurological Lyme disease in Europe (20 per cent) may be higher than in the United States (< 10 per cent). One explanation may be the greater neurotropism of *B. garinii* (a genospecies which has not been isolated in North America). The principal early neurological manifestations are cranial neuropathy (typically 7th nerve palsy), radiculopathy, and meningitis, which may occur alone or together. Late neurological manifestations are uncommon and include peripheral neuropathy, encephalopathy, and encephalomyelitis.

Antibiotics appear to hasten the resolution of meningitis but most studies are uncontrolled. The rate of resolution of motor dysfunction, which is fully reversible in the vast majority of cases, is not enhanced by antimicrobial therapy. Symptoms of encephalopathy and peripheral neuropathy improve or do not progress after treatment with antibiotics.

Rheumatological disease

Lyme arthritis is more frequently diagnosed in North America than in Europe. In a study of 55 untreated patients with erythema migrans diagnosed in the United States between 1977 and 1979, followed for a mean duration of 6 years, objective arthritis developed in more than half, occurring within 1 year for 90 per cent of patients. Without antibiotic treatment, intermittent attacks of migratory monoarthritis or asymmetric oligoarthritis occur, lasting a mean of 3 months (range 3 days to 11.5 months). The knee is affected at some point in almost all patients, but other large and (less often) small joints may be affected. Temporomandibular joint involvement occurred in 11 (39 per cent) of 28 patients with arthritis in one series. Although large effusions may occur, joint pain and erythema are often minimal. Baker's cysts may develop. Typically, synovial fluid analysis reveals a modestly elevated protein and white cell count (median 24 250 white cells/mm ^{3}; range 2100 to 72 250 white cells/mm^{3}) with a polymorphonuclear predominance and a normal glucose level. Synovitis lasting 1 year or more may ensue for a minority of American patients, sometimes associated with joint destruction. Although *B. burgdorferi* DNA can be detected by polymerase chain reaction (**PCR**) in the synovial fluid of up to 85 per cent of untreated patients with Lyme arthritis, *B. burgdorferi* has rarely been successfully cultured from joint fluid. In patients who receive antibiotics, the presence of *B. burgdorferi* can no longer be detected by PCR in repeat synovial fluid examinations.

Acrodermatitis chronica atrophicans

This develops insidiously on a distal extremity. It is a skin lesion that is swollen, bluish-red, and which ultimately atrophies. One-third of patients have an associated (usually sensory) polyneuropathy. *B. burgdorferi* has been recovered from skin biopsy specimens of acrodermatitis chronica atrophicans lesions of more than 10 years' duration. Since the usual causative agent, *B. afzelii*, does not occur in the United States, acrodermatitis chronica atrophicans is essentially a European disease.

Miscellaneous clinical manifestations

Borrelia lymphocytoma, principally caused by *B. afzelii* and *B. garinii*, is a tumour-like nodule which typically appears on the pinna of the earlobe or on the nipple or

areola of the breast. Lesions resolve spontaneously but disappear within a few weeks after antibiotics. This lesion does not occur in North America.

Direct involvement of the eye (e.g. uveitis, keratitis, vitritis, or optic neuritis) has been attributed to *B. burgdorferi* infection. However, since ophthalmological disorders have almost never been associated with the isolation of *B. burgdorferi* in culture, the actual pathogenesis in these cases is uncertain. Conjunctivitis, originally described in 11 per cent of patients with erythema migrans, was rare (< 5 per cent) in recent studies of culture-positive patients.

Case reports have suggested that adverse outcomes may be associated with pregnancies complicated by maternal Lyme borreliosis. The risk of transplacental transmission of *B. burgdorferi*, however, is probably minimal when appropriate antibiotics (Table 2) are given to pregnant women with Lyme borreliosis. There are no published data to support a congenital Lyme borreliosis syndrome.

Laboratory tests

Where Lyme borreliosis is endemic, diagnosis of erythema migrans is purely clinical. Laboratory testing is neither necessary nor recommended. However, culture is virtually 100 per cent specific and appears to be more sensitive (57 to 86 per cent) than serology (50 per cent in the United States and less than 50 per cent in Europe).

In patients with suspected extracutaneous Lyme borreliosis, serological testing is essential to support the diagnosis. Culture of *B. burgdorferi* has been a highly insensitive diagnostic technique for this group of patients, presumably because of inaccessibility of tissues which contain the organism.

A two-step approach to serological diagnosis has recently been proposed in the United States (and is being studied in Europe) to increase the specificity of a positive test. A positive or equivocal first-stage test (usually an enzyme-linked immunosorbent assay [ELISA] or indirect immunofluorescence assay [IFA]) is followed on the same serum sample by a second-stage test (immunoblot). Two-step testing, however, is not indicated for those with little or no clinical evidence of Lyme borreliosis because of a low positive predictive value. Since IgM and IgG antibodies to *B. burgdorferi* may persist in serum for years after clinical recovery, serology has no role in measuring response to treatment.

Patients with extracutaneous Lyme borreliosis almost always have diagnostic serum antibodies to *B. burgdorferi*, except for some patients with early 7th nerve palsy or occasional patients in whom antibodies to *B. burgdorferi* are present in cerebrospinal fluid only.

Coinfection

Ixodes scapularis (Plate 1) ticks are the vectors for several other infections which may be transmitted separately or simultaneously with *B. burgdorferi* such as *Babesia microti*, and the rickettsial agent that causes human granulocytic ehrlichiosis. In Europe, species of *Babesia* and *Ehrlichia* are present in *Ixodes ricinus* ticks, which are also vectors for a flavivirus causing tickborne encephalitis. Coinfection may alter the clinical presentation and response to treatment of Lyme borreliosis.

Treatment

Although most manifestations of Lyme borreliosis resolve spontaneously, antibiotics may speed the resolution of some manifestations and almost certainly will prevent the progression of disease. An approach to treatment is summarized in Table 2. Currently available quinolones, sulpha drugs, first-generation cephalosporins, rifampicin, and aminoglycosides have no appreciable activity against *B. burgdorferi* and should not be used. In addition, there is no evidence to support combination antimicrobial therapy, prolonged (> 1 month) or repeated courses of antibiotics, and 'pulse' or intermittent antibiotic therapy. Within 24 h after initiation of antibiotics, approximately 15 per cent of patients may develop transient intensified signs (e.g. rash and fever) and symptoms (e.g. arthralgias) consistent with a Jarisch–Herxheimer reaction. Treatment is symptomatic.

Most people treated for Lyme borreliosis have an excellent prognosis. Although some patients treated for erythema migrans in recent series continue to have a variety of mild non-specific complaints following antibiotic therapy, the development of objective extracutaneous disease after treatment is extremely rare. Lyme borreliosis may trigger a fibromyalgia syndrome that does not appear to respond to repeated courses of antibiotics, but may improve with symptomatic therapy. Patients with carditis and neurological disease also tend to do well, but may sometimes have residual deficits (e.g. mild 7th nerve palsy) after treatment. In patients with arthritis, clinical recovery typically occurs in conjunction with oral antibiotic therapy (often with a non-steroidal anti-inflammatory medication); occasionally such patients with subtle signs of neuroborreliosis who are treated with oral antibiotics may develop overt neuroborreliosis and require parenteral therapy. A small number of American patients with Lyme arthritis and the HLA DR4 haplotype, who continue to have synovial inflammation for months or even several years after the apparent eradication of *B. burgdorferi* from the joint following antibiotic therapy, have improved after synovectomy. An immunological mechanism rather than active infection may be responsible for the continued inflammatory response in these patients.

A sizeable number of American patients with a variety of complaints of uncertain aetiology, including pain and fatigue syndromes, have been labelled as having 'chronic Lyme disease' or 'post-Lyme syndrome'. This entity is controversial.

Prevention

This includes avoiding exposure by limiting outdoor activities in tick-infested locations, using tick repellents, tucking in clothing to decrease exposed skin surfaces, and frequent skin inspections for early detection and removal of ticks. Use of acaracides on property and construction of deer fences have also been proposed.

Antibiotic prophylaxis given after recognized *I. scapularis* tick bites has not been shown to be effective in reducing the low (< 5 per cent) risk of acquiring Lyme borreliosis after tick bites. Vaccination with a single recombinant outer surface protein A (**OspA**) preparation has been found to be safe and effective for preventing Lyme disease in the United States. The efficacy of this OspA vaccine may be related to the ability of OspA antibodies (ingested during the blood meal by the vector tick) to kill *B. burgdorferi* in the tick gut, thus preventing transmission of the spirochaete. A single antigen OspA vaccine is expected to be less effective in Eurasia where species of *Borrelia* are more heterogeneous and OspA is more variable.

7.11.30 Other borrelia infections

D. A. Warrell

The borreliae are large, loosely coiled, motile spirochaetes. *B. recurrentis* (Plate 1), first described by Obermeier in 1867, causes louse-borne relapsing fever; *B. duttonii* and a number of other species or groups of *Borrelia* cause tick-borne relapsing fever; and *B. burgdorferi* causes Lyme disease. *B. vincenti* (now renamed *Treponema vincentii*) was, with *Fusobacterium (Bacteroides) nucleatum (fusiforme)*, implicated in acute necrotizing ulcerative gingivitis and Vincent's angina but is now regarded as part of the normal oral flora.

Relapsing fevers

The borreliae that cause relapsing fevers are spirochaetes, 8 to 20 µm long and 0.2 to 0.6 µm thick with between 3 and 15 coils and, in some strains, 15 to 30 axial filaments or flagella. These motile organisms divide by transverse binary fission. Several species of *Borrelia* including *B. recurrentis* can be cultured in Kelly's BSKII artificial media. *Borrelia* spp. can also be cultured on chick chorioallantoic membrane and perpetuated in rodents and ticks. Plasmid DNA has been detected in at least three *Borrelia* species.

Epidemiology

Louse-borne (epidemic) relapsing fever (LBRF)

Humans are probably the only reservoir of LBRF. The vector is the human body louse, *Pediculus humanus* and, to a lesser extent, the head louse, *P. capitis*. *B. recurrentis*, ingested by the louse during a blood meal, multiplies in its body cavity. Under conditions of crowding and poor hygiene, lice move from person to person. When the host's body surface temperature deviates far from 37 °C, as a result of death, fever, or exposure, or if infested clothing is discarded, the louse is forced to find a new host. A new person is infected when the infected louse is crushed and its body haemolymph applied to mucous membranes, such as to the conjunctiva by rubbing the eye, or to abraded skin, or inoculated through intact skin by scratching. Transmission is possible by blood transfusion, needlestick injuries, or even, in medical personnel, by contamination of broken skin such as paronychia on the fingers, by infected patients' blood. Unlike the tick vectors or tick-borne relapsing fever, which are also reservoirs of the infection, lice cannot transmit the infection transovarially to their progeny.

Wars, famine, and other disasters and the resulting large numbers of refugees favour the spread of lice and epidemic louse-borne infections such as relapsing fever and typhus. The yellow plague in Europe in AD 550 and the famine fevers of the seventeenth and eighteenth centuries were probably LBRF. During the first half of the twentieth century there were an estimated 50 million cases worldwide with a 10 per cent mortality. Epidemics began in Europe, the Middle East, and northern Africa during 1903, 1923, and 1943. An endemic focus persists in the Horn of Africa. In Ethiopia there is an annual epidemic of thousands of cases coinciding with the cool, rainy season. Poor people with lice-infested clothes crowd together for shelter. Recent outbreaks have occurred in the Sudan, Somalia, West Africa, and Vietnam. Since there is no known animal reservoir, the infection must persist in humans between epidemics, in mild or asymptomatic form.

Tick-borne (endemic) relapsing fever (TBRF)

There is a close relationship between particular species of *Borrelia*, their soft tick vectors, and reservoirs (Argasidae genus *Ornithodoros*) and mammal reservoir species. In East and Central Africa, domestic ticks of the *O. moubata* complex transmit *B. duttonii* between humans, the only one of these infections that is not a zoonosis. In North, West, and East Africa and the Middle East small rodents have burrows in or near human dwellings, and borreliae of the *Crocidurae* group, may be transmitted to man by the rodent tick *O. sonrai* (formerly *O. erraticus sonrai*). In the Central and West United States and Mexico, *O. hermsi*, a parasite of chipmunks and other tree squirrels, transmits *B. hermsi* to humans especially to those individuals who sleep in tick-infested log cabins near the Grand Canyon, Arizona. Other important borreliae causing tick-borne relapsing fever (and their tick vectors) include: *B. hispanica* (*O. sonrai*) in Africa; *B. persica* (*O. tholozani* = *O. papillipes*) in the Middle East; *B. venezuelensis* (*O. venezuelensis*) in Central and South America; and *B. turicatae* (*O. turicatae*), *B. parkeri* (*O. parkeri*) and *B. mazzotti* (*O. mazzotti*) in North America. Tick-borne relapsing fever may result when night-feeding ticks have access to man.

TBRF has occurred in most continents except Australasia and the Pacific region. It is particularly common in West Africa, where a recent survey revealed a prevalence of 1 per cent among children (in western Senegal). Each year 1650 proven cases are treated at one health centre in Rwanda (6 per cent of all patients). Although cases are usually isolated and sporadic in North America, in 1968 a total of 11 out of a group of 42 boy scouts were infected while camping in rodent-infested cabins on Browne Mountain, Washington; and in 1973 there were 62 cases among people staying in the log cabins along the north rim of the Grand Canyon in Arizona. During the past 25 years, 280 cases of TBRF have been identified in the United States. In Colorado the incidence is increasing (23 confirmed cases since 1977). In Jordan between 1959 and 1969 there were 723 cases of TBRF with four deaths.

Spirochaetes enter the tick in its blood meal from infected humans or animals. Unlike *B. recurrentis*, they invade the tick's salivary and coccal glands and genital apparatus and so can be transmitted when the tick feeds on a new host and transovarially to the tick's progeny. Unlike lice, ticks are reservoirs of *Borrelia* spp. They infest the burrows, caves, tree stumps, and roughly built shacks that harbour their mammalian hosts—rodents, insectivores, lagomorphs, bats, and small carnivores. In western countries, TBRF is occasionally diagnosed in travellers, intravenous drug abusers, and recipients of blood transfusions.

Pathophysiology

The physiological changes during the spontaneous crisis and the Jarisch–Herxheimer reaction (**J-HR**) induced by antimicrobial treatment in LBRF are typical of an 'endotoxin reaction'. Endotoxin-like activity has been described for some spirochaetes: *B. burgdorferi*, *Treponema hyodysenteriae*, *B. vincenti* and *B. buccalis*, and *Leptospira canicola*, but not in *B. recurrentis*, *B. hispanica*, or *Treponema pallidum*. It is the outer-membrane, variable major lipoprotein (**VMP**) of *B. recurrentis* that stimulates monocytes to produce tumour necrosis factor (**TNF**) through NF-kappaB. In patients treated with antibiotics, symptoms of the severe J-HR are associated with a transient marked elevation in plasma concentrations of tumour necrosis factor-a (**TNF-a**), interleukin-6, interleukin-8, and interleukin-1b (Fig. 1). The stimulus for cytokine release is the phagocytosis of spirochaetes made susceptible by the action of penicillin. Benzylpenicillin attaches to penicillin-binding protein I in *B. hermsi* spirochaetes. Large surface blebs are produced and the damaged spirochaetes are phagocytosed rapidly by neutrophils in the blood and by the spleen. Complement may enhance phagocytosis of spirochaetes, especially in the non-immune host, but the complement system is not essential for elimination of spirochaetes whether or not specific immunoglobulins are present. *In vitro*, surface contact with spirochaetes induces mononuclear leucocytes to produce pyrogen and thromboplastin, which could be responsible for the fever and disseminated intravascular coagulation in LBRF. Kinins may be released during the J-HR of syphilis and LBRF. The marked peripheral leucopenia that develops during the reaction reflects sequestration, perhaps in the pulmonary blood vessels, rather than leucocyte destruction. Spirochaetes may be found in those organs that bear the brunt of the infection (liver, spleen (Plate 2), myocardium, and brain), but it is unclear how their pathological effects are produced. The petechial rash results from thrombocytopenia not vasculitis. The cardiorespiratory and metabolic disturbances in relapsing

fever are principally the result of persistent high fever, accentuated by the J-HR or spontaneous crisis.

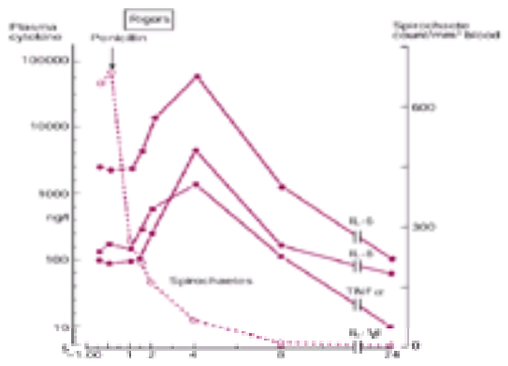

Fig. 1 Typical response in a patient treated with intravenous penicillin. Following penicillin, the number of spirochaetes fell abruptly; and circulating levels of TNF-a, IL-6, IL-8, and IL-1b started to rise after about 1 h, peaking at 4 h. This patient experienced sustained rigors as cytokine levels were increasing, which subsided before peak levels were achieved.

Immunological basis of the relapse phenomenon

Borrelia recurrentis exhibits antigenic variation of variable membrane proteins (**VMPs**), which are outer membrane lipoproteins. The organism has a repertoire of many VMPs but, at any one time, only one is expressed and is immunodominant. The expressed *VMP* gene is situated near the end of a linear plasmid and changes every 1 to 10 000 cell divisions. IgM is induced against the immunodominant VMP, leading to selection of borreliae of the next, emerging serotype. This explains the relapse phenomenon and the successive appearance of borreliae expressing different VMPs during the course of an untreated infection. These same VMPs are the principal TNF-a-inducing factors in LBRF. VMPs may differ in their potency as TNF inducers; they may also determine invasiveness of the borreliae (for example, into the central nervous system) and may affect virulence in other ways.

Pathology

The vast majority of spirochaetes are confined to the lumen of blood vessels, but tangled masses are also found in the characteristic splenic miliary abscesses (Fig. 2) (Plate 2) and infarcts as well as within the central nervous system adjacent to haemorrhages. Some strains of tick-borne borreliae can invade the CNS, aqueous humour, and other tissues. In LBRF, a perivascular histiocytic interstitial myocarditis, found in the majority of cases, may be responsible for conduction defects, arrhythmias, and myocardial failure resulting in sudden death. Splenic rupture with massive haemorrhage, cerebral haemorrhage (Plate 3), and hepatic failure are other causes of death. The liver shows hepatitis with patchy mid-zonal haemorrhages and necrosis (Fig. 3). There is meningitis and perisplenitis: most serosal cavities and surfaces of viscera are studded with petechial haemorrhages (Plate 4). Thrombi are occasionally found occluding small vessels, but the peripheral gangrene sometimes found in patients recovering from louse-borne typhus is not seen.

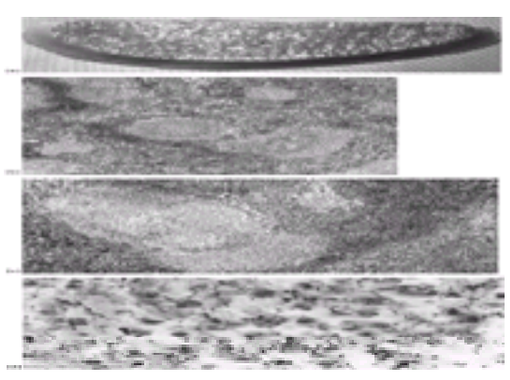

Fig. 2 Splenic miliary abscesses in louse-borne relapsing fever. (a) Section of spleen at autopsy (copyright DA Warrell). (b) Biliary microabscesses as seen under the microscope; 71 × (Armed Forces Institute of Pathology photograph, negative number 75–8838). (c) Microabscesses involve both follicles and extrafollicular areas of the spleen, the pale area of extrafollicular necrosis is clearly demarcated from the surrounding pulp; 145 × (Armed Forces Institute of Pathology photograph, negative number 77326). (d) Warthin–Starry stain showing tangled masses of spirochaetes at the periphery of an abscess; 2280 × (Armed Forces Institute of Pathology photograph, negative number 77317).

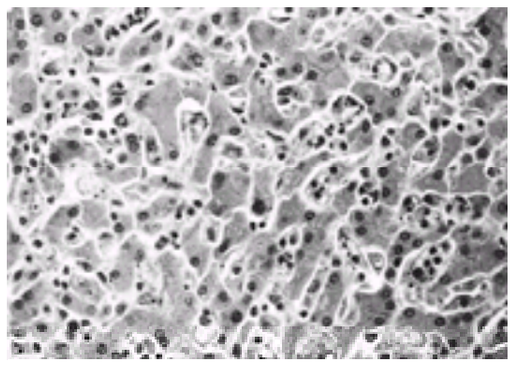

Fig. 3 Liver in louse-borne relapsing fever. Congestion with prominent Kupffer cells and lymphocytic and neutrophil infiltrate predominantly in the central and mid-zonal areas; 500 × (Armed Forces Institute of Pathology photograph, negative number 75–6523)

Clinical features

Poor, indigent, malnourished street-dwellers, beggars, and prisoners seem most likely to become infected, especially young men. Pregnant women appear to be specially susceptible to severe disease and abortions are frequent.

After an incubation period of 4 to 18 (average 7) days, the illness starts suddenly with rigors and a fever that mounts to nearly 40 °C in a few days. Early symptoms are headache, dizziness, nightmares, generalized aches and pains (especially affecting the lower back, knees, and elbows), anorexia, nausea, vomiting, and diarrhoea. Later there is upper abdominal pain, cough, and epistaxis. Patients are usually prostrated. Most are confused. Hepatic tenderness is the commonest sign (about 60 per cent). The liver is palpably enlarged in about 50 per cent of cases. Splenic tenderness and enlargement are slightly less common. Jaundice has been reported in between 10 and 80 per cent of cases. A petechial or ecchymotic rash is seen in between 10 and 60 per cent of cases: the lesions occur particularly on the trunk (Plate 5). Other sites of spontaneous bleeding include the nose in 25 per cent and less commonly the lungs, gastrointestinal tract, and conjunctivas (Plate 6) and retinas. Many patients have tender muscles. Meningism occurs in about 40 per cent of cases: other neurological features include cranial nerve lesions,

monoplegias, flaccid paraplegia, and focal convulsions attributable, perhaps, to cerebral haemorrhages.

Time course and relapses

In untreated cases of the louse-borne disease, the first attack of fever resolves by crisis in 4 to 10 (average 5) days, whereas the initial fever in tick-borne disease lasts only about 3 days. There follows an afebrile remission of 5 to 9 days, and then a series of up to five relapses in louse-borne disease and up to 13 in tick-borne disease (Fig. 4). No petechial rash occurs during the relapses, which are generally less severe than the initial attack but may be associated with iritis or iridocyclitis and severe epistaxis.

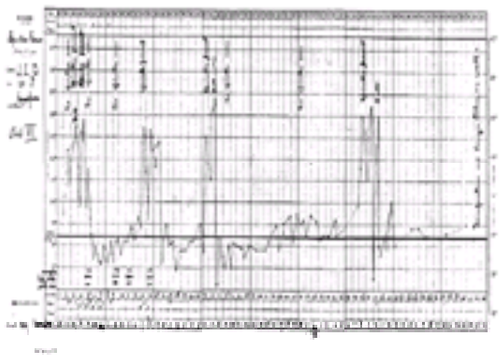

Fig. 4 Temperature chart of J Everett Dutton who, with JL Todd, discovered the transmission of tick-borne relapsing fever in the Congo. Dutton contracted tick-borne relapsing fever at the beginning of November 1904. He had relapses of fever and spirochaetaemia on the 7 and 16 December and the 8 January 1905. His death on 27 February 1905 has been attributed by some, but not by Todd, to relapsing fever (Dutton JE, Todd JL (1905). The nature of human tick-fever in the eastern part of the Congo Free State with notes on the distribution and bionomics of the tick. *Liverpool School of Tropical Medicine Memoir XVII*).

Differences between louse-borne and tick-borne relapsing fever

The tick-borne disease is generally milder and less drawn out. The incidence of some symptoms and signs in the two diseases appears strikingly different. For example, in some series of cases, only 7 per cent of patients with tick-borne relapsing fever were jaundiced and neurological signs were more common than in the louse-borne disease.

Severe manifestations

These include myocarditis that presents as acute pulmonary oedema, liver failure, and severe bleeding attributable to thrombocytopenia, liver damage, and disseminated intravascular coagulation. Dysentery, salmonellosis, typhoid, typhus, malaria, and tuberculosis have been described in association with relapsing fever.

The spontaneous crisis and Jarisch–Herxheimer reaction

Whether or not treatment is given, an attack of relapsing fever usually ends dramatically. About 1 h after intravenous tetracycline, or on about the fifth day of the untreated illness, the patient becomes restless and apprehensive and suddenly begins to have distressingly intense rigors that last between 10 and 30 min. The ensuing phenomena have features of a classical endotoxin reaction. During the initial chill phase, temperature, respiratory and pulse rates, and blood pressure rise sharply. Delirium, gastrointestinal symptoms, cough, and limb pains are associated. Some patients die of hyperpyrexia at the peak of fever. The flush phase, which lasts several hours, is characterized by profuse sweating, a fall in blood pressure, and a slow decline in temperature. Deaths during this phase follow intractable hypotension or the development of acute pulmonary oedema and are attributable to myocarditis. The classical J-HR is in syphilis. Milder reactions have been described in Lyme disease and leptospirosis (treated with penicillin), sodoku (arsenicals), *Brucella melitensis* (tetracycline), and even in meningococcal infections.

Laboratory findings

Spirochaete densities may exceed 500 000/mm^3 of blood. Other abnormalities include a moderate normochromic anaemia, neutrophil leucocytosis (with marked leucopenia during the spontaneous crisis or -HR), thrombocytopenia, mild coagulopathy, biochemical evidence of hepatocellular damage (raised levels of aminotransferases, alkaline phosphatase, direct and total bilirubin, low albumin) and mild renal impairment. The cerebrospinal fluid shows a polymorph/lymphocyte pleocytosis without visible spirochaetes.

ECG evidence of myocarditis includes prolonged Q–Tc, T-wave abnormalities, and ST-segment depression with transient acute right heart strain after the J-HR. Chest radiographs show pulmonary oedema in some cases.

Diagnosis

In febrile patients, spirochaetes can usually be demonstrated in thin or thick blood films stained with Giemsa or Wright's stain and counterstained for 10 to 30 min with 1 per cent crystal violet (Plate 1), by dark-field examination or the quantitative buffy-coat technique. Towards the end of the attack, during remissions, and particularly in children with tick-borne disease, spirochaetaemia may not be detectable. In these cases, blood or CSF can be injected intraperitoneally into young mice which will develop spirochaetaemia within 14 days. Serological methods are not generally used, but LBRF has been diagnosed by the detection of antibodies to glycerophosphodiesterase from *B. recurrentis*. The serum of patients with relapsing fever may give positive reactions with *Proteus* OXK, OX19, and OX2 and false-positive serological responses for syphilis in 5 to 10 per cent of cases.

Differential diagnosis

In a febrile patient with jaundice, petechial rash, bleeding, and hepatosplenomegaly, the differential diagnosis will include falciparum malaria, yellow fever and other viral haemorrhagic fevers, viral hepatitis, rickettsial infections (especially louse-borne typhus), and leptospirosis. The diagnosis can be quickly confirmed by examining a blood smear, but the possibility of a complicating infection, particularly typhoid, should not be forgotten.

Prognosis

The mortality in treated cases is less than 5 per cent. During major LBRF epidemics, mortalities of 40 per cent or higher have been reported. Deaths during relapses are most unusual: they occur only in the tick-borne disease.

Treatment

Antimicrobials

Although TBRF is usually milder than the louse-borne variety, it is more difficult to treat because spirochaetes persist in tissues, such as the central nervous system and eye, and produce relapses. Oral tetracycline, 500 mg every 6 h for 10 days is, however, effective. Oral erythromycin can be given to pregnant women (500 mg every 6 h for 10 days) and children (125–250 mg every 6 h for 10 days). In patients unable to swallow tablets, treatment can be initiated with 250 mg intravenous tetracycline hydrochloride or with 300 mg erythromycin lactobionate.

LBRF is readily cured with a single oral dose of 500 mg tetracycline or 500 mg erythromycin stearate. Few patients with severe louse-borne relapsing fever are able to

swallow the tablets without vomiting them up: a more reliable treatment is a single intravenous dose of 250 mg tetracycline hydrochloride or, for pregnant women and children, a single intravenous dose of 300 mg erythromycin lactobionate (children 10 mg/kg body weight). In mixed epidemics of LBRF and louse-borne typhus a single oral dose of 100 mg doxycycline has been effective.

Benzylpenicillin (300 000 units), procaine penicillin with benzylpenicillin (600 000 units), and procaine penicillin with aluminium monostearate (600 000 units), all by intramuscular injection, have been used; but they may fail to prevent relapses, and the long-acting preparations produce only slow clearance of spirochaetaemia. Chloramphenicol is effective in TBRF in a dose of 500 mg every 6 h for 10 days in adults, and 250 mg every 6 h for 10 days in older children; and in louse-borne relapsing fever in a single dose of 500 mg by mouth or intravenous injection in adults.

Jarisch–Herxheimer reaction

Antimicrobials have reduced the mortality of relapsing fevers from between 30 and 70 per cent to less than 5 per cent; however, drugs such as tetracycline, which generally rapidly eliminate spirochaetes from the blood and prevent relapses, usually induce a severe J-HR that may occasionally prove fatal. Clearly, in a disease with such a high natural mortality, treatment cannot be withheld, especially as severe spontaneous crises, which may also prove fatal, occur in a large proportion of louse-borne cases after the fifth day of fever. There is no evidence, however, that the shorter and more intense reaction following tetracycline is more dangerous than the more prolonged but apparently milder reaction following slow-release penicillin. Treatment with hydrocortisone, in doses up to 20 mg/kg, and paracetamol does not prevent the reaction but reduces peak temperatures, hastens the fall in temperature, and lessens the fall in blood pressure during the flush phase. Pretreatment with oral prednisolone can prevent the J-HR of early syphilis; but in LBRF, neither an oral dose of 3 mg/kg prednisolone given 18 h beforehand nor an infusion of 3.75 mg/kg betamethasone prevented the reaction to tetracycline treatment. However, meptazinol, an opioid antagonist with agonist properties, diminishes the reaction when given in a dose of 100 mg by intravenous injection. The discovery of an explosive release of TNFa, IL-6, and IL-8 just before the start of the J-HR prompted the testing of a polyclonal ovine Fab anti-TNFa antibody. Infused for 30 min before treatment with intramuscular penicillin, this antibody suppressed the J-HR.

Supportive treatment

Patients must be nursed in bed for at least 24 h after treatment to prevent postural hypotensive collapse and the precipitation of fatal cardiac arrhythmias. Hyperpyrexia should be prevented with antipyretics and vigorous fanning with tepid sponging. Although patients with acute LBRF have an expanded plasma volume, most are dehydrated and relatively hypovolaemic. Adults may need 4 or more litres of isotonic saline intravenously during the first 24 h. Infusion should be controlled by monitoring jugular venous, central venous, or pulmonary artery wedge pressures. Acute myocardial failure may develop, particularly during the flush phase of the J-HR or spontaneous crisis. This is signalled by a rise in central venous pressure above 15 cm H_2O; 1 mg digoxin should be given intravenously over 5 to 10 min. Because of the intense vasodilatation, diuretics may accentuate the circulatory failure by causing relative hypovolaemia. Oxygen should be given during the reaction, particularly in severe cases. Vitamin K should be given in all cases with prolonged prothrombin times. Heparin is not effective in controlling coagulopathy and should not be used. Complicating infections—typhoid, salmonellosis, bacillary dysentery, tuberculosis, typhus, and malaria—must be treated appropriately.

Control

No vaccines are available.

Delousing

Patients with LBRF are infectious until their louse-infested clothing is disinfected by heat, such as washing in water hotter than 60 °C, preferably followed by ironing. It is also recommended that infested people should wash their bodies with soap and a 1 per cent lysol (disinfectant) solution; however, most lice are attached to clothing not body hairs. These simple approaches are impracticable in epidemic situations and so insecticides are widely used for louse control. An insecticidal duster can be used to blow a 10 per cent DDT powder between the body and clothing. If DDT-resistant lice are present then dusts of 1 per cent malathion, 2 per cent temephos (Abate), 1 per cent propoxur, or 0.5 per cent permethrin can be used. Improved hygiene discourages lousiness, impregnation of clothing with a pyrethroid insecticide may give long-lasting protection against lice, and treated clothes may remain effective even after 6 to 8 washings. A study in Ethiopia demonstrated that treatment of cases of LBRF with antimicrobials was not effective in controlling an epidemic without the addition of vigorous delousing measures.

Tick control

Ticks should be searched for and removed. However, they usually feed for a short time and then detach and so are rarely found by the time the patient presents with tick-borne relapsing fever.

Ticks may be discouraged by insecticide-impregnated clothes or by applying repellents to the skin (for example, diethyltoluamide). Dwellings should be constructed with solid floors and walls to reduce tick infestation. Sleeping off the floor and under an insecticide-impregnated bed net can also reduce the risk of bites.

Tick control can be attempted by spraying buildings with insecticides such as pyrethroids, carbamates, and organophosphates and by reducing the numbers of rodent vectors.

Leptospirosis

George Watt

Leptospirosis is a worldwide zoonosis of the greatest public health importance in the tropics. Infection may be asymptomatic, but 5 to 15 per cent of cases are severe or fatal. Most cases go undiagnosed because symptoms and signs are often non-specific and serological confirmation is rarely available where most disease transmission occurs. Failure to diagnose leptospirosis is particularly unfortunate: severely ill patients often recover completely with prompt treatment but if therapy is delayed or not given, death or renal failure are likely to ensue.

Aetiology

The organism responsible is a tightly coiled spirochaete with an axial filament and hooked ends, 0.1 to 0.2 µm wide and 5 to 20 µm long. Leptospires are aerobic and travel with a corkscrew-like motion. Unstained organisms can be seen only by darkfield or phase-contrast microscopy. Silver staining is the method of choice for demonstrating leptospires in tissue specimens. The genus *Leptospira* contains two species: *Leptospira interrogans*, which is pathogenic, and *Leptospira biflexa*, which is saprophytic. Stable antigenic differences allow subclassification into serotypes, referred to in the literature as serovars (serovarieties). Antigens common to several serovars permit arrangement into broader serogroups. More than 200 serovars belonging to 23 serogroups have been identified for *L. interrogans*. Leptospirosis taxonomy is evolving and it has been proposed to establish five new species based on DNA relatedness.

Epidemiology

Measuring incidence by active surveillance confirms that leptospirosis is a surprisingly common disease. Antibody positivity rates of 37 per cent have been recorded in rural Belize and 23 per cent in Vietnam. More than 2527 human cases and 13 deaths were reported for the first 9 months of 1999 by the Ministry of Public Health in Thailand. Human leptospirosis is of significance in eastern and southern Europe, Australia, and New Zealand. In the United States, the disease is primarily of veterinary importance, with only 50 to 150 human cases reported annually.

Leptospires nest in the renal tubules of mammalian hosts and are shed in the urine. They can survive for several months in the environment under moist conditions, particularly in the presence of warmth (above 22 °C) and a neutral pH (pH 6.2 to 8.0). These conditions occur all year round in the tropics but only during the summer and autumn months in temperate climates. Roughly 160 animal species harbour organisms, but rodents are the most important reservoir. Carrier rates of over 50 per cent have been measured in Norway rats, which shed massive numbers of organisms for life without showing clinical illness. Some serovars appear to be preferentially adapted to select mammalian hosts. For example, the serovar icterohaemorrhagiae is primarily associated with the Norway rat, canicola with dogs, and pomona with swine and cattle. However, a particular host species may serve as a reservoir for one or more serovars and a particular serovar may be hosted by many different animal species.

The transmission of infection from animal to man usually occurs through contact with contaminated water or moist soil. Organisms enter man through abrasions of the skin or through the mucosal surface of the eye, mouth, nasopharynx, or oesophagus. Crowded Asian or Latin American cities that are flood-prone and have large rat populations provide ideal conditions for disease transmission. A outbreak in Nicaragua in 1995 and an urban epidemic in Salvador, Brazil in 1999 were associated with particularly heavy rains and flooding. Intense exposure to leptospires has been documented in rice, sugar cane, and rubber plantation workers. Less frequently, leptospirosis is acquired by direct contact with the blood, urine, or tissues of infected animals. Epidemiological patterns in the United States and United Kingdom have changed. Recreational exposure to fresh water (canoeing, sailing, water skiing) and animal contact at home have replaced occupational exposure as the chief source of disease.

Pathology and pathogenesis

Leptospires are disseminated by the blood and may be recovered from all organs within 48 h of entering the host. Leptospiraemia lasts from 4 to 7 days and ends when agglutinizing antibodies appear. Leptospires can persist for months in the kidneys and ocular tissue. Much of the pathogenesis of leptospirosis remains unexplained. There are only minor histopathological changes in the kidneys and livers of patients with marked functional impairment of these organs. Patients who survive severe leptospirosis have complete recovery of hepatic and renal function—consistent with the lack of structural damage to these organs.

Severely ill patients typically have marked leucocytosis but no leucocytic infiltrates in organs, a pattern produced by some toxins. Fatally infected animals and some human patients exhibit changes similar to those produced by the endotoxaemia of Gram-negative bacteraemia. An endotoxin-like substance is present in the cell wall of leptospires but lacks the ketodeoxyoctanoate of true endotoxin.

Kidney

Renal failure is the most common cause of death in leptospirosis. Leptospires are frequently found in human renal tissue, but their role in mediating kidney damage is unknown. Interstitial nephritis is found primarily in individuals who have survived until inflammation has had an opportunity to develop, but is frequently absent in patients with fulminant disease.

Impaired renal perfusion constitutes the fundamental nephropathic change. Oliguria is rapidly reversed by administration of intravenous fluid in many patients, suggesting that volume depletion is frequent. Hypovolaemia is multifactorial: insensible water loss, diarrhoea, vomiting, reduced fluid intake, and haemorrhage can all contribute. A defect in the kidney's ability to concentrate urine increases fluid loss while renal potassium wasting can lead to hypokalaemia. Widespread endothelial injury causes fluid to move from the intravascular to the extracellular space in some patients. Hypotension of cardiac origin is rare.

Liver

The pathogenesis of jaundice is unexplained; neither haemolytic anaemia nor hepatocellular necrosis are prominent features of leptospirosis. The most severe hepatic pathological changes are seen when organisms are difficult to demonstrate in tissue, suggesting subcellular toxic or metabolic insults.

Striated muscle

Myalgia is typical of early infection, and is presumably due to invasion of skeletal muscle by leptospires. Muscle biopsies in patients with early illness demonstrate vacuolation of the myofibrillar cytoplasm, loss of cellular detail, and fragmentation. Leptospiral antigen can be demonstrated by immunofluorescence within muscle tissue. Muscle pain resolves as antibody appears and organisms are cleared from the blood. Pathological changes are usually absent in muscle tissue from patients who have died, and myalgia is generally waning at the time of death.

Lungs

Localized or confluent haemorrhagic pneumonitis is the usual pulmonary finding, with petechial and ecchymotic haemorrhages noted throughout the lungs, pleura, and tracheobronchial tree. Early, life-threatening pulmonary haemorrhage has long been reported from Asia, and is now being increasingly recognized in Latin America. Necropsy findings include massive intra-alveolar haemorrhage with or without diffuse alveolar damage. Leptospires can be demonstrated in lung tissue.

Haemorrhage

A progressive severe haemorrhagic diathesis is a prominent feature of experimental leptospirosis. In humans, bleeding is generally restricted to the skin or mucosal surfaces, although occasionally massive gastrointestinal or pulmonary haemorrhage occurs. Coagulopathy and/or thrombocytopenia are common in leptospirosis but do not adequately explain bleeding. By exclusion, capillary damage is the postulated mechanism, and toxins have been suggested as the mediators of endothelial injury.

Meningitis

Organisms easily enter the cerebrospinal fluid during leptospiraemia, and this is thought to explain the high incidence of meningitis. However, signs of meningeal irritation are not due to the invasion of the meninges by leptospires, a process that elicits little reaction. Organisms are frequently isolated from cerebrospinal fluid that is otherwise normal and from individuals without clinically detectable involvement of the nervous system. Symptoms of meningitis coincide with the development of antibody and disappearance of leptospires from the blood and cerebrospinal fluid, suggesting an immunological mechanism. Pathological changes are minimal or absent, and the prognosis is excellent.

Heart

Focal haemorrhagic myocarditis has been reported, but hypovolaemia, electrolyte imbalance, and uraemia are more frequent causes of cardiac dysfunction. Minor electrocardiographic changes such as first-degree heart block are common and reversible.

Eye

The aqueous humour provides a protective environment for leptospires, which readily enter the anterior chamber of the eye during the leptospiraemic phase of the disease. There they can remain viable for months, despite the development of serum antibodies. Uveitis is common. Inflammation of the anterior uveal tract begins weeks or even months after the onset of disease and has been attributed to the persistence of organisms in the anterior chamber.

Clinical manifestations (see Table 1)

Subclinical infection is common and less than 10 per cent of symptomatic infections result in severe, icteric illness. Even relatively virulent serovars such as icterohaemorrhagiae lead more often to anicteric than to icteric disease. Old terms such as peapicker's disease, swineherd's disease, and canicola fever, which linked specific serotypes with distinct disease manifestations, are misleading and should be abandoned. The median incubation period is 10 days, with a range of 2 to 26 days. The duration of the incubation period has no prognostic significance. Once symptoms develop, they are said to follow a biphasic course: After an initial febrile illness, there is defervescence of fever and symptomatic improvement, followed by a second period of disease. However, a clear demarcation between the first and second stages is atypical of icteric leptospirosis and in mild cases the distinction can be unclear, or the second stage may never occur. The diagnostic usefulness of a history of a biphasic illness has been overemphasized. HIV coinfection does not seem to affect the clinical presentation of leptospirosis in the few coinfected patients described thus far.

Anicteric leptospirosis

Symptoms and signs

The disease typically begins with the abrupt onset of intense headache, fever, chills, and myalgia. Fever often exceeds 40 °C (103 °F) and is preceded by rigors. Muscle pain can be excruciating and occurs most commonly in the thighs, calves, lumbosacral region, and abdomen. Abdominal wall pain accompanied by palpation tenderness can mimic an acute surgical abdomen. Nausea, vomiting, diarrhoea, and sore throat are other frequent symptoms. Cough and chest pain figure prominently in reports of patients from Korea and China.

Conjunctival suffusion is a helpful diagnostic clue which usually appears 2 or 3 days after the onset of fever and involves the bulbar conjunctiva. Pus and serous secretions are absent, and there is no matting of the eyelashes and eyelids. Mild suffusion can easily be overlooked. Less common and less distinctive signs include pharyngeal injection, splenomegaly, hepatomegaly, lymphadenopathy, and skin lesions.

Within a week most patients become asymptomatic. After several days of apparent recovery, the illness resumes in some individuals. Manifestations of the second stage are more variable and mild than those of the initial illness and usually last 2 to 4 days. Leptospires disappear from the blood, cerebrospinal fluid, and tissues but appear in the urine. Serum antibody titres rise—hence the term 'immune' phase. Meningitis is the hallmark of this stage of leptospirosis. Pleocytosis of the cerebrospinal fluid can be demonstrated in 80 to 90 per cent of all patients during the second week of illness, although only about 50 per cent will have clinical signs and symptoms of meningitis. Meningeal signs can last several weeks but usually resolve within a day or two. Uveitis is a late manifestation of leptospirosis, generally seen 4 to 8 months after the illness has begun. The anterior uveal tract is most frequently affected, and pain, photophobia, and blurring of vision are the usual symptoms.

Laboratory findings

The white blood cell count varies but neutrophilia is usually found. Urinalysis may show proteinuria, pyuria, and microscopic haematuria. Enzyme markers of skeletal muscle damage, such as creatine kinase and aldolase, are elevated in the sera of 50 per cent of patients during the first week of illness. Chest radiographs from patients with pulmonary manifestations show a variety of abnormalities, but none is pathognomonic of leptospirosis. The most common finding is small, patchy, snowflake-like lesions in the periphery of the lung fields.

Icteric leptospirosis (Weil's disease)

This dramatic, life-threatening illness is characterized by jaundice, renal dysfunction, haemorrhagic manifestations, and a high mortality rate. Though jaundice is the hallmark of severe leptospirosis, fatalities do not occur because of liver failure. The degree of jaundice has no prognostic significance, but its presence or absence does—virtually all leptospirosis deaths occur in icteric patients. Icterus first appears between the fifth and ninth days of illness, reaches maximum intensity 4 or 5 days later, and continues for an average of 1 month. Hepatomegaly is found in the majority of patients and hepatic percussion tenderness is a reliable clinical marker of continuing disease activity. There is no residual liver dysfunction in survivors of Weil's disease, consistent with the absence of structural damage seen on pathological examination of this organ.

Bleeding is occasionally seen in anicteric cases but is most prevalent in severe disease. Purpura, petechiae, epistaxis, bleeding of the gums, and minor haemoptysis are the most common haemorrhagic manifestations, but deaths occur from subarachnoid haemorrhage and exsanguination from gastrointestinal bleeding.

Conjunctival haemorrhage is an extremely useful diagnostic finding, and when combined with scleral icterus and conjunctival suffusion, produces eye findings strongly suggestive of leptospirosis (see Fig. 1 and Plate 1). The frequency with which severe pulmonary haemorrhage complicates leptospirosis is variable, but is a cardinal feature of some outbreaks.

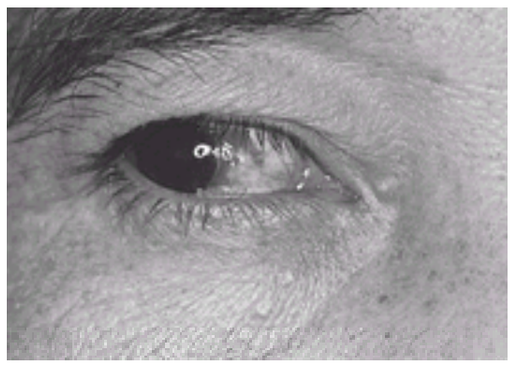

Fig. 1 Jaundice, haemorrhage, and conjunctival suffusion in acute leptospirosis. (See also Plate 1.)

Life-threatening renal failure is a complication of icteric disease, though all forms of leptospirosis may be associated with mild kidney dysfunction. Oliguria or anuria usually develop during the second week of illness, but may appear earlier. Complete anuria is a grave prognostic sign, often seen in patients who present late in the course of illness with frank uraemia and irreversible disease. Because renal failure develops very quickly in leptospirosis, symptoms and signs of uraemia are frequently encountered. Anorexia, vomiting, drowsiness, disorientation, and confusion are seen early and progress rapidly to convulsions, stupor, and coma in severe cases. Disturbances of consciousness in a patient with severe leptospirosis are usually due to uraemic encephalopathy, whereas in anicteric cases aseptic encephalitis is the usual cause. Renal function eventually returns to normal in survivors of Weil's disease, through detectable abnormalities may persist for several months.

Laboratory features of Weil's disease

Hyperbilirubinaemia results from increases in both conjugated (direct) and unconjugated (indirect) bilirubin, but elevations of the direct fraction predominate. Prolongations of the prothrombin time occur commonly but are easily corrected by the administration of vitamin K; modest elevations of serum alkaline phosphatase are typical. There is mild hepatocellular necrosis; greater than fivefold increases of transaminase (aminotransferase) levels are exceptional.

Jaundiced patients usually have leucocytosis in the range of 15 000 to 30 000 per mm ^{3}, and neutrophilia is constant. Anaemia is common and multifactorial; blood loss and azotaemia contribute frequently, intravascular haemolysis less often. Mild thrombocytopenia often occurs, but decreases in platelet count sufficient to be associated with bleeding are exceptional. The specific gravity of the urine is high. Hypokalaemia due to renal potassium wasting can occur.

Diagnosis

The diagnosis of leptospirosis is usually based on serology. The old commercially available microscopic slide agglutination test is being supplanted by a new generation of rapid serodiagnostic kits. Some enzyme-linked immunosorbent (EIA), agglutination, and immunofluorescent assays are very promising, although more data from prospective evaluations conducted in endemic areas are required. The need for practical, affordable diagnostic kits to be available in areas where leptospirosis is common cannot be overemphasized. The polymerase chain reaction and urine antigen detection are research tools which would be of greatest potential diagnostic value in patients who present early, before antibodies have reached detectable levels. The microscopic agglutination test is considered the serodiagnostic method of choice for leptospirosis, but its complexity limits its use to reference laboratories. Dilutions of patient sera are applied to a panel of live, pathogenic leptospires. The results are viewed under dark-field microscopy and expressed as the percentage of organisms cleared from the field by agglutination.

Isolation of leptospires from blood or cerebrospinal fluid is possible during the first 10 days of clinical illness, but specialized media are necessary. Serially diluted urine provides the highest yield. Unfortunately, culture results are only known 4 to 6 weeks later—too late to benefit hospitalized, severely ill patients.

Treatment

The approach to the patient with possible leptospirosis is summarized in Fig. 2. Placebo-controlled double-blind trials have proved that doxycycline benefits patients with early, mild leptospirosis, and that intravenous penicillin helps adults with severe, late disease. The outcome of severe, paediatric leptospirosis is also improved by penicillin therapy. Antibiotics should therefore be given to all patients with leptospirosis, regardless of age or when in their disease course they are seen. Doxycycline is given at doses of 100 mg orally twice a day for 1 week. Patients who are vomiting or are seriously ill require parenteral therapy. Intravenous penicillin G is administered as 1.5 million units every 6 h for 1 week. There is controversy regarding the occurrence of a Jarisch–Herxheimer reaction in leptospirosis. If present, it is much less prominent in leptospirosis than in other spiro-chaetal illnesses. The important practical consideration is that antibiotics should not be withheld because of the fear of a possible Jarisch–Herx-heimer reaction.

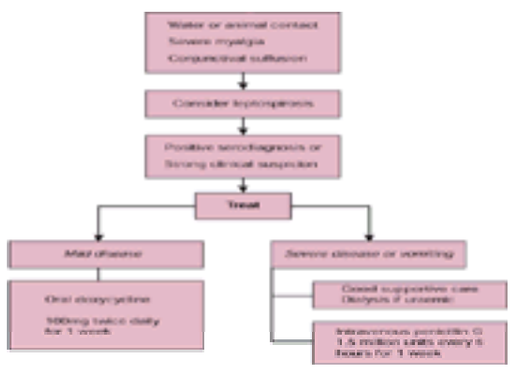

Fig. 2 Management of a febrile patient with possible leptospirosis.

The management of pulmonary haemorrhage often requires prompt intubation and mechanical ventilation. Respiratory support to maintain adequate tissue oxygenation is essential because in non-fatal cases complete recovery of pulmonary function can be achieved. Ensuring adequate renal perfusion prevents renal failure in the vast majority of oliguric individuals. Peritoneal dialysis is preferred to haemodialysis; frequent dialyses may be necessary because renal failure in leptospirosis is hypercatabolic.

Prevention

Doxycycline, 200 mg taken once a week, prevents infection by *L. interrogans*. Widespread use of doxycycline prophylaxis is not indicated, but it can benefit those who are at high risk for a short time, such as military personnel and certain agricultural workers.

Infection by leptospires confers only serovar-specific immunity; second attacks due to different serovars can occur. The efficacy and safety of human leptospiral

vaccines have yet to be conclusively demonstrated. Prevention of leptospirosis in the tropics is particularly difficult. The large animal reservoir of infection is impossible to eliminate, the occurrence of numerous serovars limits the usefulness of serovar-specific vaccine, and the wearing of protective clothing (e.g. rubber boots in rice fields) is both prohibitively expensive and impractical.

Prognosis

It is imperative to bring affordable tests to areas where leptospirosis is common because treatment (or lack of it) has a substantial impact on outcome. Atypical or mild cases are often confused with other entities such as aseptic meningitis, influenza, appendicitis, and gastroenteritis. Viral hepatitis is a common misdiagnosis in patients with Weil's disease. Leucocytosis, elevated serum bilirubin levels without marked transaminase elevations, and renal dysfunction are typical of leptospirosis but unusual in hepatitis. Malaria, typhoid fever, relapsing fever, scrub typhus, and Hantaan virus infection (haemorrhagic fever with renal syndrome) are important differential diagnoses in the tropics. Leptospirosis with prominent haemorrhagic manifestations is commonly misdiagnosed as dengue fever.

7.11.32 Non-venereal endemic treponemoses: yaws, endemic syphilis (bejel), and pinta

P. L. Perine and D. A. Warrell

The endemic treponematoses are chronic, granulomatous diseases caused by spirochaetes belonging to the genus *Treponema*. Yaws occurs mainly in children living in rural areas in warm, humid climates in tropical countries. About 10 per cent of untreated cases develop late, disfiguring or crippling lesions of skin, bone, and cartilage.

Aetiology

Yaws is caused by *Treponema pallidum* ssp. *pertenue*, a spirochaete that is morphologically identical to *T. pallidum* ssp. *pallidum* (the cause of venereal syphilis) and *T. pallidum* spp. *endemicum* (the cause of non-venereal syphilis (bejel)), and to *T. carateum* (the cause of pinta). These treponemes share common antigens, so that infection by one species produces varying degrees of cross-immunity to the others. No serological test can differentiate the antibodies produced, and none of these organisms grows *in vitro*. The only means of differentiating yaws, syphilis, and non-venereal syphilis are their epidemiological characteristics and the pattern of infection produced in humans and experimentally infected laboratory animals (Table 1). Pathogenic treponemes can be differentiated at the molecular level by differences in the 5'- and 3'-flanking regions of their 15-kDa lipoprotein genes (*tpp*15).

The treponemes of yaws, syphilis, and pinta are fragile and readily killed by exposure to atmospheric oxygen, drying, mild detergents, or antiseptics. They prefer temperatures below 37 °C, which may explain their predilection for the skin and bones of the extremities. These organisms cannot penetrate intact skin, and gain entry to the body through small abrasions and lacerations.

Epidemiology (Table 1)

Yaws is transmitted by direct contact with an infectious lesion or by fingers contaminated with lesion exudate. It is enhanced by a crowded environment with poor sanitation and personal hygiene. The disease is usually acquired in childhood between the ages of 5 and 15. In endemic areas more than 80 per cent of the population are infected. In humid, warm environments the early lesion tends to proliferate and teems with spirochaetes, thus increasing the infectious reservoir; whereas in dry, arid climates or seasons the reverse is true.

There was a precipitous decrease in cases of yaws and other endemic treponematoses following mass penicillin-treatment campaigns during the 1950s and 1960s sponsored by the World Health Organization. An estimated 152 million people were examined and 46.1 million clinical cases, latent infections, and contacts were treated. The yaws reservoir was greatly reduced in West and Central Africa, Central and South America, and Oceania. However, over the past decade, yaws has been resurgent in the rural populations of Ecuador, the Ivory Coast, Ghana, Togo, Benin, Zaire, the Central African Republic, and Ethiopia in Africa, and in the island nations in the Pacific. Several nations initiated new campaigns of mass treatment during the 1980s.

Some African nations, such as Nigeria, previously rendered yaws-free by mass treatment campaigns, have also experienced a sharp rise in the incidence of venereal syphilis, perhaps representing a decline of herd immunity to yaws, and thereby to syphilis.

Endemic syphilis is transmitted by non-venereal contact among children. In contrast to yaws, transmission of infection by contaminated drinking vessels may be more common than by direct contact with infectious lesions. The disease tends to be familial, with spread of infection from children to adults rather than to the community in general. Endemic syphilis lesions are virtually indistinguishable from early yaws, and the two diseases may occur at different times in the same population but not in the same person. Venereal syphilis can be acquired by children through social contact with adults suffering from venereal syphilis, and then be spread by non-venereal, person-to-person contact if levels of sanitation and personal hygiene are low.

The Sahelian nations of Mauritania, Mali, Niger, Burkina Faso, and Senegal have reported dramatic increases in the number of cases of endemic syphilis. In Naimey (Niger), seroprevalence was 12 per cent among children under 5 years of age. The disease is also prevalent among the nomadic tribes of the Arabian peninsula, where late complications such as osteoperiostitis predominate.

Several variants of endemic syphilis are recognized by their geographical distribution: bejel of the Eastern Mediterranean, North Africa, and Niger; and njovera or dichuchwa of Africa; Bejel is the only type of endemic syphilis still prevalent. It is found in mainly seminomadic people such as the Tuareg living in the Saharan regions of Africa. Pinta is found only in remote parts of Central and South America, principally in the semiarid region of the Tepalcatepec Basin of southern Mexico and focal areas of Colombia, Peru, Ecuador, and Venezuela.

Pathogenesis

The lesion of yaws and the other treponematoses are due largely to the host's immune response to the treponeme. None of these treponemes carries or produces toxic substances. They have the ability to invade living cells without causing apparent injury. Cell destruction and tissue damage are probably due to the action of immune cells that injure normal tissue in the process of killing treponemes.

Host immunity reaches its highest level after several months of infection, just before disseminated lesions heal and latency begins. Thereafter the host is immune to reinfection and is not contagious, but since not all treponemes are killed, infectious lesions may reappear as immunity wanes over time. Most patients with yaws experience two or three infectious relapses during the first 5 years of infection.

In venereal, and possibly endemic, syphilis, infection is systemic and late lesions may develop in any organ or tissue of the body. In yaws, *T. pertenue* produce lesions only in skin and osseous tissue, although it is certain that periodically the organism spreads systemically; *T carateum* resides only in the skin. This peculiar tissue tropism is unexplained. It is probably an inherent property of the treponeme, acting in contact with climatic factors.

Clinical features

Like venereal syphilis, the clinical course of yaws and endemic syphilis have primary, secondary, and tertiary or late stages, separated by quiescent or latent periods.

The initial lesion in yaws usually appears on the extremities after an incubation period of 3 to 5 weeks. Characteristically it is a papule; a painless lesion that appears at the site of infection, enlarges, forming a raspberry-like ('framboesia'), vegetative lesion called a papilloma. The papilloma is round to oval, elevated and not indurated, ranging in size from 1 to 3 cm in diameter. The surface teems with spirochaetes and is often covered by a thin yellow crust, which is easily removed. The papilloma may ulcerate as it enlarges and becomes secondarily infected with other micro-organisms. Lymph nodes draining the initial lesion may enlarge and become tender, but systemic symptoms are rare.

Secondary or disseminated papillomas appear after 2 to 6 months, often without an intervening latent period, on the skin of moist areas such as the axillas, joint flexures, genitalia, and the gluteal cleft (Fig. 1). They also occur on the soles and palms and, because they are tender, may interfere with gait and use of the hands. Papillomas in different stages of development persist for 6 to 8 months and heal without scars unless they become secondarily infected. Despite the size and number

of lesions, children with generalized papillomas experience little discomfort or other constitutional symptoms.

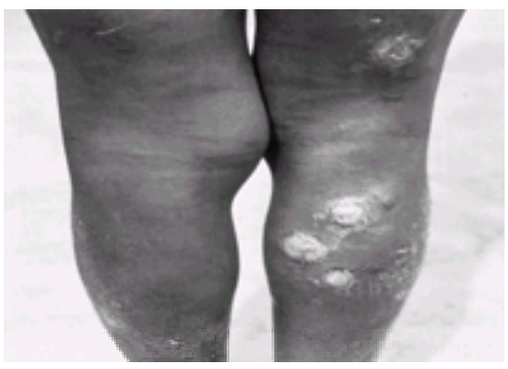

Fig. 1 Early ulceropapillomatous yaws. (Copyright PL Perine.)

Slightly raised, scaly, pigmented, macular yaws lesions measuring between 1 and 4 cm in diameter commonly occur when the climate is dry and arid. These lesions have the same distribution as papillomas and may appear together with lesions of different morphology in the same patient (maculopapular yaws).

The periosteum and osseous tissue of the bones of the extremities are frequently inflamed during early yaws, causing swelling, night-pain, and tenderness. There is dactylitis of the proximal phalanges. Painful osteoperiostitis of the legs, affecting mainly the tibias and fibulas, is especially common. Hypertrophic osteitis of the maxilla, either side of the bridge of the nose, can cause grotesque swellings ('goundo'). Scaly, tender, hyperkeratotic lesions of the palms and soles also occur and may be incapacitating. Hyperkeratotic and bone lesions are not contagious, and macular lesions are only minimally so.

One or more relapses of secondary-type lesions usually occur during the first 5 years of infection, each separated by a period of latency. Late yaws' lesions occur thereafter in about 10 per cent of untreated cases.

Late yaws' lesions are not infectious because they contain few treponemes. Cutaneous plaques produce atrophic scars; subcutaneous, granulomatous nodules erode skin and produce deep ulcers that destroy underlying tissue and disfigure. Hyperkeratotic palmar and plantar yaws are incapacitating and often prevent use of the hands, or the ability to walk normally. The weight is placed on the sides of the feet, which produces a gait much like that of a crab ('crab' yaws; Fig. 2).

Fig. 2 Planter papillomas with hyperkeratotic, macular, early plantar yaws ('crab yaws'); these lesions are painful. (Copyright PL Perine.)

The granulomas of late yaws have a histological appearance like the gummas of syphilis. These proliferative lesions may involve the palate and destroy the soft tissues of the nose, causing a terrible disfiguration called gangosa (Fig. 3). Gummatous periostitis of the skull, fingers, and long bones is erosive and often retards or stops growth. Active periostitis is occasionally found in young and middle-aged adults who had yaws in childhood.

Fig. 3 Gangosa (rhinopharyngitis mutilans) of endemic syphilis and yaws in an adolescent child. (Copyright PL Perine.)

The initial lesions of endemic syphilis usually appear at the mucocutaneous borders of the mouth or on the oral mucous membranes (mucous patches) as the result of transmission by contaminated drinking vessels. Late ulceronodules and osteoperiostitis are seen in late endemic syphilis, but cardiovascular and neurological complications are extremely rare.

In pinta, the initial papule appears on the skin of the extremities and enlarges slowly over a period of several weeks or months to form an erythematous plaque. Satellite papules form at the edge of the lesion and undergo a similar type of evolution. The plaques coalesce to form violaceous, pigmented plaques that, in several years, slowly depigment from lighter shades of blue to white, leaving atrophic depigmented scars.

Ulceronodular skin lesions of yaws and endemic syphilis resemble tropical ulcers. Yaws' lesions are not as painful, necrotic, nor as deep as tropical ulcers, which are usually singular and restricted to the lower one-third of the leg.

Plantar warts are frequently confused with plantar papillomas of yaws, and both conditions may occur in the same patient.

Diagnosis

The diagnosis of yaws is made by a combination of clinical assessment, of positive dark-ground examination of lesions, and of reactive serological tests for syphilis.

The diagnosis of early yaws, or endemic syphilis, is not difficult in endemic areas where the disease is familiar. The most difficult diagnostic problem arises when a

person who had yaws as a child emigrates to an area of the world where the disease never existed. Such a person usually has reactive serological tests for syphilis and may have a few atrophic scars suggestive of earlier infection. What are the chances that this patient has or has had venereal syphilis? Should he be treated for latent yaws or syphilis?

The patient's social and medical history should be carefully reviewed. Clinical findings suggestive of old yaws (scars, inactive tibial periostitis), and the absence of signs of congenital and venereal syphilis support the diagnosis of inactive or treated yaws.

If the patient has a reagin titre of less than 1:8 dilutions, they probably do not have active latent yaws or syphilis. If they received at least one therapeutic dose of long-acting penicillin in their native country during a yaws campaign, they require no further treatment. On the other hand, if the patient is a contact of a case of infectious venereal syphilis, they should be treated as being potentially infected with syphilis, because *T.p. pallidum* occasionally superinfects people who had yaws as children. If treatment is given, the patient should receive a certificate stating the drug and dosage used and the results of their serological tests to prevent unnecessary future treatment.

Treatment and prevention

Long-acting benzylpenicillin given by intramuscular injection is the recommended treatment for all the endemic treponematoses. The preparation used in previous mass treatment campaigns was penicillin aluminium monostearate (**PAM**), but benzathine penicillin is currently recommended because it is longer acting and more readily available than is PAM. Active infections and non-infectious cases should be given 1.2 mega units in a single intramuscular injection; children under 10 years of age receive 0.6 mega units. Patients allergic to penicillin may be given tetracycline or erythromycin, 500 mg by mouth four-times daily for 2 weeks; children under 10 years of age should be given erythromycin in dosages adjusted for their age. Treatment failures have been reported in Papua New Guinea.

Prevention of yaws in a community requires elimination of the reservoir of infection, often by treating the entire population with penicillin.

Syphilis

D. J. M. Wright and S. E. Jones

Definition

Venereal syphilis is a systemic, contagious disease of great chronicity, caused by *Treponema pallidum*, and capable of congenital transmission. The natural host is man. The incubation period is around 3 weeks, at the end of which a primary sore develops at the site of inoculation, usually on the genitalia, associated with regional lymphadenitis. In most patients, this is followed by the secondary bacteraemic stage characterized by a symmetrical rash, generalized lymphadenopathy, and other lesions. After a latent period of many years, in 40 per cent of cases a destructive late stage develops involving the skin, mucous membranes, skeleton, central nervous system, eyes, hearing, and, especially, the aorta. Any of these stages may be absent or inapparent. Venereal syphilis, unlike non-venereal syphilis, is distributed world-wide.

Bacterial taxonomy

T. pallidum is a bacterium which causes venereal syphilis and the non-venereal, endemic childhood syphilis, bejel and njovera. Other pathogenic treponemes include *T. pertenue* (yaws) and *T. carateum* (pinta). Although these spirochaetes produce distinct diseases, molecular techniques have not yet been able to demonstrate consistent differences in their genomic DNA.

There are a number of non-pathogenic treponemes (*T. denticola* etc.) in the mouth which are difficult to distinguish from *T. pallidum*. For that reason dark-field examination of samples from mouth lesions should be avoided because of the danger of misdiagnosis. Other treponemes of low pathogenicity (e.g. *T. balanitides*) reside in the genital tract and, together with fusiform bacilli, can under anaerobic conditions superinfect genital lesions producing 'fusospirochaetosis'.

The completed sequence of the 1.14 Mb genome of *T. pallidum* (website 1) revealed that this parasitic spirochaete had few sets of enzymes for basic metabolic processes—as expected, since *T. pallidum* has remained unculturable *in vitro*. Transporter systems (for amino acids, carbohydrates, and cations) comprise 5 per cent of the genome, and the lack of genes coding for protection from oxygen-derived free radicals indicates that *T. pallidum* will only survive in oxygen-depleted conditions.

T. pallidum is a delicate, motile spiral organism, 6 to 15 µm long and 0. 15 µm wide which renders it below the level of resolution of light microscopy and hence the need for dark-field or phase contrast illumination. It has an outer membrane, an electron-dense layer, and a cytoplasmic membrane. As with other bacteria, the cell wall has a trilaminar structure, the inner membrane constituting of a cytoplasmic membrane, while between the outer two layers there are axial filaments, structurally analogous to bacterial flagella, which wind around the axis of the organism and may be responsible for the motility of *T. pallidum*. All treponemes have not more than nine axial filaments, which distinguishes treponemes from borrelia (Table 1). *T. pallidum* has the unique ability of being able to bend in the middle to form a V-shape, if suspended in a medium of low viscosity. Motility does not necessarily indicate viability as mobile *T. pallidum* have been observed after they have been retained for 90 days in capillary tubes. *T. pallidum* may remain infective for up to a week in 'survival media' and, depending on the nature of the media, show limited multiplication; however, attempts at reproducible subculture of the microbe have to date been unsuccessful. Low concentrations of oxygen (between 3 and 5 per cent) may enhance survival. In practice, *T. pallidum* is propagated in rabbits.

Experimental inoculation of *T. pallidum* into man or animals shows that the organism divides every 30 to 32 h, suggesting approximate infective dose are between 10^6 and 10^7 organisms and an average incubation period of 3 weeks. Peptidoglycan in the inner layer of the bacterial membrane accounts for its susceptibility to penicillin. The phospholipids in the outer membrane, of which cardiolipin is the most prominent hapten, provides the antigenic basis for the synthetically substituted VDRL (Venereal Disease Reference Laboratory (test)) used as a serological test for syphilis. Flagella antigen reacts non-specifically with antibodies found in most known sera.

Origin of syphilis

Clinical differences between treponematoses have been explained as an adaptation of the organism to changing climatic factors, especially humidity and temperature, and with improvement in hygiene, the wearing of clothes, and less frequent intimate contacts between children. Yaws is found throughout the tropical belt, while pinta was forced to retreat into remote indigenous communities in South and Central America. Non-venereal childhood syphilis, such as bejel and similar conditions, was formerly found in more temperate climes including the Middle East, Yugoslavia, British Isles, Scandinavia, and South Africa. The lack of congenital transmission of these venereal treponematoses arose because they were essentially childhood infections and by the time these children were old enough to have their own offspring, the disease had become non-infectious. The treponeme causing venereal syphilis was perhaps an adaptation to people wearing clothes, when it was obliged to seek shelter in the protected, warm, and moist regions of the genitalia, so becoming sexually transmitted. It spread throughout the world as an adult disease and, because there appears to be no solid cross-immunity, may coexist with non-venereal treponematoses.

This adaptive theory fails to explain why *T. pallidum, sensu stricto*, unlike the other treponematoses, involves the central nervous system, aorta, and visceral organs and why, at the end of the fifteenth century, the virulent venereal form swept through Europe and Asia, eventually to become the milder modern syphilis. The alternative Columbian theory suggests that Columbus introduced this new disease from the Caribbean islands.

There are no definite descriptions of syphilis before this time. The finding of skeletons with long bone lesions compatible with syphilis, centuries before the fifteenth century epidemic of syphilis, remains speculative, though Boylston (reviewed by Morton (2001)) has reported syphilitic changes in the bones of pre-1450 skeletons found in Hull. The lack of such skeletons from America makes the relationship with the coincidental discovery of America and the advent of 'new world' syphilis even

more doubtful.

The recognition of the contagious nature of the disease was recorded in 1530 by Fracastro. Klebs ultimately proved the infectivity of syphilis by reproducing syphilitic lesions by inoculating of syphilitic tissue into rabbits. The use of a prolonged Giemsa stain, allowed Schaudinn finally to identify the treponemes in 1905.

Epidemiology (see also Chapter 21.1)

Transmission

Sexual transmission is the rule in adult patients. The untreated patient remains infective for 4 years after acquiring the infection. Asexual transmission by close contact with an open lesion of early acquired or congenital syphilis is rare, as is direct blood transfusion with blood from an infectious individual or contact with infected fomites. Congenital syphilis still remains a problem, except in Northern Europe.

Incidence

There has been a steady decline in the incidence of syphilis in the West since the 1850s, interrupted only by major wars. Since 1940, there has been a 99 per cent drop in admissions of general paresis of the insane and congenital syphilis in the United States, with similar trends in the United Kingdom and Europe. There has also been a sharp reduction in all other forms of late syphilis. Gumma have almost disappeared. Early syphilis has not declined to the same degree since the Second World War. In the United States, syphilis reached a low in 1956, with 6576 reported cases but by 1992 had risen to 83 902 acquired cases. The introduction of health measures is reflected in the recent fall in the number of cases. A similar pattern is also found in most European countries. During the 1970s and 1980s, there was a steady increase in the number of cases of early syphilis. In the Russian Federation, where there has been a breakdown in public health, up to 1 per cent of the population has been affected by syphilis, especially around St Petersburg and Moscow. In 1980, 58 per cent of cases of syphilis in the United Kingdom were in homosexuals.

Since that time, the United Kingdom and American rates have diverged. The appearance of AIDS and the national programmes for 'safe sex' has resulted in the annual number of cases of infectious syphilis falling to 337 in the United Kingdom in 1993, most of the recent infections being acquired heterosexually abroad. In the United States, however, despite the fall in the number of homosexual males infected, the number of cases of syphilis has continued to rise, especially in the underprivileged Afro-American and Hispanic community and among HIV-infected drug abusers. In 1992, there were approximately 34 000 cases of primary and secondary syphilis, and 3850 cases of congenital syphilis in children under the age of 2 years, compared with 1986 when only 57 such cases were recorded in the United States. The failure of the Public Health Service in the United States to cope is reflected in the resurgence of congenital syphilis. Following the public health initiative in the United States, started in 1997, the number of cases of primary and secondary syphilis reported for 2000 was 5979, while congenital syphilis had fallen to 529 cases. The comparative number of cases of syphilis seen in the genitourinary medicine clinics in England and Wales in 2000 was 328. In other parts of the world, notably in the Far East, infected prostitutes may play a central role in the spread of early syphilis. Estimates by the World Health Organization suggest that there are 10 to 20 million cases of syphilis each year.

The changing clinical presentation of syphilis

There is some clinical evidence that syphilis is becoming milder and less typical. This has been especially noted in neurosyphilis and the virtual disappearance of the gumma. The widespread use of antibiotics for unrelated conditions may be responsible. This is supported by finding that meningovascular syphilis has not shown the dramatic decrease of general paresis of the insane and tabes dorsalis, possibly because the last two conditions take many more years to develop, giving cumulative chances of antibiotics being given. It is also possible that the disease is tending to become milder and less typical as a result of 'natural' changes which appear to have started long before the antibiotic era. For whatever reasons, syphilis is apparently becoming clinically less clear-cut . Its exclusion by serology and other tests becomes more important in patients attending the dermatologist, neurologist, ophthalmologist, the ENT specialist, or cardiologist with conditions of uncertain pedigree.

The advent of AIDS has led to a re-examination of the progression and manifestations of concomitant syphilis. Although a variety of unusual syphilitic rashes, in particular more ulcerating multiple chancres and florid secondary rashes, have been described in association with HIV infections, all of them are recorded in the older literature. The suggestions that there might be an increase in syphilitic meningovascular relapse in patients with HIV infections, again may reflect the natural history of syphilis, since approximately 20 per cent of patients with early syphilis have a pleocytosis in the cerebrospinal fluid. If these patients are untreated, about one-fifth develop neurosyphilis. The high prevalence of syphilis in HIV patients leads to an apparent, rather than a real, increase in syphilis complications. Holtom, in California, found that in patients partially treated for syphilis with concomitant HIV infections, about 9 per cent developed a pleocytosis and 1 per cent then developed neurological disease. Unlike mycobacterial infections where unusual presentations of tuberculosis occur in patients with AIDS, the presentation of early neurosyphilis seems to be characteristic of the disease. This is possibly because the vasculitis of syphilis is not due to the cellular immune response but to the adherence of the spirochaete to the endothelial layer of the blood vessel. The blood vessel first becomes more permeable and subsequently there is proliferation of this layer. Simultaneously, the spirochaete induces a cellular infiltrate. These changes lead to endarteritis, which is the hallmark of the disease. What is true is that syphilitic relapses do not occur despite the potential for the persistence of spirochaetes (see below) and that benzathine penicillin G is less effective in eliminating spirochaetes (see below) in patients with altered immunity. Any persistence of cerebrospinal fluid pleocytosis in the neurosyphilitic patient with HIV after adequate penicillin treatment should lead to an investigation of causes of meningitis other than syphilis. However, doubt has been cast as to whether eradication of spirochaetes always occurs in the non-immunocompromised patient. Wilner and Brody found that one-third of the patients with a syphilitic encephalitis (general paresis of the insane) who had been followed for 30 years, developed neurological signs at the end of the period, despite having had 'adequate' penicillin therapy. Only 7 per cent of the non-syphilitic control group of demented patients, evinced new neurological signs. These were presumably due to cerebrovascular degenerative disease. Even in the pre-AIDS era, Rothenberg, when he reviewed the efficacy of penicillin in the treatment of neurosyphilis, found that it was not always effective. Lastly, laboratory experiments show that it is more likely that syphilis has a deleterious effect on the progression of AIDS rather than the reverse.

Sex and race

Early syphilis is less florid in women than men and is almost asymptomatic during pregnancy. Cardiovascular syphilis is at least twice as common in men than women, where it is more severe and appears earlier. Neurosyphilis is always more common in men than women. The reasons for these differences are not known.

Caucasians suffer more commonly from neurosyphilis than black Africans and they in turn are much more prone to develop cardiovascular syphilis than Caucasians.

Infectivity

The estimated figure for infectivity varies but is commonly assumed to be around 50 per cent for both homosexual and heterosexual patients. After a single exposure the figure is nearer 25 per cent.

Some control measures

The main reason for increased case identification is the more intensive use of serological tests for syphilis. Another valuable control measure is contact tracing, which varies greatly in different countries, but should be standard practice everywhere. Its use across international borders should be developed with proper safeguards to preserve confidentiality. This has proved especially useful in tracing networks of infection seen in the United Kingdom in recent years, such as the mini-outbreaks in Bristol (1999) and Manchester (2000). The application of social network analysis often traces more sexual contacts than direct partner notifications. Other measures which should prove valuable are the education of the young without inducing anxiety, information about sexually transmitted diseases on internet sex clubs, the education of doctors, and the encouragement of regular check-ups of high-risk individuals, such as homosexual men and prostitutes. A more controversial suggestion is to treat contacts of infectious syphilis epidemiologically in certain situations, for example promiscuous individuals, known defaulters, and those who may infect their regular consort if not treated. In England and Wales, during the years 1995 to 2000, 425 such contacts were so treated in genitourinary (STD) clinics (PHLS and DHSS Report, 2001). These measures can be expected to uncover up to 75 per cent of all cases of syphilis.

Persistence of treponemal forms

Persistence of *T. pallidum*-like forms in the cerebrospinal fluid, aqueous humour, lymph nodes, and other tissues in penicillin-treated patients with late or late latent

syphilis has been reported from several centres.

The natural course of untreated syphilis

T. pallidum penetrates the abraded skin and intact mucous membrane. Within hours it has disseminated via the bloodstream and lymphatics and is beyond any effective local treatment. The incubation period is traditionally given as 9 to 90 days but in practice it is around 3 weeks (range, 2 to 6 weeks). The time depends on the size of the inoculum, sexual practice, and hygienic measures. A single treponeme leads to the longest incubation period. The primary lesion develops at the site of contact and heals in 2 to 6 weeks. In a proportion of patients, a secondary stage appears 6 weeks after the primary lesion has healed but there may be an overlap of the healing primary and the onset of the secondary stage. In some cases, the period between these stages can be prolonged to several months. The main characteristic of the secondary stage is a generalized, symmetrical, painless, and non-irritating rash. In about 20 per cent of cases, infectious relapses occur during the following year (range, 1 to 4 years). In the rest, the latent symptomatic period follows and may persist for life in at least 60 per cent . In 30 to 40 per cent, a third, late destructive stage develops. Its more benign form involves only the skin, mucous membranes, and bones. In the serious form, the central nervous system, aorta, and other internal organs are affected. The major events are shown in Fig. 1 and Fig. 2.

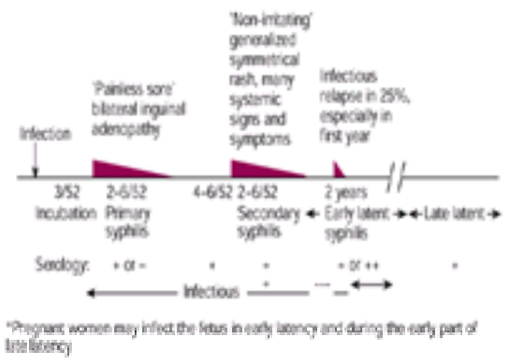

Fig. 1 The course of untreated, early-acquired syphilis.

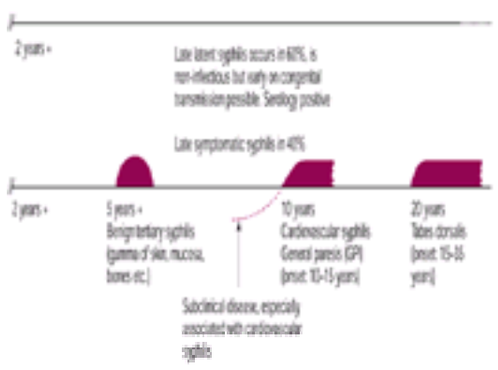

Fig. 2 The course of untreated, late-acquired syphilis. Asymptomatic neurosyphilis is present in 20 per cent and 20 per cent of these develop clinical neurosyphilis. Cardiovascular syphilis starts subclinically many years earlier and when clinically apparent, it is in fact in an advanced state. Prognosis: gumma heals spontaneously in a few years. Cardiovascular syphilis is usually fatal without treatment . Neurosyphilis: general paresis has a poor prognosis without treatment, meningovascular syphilis commonly responds well to penicillin, tabes progresses slowly but penicillin has no obvious influence. Overall mortality of untreated syphilis: 20 to 30 per cent.

Clinical features

Primary syphilis

The first sign is a small, painless papule which rapidly ulcerates. The ulcer (chancre) is usually solitary, round or oval, painless, and often indurated (Fig. 3). It is surrounded by a bright red margin. It is not usually secondarily infected, a feature of all open syphilitic lesions of any stage. *T. pallidum* can be demonstrated in the serum from the sore which is easily obtained after slightly abrading the base. In heterosexual men, the common sites are the coronal sulcus, the glans, and inner surface of the prepuce but may be found on the shaft of the penis and beyond. In homosexual men, the ulcer is usually present in the anal canal, less commonly in the mouth and genitalia. In women, most chancres occur on the vulva, the labia, and, more rarely, the cervix where they are liable to be overlooked.

Fig. 3 Large primary sore. Note the even shape and the absence of secondary infection.

Extragenital chancres usually involve the lips, where they become large and associated with some oedema. Other sites are the mouth, buttocks, and fingers. The regional lymph nodes are invariably enlarged a few days after the appearance of the chancre and with genital sores the lymph nodes are bilaterally involved. They are painless, discrete, firm, and not fixed to surrounding tissues.

Atypical primary sores are not uncommon and depend on the size of the inoculum and the immunological status of the patient; thus a small inoculum usually produces a small, atypical ulcer or papule and looks trivial. This may also be the case in patients who had previously treated syphilis and the lesion may be dark-field negative.

Histologically, the chancre shows perivascular infiltration with plasma cells and histiocytes, capillary proliferation and obliterative endarteritis and periarteritis. The affected lymph nodes contain numerous treponemes, a depletion of lymphocytes, follicular hyperplasia, and histiocytic infiltration. If *T. pallidum* cannot be recovered from the primary sore, it may possibly be demonstrated from a needle aspirate of the regional lymph node.

Differential diagnosis (see also Chapter 23.1)

All genital sores must be regarded as syphilitic until proven otherwise, especially when solitary and painless. The following must be differentiated:

1. Genital herpes (see Chapter 7.10.2), which is much more common than syphilis in either sex, produces a crop of painful or irritating vesicles which develop into shallow erosions. In the first attack there is also painful inguinal adenitis.
2. Traumatic sores are painful, irregular erosions which may become secondarily infected.
3. Erosive balanitis causes inflammatory, irregular erosions which may become purulent in the uncircumcized.
4. Fixed drug eruptions are macules or occasionally ulcers following various drugs, especially tetracyclines.
5. Chancroid is mostly seen in the tropics, presenting as painful, superficial, 'soft chancre', often multiple, with painful suppurative regional adenitis.

Other conditions include scabies, Behçet's syndrome, donovanosis, and lymphogranuloma venereum.

Secondary syphilis

The lesions are numerous, variable, and affect many systems. Inevitably there is a symmetrical, non-irritating rash and generalized, painless lymphadenopathy. Constitutional symptoms are mild or absent; they include headaches, which are often nocturnal, malaise, slight fever, and aches in joints and muscles. The rash is commonly macular, pale red, and sometimes so faint as to be appreciated only in tangential light . It may be papular and sometimes squamous (Fig. 4). Pustular and necrotic rashes are rarely seen in temperate climates but still occur in tropical regions. The later the secondary rash develops, the more exuberant it becomes. The distribution of the rash can be of great diagnostic help. It usually covers the trunk and proximal limbs, but when it is seen on the palms, soles, and the face, syphilis should always be high on the list of probable causes (Fig. 5 and Fig. 6). In warm and moist areas such as the perineum, female external genitalia, perianal region, axillae, and under pendulous breasts, the papules enlarge into pink or grey discs, the condylomata lata, which are highly infectious (Fig. 7). Mucous patches in the mouth and genitalia are painless greyish-white erosions forming circles and arcs ('snail-track ulcers'). They too are very infectious.

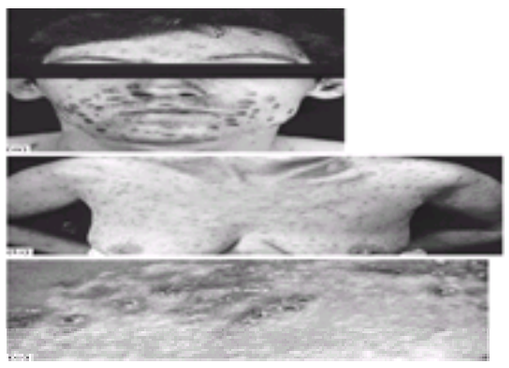

Fig. 4 (a and b) Secondary maculo-papular syphilitic rashes. (c) Late secondary early/tertiary papulosquamous lesions.

Fig. 5 Secondary papulosquamous rash of the soles.

Fig. 6 Secondary rash of the palms.

Fig. 7 Condylomata lata.

Meningism and headache, especially at night, are due to low-grade meningitis which can be confirmed by a raised cell count and raised protein in the cerebrospinal fluid. Less common lesions include alopecia and laryngitis. Syphilitic hepatitis is usually associated with a marked rise in serum alkaline phosphatase. The non-specific inflammatory changes in liver biopsy material are quite unlike those of viral hepatitis. Nephrotic syndrome may develop with glomerular immune-complex

deposits. Pain in the bones, often worse at night, is attributable to periostitis. Uveitis occurs in secondary and tertiary syphilis. In about one-fifth of patients, recurrent infectious episodes occur especially during the first year after the secondary stage. All these lesions disappear spontaneously leaving no trace.

Latent syphilis

By definition the patient is asymptomatic with normal cerebrospinal fluid findings but positive serology for syphilis. It is arbitrarily divided into early (<2 years) and late latent (>2 years) syphilis. Infectiousness does not stop with the advent of latency, as women may continue to give birth to congenitally infected infants during the early latent stage and for at least 2 years into the late latent stage. Approximately 60 per cent of patients remain latent for the rest of their lives, the only evidence of syphilis being positive serology, usually with a low titre. The rest develop clinical late syphilis but autopsy studies indicate that a higher proportion has subclinical infection, especially of the cardiovascular system.

Late syphilis (tertiary syphilis)

This includes late latent syphilis already referred to, benign tertiary syphilis, involvement of viscera, the central nervous system, and the aorta.

Pathogenesis of late benign syphilis

The gumma is a chronic, granulomatous lesion which is an intense inflammatory response to a few treponemes. Histologically, there is central necrosis with peripheral cellular infiltration of lymphocytes, mononuclear cells, and occasional giant cells with perivasculitis and obliterating endarteritis. *T. pallidum* is present and can be demonstrated by rabbit inoculation.

Clinical manifestations

Cutaneous gumma

Gummas are usually single but may be multiple or diffuse (Fig. 8). Clinically, it starts as a slowly progressive, painless nodule which becomes dull red and breaks down into one or several indolent punched-out ulcers. The base has a 'wash-leather' appearance, is remarkably free from secondary infection (Fig. 9), and often resembles other granulomatous conditions. It heals slowly from the centre which may become depigmented, whilst the periphery shows hyperpigmentation. Eventually, a paper-thin scar forms. Common sites are the face, legs, buttocks, upper trunk, and scalp.

Fig. 8 Multiple gummatous ulcers. This is a typical site.

Fig. 9 Single gumma. Note the punched-out ulcer and absence of secondary infection.

Mucosal gumma

These are most commonly seen in the oropharynx, involving the palate, pharynx, and the nasal septum. They tend to be destructive, causing perforation of the hard palate and the nasal septum and severe scarring of the pharynx and larynx. The most serious lesion is the diffuse gummatous infiltration of the tongue, leading first to a general swelling of the organ, then due to loss of papillae to a smooth red surface. After a while, the poor blood supply produces necrotic white patches on the dorsum of the tongue (Fig. 10). This leucoplakia has a strong tendency to become malignant. Penicillin has no effect on the progress of late syphilitic glossitis.

Fig. 10 Late syphilitic glossitis, early stage.

Late syphilis of bones

Osteoperiostitis of long bones such as the tibia and fibula causes thickening and irregularities which may be diffuse as in the 'sabre tibia' or localized as a

circumscribed bony swelling. Unlike most other syphilitic lesions, those of the bone are often painful, especially at night . Very rarely the process breaks through the skin producing a chronic 'syphilitic osteomyelitis'. Lesions of the palate, nasal septum, and the skull are destructive, leading to bone defects of the hard palate and nasal septum and multiple osteolytic lesions of the skull.

Differential diagnosis

Mucocutaneous gumma

Superficial skin lesions must be differentiated from fungal skin lesions, psoriasis, Kaposi's sarcoma, and iodide rashes. Deep gummas may resemble deep mycoses, sarcoidosis, tuberculosis, leprosy, donovanosis, lymphogranuloma venereum, reticulosis, and epithelioma of the skin. Serological tests for syphilis, which must include specific reactions such as the FTA–ABS (fluorescent treponemal antibody-absorbed test), prompt response to penicillin, and evidence of syphilis elsewhere clarify the diagnosis.

Late syphilis of bones

Primary and secondary carcinoma, Paget's disease, chronic osteomyelitis, tuberculosis, and leprosy should be considered. All forms of non-venereal syphilis, except pinta, give rise to similar lesions.

Visceral syphilis

This is not common and response to treatment is variable.

Liver

Multiple gummas of the liver give rise to irregular hepatomegaly ('hepar lobatum'), which may be asymptomatic. Symptoms may result from pressure on bile ducts or blood vessels or destruction of liver parenchyma.

Eyes

Uveitis, choroidoretinitis, or optic atrophy may sometimes be the sole feature of late syphilis. Uveitis can also develop during early syphilis, particularly in association with HIV, where bilateral uveitis is more commonly seen. Response of the late form to penicillin is poor. Optic atrophy is further discussed under neurosyphilis. The cerebrospinal fluid should be examined in all patients.

Stomach

Single or diffuse gummatous infiltrations of the stomach may respond to antisyphilitic treatment .

Lungs

Single or multiple gummas are rare and respond to treatment.

Testis

Gummatous infiltration and dense fibrosis may produce smooth, painless enlargement of a testis. Testicular sensation is lost .

For discussion of paroxysmal cold haemoglobinuria and neurosyphilis see Chapter 24.14.4.

Laboratory diagnosis of syphilis

Dark-field microscopy

The organism is seen in the wet preparation by dark-field microscopy in fluid taken from open lesions in early syphilis or needle aspirate from affected lymph nodes. In late lesions, the organism is not readily demonstrable by microscopy. Treponemes causing syphilis, non-venereal syphilis, yaws, and pinta cannot be differentiated morphologically. They give rise to the same serological reactions and are susceptible to penicillin.

Immunostaining directly with monoclonal antibody or by indirect fluorescent antibody staining of air-dried smears or tissue specimen has recently been reported to show numerous *T. pallidum* in a cutaneous gumma but that were not observed by dark-field microscopy or silver staining. Immunoperoxidase staining is useful in archival material.

Serology

Two classes of antibody tests are available:

a. those that measure non-specific antibodies (IgG and IgM) against lipoidal antigens (lipoidal antibody tests formerly called reagin tests);
b. those that measure specific antibodies stimulated by antigenic components of the treponeme and further divided into those stimulated by antigens found in pathogenic treponemes only and those shared with non-pathogenic treponemes.,

The non-specific cardiolipin antibodies act on lipoidal antigen which results from the action of *T. pallidum* on host tissue; it mirrors disease activity. The specific antigen is derived from *T. pallidum* and does not differentiate between past or present infection and is therefore of no value in assessing current activity. None of the tests distinguishes syphilis from other treponematoses. The interpretation of the tests is given in Table 2.

Animal inoculation

Animal inoculation with material from late lesions or from cases of 'persistent *T. pallidum*-like forms' is usually reserved for research purposes. PCR detection of treponemal nucleotides in amniotic or cerebrospinal fluid has proved no more sensitive than the detection of live spirochaetes by animal inoculation of these fluids.

Current serological tests for syphilis

The basis of these tests is shown in Table 3.

Lipoidal antigen tests

Rapid plasma reagin (RPR) test

This can be automated and is useful for screening purposes. It is the least technically demanding test (no microscope needed). It uses carbon-containing cardiolipin antigen and requires a minimal amount of blood. Filter paper or glass fibre discs can be used to post samples to laboratories; they are therefore mainly for use by primary health centres in outlying rural areas.

VDRL test

This is the preferred test and as it is used world-wide there is a good chance of it becoming standardized. It is simple and inexpensive. It is, above all, a quantitative test and as the titres reflect activity, it is of great value for this purpose. It may, for example, be the only evidence of reinfection in a patient with previous syphilis whose VDRL was either negative or weakly positive after treatment. A sharp, sustained rise of the titre, four-fold or higher, even in the absence of clinical signs is good evidence of active infection. False-positive VDRL is usually of a low titre (1:8 or less). The VDRL test becomes positive during the primary stage and rises to its maximum during the secondary stage (1:32 or more). After successful treatment, the titre declines (1:4 or less) and if treatment was given early in the disease it often becomes negative. An occasional, small and transient rise in titre (two tubes) is of no significance. The immunofluorescent test which detects cardiolipin F levels tends to be positive only in active infections.

Specific antitreponemal tests

T. pallidum haemagglutination (TPHA) test or T. pallidum particle agglutination test (TPPA)

This is a very valuable and simple test using an indirect haemagglutination method with red cells or by gelatin particles attached to sonicate of *T. pallidum* extract. It is almost as specific as the near-obsolescent TPI (treponemal immobilization test) reaction but is less sensitive than the FTA–ABS test. False-positive reactions occur in up to 2 per cent. The micromethod is particularly suitable for screening purposes. This test together with the VDRL it is probably the best combination for routine use. In cases of doubt, the FTA–ABS test is added. TPHA can be adapted for automation. There is no standard 'cut off' for the TPHA in the cerebrospinal fluid.

The FTA–ABS test

This uses the indirect fluorescent technique with killed *T. pallidum* as antigen. The organisms are fixed on a slide to which the serum is added. The antibody in the serum will unite with the treponemes and this can be made visible by adding antihuman globulin conjugated with a fluorescent stain which attaches itself and produces fluorescence of the treponemes seen by fluorescent microscopy. The test has been made more specific by absorbing the group antibodies with a sonicate derived from Reiter's treponemes. The test is then called FTA–ABS. The FTA–ABS is the most sensitive test available and is also specific. It becomes positive earlier during the primary stage of syphilis than other procedures. It is not suitable for assessing activity, as it persists long after successful treatment . When the routine serology includes the VDRL and TPHA tests, the FTA–ABS test should be added in cases of problem sera.

The FTA–ABS–IGM test

In the search for a specific test to differentiate active infection which has to be treated from adequately treated or 'burnt-out' inactive disease, the FTA–ABS–IGM is being evaluated to test for specific IgM which develops in the course of syphilis. This test sometimes gives false-positive reactions owing to the presence of anti-IgG globulins (e.g. rheumatoid factor) and false-negative reactions have also occurred; thus there are problems in the use of this test in the elderly. Its use in the rapid, early diagnosis of congenital syphilis was considered some years ago to be great advance. The basis for its use is that IgG is a small molecule and passes through the placenta; thus the baby may inherit maternal IgG but not necessarily the infection. Tests such as the VDRL may therefore be positive in the newborn by passive transfer and may take 3 months to disappear. IgM is a large molecule and does not pass through the placenta; thus if it is found in the neonate, it must be assumed that it has been produced by the infected infant.

Newer tests

Enzyme immunoassay (EIA) tests (e.g. CAPTIA IgG, IgM) have no practical advantage over current tests. Attempts with purified antigens from *T. pallidum* may be specific, although they tend to loose sensitivity, for example, those employing the TpN19 or Tp44.5 antigens. The problem is that early cases may not always have antibodies to a specific antigen. It would be better, therefore, to screen with as many antigens as possible. This is achieved by western blotting, which allows the separation by gel electrophoresis of all the major, stable antigens of the spirochaete, and enables a distinction to be made between the non-specific and specific antibody reactions with given bands. The major antigens are shown in Table 4.

This technique may have special application in seronegative syphilis (perhaps syphilis occurring with HIV infection) but not in primary syphilis, where up to half the cases show no reaction. The immunoblot may also be helpful in distinguishing false positive tests caused by borrelia infections.

Diagnosis of neurosyphilis by examination of the cerebrospinal fluid

The traditional tests include the VDRL, cell count, total protein globulin, and goldsol curve. The last two tests are now obsolete. The cerebrospinal fluid VDRL is unreliable as it can be negative in up to 50 per cent of samples from patients with active neurosyphilis. Cell counts exceeding 5/mm ^{2} (but usually not above 50/mm^2) and protein above 40 mg/ml (60 mg/ml in patients older than 65 years) are non-specific signs of inflammation. The specific FTA–ABS and TPHA tests in the cerebrospinal fluid may be positive due to passive transfer of serum IgG from adequately treated patients. If they are negative, active neurosyphilis can almost certainly be excluded.

Biological false-positive tests for syphilis

These concern mainly the cardiolipin tests and are classified as acute, as in drug addicts, or chronic if they occur in autoimmune disease (when they may precede the symptoms by years), leprosy, and in a small proportion of people over 70. The concurrence of HIV and syphilis in drug abusers makes the investigation of these false-positive reactions particularly important. There is no evidence for an increase in false-positive tests in patients with HIV. Particular mention should be made of the thrombotic antiphospholipid syndrome since the condition is associated with early miscarriage and cerebral thrombosis, manifestations which might be confused with syphilis. The confirmatory TPHA and FTA–ABS tests are always negative. A biological false-positive test may occur acutely in the cerebrospinal fluid in aseptic meningitis or in a seropositive patient, when a traumatic tap may give a false impression of a positive cardiolipin test in the cerebrospinal fluid, following transfer of plasma antibody.

The management of syphilis

Suggestions for drug treatment of syphilis are given in Table 5. It has been found that adherence to clinical guidelines is better maintained when treatment and follow-up is performed by a sexually transmitted disease clinics than by a non-institutional practitioner. As soon as a diagnosis of infectious syphilis has been made, the patient should be interviewed by a social worker regarding all sexual contacts. In the case of primary syphilis, this should cover the previous 3 months; in patients with secondary syphilis this should be extended to 1 year; and in patients with early latent syphilis to 2 years because of the possibility of infectious relapses during that period. The patient is warned against intercourse during treatment and for a further 2 weeks. Experience suggests that advice for longer abstinence will be disregarded in many cases and is almost certainly unnecessary.

If the patient gives no history of penicillin allergy, it is the first choice for the treatment of all stages of the disease. Penicillin is as effective now as it was more than 40 years ago when it was first introduced. Resistance to penicillin has not been described, perhaps related to the novel penicillin binding of the T $_P$47 (TPO971) protein. If there is penicillin allergy, the alternative drugs are tetracycline/doxycycline and erythromycin. The recent finding of a wild strain of *T. pallidum* resistant to erythromycin has led to an extensive investigation into the use of newer cephalosporins. Cephalosporins are effective but there is cross-allergy with penicillin in 5 to 7 per cent of patients.

The optimal dose or duration of treatment with penicillin, or the other drugs, has not been established and therefore a great variety of treatment schemes have been put forward, although the results appear to be similar, suggesting that a fair degree of variation is permissible. The general tendency is to treat with larger doses and over a longer period of time in the later stages of syphilis; some prefer to repeat the course. There is no convincing evidence that large, much extended, or repeated courses give any added benefit.

There is good experimental evidence that serum concentrations of penicillin should be at least 0.003 µg/ml, should be maintained for 8 to 10 days, and that troughs in the concentration should not exceed 15 h. Some physicians prefer a single injection of the long-acting benzathine penicillin (2.4 million units) for simplicity, but the

concentration reached is low and does not give a useful level in the cerebrospinal fluid; also the injection is quite painful. Others repeat this dose weekly, for 3 weeks. In patients with neurosyphilis and HIV infections, treponemes have been demonstrated in the cerebrospinal fluid after benzathine penicillin G treatments and in these patients the expected decline in VDRL cerebrospinal fluid titres after treatment occurred less often than in those without concurrent HIV infection. All treponemal infections are unaffected by sulphonamides, gentamicin, rifampicin, and quinolones in clinical dosage.

Procaine penicillin has several advantages over other penicillin preparations and is preferred by many. In some centres, the course is 1 million units/day for 10 days; in others it is given for 20 days though evidence that such a prolonged course gives better results is lacking. Procaine penicillin in 2 per cent aluminium monostearate (PAM) has a prolonged action and was used extensively by the World Health Organization in their mass campaign against non-venereal syphilis.

Penicillin reactions

All patients receiving penicillin injections should be kept in the clinic for 15 to 20 min as severe reactions needing immediate treatment will develop well within this period. An emergency tray to deal with anaphylactic penicillin reaction must be readily available wherever penicillin is given. It should contain ampoules of 1:1000 adrenaline (epinephrine) solution, syringes and needles, intravenous hydrocortisone, injectable antihistamine, aminophylline, an airway respirator (Ambu bag or Brooke's respirator), and oxygen with face mask or nasal catheter.

Prevention of penicillin reactions

Some 3 to 5 per cent of the population in the United Kingdom are allergic to penicillin and it is essential to enquire about this; if there is a history, penicillin must not be given. This fact should be displayed prominently on the cover of the medical notes and the patient told to inform any doctor who may wish to give this antibiotic. Careful history taking may, however, show that the 'allergy' to penicillin is doubtful, for example the rash antedated the giving of penicillin and may have been due to one of the childhood infections. It is quite common to be told that patients who apparently did have a penicillin reaction, had no problems when the antibiotic was inadvertently given subsequently as penicillin allergy is a transient phenomenon. In such cases we still prefer to avoid giving penicillin.

Clinical features

The most serious reaction is anaphylactic shock appearing immediately or within a minute or two after the injection. The more immediate the onset, the more severe the attack. The patient becomes unconscious, stops breathing, and becomes pulseless. Very rarely, the patient dies immediately. A fatal outcome is estimated to occur one or two times per 100 000 injections. In the more moderate reaction, the patient feels faint with acute anxiety and a feeling of impending death; there may be oedema of the face, possibly with an asthmatic attack, soon followed by urticaria. Arthralgia and some pyrexia may develop. The urticaria is liable to last 1 to 2 weeks.

The commonest form is the delayed reaction when urticaria appears days after injection or oral penicillin. Arthralgia and fever may develop. Sometimes a local reaction around the injection site is seen. It can be urticarial but is more commonly a painful red swelling and usually responds to rest . It is best to discontinue the course, as recurrences are otherwise common. In some patients a hysterical episode follows an injection and this may be due to procaine or possibly inadvertent intravenous injection. It passes off spontaneously.

Treatment of the anaphylactic reaction

The patient is laid flat with feet up and head down. Blood pressure and pulse are monitored throughout . Adrenaline 1:1000 (adult dose 0.5–1.0 ml) is given intramuscularly without delay. If bronchospasm develops, 250 mg aminophylline in 10 ml water is administered by slow intravenous injection. Intravenous hydrocortisone (100 mg) may also be tried and may be repeated. Some prefer intravenous antihistamine (chlorpheniramine injection 10–20 mg). Adrenaline, nevertheless, is the mainstay of treatment. If there is no response, the cardiac arrest team is summoned. If recovery is slow, the patient should be admitted as recurrences may occasionally occur. In any case, the patient must be kept under observation for several hours. Later, urticaria develops in most patients and prophylactic antihistamines by mouth are indicated.

Treatment of the delayed reaction

The leading feature is urticaria, possibly with oedema of the face, arthralgia, and some fever. Such patients respond to oral antihistamines such as chlorpheniramine 4 mg four times daily or terfenadine 60 mg twice daily until the condition is controlled. If it is very severe, prednisolone 10 mg four times daily may be added for a few days, reducing it as soon as possible. Penicillinase is not recommended as it may produce reactions of its own.

Procaine reaction

Two types of reaction are recognized:

1. The patient shows extreme anxiety with a feeling of impending death. Sometimes there are hallucinations, disorientation, and depersonalization. The reaction is self-limiting. It may be due to reduced procaine esterase leading to high procaine blood levels. Patients should be restrained and reassured.
2. The reaction is similar but associated with hyperventilation, hypertension, tachycardia, and vomiting. Rarely cardiovascular collapse has been reported but without fatalities. The reaction is thought to follow accidental intravenous administration of procaine penicillin leading to microemboli of the lungs and brain. Supportive treatment is usually sufficient.

Vasovagal attacks

These occur most commonly in young men following intramuscular injection or after having blood taken. The patient looks very pale and may faint . He may slump to the floor and occasionally go stiff and have jerky movements. The most important diagnostic sign is a slow pulse. Recovery is rapid once he is laid flat on a couch. There is a tendency for recurrence in the same individual under similar circumstances and this can usually be prevented by giving injections or taking blood whilst the patient is lying down.

Jarisch–Herxheimer reaction (see also Chapter 7.11.30)

This systemic reaction is believed to be due to the release of endotoxin-like substances when large numbers of *T. pallidum* are killed by antibiotics. It is mainly associated with early syphilis. The incidence of the reaction appears to be related to the total number of the organism in the body. The mechanism may not be straightforward as it is not a feature of neonatal syphilis or non-venereal syphilis in childhood. The reaction can be expected in 50 per cent of primary syphilis, 90 per cent of secondary syphilis, and in 25 per cent of early latent infection, but is very rare in late syphilis. It has been suggested that it is more often seen in patients with HIV.

The reaction begins 4 to 12 h after the first injection, lasts for a few hours or up to a day, and is not seen with subsequent treatment . There is malaise, slight to moderate pyrexia, a flush due to vasodilation, tachycardia, and leucocytosis, and existing lesions become more prominent. In some patients with early syphilis, a secondary rash may become visible which was absent before treatment. Rarely, syphilis may be suspected by the appearance of the febrile reaction of the Jarisch–Herxheimer, perhaps with a fleeting rash, when treating another infection with a treponemocidal antibiotic (e.g. penicillin in gonorrhoea).

In early syphilis the reaction is only a minor nuisance. In late syphilis it can on very rare occasions be more serious. Thus in neurosyphilis it may lead to epilepsy or a rapid. irreversible progression, and in general paresis it can cause exacerbation amounting to temporary psychosis. Sudden death has been reported in cardiovascular syphilis. In laryngeal gumma, local oedema may necessitate tracheotomy. In the later stages of pregnancy, fetal monitoring is advised.

It is customary to give corticosteroids in late symptomatic syphilis starting a day before the first penicillin injection and tailing it off the day after the first injection. This does not prevent the Jarisch–Herxheimer reaction but is said to ameliorate it . The analogous reactions in relapsing fever have been modified by meptazinol or pretreatment with infusions of polyclonal anti-TNF-a Fab with concomitant reduction in the plasma concentration of interleukin 6 and 8.

Follow-up

It is generally sufficient to perform blood tests 1, 3, 6, and 12 months after treatment of early syphilis. In late symptomatic syphilis, surveillance is for life. Patients with leucoplakia of the tongue should be checked every 3 months. In symptomatic cardiovascular syphilis regular radiological and clinical examination is essential to determine any change which might suggest the need for cardiac surgery. In neurosyphilis an annual review might be adequate.

In latent syphilis, if there is a satisfactory serological response, 2 to 3-yearly follow-up seems reasonable. The cerebrospinal fluid need not be examined in the non-immunocompromised patient, except in the presence of neurological signs. In early congenital syphilis, the observation time should be similar to that of early acquired syphilis. In late latent congenital syphilis, no further attendance is necessary unless symptoms of interstitial keratitis or other lesions not prevented by penicillin develop.

In high-risk patients such as male homosexuals and prostitutes a regular check-up every 3 months is advised. If such patients have had syphilis, the VDRL should have become negative or of a low titre after treatment. If the titre suddenly rises four-fold or more, reinfection must be assumed and treatment is indicated.

Prophylaxis

Treatment of asymptomatic contacts of early syphilis is recommended in the United States as there is a 50 per cent chance of infection. Such pre-emptive treatment is likely to reduce the spread of infection in the promiscuous or in those likely to infect their spouses or regular sexual partners. Use of condoms should be recommended. Various vaginal chemical spermicidal creams give a small degree of protection but are unreliable.

7.11.34 Listeriosis

P. J. Wilkinson

Listeriosis has been recognized since the 1920s as a systemic infection of man, domestic and farm animals, and rodents. Because the disease in rabbits and guinea pigs was characterized by a marked mononuclear leucocytosis, the causative Gram-positive bacillus was named *Bacterium monocytogenes*, then (in honour of Lord Lister) *Listerella* and finally *Listeria.* Human listeriosis was a relatively obscure disease until the 1980s, when a series of food-borne outbreaks awakened interest. Listeriosis remains a rare infection but carries a significant morbidity and mortality.

Listeria monocytogenes

*Listeria*spp. are non-sporing, facultatively anaerobic, Gram-positive bacilli that are ubiquitous in the environment and distributed world-wide. *L. monocytogenes* is the major pathogen, although occasional human infections with *L. ivanovii* and *L. seeligeri* have been reported. *L. ivanovii* and *L. innocua* can infect animals. *L. welshimeri* and *L. grayii* are not known to cause disease. Enrichment and selective methods are now well established for the isolation of listeria from food or the environment; immunoassays and nucleic acid amplification techniques have also been used. The ability to multiply at temperatures of 0 to 40° C and tolerate preserving agents makes listeria of particular concern if present in refrigerated foods that are consumed without further cooking.

Several typing methods are used to trace food sources, distinguish relapses from reinfections, and investigate outbreaks. Thirteen serovars are currently recognized, of which three (1/2a, 1/2b, and 4b) cause more than 90 per cent of human and animal infections. Phenotypic subtyping systems, based on patterns of lytic reactions with bacteriophages, bacteriocin (monocin) production, and multilocus enzyme electrophoresis have been enhanced by genotypic analysis, particularly pulsed field gel electrophoresis (PFGE).

Epidemiological associations

L. monocytogenes has been isolated from many foods, and the consumption of contaminated meat, milk, seafood, or vegetables is the principal route of infection. Outbreaks have been associated with coleslaw, raw fish, raw hot dogs, undercooked chicken, meat paté, pork rillettes, turkey franks, smoked fish or shellfish, and cheese and dairy products, particularly when pasteurization has been ineffective. The United Kingdom Department of Health advises pregnant women and immunocompromised persons not to eat soft ripened cheese (e.g. Brie, Camembert, and blue-vein types), all types of paté, and cook-chill meals and poultry unless thoroughly reheated until piping hot.

Direct transmission through contact with infected animals can give rise to primary cutaneous listeriosis, an occupational disease of farmers and veterinarians. Laboratory workers have acquired eye and skin infections from direct exposure to culture material. Nosocomial infection has spread between neonates in association with poor hand hygiene, close contact between infected patients and their mothers, and fomites such as rectal thermometers. Hospital outbreaks, which may have been food-borne, have also occurred in adult immunosuppressed patients.

Pathogenesis

Although listeria displays many characteristics of saprophytes, specific adaptations allow *L. monocytogenes* to become an intracellular pathogen where invasion and multiplication in both phagocytic and non-phagocytic cells occurs. CR3 complement receptors may be involved in the adhesion to phagocytes. Internalin, a listerial surface protein similar to the M protein of group A streptococci, plays a part in the initial stages of invasion of all cell types, as may p60, another cell surface protein with murein hydrolase activity. After internalization, *L. monocytogenes* becomes encapsulated in a vacuole, the membrane of which is dissolved by a thiol-activated haemolysin (listeriolysin O) and possibly also by phospholipase C. Having entered the host cell cytoplasm, the organisms grow, polymerize actin, acquire intracellular mobility, and spread to adjacent cells.

Clinical features

Although listeriosis is generally an opportunistic infection of the elderly, patients with severe underlying illness, pregnant women, newborn babies, and individuals without these risk factors can also become infected. The clinical presentation varies from a mild, influenza-like illness to fatal septicaemia and meningoencephalitis. The syndromes recognized include maternofetal and neonatal listeriosis, septicaemia, meningoencephalitis, cerebritis, gastroenteritis, and localized infections.

- In maternofetal listeriosis, the mother may develop a fever, headache, myalgia, and low back pain, associated with the bacteraemic phase of the disease. Transplacental infection causes amnionitis and usually leads to spontaneous septic abortion or to premature labour with the delivery of a severely infected fetus or baby.
- Neonatal listeriosis of early onset results from intrauterine infection and has a high mortality. The liquor is meconium-stained and the baby septic and jaundiced, with signs of purulent conjunctivitis, bronchopneumonia, meningitis, or encephalitis. Granulomas affect many organs, hence the term 'granulomatosis infantisepticum'. Late-onset disease, which develops several days to weeks in a baby who was initially healthy but subsequently develops meningitis, which may be acquired from the mother's genital tract or through cross-infection from an early-onset case.
- Septicaemia occurs mainly in adult patients with malignancies, in transplant recipients, and in immunosuppressed and elderly people. Most present with fever, hypotension, and shock but a third to a half develop meningitis, which is often then the presenting feature.
- Meningoencephalitis may start abruptly but, in adults, can also develop insidiously, with progressive focal neurological signs even in the absence of a brain abscess. Most patients have meningism, but fever may not be marked, particularly in elderly or immunosuppressed people. This infection should be considered in any patient with an acute brain-stem disorder associated with fever, particularly if there are no risk factors for cerebrovascular disease.
- Cerebritis is increasingly recognized, particularly in the immunosuppressed patient. Headache, fever, and varying degrees of paralysis can resemble a cerebrovascular accident. Rhomboencephalitis begins with a headache, fever, nausea, and vomiting followed in several days by symmetrical, progressive cranial nerve palsies, decreased consciousness, and cerebellar signs. Areas of uptake without ring enhancement may be shown by MRI or CT scan, and the cerebrospinal fluid shows few, if any, cells, and normal protein and sugar concentrations.
- Gastroenteritis with arthromyalgia, fever, diarrhoea, nausea, vomiting, and an incubation period of 1 to 3 days has recently been described in outbreaks of infection in immunocompetent adults who have ingested contaminated food. Because diagnostic laboratories do not usually culture diarrhoeal stools selectively for listeria, *L. monocytogenes* may be missed. Recent outbreaks have come to light when blood cultures from hospitalized patients have yielded the organism, or when serological testing of the blood of recently affected patients has shown antibody to listeria.
- Localized infections are rare, occur mainly in immunosuppressed people, and include abscesses, cholecystitis, endocarditis, endophthalmitis, osteomyelitis, septic arthritis, and peritonitis. They usually result from seeding during an initial bacteraemic phase, but focal skin and eye infection can also result from direct, occupational exposure.

Diagnosis

The microbiological diagnosis of invasive listeriosis is made by culture of the organism from meconium, nose or eye swabs, urine, cerebrospinal fluid, blood, tracheal aspirate, placental tissue, and/or lochia. Gram-positive bacilli may be seen in a stained smear. In listeria meningoencephalitis, the cerebrospinal fluid exudate is predominantly mononuclear and, if no bacteria are seen in a Gram-stained film, may be confused with viral meningitis; however, unlike viral meningitis, the cerebrospinal fluid protein is high and the glucose concentration low in relation to that in the peripheral blood. Tests for listeria antibodies in maternal and cord blood

samples do not contribute to the diagnosis of the acute infection. Selective culture techniques have considerably improved the isolation rate.

Antibiotic treatment

There are no controlled trials of antibiotic treatment for listeriosis. All strains are susceptible to ampicillin, which acts synergistically with aminoglycoside antibiotics, and high-dose intravenous ampicillin in combination with gentamicin remains the treatment of choice. Gentamicin is best avoided in pregnancy, when ampicillin may be used alone, or erythromycin if the patient is penicillin-allergic. Intravenous co-trimoxazole is the best second-line treatment for listeria meningoencephalitis. Vancomycin has been successfully used with gentamicin to treat bacteraemic illness, but does not cross the blood–brain barrier. Rifampicin and ciprofloxacin have not been evaluated in human listeriosis.

L. monocytogenes is inherently resistant to the cephalosporins and it is very important to be aware that treatment with this class of antibiotics is likely to fail. Since acute pyogenic meningitis is usually treated, until the pathogen is known, with ceftriaxone or cefotaxime, ampicillin should also be given with this initial treatment whenever listeriosis is a clinical possibility, unless the cerebrospinal fluid Gram-film shows good evidence of another bacterial cause, or the patient has unequivocal clinical features of meningococcal disease.

Intravenous ampicillin should be given in a daily dose of 200 to 300 mg/kg (neonates) or 6 to 12 g (adults) in three to four divided doses for 2 weeks (uncomplicated bacteraemia), 4 to 6 weeks (meningoencephalitis), or 6 to 8 weeks (endocarditis). Intravenous gentamicin should be given for the first 14 days in a dosage adjusted with the help of plasma concentration measurement. Focal listeriosis may be treated with ampicillin or amoxicillin, 3 to 6 g daily, until clinical resolution. In cases of genuine penicillin allergy, intravenous co-trimoxazole, 20 mg/kg per day (trimethoprim component) may be given in four divided doses. Alternatively, intravenous minocycline, which may have to be obtained specially from the manufacturer, can be used in a daily dose of 200 mg (adults) or 4 mg/kg (children), in combination with gentamicin.

Prognosis

Despite antibiotic therapy, the mortality of septicaemia and meningoencephalitis with *L. monocytogenes* remains high (20–50 per cent). There is significant long-term morbidity in the survivors. Efforts should therefore continue to be focused on the prevention of this infection by improvement in the microbiological safety of methods of food production and preparation and by the continued education of the public so that vulnerable people can avoid high-risk foods.

7.11.35 Legionellosis and legionnaires' disease

J. B. Kurtz and J. T. Macfarlane

In 1976 an outbreak of pneumonia occurred among American legionnaires who had attended a convention in a Philadelphia hotel. A total of 221 people developed pneumonia, 'legionnaires' disease', of whom 34 died. A newly identified organism, named after this outbreak, *Legionella pneumophila*, was responsible. Since then other outbreaks and sporadic cases have been recognized and 16 *L. pneumophila* serogroups, and other species of legionella besides *L. pneumophila* have been isolated from clinical and environmental samples. There are now at least 43 recognized species in the Legionellaceae family. Clinical illness caused by members of the family Legionellaceae is referred to as legionellosis. The pneumonia is called legionnaires' disease. Non-pneumonic legionellosis ('Pontiac fever') is a self-limiting, influenza-like illness, without radiographic changes in the lung, caused by many different legionella species. What determines the type of illness that will follow infection is unknown. Although, in a given outbreak, disease of both pneumonic and non-pneumonic types occurs, usually either one or other form predominates. *L. pneumophila* is responsible for over 80 per cent of legionellosis, and of the 16 serogroups serogroup 1 is the most frequently encountered in human infections. In some parts of Australia, however, *L. longbeachae* is the most frequently identified species causing legionnaires' disease. Other legionella species appear to be less pathogenic and are more frequently found as opportunist pathogens in immunocompromised people. Some have caused disease, others have only been isolated from the environment and have yet to be implicated as human pathogens.

The organism

The Legionellaceae are aerobic, non-sporing bacilli whose cell walls contain distinctive branched-chain fatty acids.

In the laboratory, legionellae are fastidious in their growth requirements and will not grow on standard bacteriological media. Aces buffered charcoal yeast-extract agar, pH 6.9, supplemented with L-cysteine, a-ketoglutarate, and iron, is a very satisfactory medium. On this medium, incubated at 35 to 37 °C, typical colonies usually appear in 3 to 5 days; occasional slow-growing strains require the plates to be incubated for 10 days. When isolates from a patient and a suspected environmental source (see below) have been obtained, an accurate comparison of the strains should be undertaken. Both genotypic (e.g. amplified fragment length polymorphism) and phenotypic (e.g. monoclonal antibody reaction pattern) methods of identification should be used in parallel to see whether the two isolates are indistinguishable or different.

Epidemiology

The natural habitat of legionellae is in freshwater streams, lakes, and thermal springs, moist soil, and mud. They have been found worldwide in waters with temperatures varying from 5 to 62 °C and pH values of 5.4 to 8.2. These organisms are inhibited by sodium chloride and are not found in sea water. In natural habitats they are found in only small numbers, forming part of the consortium of micro-organisms that makes up the biofilm. This includes amoebae and other protozoa, in certain of which legionellae multiply and later re-emerge. Inside these protozoa the bacteria form microcolonies, which are protected from adverse conditions (for example, in amoebic cysts from desiccation and up to 50 parts per million of free chlorine). This association enables the bacteria to survive and to disseminate widely in the natural environment.

Legionellae have been found in small numbers in water distribution systems, through which they can colonize man-made habitats, again as part of the biofilm from which they are shed into the water. Factors that encourage colonization and multiplication are temperature (20–45 °C) and stagnation. The most common sites in buildings in which legionellae have been found are hot-water calorifiers and storage tanks. Piped water, especially hot water from the calorifiers in large buildings and industrial complexes with long runs of pipework, is a potential source of infection. Other well-recognized sources include:

- recirculating water in air-conditioning and cooling systems;
- whirlpool spas and other warm-water baths;
- decorative fountains;
- nebulizers and humidifier reservoirs of hospital ventilation machines if topped up with contaminated tap water;
- potting compost for *L. longbeachae* serogroup 1 in Australia.

Dissemination of infection is by contaminated water droplets (aerosol), which are inhaled. In order to cause infection the droplets must be of a size (less than 5 µm diameter) that can reach the alveoli of the lungs. Taps and shower heads produce very localized aerosols, whereas the water droplets (drift) contained in the airstream released from a cooling tower may be carried a considerable distance and expose a greater number of people to risk. For example, in the 1976 Philadelphia outbreak, those infected in the street developed 'Broad Street pneumonia' and passers-by were infected in both the Stafford District General Hospital outbreak in 1985 (101 cases, 28 deaths) and near the BBC building, London, in 1988 (79 cases, 2 deaths). Person-to-person spread of legionellosis has never been recorded. Aspiration of contaminated water as might occur in hospital following an anaesthetic is also a well-recognized route of infection.

Although most studies of legionnaires' disease have been of outbreaks, sporadic cases account for about three-quarters of those reported in England and Wales. A source is only exceptionally found for them. Some of these sporadic events become part of an outbreak when other cases can be linked to them epidemiologically, as when patients from different geographical areas give a history of visiting a common site within the incubation period of their illnesses. An association with overseas travel was found in one-third of the sporadic cases in England and Wales for the years 1979 to 1986. Apart from travel, an analysis of sporadic (better called non-travel, non-outbreak) cases in Glasgow between 1978 and 1986 supported the hypothesis that cooling towers were the source of the infections. The relative risk was three times greater for people living within 500 m of a cooling tower compared with those living more than 1000 m away.

In temperate countries legionellosis has a seasonal pattern, most cases occurring in the summer and autumn. A multicentre British Thoracic Society study of community-acquired pneumonia requiring hospital admission in 1982 to 1983 showed that 2 per cent had legionnaires' disease. This suggests that about 1500 cases occur per year in Britain.

The susceptibility to infection of exposed people varies. For non-pneumonic legionellosis the attack rate is very high. In contrast, the attack rate for legionnaires' disease is about 1 per cent, although subclinical or mild infections can follow exposure, as indicated by serological surveys. For example, of the staff at the Stafford District General Hospital who were tested following the outbreak in 1985, 42 per cent had an antibody titre of 1 in 16 or greater.

Hospital-acquired legionellosis has been a particular problem. This is because of the complexity of the buildings and the difficulty of keeping the hot water hot (storage at 60 °C and 50 °C at the taps), either because of the length of pipework or for fear of scalding patients. Hospital patients, too, are a highly susceptible population and species other than *L. pneumophila* more frequently cause infections in these circumstances. In intensive care units, inhalation of air passed through contaminated humidifiers or aspiration of contaminated water are other potential sources of infection.

Clinical manifestations

Legionella pneumonia

Large studies have suggested that legionella infection is the cause of around 2 to 5 per cent of cases of community-acquired pneumonia admitted to hospital, although there is wider geographical and seasonal variation. Infection tends to lead to moderate or severe infection rather than mild illness, and most patients require hospital admission within 5 to 7 days of the start of symptoms.

The incubation period is usually 2 to 10 days, with a mean of 7 days; males are two to three times more frequently affected than females. Infection at the extremes of age is rare and the highest incidence is in 40- to 70-year-old people, with a mean age of 53 years. People particularly at risk include cigarette smokers, alcoholics, diabetics, and those with chronic illness or who are receiving corticosteroids or immunosuppressive therapy. Consequently, the type of patient who requires admission to hospital is particularly at risk from a nosocomial source.

Clinical features (Table 1)

Typically, the illness starts fairly abruptly with high fever, shivers, bad headache, and muscle pains. Upper respiratory tract symptoms, herpes labialis, and skin rashes are uncommon. The cough is usually dry initially but dyspnoea is common and the illness often progresses quickly. Sometimes there may be a history of a recent hotel holiday abroad or a stay in hospital, which can alert the clinician to the possible diagnosis.

The patient commonly looks toxic and ill, with a high fever over 39 °C. Confusion and delirium or diarrhoea can dominate the clinical picture, masking the true diagnosis of pneumonia. Focal neurological signs, particularly of a cerebellar type, are well described. Amnesia on recovery is common.

Laboratory findings

The total white count is usually only moderately raised, to 15 000 × 10^{6}/litre, often with a lymphopenia. Hyponatraemia, hypoalbuminaemia, and abnormality of liver function tests are detected in over half of the cases. Other non-specific features may include raised blood urea and muscle enzymes, hypoxaemia, haematuria, and proteinuria. Gram staining of sputum typically shows few pus cells and no predominant pathogen; initial blood and sputum cultures are negative unless dual infection is present.

Radiographic features

Radiographic shadowing is usually homogeneous. Characteristically, radiographic deterioration occurs with spread of shadows both within the same lung and to the opposite side. (Fig. 1).

Fig. 1 Chest radiograph of a 58-year-old man who returned from a Mediterranean hotel holiday with legionella pneumonia. There is extensive, bilateral, homogeneous consolidation. He required assisted ventilation for worsening respiratory failure.

Clearance of pulmonary shadows in survivors is particularly slow, with only two-thirds of radiographs being clear within 3 months and some taking more than 6 months to clear.

Complications

A wide variety of complications has been reported. The most important complication is acute respiratory failure requiring assisted ventilation, which occurs in up to 20 per cent of cases. Cardiac complications including pericardial and myocardial involvement are well recognized. A wide variety of neurological complications has been reported, leading to the suggestion of a specific neurotoxin. Acute, but usually reversible, renal failure may be seen in severe disease. There is anecdotal evidence that full clinical recovery may be very slow.

Pontiac fever

This is the acute non-pneumonic form of legionella infection and presents as a short-lived, self-limiting, influenza-like illness, dry cough, but no localizing signs in the chest (Fig. 2). The attack rate is extremely high, with an incubation period of usually 36 to 48 h. Investigations and chest radiograph are normal, and the illness improves spontaneously, usually within 5 days.

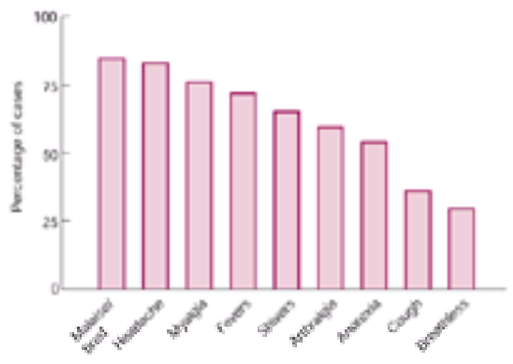

Fig. 2 Clinical features of 314 patients with non-pneumonic legionellosis (Pontiac fever). (Data adapted from Glick *et al.* (1978). *American Journal of Epidemiology* **107**, 149–60 and Goldberg *et al.* (1989). *Lancet* **i**, 316–18.)

Laboratory diagnosis

There is a range of laboratory procedures that can be used to diagnose legionellosis:

1. culture on a permissive medium, e.g. Aces buffered charcoal yeast-extract agar;

2. direct detection of bacteria or their nucleic acid;
3. urinary antigen detection;
4. serological response.

Suitable specimens from which legionellae can be isolated are expectorated sputum, endotracheal aspirates, bronchoalveolar lavage fluid, pleural aspirates, and lung. Isolation provides definite proof of infection, as colonization without infection has not been demonstrated. In addition it allows the causative strain to be typed and compared with those from the environment. A quicker diagnosis can be made by examining these samples directly for evidence of legionellae. With specific monoclonal antisera the bacteria can be visualized by immunofluorescence or immunoperoxidase techniques. Alternatively the use of the polymerase chain reaction can detect the bacterial nucleic acid directly in a specimen.

Soluble antigen is excreted in the urine for 1 to 3 weeks during the acute pneumonia and longer in immunocompromised infected patients. Tests to detect *L. pneumophila* serogroup 1 urinary antigen have a high specificity and sensitivity, making this assay the most valuable for the prompt diagnosis of legionnaires' disease. Urine antigen testing for legionella should be undertaken for any patient with severe community-acquired pneumonia.

Serology is the most widely used diagnostic approach. The major problem with serodiagnosis is the delay due to the slow production of antibodies. Only 20 per cent of patients with legionnaires' disease have diagnostic titres of antibody within 3 days of hospital admission, although about 40 per cent will have lesser but suggestive antibody levels by that time. Approximately 20 per cent of those infected appear not to respond serologically.

Although some heterologous cross-reacting antibodies may be produced, infections with legionellae other than *L. pneumophila* serogroup 1 do not necessarily give rise to antibody to the latter. Reference laboratories therefore use a battery of antigens to increase their ability to diagnose legionellosis. In Denmark, for example, 13 antigens are used and, in 1990, of 171 serologically diagnosed cases, 93 were *L. pneumophila* serogroup 1 to 6 while 78 were non-*L. pneumophila* legionellosis caused by other species. Occasionally patients with Q fever, leptospirosis, *Citrobacter freundii*, and more commonly with campylobacter infections make antibodies that cross-react with *L. pneumophila* serogroup 1. As diarrhoea can be an early feature of legionnaires' disease as well as the major consequence of campylobacter enteritis, it is important to culture stool samples and interpret with caution the legionella serology from such patients.

Differential diagnosis

Unfortunately there is no distinctive pattern that allows the early clinical differentiation of legionella infection from other, more common, causes of pneumonia. Epidemiological clues such as recent foreign travel can be valuable pointers, as well, of course, as knowledge of a local epidemic. Important clues suggesting legionella pneumonia in this context include high fever, confusion, multisystem involvement, absence of a predominant bacterial pathogen on sputum examination, and lack of response to b-lactam antibiotics.

Therapy

There are no clinical trials, and recommendations are based on retrospective case studies as well as *in vitro* and animal experiments. The most relevant factor is the ability of the antibiotic to penetrate intracellularly into alveolar macrophages where the legionella organism hides and divides. A macrolide such as erythromycin or clarythromycin is at present recommended as the drug of first choice, in dosages of 500 to 1000 mg every 6 h for erythromycin and 500 mg twice daily for clarithromycin, being given intravenously if required.

In vitro and animal experiments and clinical experience support the efficacy of rifampicin and fluoroquinolones. Rifampicin is often recommended as additional therapy to erythromycin, in a dose of 600 mg once or twice daily in patients with severe infection or who are deteriorating. Fluoroquinolones are preferred by some experts in immunocompromised patients. Anecdotal reports also support the use of doxycycline.

General supportive measures are particularly important, with attention to adequate hydration and correction of hypoxaemia with the early use of assisted ventilation for advancing respiratory failure.

Prognosis and mortality

The two most important factors affecting outcome include the prior health of the patient and appropriate, early therapy. The fatality rate in previously fit patients is low, of the order of 5 to 15 per cent, but in immunosuppressed individuals it can approach 75 per cent. The mortality is about 30 per cent in those requiring assisted ventilation.

Pathology

Legionellae are intracellular pathogens, both in protozoa in the environment and in animal hosts. Following infection, the bacteria are taken up by macrophages and internalized in macrophage endosomes. Legionellae block the development of the endosome to a phagolysosome which prevents the normal cellular killing mechanism of the ingested bacteria. Instead, legionellae multiply within the cell with a generation time of 1 to 2 h. When an intracellular microcolony has formed, the legionellae produce a pore-forming toxin which damages the cell's membrane and allows the bacteria to escape from the cell.

The lungs are usually the only organs affected in fatal cases and reveal lobar consolidation. Affected lung tissue shows a severe inflammatory response, with alveoli and terminal bronchioles distended by fibrin-rich debris, mononuclear inflammatory cells, and neutrophils. Organisms can be demonstrated within alveolar spaces by silver or immunofluorescence stains. In survivors alveolar and interstitial fibrotic changes can result.

Prevention

There are three aspects to consider in reducing the risk of legionellosis:

1. Measures to minimize colonization, growth, and release of legionellae into the atmosphere.
2. Physical or chemical treatment of water to kill the bacteria.
3. The protection of maintenance personnel who work on contaminated systems.

In Britain, particularly following the Stafford District General Hospital outbreak, a large number of publications aimed at minimizing the risk of legionellosis have appeared. In 1991 in Britain the Health and Safety Executive booklet HS(G)70 *The control of legionellosis including legionnaires' disease* was published, and it should be consulted for more details.

The most important principle to follow is to avoid holding water at temperatures between 20 and 45 °C, which is the range in which legionella multiplication occurs.

7.11.36 Rickettsial diseases including ehrlichioses

D. H. Walker

Introduction

Rickettsiae (Table 1) are obligate intracellular bacteria, which, during at least a part of their existence, occupy specific arthropods as their environmental niche. Rickettsiae are transmitted to man by their arthropod hosts and invade the endothelial cells of the blood vessel. In contrast, organisms of the genus *Ehrlichia* invade mainly phagocytes and do not cause primary vascular injury. Humans acquire *Coxiella burnetii* mainly by inhalation of aerosols from birth products of infected animals. The organisms proliferate within the acidic phagolysosome of host macrophages and cause an illness that ranges from acute atypical pneumonia to chronic endocarditis.

The public health importance of rickettsioses is underestimated because of difficulties with clinical diagnosis and lack of laboratory methods in many geographical areas. Active surveillance and serological surveys suggest that there is significant, unrecognized exposure to rickettsial organisms. It is particularly important to consider a rickettsial diagnosis when caring for the neglected poor of developing countries and travellers returning from areas endemic for murine typhus, scrub typhus, boutonneuse fever, African tick-bite fever, other spotted fevers, and Q fever. Rickettsiae infect previously healthy, active persons, and if undiagnosed, diagnosed late, or untreated, Rocky Mountain spotted fever, epidemic typhus, scrub typhus, Q fever endocarditis, boutonneuse fever (Plate 1, Plate 2, Plate 3), human ehrlichioses, and murine typhus are life threatening.

Many commonly prescribed antibiotics, including the penicillins, cephalosporins, and aminoglycosides, have no effect on the course of rickettsial diseases, but those antimicrobials active against rickettsial organisms can reduce morbidity and mortality.

Epidemics of louse-borne typhus fever have influenced the outcome of many wars between the 1500s and the 1920s. Wherever there are wars, famines, floods, and other massive disasters leading to widespread louse infestation of a population, the threat of epidemic typhus exists. Recent epidemics have occurred in Burundi, the economically devasted former USSR, and in extremely poor populations in the Andes.

Contemporary molecular analyses reveal that the spotted fever and typhus groups of the genus *Rickettsia* are very closely related to one another but not to *Orientia* (formerly *Rickettsia*)*tsutsugamushi*. They are relatively close relatives of *Ehrlichia* and the facultatively intracellular *Bartonella* and are evolutionarily distant from *Coxiella* and *Chlamydia*.

Vasculopathic rickettsial diseases of the spotted fever and typhus groups

Aetiological agents

These organisms measure approximately 0.3 by 1.0 µm and have a cell wall typical of Gram-negative bacteria.

Epidemiology

Seasonal incidence and geographical distribution are determined by the vector's activity. Spotted fever group rickettsiae are maintained in nature principally by transovarial and transstadial transmission in their tick or mite hosts. The most virulent rickettsiae are capable of killing their arthropod hosts (e.g. *R. prowazeki*) and require horizontal transmission to initiate epidemics of typhus fever. Reactivation of latent *R. prowazeki* infection in humans is the source for infection of lice that initiates epidemics of typhus fever.

Spotted fever group rickettsiae are transmitted to humans by secretion of infected tick saliva into the blood pooled in the site of the bite, and typhus group rickettsiae by infected louse or flea faeces deposited on human skin during arthropod feeding. Fluid or faeces of infected arthropods crushed between the fingers may enter a cutaneous wound or be rubbed into the conjunctiva.

Pathogenesis

Rickettsiae of some species of the spotted fever group frequently invade endothelial cells at the cutaneous portal of entry, proliferate, and cause a focus of dermal and epidermal necrosis, an eschar. Rickettsiae spread via the bloodstream to all parts of the body, where they infect endothelial cells lining the blood vessels. Typhus rickettsiae reach massive numbers intracellularly until the endothelial cell bursts. Spotted fever group rickettsiae are propelled through the cytosol by stimulating F-actin polymerization at one pole and spreading from cell to cell. Rickettsial lipopolysaccharides are non-endotoxic, and there is no evidence of any rickettsial exotoxin.

Host immune, inflammatory, and coagulation systems are activated with apparent overall benefit to the patient.

Progressive, disseminated infection and injury to endothelial cells cause increased vascular permeability, oedema, hypovolaemia, and signs and symptoms resulting from multifocal vascular injury in affected organs (Fig. 1). Infection of the pulmonary microcirculation and the resulting increased vascular permeability produce adult respiratory distress syndrome. Despite an interstitial myocarditis, myocardial function is usually preserved. Arrhythmias may result from vascular lesions affecting the conduction system. The vascular lesions in the brain are associated with coma and seizures in severe cases (Fig. 2). Multifocal infectious lesions in the dermis are the basis for the maculopapular, sometimes petechial, rash. Acute renal failure occurs in severe cases, usually as prerenal azotaemia or less frequently as acute tubular necrosis associated with severe hypotension.

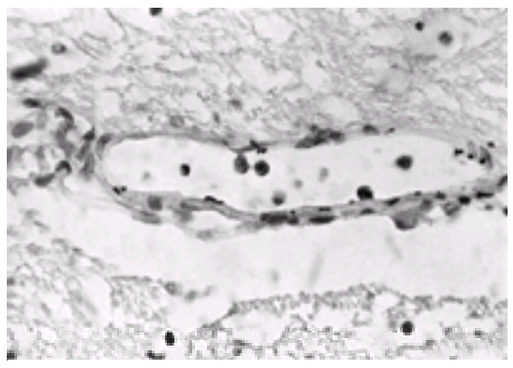

Fig. 1 Immunoperoxidase-stained *Rickettsia rickettsi* appear as dark bacilli in endothelial cells of a cerebral blood vessel with perivascular oedema but no host immune-cell infiltration.

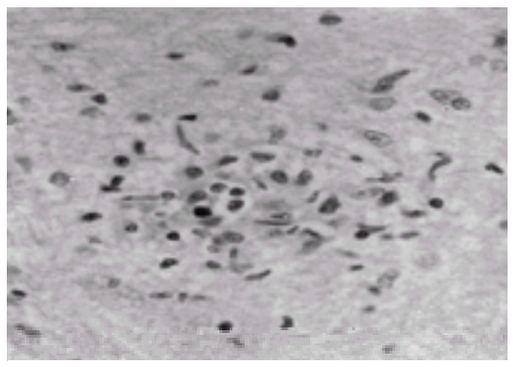

Fig. 2 Epidemic typhus fever. The typical lesion of rickettsial encephalitis is exemplified by the typhus nodule in the brain of a patient (death about 12th day) showing perivascular infiltration by macrophages and lymphocytes. (Reproduced from *Medical Clinics of North America* (1959),**43**, 1512, with permission.)

Clinical manifestations

The incubation period averages 1 week (range: 4 days to 2 weeks) after cutaneous inoculation. It is related inversely to the dose of inoculum.

Symptoms start with non-specific malaise, chills, fever, myalgia, and headache that is often severe, followed by anorexia, nausea, vomiting, abdominal pain, photophobia, and cough. A rash usually appears after 3 to 5 days of illness. Initially, it consists of macular or maculopapular lesions, 1 to 5 mm in diameter, that blanch on pressure. Later petechiae appear.

Pulmonary involvement causes cough, pulmonary oedema, radiographic infiltrates, hypoxaemia, dyspnoea, and pleural effusions in severe cases. Neurological manifestations consist of lethargy, progressing to confusion, delirium, stupor, ataxia, coma, focal neurological signs, and seizures. There may be a cerebrospinal fluid pleocytosis of 10 to 100 cells/µl with variable proportions of mononuclear and polymorphonuclear leucocytes, and/or an increased protein concentration.

Although serum aminotransferases and bilirubin may be elevated, jaundice is observed in fewer than 10 per cent of patients, and hepatic failure does not occur. The white blood-cell count is usually normal. The acute-phase reaction occurs in many patients. Hypoalbuminaemia is the result of leakage of this plasma protein into the interstitial space because of increased permeability of the microcirculation. Hyponatraemia is most often the result of the appropriate secretion of antidiuretic hormone in response to the hypovolaemic state.

Diagnosis

Differential diagnosis

Early, before the rash appears, the differential diagnosis includes influenza, typhoid fever, enteroviral infection, and infectious diseases suggested by geographical exposure (e.g. malaria, Lassa fever, louse-borne relapsing fever). Nausea, vomiting, and abdominal pain may suggest infectious enterocolitis. Prominent abdominal tenderness has occasionally led to the differential diagnosis of acute surgical abdomen and to exploratory laparotomy. Cough and abnormalities of physical and radiographic examination of the chest may suggest bronchitis or pneumonia. Fever, seizures, coma, neurological signs, and abnormalities of the cerebrospinal fluid may lead to consideration of meningitis and arboviral or herpes viral encephalitis. If an eschar is detected, the differential diagnosis may include cutaneous anthrax, tularaemia, syphilis, and chancroid. Once a rash has developed, differential diagnosis includes meningococcaemia, toxic-shock syndrome, leptospirosis, disseminated gonococcal infection, secondary syphilis, measles, rubella, enteroviral exanthem, infectious mononucleosis, dengue, filoviral or arenaviral haemorrhagic fevers, idiopathic or thrombotic thrombo-cytopenic purpura, and immune-complex vasculitides (e.g. systemic lupus erythematosus). It is important to enquire about exposure to ticks, fleas, mites, and lice and to consider the seasonal occurrence and geographical exposure, but people are frequently unaware of their exposure to arthropods, and cases may occur outside of the seasonal peak.

Laboratory diagnosis

Serological tests are useful in confirming the diagnosis in the convalescent stage, but seldom detect specific antibodies during the first week of illness. At present, the generally available serological assays are an indirect immunofluorescent antibody test, indirect immunoperoxidase antibody test, and dot enzyme immunoassay. These tests detect antibodies that are cross-reactive within the spotted fever or typhus group. The Weil–Felix test should be replaced because of poor sensitivity and specificity unless, as in some underdeveloped areas, nothing else is available. Isolation of the aetiological rickettsia, the definitive diagnosis of an infectious disesae, is seldom attempted because of the biohazard and technical challenges.

Detection of rickettsiae by immunohistochemistry in skin requires the presence of a rash to determine the site for biopsy and has sensitivity of approximately 70 per cent and a specificity of 100 per cent in the hands of an experienced microscopist. An approach that can be employed even during the period of illness before the onset of rash is immunofluorescent staining of rickettsiae in circulating endothelial cells captured by a monoclonal antibody fixed to immunomagnetic beads. Polymerase chain reaction has not been very successful in diagnosing Rocky Mountain spotted fever early in the course of illness, but has proved useful in murine typhus, epidemic typhus, Japanese spotted fever, boutonneuse fever, *R. felis* infection, and scrub typhus. Treatment should never be withheld while awaiting the results of laboratory tests.

Treatment

Spotted-fever and typhus-group rickettsioses respond favourably to treatment with doxycycline (200 mg/day for adults and children heavier than 45 kg, and 4.4 mg/kg body weight per day for smaller children), tetracycline (2 g/day in four divided doses for adults, and 25 mg/kg body weight per day in four divided doses for children), or chloramphenicol (2 g/day in four divided doses for adults, and 50 mg/kg body weight per day in four divided doses for children). Ciprofloxacin (200 mg intravenously every 12 h, or 750 mg orally every 12 h), ofloxacin (200 mg orally every 12 h), and pefloxacin (400 mg intravenously or orally every 12 h) have been used successfully to treat boutonneuse fever. Epidemic typhus fever has been treated effectively under field conditions with a single, 200 mg dose of doxycycline. Treatment is generally continued for 2 or 3 days after defervescence to avoid relapse of the infection.

Intravenously administered doxycycline or chloramphenicol is employed when oral treatment cannot be used because of vomiting or coma. Chloramphenicol and

josamycin (3 g/day for 8 days) have been used to treat rickettsioses during pregnancy when the tetracyclines are contraindicated.

Seizures should be treated with anticonvulsants. Renal failure is managed by haemodialysis, and hypoxaemia associated with interstitial pneumonitis and adult respiratory distress syndrome may require oxygen and mechanical ventilation.

Prevention

Immunization

Immunity to reinfection with spotted-fever or typhus-group rickettsiae is quite strong, although some patients with epidemic typhus fever will develop recrudescence of latent *R. prowazekii* infection many years after their acute infection.

Vaccines containing whole, killed organisms can reduce severity of illness and mortality, but a live, attenuated vaccine against *R. prowazekii* confers protection. However, some vaccine recipients develop mild typhus fever, and the vaccine strain may revert to a pathogenic state. Thus, there are at present no vaccines in general use against rickettsial diseases.

Vector control

Delousing reduces the spread of louse-borne epidemic typhus. Rodent control and insecticides decrease the incidence of murine typhus and rickettsialpox.

Regular daily or twice-daily inspection of the entire body, especially the scalp and groin, and prompt removal of ticks prevents inoculation of rickettsiae. Ticks are best removed by grasping their anterior parts firmly with pointed forceps flush with the skin and exerting steady traction until the intact tick is removed, frequently with a bit of attached skin. Care should be taken to avoid introduction of potentially infected tick fluids into the wound or mucous membranes.

Spotted fevers

Boutonneuse fever

Aetiology

The most prevalent spotted-fever rickettsiosis in Europe is boutonneuse fever, or Mediterranean spotted fever. *Rickettsia conorii* has been isolated in Spain, France, Italy, Croatia, Georgia, Russia, Ukraine, India, Pakistan, South Africa, Kenya, Somalia, and Ethiopia. *R. conorii* has more antigenic diversity than the other carefully analysed spotted-fever group rickettsia, *R. rickettsii*.

Epidemiology

The incidence of boutonneuse fever underwent a dramatic increase in Spain, France, Italy, and Portugal a decade or two ago. *R. conorii* is maintained transovarially in *Rhipicephalus sanguineus* and is transmitted to humans by tick bite. The peak incidence along the Mediterranean coast of southern Europe is in July and August when immature stages of the tick predominate.

Mortality rates of 1.4 to 5.6 per cent have been observed in patients admitted to hospital. In those who are elderly or have underlying diseases, suffer from alcoholism, or glucose-6-phosphate dehydrogenase deficiency, case fatality may be 33 per cent.

Pathogenesis

Reduction in the number of rickettsiae in the *tache noire* (black spot) or eschar at the site of the infective tick-bite eschar is associated with a perivascular influx of lymphocytes and macrophages. Autopsies of fatal cases of boutonneuse fever show systemic vascular infection and injury by *R. conorii*, with lesions in the brain, meninges, lungs, kidney, gastrointestinal tract, liver, pancreas, heart, spleen, and skin including sites of peripheral gangrene. Direct rickettsial injury of infected endothelial cells is the major pathogenic event. Hepatic biopsies show multifocal dead hepatocytes with a predominantly mononuclear cellular response.

Clinical manifestations

During the incubation period of boutonneuse fever, a red papule appears at the site of the tick bite and progresses to an eschar in approximately 70 per cent of cases, often associated with regional lymphadenopathy. The illness starts with fever, sometimes accompanied by headache and myalgias. The rash usually appears on the fourth day of illness as maculopapules, is petechial in 10 per cent of patients, and often involves the palms and soles. Other features include nausea, vomiting, cough, dyspnoea, conjunctivitis, stupor, meningismus, and hepatomegaly. Increased vascular permeability manifests as mild oedema, hypoalbuminaemia, and arterial hypotension. The white blood-cell count is usually normal. Platelet counts less than 100×10^{9}/l are detected in 12.5 per cent of the patients. Hyponatraemia of less than 130 mmol/l occurs in 23 per cent, and hypoproteinaemia is observed in 23 per cent of patients.

Serum urea and creatinine concentrations are elevated in 25 and 17 per cent of patients, respectively. Serum concentrations of aspartate and alanine aminotransferases are increased in 39 and 37 per cent, respectively, and serum bilirubin is greater than 20 µmol/l in 9 per cent. Severe features (6 per cent of patients) include cutaneous purpura and other haemorrhagic phenomena, neurological signs, altered mental status, respiratory symptoms, hypoxaemia, and acute renal failure.

Diagnosis

In the acute stage, diagnosis can be established by immunohistological demonstration of *R. conorii* in a biopsy of the *tache noire* or rash, or in circulating endothelial cells (see above). *R. conorii* can be isolated in cell culture. Serological methods include immunofluorescent antibody assay, latex agglutination test, indirect immunoperoxidase assay, dot enzyme immunoassay, and complement fixation test.

Treatment

See above.

Prevention

There is no vaccine to protect against *R. conorii*.

Rocky Mountain spotted fever

R. rickettsii is pathogenic for *Dermacentor* ticks, perhaps explaining why fewer than 1 in 1000 ticks in endemic areas contains this organism. *R. rickettsii*, the most virulent rickettsia, is also more invasive than other rickettsial species, causing infection not only of endothelial cells but also vascular smooth-muscle cells. Host factors also play a part in severity of illness. Fatality rates are higher in older patients, males, and black people. Fulminant Rocky Mountain spotted fever with death occurring within 5 days after onset is associated with haemolysis, particularly in black males with glucose-6-phosphate dehydrogenase deficiency.

Untreated, Rocky Mountain spotted fever has a 20 per cent fatality rate. In recent series, the death rate has been 5 per cent, with respiratory failure in 12 per cent, acute renal failure in 14 per cent, and anaemia requiring red-cell transfusion in 11 per cent. Thrombocytopenia occurs in 32 to 52 per cent of patients. Coma is a grave prognostic sign.

Early in the illness, nausea or vomiting occurs in 38 to 56 per cent of cases and abdominal pain in 30 to 34 per cent. The rash usually appears on the third day of illness, but may be delayed to or after day 6 in 20 per cent (Fig. 3). In 10 per cent of patients, a rash never appears. Petechiae occur in only 41 to 59 per cent of cases and appear late in the course, often only on or after day 6. The palms and soles are affected by the rash in 36 to 82 per cent with involvement often occurring after day 5 (Fig. 4).

Fig. 3 The early rash of Rocky Mountain spotted fever consists of pink macules in this 4-year-old boy on the fourth day of illness.

Fig. 4 Rocky Mountain spotted fever. Series showing haemorrhagic exanthem in a 4-year-old boy on about the eighth day of illness. Note oedema of face, hands, arms, and feet, and bleeding from mouth. Specific therapy with chloramphenicol resulted in complete recovery.

A history of tick exposure is obtained from only 60 per cent of patients. Reagents for indirect immunofluorescent antibody assay, latex agglutination test, and dot enzyme immunoassay for antibodies to *R. rickettsii* are commercially available.

Rickettsialpox

R. akari has been isolated in the United States, Ukraine, Croatia, and Korea. It is maintained by transovarian transmission in the gamasid mite *Liponyssoides sanguineus*, whose host is the domestic mouse, *Mus musculus*.

A cutaneous papule appears during the incubation period at the site where the mite has fed and evolves into an eschar over the next 2 to 7 days. About 10 days later, malaise, fever, chills, severe headache, and myalgia develop. A macular rash of discrete erythematous lesions, 2 to 3 mm in diameter, appears 2 to 6 days later and evolves into maculopapules, some of which develop central, deep-seated vesicles.

Other spotted-fever rickettsioses

R. sibirica, *R. australis*, *R. japonica*, *R. honei*, and *R. africae* differ antigenically in their surface proteins, DNA sequences, tick hosts, and known geographical distribution, but their clinical manifestations are similar to boutonneuse fever. The spotted-fever rickettsiosis of Flinders Island, Australia and Queensland tick typhus are clinically similar. Israeli spotted fever is a variant of boutonneuse fever in which eschar formation is usually lacking. *R. africae* is associated with a relatively less severe illness in which rash is less prevalent, but there are often multiple eschars. *Rickettsia slovaca*, previously considered as non-pathogenic, has recently been associated with clinical illness in Europe. *R. felis* is maintained in cat fleas and causes an emerging infectious disease.

In Sweden, *R. helvetica*, transmitted by *Ixodes ricinus* ticks, has been suggested to cause fatal chronic perimyocarditis. *R. conorii*, *R. typhi*, and *R. rickettsii* are also known to affect the microcirculation of the myocardium.

Typhus fevers

Murine typhus

Endemic flea-borne typhus fever caused by *R. typhi* is more prevalent in warm, coastal ports. It is maintained in a commensal cycle involving rat fleas, *Xenopsylla cheopis*, and rats, *Rattus rattus* and *Rattus norvegicus*. Rats are infected by *R. typhi* in flea faeces deposited on the skin. Fleas become infected for life after a rickettsaemic blood meal. Other species of fleas and other mammals can also maintain an infectious cycle of *R. typhi* (see Table 1).

A rash is detected in 80 per cent of fair-skinned and 20 per cent of black people. Other features include nausea (48 per cent), vomiting (40 per cent), abdominal pain (23 per cent), diarrhoea (26 per cent), cough (35 per cent), abnormal chest radiographs (23 per cent), thrombocytopenia (48 per cent), elevated serum aminotransferases (90 per cent), and central nervous abnormalities (8 per cent) including confusion, stupor, and hallucinations. Nearly 10 per cent of patients admitted to hospital are severely ill with acute renal failure, respiratory failure, or severe neurological abnormalities including seizures. Older age, delayed treatment, and initial treatment with sulphonamides are risk factors for severe disease. Case fatality is 1 to 2 per cent.

Epidemic typhus, recrudescent typhus, and sylvatic typhus

R. prowazekii causes epidemic louse-borne typhus fever, recrudescence of latent infection years after acute epidemic typhus, and zoonotic infection acquired from the ectoparasites of infected flying squirrels in North America. There is intense headache, prostration, continuous high fever, a macular rash usually appearing on the fourth or fifth day of illness, myalgia, and neurological abnormalities. Within 24 to 48 h of its appearance, the rash becomes petechial and does not blanch on pressure (Fig. 5). Its development is centrifugal from the trunk to the extremities. Other symptoms include cough, rales (71 per cent), nausea (30 per cent), abdominal pain (30 per cent), mental dullness (14 per cent), delirium (48 per cent), coma (6 per cent), seizures (1 per cent), and gangrene (3 per cent).

Fig. 5 Epidemic typhus fever. Typical truncal rash in louse-borne typhus on about the eighth day of illness showing many discrete haemorrhagic lesions.

The infection is now restricted to a few foci of sporadic occurrence in eastern Europe, central Africa, Ethiopia, southern Africa, Afghanistan, northern India, China, Mexico, Central America, and the Andes Mountains of South America. However, the danger of spread still exists as occurred recently during the war in Burundi where it is estimated that 100,000 cases occurred.

Recrudescent typhus (Brill–Zinsser disease) is the most important reservoir for initiation of epidemic louse-borne typhus in a susceptible population. Clinically it is milder than epidemic typhus (Fig. 6).

Fig. 6 Recrudescent typhus (Brill–Zinsser disease). Note the erythematous macular rash on the trunk. Illness is in an adult whose initial infection with typhus was 30 years earlier in Poland; the second attack was a week after appendicectomy and there was full recovery.

Ehrlichial diseases

Aetiological agents

Ehrlichiae are small, Gram-negative obligately intracellular bacteria that reside in a cytoplasmic vacuole and are transmitted by ticks. The four established human pathogens are *Ehrlichia chaffeensis*, *Anaplasma phagocytophila*, *E. ewingii*, and *Neorickettsia sennetsu*.

Ehrlichiae enter the host cell via phagocytosis, and they actively inhibit fusion of lysosomes with the phagosomes. They undergo binary fission to form clusters within a host vacuole. When stained by the Wright–Giemsa method, the cluster of organisms appears dark violet-blue and stippled and is called a morula from the Latin word for mulberry.

Epidemiology (see Table 1)

Ehrlichioses are maintained in cycles involving a mammalian host and a tick vector. *N. sennetsu* is a member of a genus which resides in flukes that parasitize fish and snails.

Most patients recall a recent tick bite. *E. chaffeensis* and *A. phagocytophila* infections peak between May and July in the United States, the season of greatest tick activity.

Human ehrlichioses

Haemopoietic cells are the primary targets of infection by *E. chaffeensis*, *A. phagocytophila*, and *E. ewingii*. Leucopenia and thrombocytopenia are probably caused by peripheral sequestration. Perivascular lymphohistiocytic infiltrations without vascular damage are observed in virtually any organ, including meninges. Hepatic involvement may include focal hepatocellular apoptosis and granulomas. Interstitial mononuclear pneumonitis has been observed, as well as diffuse alveolar damage.

Clinical severity ranges from asymptomatic seroconversion to fatal infection, very likely related to both host and microbial virulence factors. *E. chaffeensis* is the most pathogenic. Most patients have a fever, headache, chills, malaise, nausea, myalgias, and anorexia. Respiratory or renal insufficiency and abnormalities of the central nervous system have been reported. Pleocytosis, leucopenia, thrombocytopenia, and elevations in serum hepatic aminotransferases are the most often demonstrated clinical laboratory abnormalities. Overwhelming, often fatal, cases occur in immunosuppressed patients, particularly those with HIV-1 infection.

Differential diagnoses include Rocky Mountain spotted fever, meningococcaemia, bacterial sepsis, and infective endocarditis.

Human isolates of *E. chaffeensis* and *A. phagocytophila* have been obtained in cell culture of a dog histiocytoma cell line and a human promyelocytic leukemia cell line, respectively. Ehrlichiae, particularly *A. phagocytophila*, can sometimes be seen in peripheral white blood cells. The standard diagnostic test is indirect immunofluorescent antibody assay. A fourfold rise or fall in titre with a peak of 64 or greater is considered diagnostic. Human ehrlichiosis can also be diagnosed by detection of ehrlichial DNA amplified from the peripheral blood by polymerase chain reaction. Although these tick-borne human ehrlichioses were discovered only recently in the United States, human infections with *A. phagocytophila* have been reported in Europe.

Human ehrlichioses respond to treatment with doxycycline (200 mg/day in two divided doses) or tetracycline (25 mg/kg body weight per day in four divided doses).

Prevention is by avoiding tick bites.

7.11.37 Scrub typhus

George Watt

Scrub typhus, or tsutsugamushi fever, is a zoonosis of rural Asia and the western Pacific islands. The causative organism, *Orientia* (formerly *Rickettsia*) *tsutsugamushi*, is transmitted to humans by the bite of a larval *Leptotrombidium* mite (chigger). An eschar and regional lymphadenopathy often develop at the site of infection, and may by followed by a systemic illness ranging in severity from inapparent to fatal. Many cases go undiagnosed, particularly those in which an eschar cannot be found. Rapid non-microscopic diagnostic tests are available and should enable more *O. tsutsugamushi* infections to be diagnosed.

Aetiology and epidemiology

Orientia tsutsugamushi has a different cell wall structure and genetic makeup from rickettsiae but looks like a rickettsia under light microscopy. The organism is an obligately intracellular Gram-negative bacterium. There are multiple serotypes of *O. tsutsugamushi*, and infection with one type confers only transient cross-immunity to another. Scrub typhus is a zoonosis. Larval mites (of the *Leptotrombidium deliense* group) usually feed on small rodents, particularly wild rats of the subgenus *Rattus*. Man becomes infected when he accidentally encroaches in a zone where there are infected mites. These zones are often made up of secondary or 'scrub' growth, hence the term scrub typhus. However, mite habitats as diverse as seashores, rice fields, and semideserts have been described. Infected chiggers are generally found in only very circumscribed foci within these zones. Large numbers of cases can occur when humans enter these so-called 'mite islands.' Disease transmission occurs when infected mites burrow into the skin, take a meal of tissue fluid, and inoculate the infectious organisms. Human to human transmission of scrub typhus via contaminated blood has never been documented. The endemic area forms a triangle bounded by northern Japan and southeastern Siberia to the north, Queensland, Australia, to the south and Pakistan to the west (Fig. 1). Disease transmission occurs in rural and suburban areas as well as in villages, but inhabitants of city centres are not at risk.

Fig. 1 Geographical distribution of scrub typhus.

Pathology and pathogenesis

Much remains unknown about the pathogenesis of scrub typhus, partly because most descriptions of severe cases pre-date advances made in immunohistology since the 1950s. Marked geographical variations in severity of the illness occur but determinants of severity are poorly characterized. Strains which differ in virulence, partial immunity, and regional differences in general health could affect disease presentation, but coinfection with the HIV-1 virus does not. Scrub typhus is a vasculitis, but clinical and pathological findings do not correlate closely. The host cell of *O. tsutsugamushi* in humans is thought to be the endothelial cell because of findings in experimental animals and by analogy with other rickettsial infections. However, in human liver infected with scrub typhus examined by electron microscopy, organisms predominate in Kupffer cells and hepatocytes rather than within endothelial cells (Fig. 2). *O. tsutsagamushi* is present in peripheral white blood cells of patients with scrub typhus. The HIV-1 viral load falls markedly in some AIDS patients who acquire acute *O. tsutsagamushi* infection. Some sera from HIV-seronegative patients with scrub typhus inhibit HIV replication *in vitro*.

Clinical features

The painless chigger bite can occur on any part of the body, but is often in difficult to see in locations such as under the axilla or in the genital area. An eschar (Plate 1) forms at the bite site in about half of primary infections, but in a minority of secondary infections. The eschar begins as a small, painless papule which develops during the 6- to 18-day (median 10 days) incubation period. It enlarges, undergoes central necrosis, and acquires a blackened scab to form a lesion resembling a cigarette burn. Regional lymph nodes are enlarged and tender. The eschar is usually well developed by the time fever appears and is often healing by the time the patient presents to hospital.

Fever, headache, myalgia, and non-specific malaise are common symptoms. Hearing loss concurrent with fever is reported by as many as one-third of patients and is a useful diagnostic clue. Conjunctival suffusion and generalized lymphadenopathy are common, helpful physical signs. A transient macular rash may appear at the end of the first week of illness but is often difficult to see. The rash first appears on the trunk and becomes maculopapular as it spreads peripherally. Cough sometimes accompanied by infiltrates on the chest radiograph is one of the commonest presentations of *O. tsutsugamushi* infection. In severe cases, tachypnoea progresses to dyspnoea, the patient becomes cyanotic and full-blown adult respiratory distress syndrome may ensue. Apathy, confusion, and personality changes

frequently occur and only rarely progress to stupor, convulsions, and coma. Abnormalities resolve completely in non-fatal cases.

Diagnosis

The eschar is the single most useful diagnostic clue, and is pathognomonic when seen by a physician experienced in diagnosis of scrub typhus. Even typical eschars can be overlooked or misdiagnosed, however, and atypical presentations are common. Eschars in the genital area often lose their crust and can be confused with the ulcers of chancroid, syphilis, or lymphogranuloma venereum.

There is no constellation of laboratory test results which strongly suggests *O. tsutsugamushi* infection. Slight increases in the number of circulating white blood cells are common. Atypical lymphocytes and moderately elevated serum transaminase levels are not uncommon. Laboratory findings are chiefly useful to rule out other infections. A low white cell count and thrombocytopenia with a haemorrhagic rash suggest infection with dengue virus rather than *O. tsutsugamushi*. Raised serum creatinine and serum bilirubin levels with marked myalgia suggest leptospirosis rather than scrub typhus. Enteric fever rarely causes generalized lymphadenopathy or conjunctival suffusion.

The Weil–Felix test using the Proteus OX-K antigen is a commercially available serodiagnostic test which has been used for many years, but is insensitive. Immunofluorescent assay and the immunoperoxidase test are the confirmatory tests of choice but their complexity limits their use to a small number of reference centres. An accurate, rapid, dotblot immunoassay which does not require a microscope has been developed (Plate 2). Such kits would be of enormous benefit if they could be made affordable for use in rural tropical Asia where most scrub typhus cases occur.

Treatment

Prompt antibiotic therapy shortens the course of the disease and reduces mortality. Treatment must often be presumptive, but the benefits of avoiding severe scrub typhus by early antibiotic administration generally far outweigh the risks of a 1-week course of tetracycline—the treatment of choice. Either oral tetracycline 500 mg four times daily, or oral doxycycline 100 mg twice daily for 7 days are recommended. Oral chloramphenicol 500 mg four times a day is a cheaper alternative. Treatment for less than a week is initially curative, but may be followed by relapse. Parenteral doxycycline should be administered to patients who cannot swallow tablets or who are severely ill. A 7-day course of parenteral chloramphenicol (50–75 mg/kg/day) is an effective alternative in areas where parenteral formulations of tetracyclines are unavailable. Good supportive care and early detection of complications is important in severe cases if a good outcome is to be obtained.

Scrub typhus cases from northern Thailand which respond poorly to conventional therapy have been described, but neither the mechanism of resistance nor its geographical distribution have been defined. A controlled, blinded study demonstrated that patients treated with rifampin in northern Thailand became afebrile twice as quickly as did patients who received doxycycline. However, the optimum therapeutic regimen for the treatment of drug-resistant scrub typhus has not yet been determined. Therapy for pregnant women and children poses several problems. Chloramphenicol is best avoided during pregnancy and cannot be given to neonates; tetracycline is contraindicated in pregnancy and long courses administered to young children cause staining of the permanent teeth. Newer macrolide antibiotics appear to be effective for scrub typhus. Cases of both drug-sensitive and drug-resistant scrub typhus have been cured by azithromycin and three Japanese patients were treated successfully with clarithromycin. If their efficacy is confirmed, macrolides would be particularly useful for the treatment of infection during pregnancy and early childhood.

Prevention and control

Weekly doses of 200 mg of doxycycline can prevent *O. tsutsugamushi* infection. Chemoprophylaxis should be considered for non-immunes sent to an enzootic area to perform work which places them at high risk of acquiring scrub typhus. Soldiers and road construction crews are typical examples, but chemoprophylaxis should also be considered in high-risk travellers such as trekkers. Contact with chiggers can be reduced by applying repellant to the tops of boots, socks, and on the lower trousers and by not sitting or lying directly on the ground. Unfortunately these measures are frequently not practicable in those exposed occupationally. There is no vaccine for scrub typhus.

Prognosis

Scrub typhus was a dreaded disease in the preantibiotic era; case fatality rates reached as high as 50 per cent. Prompt antibiotic therapy generally prevents death, but up to 15 per cent of patients still die in northern Thailand. Deaths are attributable to a variety of factors including late presentation, delayed diagnosis, and drug resistance.

7.11.38*Coxiella burnetii* infections (Q fever)

T. J. Marrie

History

In August 1935, Dr Edward Holbrook Derrick, Director of the Laboratory of Microbiology and Pathology of the Queensland Health Department in Brisbane, Australia, was asked to investigate an outbreak of undiagnosed febrile illness among workers at the Cannon Hill abattoir. Derrick realized that he was dealing with a type of fever that had not been previously described—he named it Q (for query) fever. A couple of years later, Sir Frank Macfarlane Burnet in Australia and Herald Rea Cox in the United States isolated the micro-organism responsible for Q fever.

Coxiella burnetii (Fig. 1)

This micro-organism, the sole species of its genus, has a Gram-negative cell wall and measures 0.3 × 0.7 µm. It is an obligate phagolysosomal parasite of eukaryotes that sporulates, stains well by the Gimenez stain, and multiplies by transverse binary fission. *C. burnetii* undergoes phase variation akin to the smooth to rough transition in some enteric Gram-negative bacilli. In nature and laboratory animals it exists in the phase-I state. Repeated passage of phase-I virulent organisms in embryonated chicken eggs lead to the conversion to phase-II avirulent forms. Antibodies to phase-I antigens predominate in chronic Q fever, while phase-II antibodies are higher than phase I in acute Q fever.

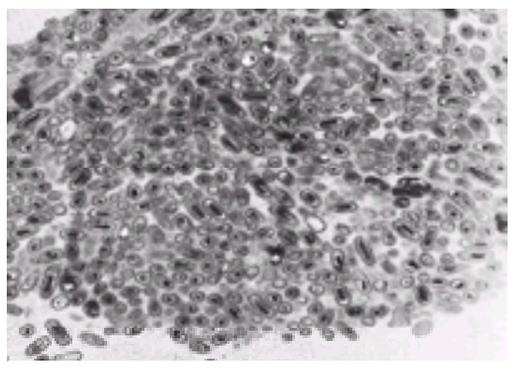

Fig. 1 Transmission electron micrograph showing *Coxiella burnetii* cells within a macrophage in the heart valve of a patient with Q fever endocarditis. The dark material in the centre of each cell is condensed DNA. 15 000 ×.

C. burnetii has survived for 586 days in tick faeces at room temperature, 160 days or more in water, in dried cheese made from contaminated milk for 30 to 40 days, and for up to 150 days in soil.

Epidemiology

Q fever is a zoonosis. There is an extensive wildlife and arthropod (mainly ticks) reservoir of *C. burnetii*. Domestic animals are infected through inhaling contaminated aerosols or by ingesting infected material. These animals rarely become ill but abortion and stillbirths may occur. *C. burnetii* localizes in the uterus and mammary glands of infected animals. During pregnancy there is reactivation of *C. burnetii* and it multiplies in the placenta, reaching 10^9 hamster infective doses per gram of tissue. The organisms are shed into the environment at the time of parturition. Man becomes infected after inhaling organisms aerosolized at the time of parturition, or later when organisms in dust are stirred up on a windy day. Infected cattle, sheep, goats, and cats are the animals primarily responsible for transmitting *C. burnetii* to man. There have been several outbreaks of Q fever in hospitals and research institutes due to the transportation of infected sheep to research laboratories. Some studies have suggested that ingestion of contaminated milk is a risk factor for the acquisition of Q fever; volunteers seroconverted but did not become ill after ingesting such milk.

Percutaneous infection, such as when an infected tick is crushed between the fingers, may occur but is rare. Transmission via a contaminated blood transfusion has rarely occurred.

Vertical transmission from mother to child has been infrequently reported. A 1988 review documents 23 cases of Q fever in pregnant women. These authors found that Q fever was present in 1 per 540 pregnancies in an area of endemic Q fever in Southern France.

Person-to-person transmission has been documented on a few occasions. To date, 45 countries on five continents have reported cases of Q fever. Q fever is estimated to cost $A1 million in Australia each year and results in the loss of more than 1700 weeks of work.

Clinical features

Man is the only animal known consistently to develop illness following infection with *C. burnetii*. There is an incubation period of about 2 weeks (range 2 to 29 days) following inhalation of *C. burnetii*. A dose–response effect has been demonstrated experimentally and clinically. *C. burnetii* is one of the most infectious agents known to man; a single micro-organism is able to initiate infection. The resulting illness in man can be divided into acute and chronic varieties.

Acute Q fever

Self-limiting febrile illness

The most common manifestation of acute Q fever is a self-limiting febrile illness.

Q fever pneumonia (Fig. 2 and Fig. 3)

This is the most commonly recognized manifestation of Q fever. There is often a seasonal distribution, most of the cases occurring between February and May. The onset is non-specific with fever, fatigue, and headache. The headache may be very severe, occasionally so severe that it prompts a lumbar puncture. A dry cough of mild to moderate intensity is present in 24 to 90 per cent of patients. About one-third have pleuritic chest pain. Nausea, vomiting, and diarrhoea occur in 10 to 30 per

cent of patients. Most cases of *C. burnetii* pneumonia are mild; however, about 10 per cent are severe enough to require admission to hospital; rarely, assisted ventilation is necessary. Death is rare in Q fever pneumonia and is usually due to comorbid illness. The white blood-cell count is usually normal, but is elevated in one-third of patients. Liver enzyme levels may be mildly elevated, at two to three times normal. Alkaline phosphatase is raised in up to 70 per cent of cases and 28 per cent are hyponatraemic. Reactive thrombocytosis is surprisingly common. Microscopic haematuria is a common finding.
