Among patients presenting with an acute coronary syndrome approximately 40 per cent have evidence of prior coronary artery disease (**CAD**) (myocardial infarction, angiographically demonstrated CAD, documented angina with a positive stress test). Appropriate lifestyle, dietary, and non-smoking measures should be introduced for all such patients in addition to the prescription of long-term aspirin (75 mg per day). Implementation of secondary prevention drug treatment will also reduce the risk of subsequent acute coronary syndrome events and deaths, for example lipid-lowering therapy and angiotensin-converting enzyme inhibitors (**ACE** inhibitors).

Access to hospital care

Patients with acute coronary syndromes may present to primary care physicians or directly to emergency hospital services. In addition, 15 to 20 per cent of those presenting directly to chest-pain clinics may have acute coronary syndromes. Patients with previously documented coronary artery disease need specific advice about seeking emergency medical care for episodes of typical anginal pain that persist beyond 20 min at rest, especially if unrelieved by glyceryl trinitrate, or if symptoms are consistent with crescendo angina.

Emergency department triage

For the patient with chest pain, two issues must be resolved urgently:

- Is the chest pain/discomfort thought to be of cardiac origin? This is a clinical judgement and requires prompt and skilled assessment.
- In those with suspected cardiac pain, is there evidence of evolving infarction?

Patients with evolving infarction (*ST-segment* elevation or bundle-branch block and clinical features of infarction) require 'fast-track' reperfusion with thrombolysis or primary angioplasty (see Fig. 1 and below). The remaining patients can be triaged into low- or high-risk categories:

- Patients with typical clinical features of ischaemia and ST-segment depression or transient ST-segment elevation or with cardiac enzyme or troponinelevation are high-risk acute coronary syndrome. Those with elevated levels of cardiac enzymes (troponins or CK, CK-MB) are termed minimal myocardial injury or non-ST-elevation MI.
- Patients with clinical features of acute coronary syndrome and non-specific ECG changes (T-wave inversion, T-wave flattening, minor conduction abnormalities) have intermediate or low-risk acute coronary syndrome (unless enzymes/markers are elevated).
- Patients with a normal electrocardiogram and normal cardiac examination have a potentially low-risk acute coronary syndrome or alternative diagnosis.

Evaluation of patients at intermediate or low risk

Patients who initially seem to be at intermediate or low risk require further assessment to determine their risk status and management. They should be admitted to a cardiac or medical acute assessment area, where further clinical, electrocardiographic, and enzyme assessments will resolve them into relatively high- and low-risk groups.

- Patients with an indeterminate risk and those with a suspected evolving infarction require repeat 12-lead electrocardiography or continuous ST-segment analysis, ideally in a cardiac-care or intensive-care unit setting. Such patients require baseline and repeat troponin estimations to identify those at higher risk (see Fig. 1*).*
- Clinically stable patients with minor or non-specific ECG abnormalities can be separated into those at very low risk on the basis of negative troponins and the absence of diagnostic ECG changes on repeat evaluation. Such patients may nevertheless have significant underlying coronary artery disease. They require stress testing or perfusion scanning, ideally prior to discharge.

Patients with an indeterminate or low risk on clinical grounds can therefore be resolved into those that require further investigation and treatment for acute coronary syndromes (ECG evidence of ischaemia, positive troponins, or positive stress test) and those without (Fig. 4). Follow-up studies have demonstrated that those without significant ECG abnormality, without troponin elevation (at 12 h after the acute event), and with a low-risk stress test have a very low risk of subsequent cardiac events and prompt hospital discharge should be appropriate. In studies from Hamm and colleagues only one such patient out of 850 went on to have a cardiac event.

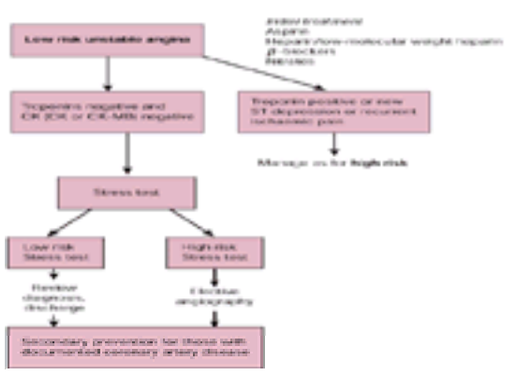

Fig. 4 Uncertain and low-risk unstable angina: initial treatment and diagnostic triage.

Management of patients at high risk

High-risk patients with acute ischaemia at initial presentation, and especially those with haemodynamic compromise, require emergency assessment for possible revascularization. Such patients should also benefit from glycoprotein IIb/IIIa inhibition (Fig. 5). Trial evidence also supports an improved outcome with glycoprotein IIb/IIIa inhibition amongst the remainder of patients with troponin positivity or *ST-segment* depression. Those proceeding to emergency revascularization should receive aspirin, unfractionated heparin, and glycoprotein IIb/IIIa inhibition. Large-scale safety studies have not yet been completed for the combination of low-molecular-weight heparin with glycoprotein IIb/IIIa inhibition, especially in the context of acute revascularization.

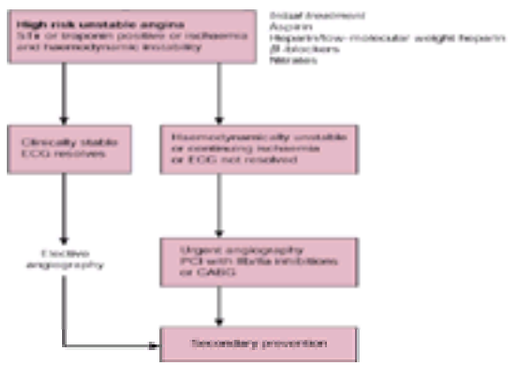

Fig. 5 High-risk unstable angina: initial treatment and diagnostic triage.

Coronary artery bypass surgery

As demonstrated by the FRISC II study, those with three-vessel or left main coronary artery disease and an acute coronary syndrome can be stabilized in the acute phase on low-molecular-weight heparin and aspirin, and can proceed to coronary artery bypass surgery (median 17 days) which carries a low perioperative and postoperative morbidity and mortality in experienced centres (2 per cent, 30-day mortality). A substantial part of the benefits seen in the FRISC II study were amongst those patients undergoing surgical revascularization.

Secondary prevention and rehabilitation

These issues are the same in those patients with unstable angina/non-ST-elevation MI as they are in those with ST-elevation MI (see below for details).

ST-segment-elevation MI

Introduction

In *ST-segment*-elevation myocardial infarction (MI), outcome is critically determined by the extent and severity of myocardial ischaemia. In addition, the eventual extent of irreversibly injured myocardium is influenced by residual myocardial perfusion, the duration of myocardial ischaemia, and cytoprotective mechanisms including preconditioning (see Chapter 15.4.2.1). As a result, the clinical consequences of abrupt coronary occlusion can range from an entirely silent episode, to profound ischaemia with major cardiac rhythm disturbances (ventricular fibrillation or asystole), to acute mechanical decompensation with heart failure. The outcome and management are influenced by the presence or absence of such complications, especially arrhythmias and acute heart failure.

The priorities in the management of *ST-segment*-elevation MI are to relieve acute distress and to limit the extent of infarction, mainly by reperfusion, and to treat complications. Beyond the acute phase, attention focuses on secondary prevention and rehabilitation.

Outcome in ST-segment-elevation MI

Community-based studies in various populations have demonstrated that the case fatality from acute MI is approximately 50 per cent by 1 month after the onset (MONICA studies). Approximately half of the deaths occur within the first 2 h. However, the risks of death, prior to hospitalization, vary with age: 80 per cent of those above 85 years die reaching hospital but only 40 per cent below 55 years. Prior to the introduction of cardiac care units in the 1960s, inpatient mortality was in the range of 25 to 30 per cent and in the 1980s, prior to the introduction of thrombolysis, inpatient mortality averaged approximately 18 per cent. More recently, the MONICA study from five cities has indicated that the 28-day mortality for patients admitted to hospital with a myocardial infarction ranged from 13 to 27 per cent, and other studies have provided figures of 10 to 20 per cent.

A marked discrepancy exists between mortality figures from randomized clinical trials and those from observational studies. Recent thrombolytic clinical trial data have consistently found that the 30-day mortality ranges from 6 to 8 per cent for those randomized within the trials. Some trials have analysed the outcome for individuals ineligible for inclusion and have demonstrated substantially higher death rates. Thus, although clinical trial data are accurate for the populations studied, they do not provide a comprehensive picture of outcome. This is the result of the exclusion of higher risk and complicated patients, including the elderly. In addition, the standards of care achieved in trial centres are not necessarily achieved in routine clinical practice. Although there is relatively little possibility of improving outcome amongst those eligible for randomization in clinical trials, substantial scope does exist in the remainder. Special attention needs to be drawn to the provision of acute resuscitation and defibrillation in the community.

Prehospital care

The priorities in prehospital care are to establish a prompt diagnosis of suspected acute infarction, to treat ventricular fibrillation, and to arrange emergency hospital admission for reperfusion therapy. In rural and other communities with more than a 30-min transfer time to hospital appropriate equipment and training facilities need to be established to allow prehospital thrombolysis to be administered safely and effectively.

The diagnosis of suspected infarction

A working diagnosis of suspected infarction is based upon typical severe chest discomfort of more than 15-min duration and which is unresponsive to glyceryl trinitrate. Characteristically, the pain may radiate to the neck, lower jaw, and arms and is often accompanied by autonomic features including sweating and pallor. Unless complications are present, physical examination may reveal no significant abnormalities, other than those associated with autonomic disturbance, but signs can include tachycardia or bradycardia, the presence of a third or fourth heart sound, and features of heart failure.

The initial electrocardiogram is seldom normal but may not show the classical features of *ST-segment* elevation or the development of Q-waves. Within minutes of the onset of ischaemia hyperacute T-wave changes can be present, and this may be followed by the evolution of characteristic ST-segment elevation, but minor or non-specific ECG abnormalities in conjunction with a characteristic history may signal the early stages of infarction. The working diagnosis relies heavily on the clinical history, and when this suggests myocardial infarction repeat electrocardiography within 30 to 60 min will frequently reveal the evolution of recognizable electrocardiographic changes.

In the prehospital setting a primary care physician may have to rely on the clinical findings to establish the working diagnosis and to initiate immediate treatment. Prompt relief of pain is important, not only for humanitarian reasons, but because pain is associated with sympathetic activation, vasoconstriction, and increased myocardial work. Effective analgesia is achieved by the titration of intravenous opioids, but paramedic crews only have access to non-opioid analgesia. Side-effects of analgesia include nausea and vomiting, hypotension, and respiratory depression. Antiemetics can be administered concurrently; hypotension and bradycardia will usually respond to atropine and respiratory depression to naloxone. Oxygen should be administered, especially to those who are breathless or those with any features of heart failure or shock (see Chapter 16.3 for information on basic and advanced life support in the management of cardiac arrest or ventricular fibrillation).

The logistics of providing acute care for patients with myocardial infarction depend upon the locally available facilities. Guidelines recommend integrated planning involving the emergency care system (ambulance and paramedic personnel), primary care physicians (general practitioners), and hospital-based specialists, including cardiologists and emergency care physicians. Within an urban setting, with relatively short transfer times, the shortest delays and the most prompt initiation of reperfusion occurs when the patient seeks an emergency medical ambulance and direct access to the hospital emergency department.

Prehospital versus inhospital thrombolysis

If patients initially call their primary care physician, this inevitably produces additional delays prior to reperfusion therapy. However, a general practitioner can administer intravenous opioids for the relief of pain. In the ideal scenario, the primary care physician and paramedic ambulance crew arrive together, analgesia is administered, acute complications managed, and the patient transferred rapidly to hospital. Telemetry of the electrocardiogram is possible, with physician-guided thrombolysis administered by paramedic and ambulance crews: the feasibility and safety of this approach has been established in The Netherlands. If a doctor is available in the ambulance, then after assessment and electrocardiography, thrombolysis can be initiated prior to transfer to hospital. In remote settings the feasibility and efficacy of prehospital thrombolysis administered by the general practitioner has been established (GREAT study).

To date, eight trials have been conducted comparing prehospital with inhospital administration of thrombolytic therapy. Depending upon the clinical setting, between 30 and 130 min are saved by prehospital thrombolysis (fibrinolytic drug plus aspirin). Overall, for the complete study population of 6607 patients, the 30-day mortality was 10.7 per cent for those receiving inhospital administration of thrombolysis and 9.1 per cent for those where it was administered prior to hospital admission. This amounts to a 17 per cent relative reduction in early mortality with a *p* value of 0.02 (1.6 per cent absolute reduction). Complication rates were similar for community-treated and hospital-initiated thrombolysis, although ventricular fibrillation occurred more frequently with community administration and necessitated well-trained staff and the availability of defibrillators. The greatest benefit is seen where prehospital treatment is applied in remote settings where transport delays are more than 1 h. Several studies have indicated that about 20 patients with chest pain require evaluation for each patient found to be eligible for thrombolytic therapy in the community. Nevertheless, with appropriate training and facilities prehospital care can provide a gain of approximately 20 lives per 1000 treated, amongst eligible patients.

Prehospital cardiac arrest

The management of prehospital cardiac arrest requires special attention. At least as many lives can be saved by prompt resuscitation and defibrillation as by prompt thrombolysis. For these reasons, emergency assessment of the patient with suspected infarction necessitates that the clinician or paramedic has access to a defibrillator and the skills to manage cardiac arrest promptly and effectively. The provision of basic or advanced life support training to paramedic ambulance crews, together with semiautomatic defibrillators, has resulted in a substantial increase in the number of patients surviving out-of-hospital cardiac arrest. Prior to the institution of such programmes successful resuscitations were opportunistic and often relied on the availability of a medical- or nursing-trained bystander. Nationwide figures indicate that resuscitation now achieves survival in 7 to 10 per cent of those patients found with cardiac arrest and in whom the initial rhythm is thought to be ventricular fibrillation. With effective integrated programmes higher success rates have been achieved. In the south-eastern region of Scotland about 14 per cent survive to reach hospital alive, and in Seattle, with a well-established community training and resuscitation programme, the figure exceeds 20 per cent. Of those reaching hospital alive, approximately half survive to be discharged home.

Emergency inhospital management and patient triage

The priority immediately after arrival at the hospital is to identify those patients with ST-elevation infarction for prompt reperfusion therapy (Fig. 6). The triage is usually performed in a casualty or similar emergency receiving department, but in some institutions patients with a high probability of infarction gain direct access to a cardiac-care assessment area. An integrated strategy involving the paramedic or ambulance system, the emergency physicians, and the cardiologists is required. 'Fast track' systems have been developed to minimize inhospital delay to thrombolysis: these are facilitated by specifically trained medical and nursing staff, with the aim of ensuring clinical assessment and electrocardiography within 15 min of arrival and the institution of thrombolytic therapy within 30 min. Audit programmes and continuous training are necessary for centres to achieve this 30-min median 'door to needle time'. Prior to the advent of 'fast track' systems, door to needle times of between 60 and 90 min were frequently recorded in clinical trials and in observational studies.

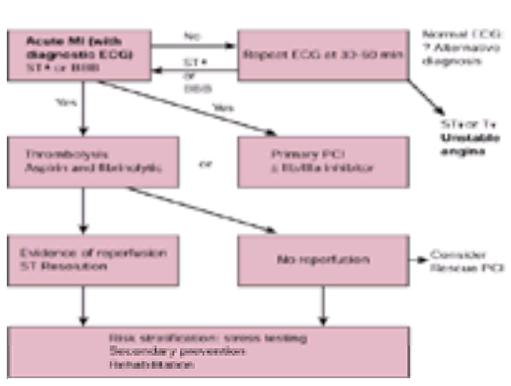

Fig. 6 Management of acute MI.

Definite versus suspected infarction

Rapid triage systems allow the identification of patients with clearly defined clinical and electrocardiographic features of infarction (characteristic symptoms of infarction which persist at rest and are not relieved by glyceryl trinitrate, in the presence of at least 1-mm ST-segment elevation in two or more contiguous leads, or the development of bundle-branch block). Clinical trials have employed ECG criteria of a 1-mm ST elevation for limb leads and 2 mm for chest leads. Although this definition improves specificity it is associated with reduced sensitivity.

Amongst those without diagnostic ECG changes a working diagnosis of suspected myocardial infarction or possible unstable angina can be established. Such patients require repeat clinical and electrocardiographic assessments to detect those with evolving infarction and to separate them from the remainder of patients with unstable angina or non-ST-elevation infarction (see Fig. 1 and Fig. 6). Patients with unstable angina or non-ST-segment elevation infarction do not benefit from thrombolytic treatment, and large-scale clinical trials and meta-analyses have demonstrated that they experience the hazards of bleeding complications from thrombolytic treatment with no evidence of improved survival.

The rationale for minimizing delays to thrombolysis

Experimental and clinical data demonstrate that the duration of ischaemia, prior to reperfusion, is a critical determinant of the eventual extent of myocardial damage. These data are supported by the improved outcome seen with prehospital *versus* inhospital thrombolysis and observational data from large clinical trials in which survival gain diminishes with each additional hour of ischaemia. The Fibrinolytic Trials Overview (Fig. 7) suggests about 1.6 additional deaths per hour of delay per 1000 treated.

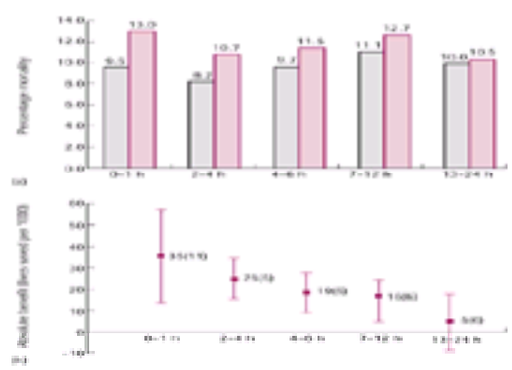

Fig. 7 Effects of thrombolytic therapy on mortality in subsets of patients with suspected MI, according to the time from the onset of symptoms. (a) Mortality rates in the fibrinolytic group (grey bars) versus control groups (pink bars); (b) absolute benefit (lives saved per 1000 treated, standard deviation in parentheses) by time to presentation. (Based on data from the FTT Collaborative Group and reproduced with permission.)

The relationship between the duration of ischaemia and the extent of infarction is non-linear: the greatest potential for salvage occurs when reperfusion is initiated within 60 min of the onset of infarction (Fig. 8). Under such circumstances, a proportion of patients (5 to 7 per cent) will have the infarction aborted and will not develop Q-waves or significant enzyme elevation despite characteristic ST elevation on the initial electrocardiogram. Minimizing the time delay is therefore critical in salvaging myocardium. Based on data from individual trials, and from the Fibrinolytic Trials Overview, most benefit occurs within the first 3 h of the onset of infarction, and highly significant benefits still occur at up to 6 h (Fig. 7). Statistically significant gains are still present at 12 h, but beyond 12 h the benefits are marginal. However, some patients present with a stuttering pattern and in the presence of persistent or intermittent ST-segment elevation and continuing symptoms of ischaemia, reperfusion beyond 12 h may salvage a significant proportion of ischaemic myocardium.

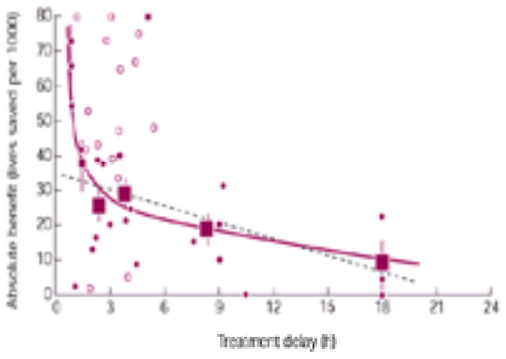

Fig. 8 Absolute benefit in lives saved per 1000 patients treated versus treatment delay. The relationship is non-linear, with most benefit occurring within the first 1 h of symptom onset. Small closed circles, information from trials included in the FTT analysis; open circles, information from additional trials; small squares, data beyond the scale of *x*/*y* cross. The linear (34.7 – 1.6*x*) and non-linear (19.4 – 0.6*x* +29.3x^{-1}) closed regression lines are fitted within these data, weighted by the inverse of the variance of the absolute benefit at each data point. The pink squares denote the average effects in six time-to-treatment groups (areas of the squares are inversely proportional to the variance of the absolute benefits described). (From Boeersma E, Maas ACP, Deckers JW, *et al*. Early thrombolytic treatment in acute myocardial infarction: reappraisal of the golden hour. *Lancet* 1996, **348**, 771–5 and reproduced with permission.)

Differential diagnosis

It is important to remember that thrombolytic therapy or angiography for anticipated primary angioplasty will be of no benefit to those who do not have myocardial infarction. Such patients suffer the dual hazards of thrombolysis or angiography in the acute phase of their illness and the delay in initiating appropriate treatment. Furthermore, those treated inappropriately with thrombolysis will experience the bleeding hazards of the drug (a net increase in intracerebral haemorrhage of approximately 0.5 per cent) and the disrupted coagulation system will render other emergency surgery (for example, for perforated peptic ulceration) more hazardous. Alternative cardiac diagnoses include unstable angina and non-ST- *segment-elevation MI*, myocarditis, pericarditis, and aortic dissection. Non-cardiac diagnoses include gastrointestinal pain of oesophageal, peptic, or biliary origin; pancreatitis; respiratory and musculoskeletal abnormalities.

Aortic dissection presents a particular problem when it extends proximally to the origin of the right coronary artery and produces inferior infarction. Computed tomography, magnetic resonance imaging, or transoesophageal echocardiography may be required to establish the diagnosis (see Chapter 15.14.1).

Transthoracic echocardiography can be valuable when infarction is suspected but characteristic electrocardiographic features are absent. Normal left ventricular function excludes significant infarction. Conversely, a regional contraction abnormality helps to confirm the diagnosis of ischaemia or possible infarction. However, in those with prior myocardial damage the differentiation of new from old mechanical dysfunction is complex and requires specialist assistance.

Cardiac enzymes are helpful when abnormal, but most patients present within 3 h of the onset of symptoms and insufficient time has elapsed to produce a diagnostic release of creatine kinase (CK) or CK-MB, or troponins. Patients with suspected infarction, but normal electrocardiograms, require further clinical electrocardiographic and enzyme estimations 4 to 6 h after the suspected event.

Among elderly and very elderly patients (over 90 years of age) the presentation of infarction is often atypical. They may not experience a typical pattern of symptoms and concomitant multisystem disorders may obscure the diagnosis. Myocardial infarction must be considered in the differential diagnosis of abrupt collapse, haemodynamic disturbance of sudden onset, or severe non-specific symptoms in elderly patients.

Treatment

Thrombolytic treatment

Thrombolytic treatment refers to the combination of antiplatelet therapy (usually aspirin) with fibrinolytic treatment. The fibrinolytic agent directly or indirectly converts plasminogen to plasmin and plasmin lyses fibrin in the clot. Crosslinked fibrin is more resistant to fibrinolytic drugs than a newly formed fibrin clot.

The combination of aspirin and a fibrinolytic agent has undergone extensive clinical testing in trials involving more than 100 000 patients. Additional trials have been conducted comparing one fibrinolytic agent with another. For patients presenting within 6 h of symptom onset, and with ST elevation or bundle-branch block, approximately 30 deaths are prevented per 1000 patients treated. For those presenting between 7 and 12 h, approximately 20 deaths are prevented per 1000 patients treated, and beyond 12 h the benefits are inconclusive.

The ISIS-2 trial demonstrated that the benefits of aspirin treatment were additional to those of fibrinolytic treatment, each achieving about 25 lives saved per 1000 patients treated (for the whole of the study population). Thus, in combination, about 50 lives are saved per 1000 patients treated, but the benefits are larger than this among those presenting within 3 h of infarction with ST-segment elevation or bundle-branch block. Overall, the largest *absolute* benefit is seen in patients at highest risk, although the proportional benefit may be similar for all. High-risk patients include those over 65 years of age, those with a systolic blood pressure below 100 mmHg, and those with anterior infarction or more extensive ischaemia (see primary angioplasty below). The absolute benefit in lives saved per 1000 treated is 11 ± 3 for those under 55 years of age; 18 ± 4 for those between 55 and 64; 27 ± 5 for those 65 to 74; and 10 ± 13 for those over 75 (Fibrinolytic Trials Overview). Similarly, for those patients with more extensive infarction or hypotension, the absolute benefit for the following systolic blood pressures is: 62 ± 18 for less than 100 mmHg; 18 ± 3 for 100 to 149 mmHg; 15 ± 4 for between 150 and 174 mmHg; and 11 ± 8 for those more than 174 mmHg (Fibrinolytic Trials Overview). For patients with bundle-branch block and acute MI, the absolute benefit in lives saved per 1000 treated is 49. For those with anterior ST elevation it is 37, and for inferior ST elevation it is 8. However, for ST depression there is a net hazard of 14 lives lost per 1000 treated, and for those with a normal ECG 7 lives lost per 1000 treated (Fibrinolytic Trials Overview). Thus, evidence supports thrombolysis treatment only for those patients with ST elevation or bundle-branch block.

Hazards of thrombolysis

Thrombolytic therapy is associated with a significant excess of haemorrhagic complications, including cerebral haemorrhage. Overall, about two non-fatal strokes occur per 1000 patients treated, and of these half are moderately or severely disabling. An additional two strokes per 1000 patients are fatal, and the net impact on mortality includes such patients. The risk of stroke increases with age, especially for those over 75 years of age, and for those with systolic hypertension. The excess

of non-cerebral bleeds is about 7 per 1000 treated, including those that require blood transfusion, or are life-threatening, or result in a longer hospital stay. Bleeding occurs at arterial and venous puncture sites, hence blood sampling or cannulation of vessels should be limited to sites where external compression can achieve haemostasis.

Streptokinase and other streptokinase-containing agents (anistreplase) can produce hypotension and, rarely, allergic reactions. Routine administration of hydrocortisone is not indicated. When hypotension occurs it can be managed by interrupting the streptokinase infusion, lying the patient flat or head down and by the administration of atropine, or intravascular volume expansion.

Comparison of thrombolytic agents

The most widely used thrombolytic agents are streptokinase and alteplase (tissue plasminogen activator, **tPA**). The GISSI International Trial and ISIS-3 international trial both failed to find a difference in outcome between streptokinase and tissue plasminogen activator. However, the **GUSTO** trial (Global Utilization of Streptokinase and Tissue plasminogen active for Occluded coronary arteries) employed an accelerated administration of alteplase over 90 min, and intravenous heparin adjusted using the activated partial thromboplastin time (Table 4). The GUSTO trial resulted in 10 fewer deaths per 1000 patients treated with alteplase compared with the streptokinase group. However, this was partially offset by 1 per 1000 additional non-fatal strokes (with residual neurological deficit).

Newer fibrinolytic agents

Novel agents have been developed with the aim of improved clot lysis and simpler administration. Such agents include mutants of native tPA (reteplase, lanoteplase, tenecteplase (TNK-tPA)), and a derivative of streptokinase with increased fibrin specificity and reduced antigenicity, staphylokinase.

Only reteplase, lanoteplase, and tenecteplase have been tested in large-scale comparative trials. Reteplase is administered as two 10-IU boluses given 30 min apart, and the mortality outcome is very similar to that of alteplase (0.23 per cent in favour of alteplase with confidence intervals of –1.11 per cent to +0.66 per cent). The impact on death or disabling stroke is also similar, with stroke occurring in 1.64 per cent of those treated with reteplase and 1.79 per cent of those treated with alteplase (results that are not significant). Lanoteplase or n-PA is a deletion mutant of alteplase that is administered as a single bolus. In the large In-TIME-2 trial 15 078 patients were randomized to lanoteplase versus alteplase, and the results were broadly similar with respect to mortality (6.77 per cent versus 6.60 per cent, respectively), but lanoteplase treatment was associated with slightly more bleeding events. Tenecteplase (TNK-tPA), administered as a single bolus, has been tested against the reference standard of accelerated tPA in a large-scale ASSENT-2 trial involving 17 000 patients. The 30-day mortality figures were virtually identical to those of alteplase (6.18 per cent versus 6.15 per cent, respectively); bleeding events were also similar (intracerebral haemorrhage 0.93 per cent versus 0.94 per cent and blood transfusions 4.25 per cent versus 5.49 per cent, respectively).

Neither staphylokinase nor prourokinase (saruplase) have been tested in large-scale trials, but patency studies have produced encouraging data for both agents.

Conclusion: comparison of thrombolytic agents

The current reference standard for the comparison of fibrinolytic agents is the accelerated infusion regimen of alteplase (tPA). However, streptokinase remains the most widely used fibrinolytic agent internationally. This is largely because the cost of alteplase is substantially higher than that of streptokinase. Newer agents are more convenient to administer than the rather complex infusion regimen of alteplase and have a lower frequency of hypotension and bradycardia than streptokinase. However, there is no evidence that any 'third generation' fibrinolytic agent has improved clinical outcome nor substantially different bleeding complications compared with alteplase. Their main advantage lies in ease of administration. Indeed, recent trials have been associated with a modest but progressive increase in intracerebral bleeding, which may be associated with more aggressive heparin anticoagulation.

In summary:

- The limit appears to have been reached in achieving reperfusion with fibrinolytic agents, and alternative strategies involving adjunctive glycoprotein IIb/IIIa inhibitor therapy have not demonstrated improved outcome or substantially improved safety profile.
- The limit in treating all potentially eligible patients with reperfusion therapy has not been reached. Between 45 per cent (Europe, ENACT study) and 60 per cent (United States, NRMI Registry) of all myocardial infarctions receive neither thrombolysis nor primary angioplasty (percutaneous coronary intervention, **PCI**).
- Thrombolysis is a very cost-effective treatment for acute MI. A sustained benefit on survival has been demonstrated 14 years after thrombolysis.

Combination of fibrinolytic agents with glycoprotein IIb/IIIa inhibitors

The importance of combining antiplatelet agents with fibrinolytic agents was demonstrated in the original ISIS-2 trial, where the benefits of aspirin treatment were additive to those of fibrinolysis. More potent and specific platelet inhibition with glycoprotein IIb/IIIa inhibitors offered the potential for enhanced thrombolysis, and dose-ranging studies were encouraging (TIMI-14).

The large scale randomized trials (ASSENT-S and GUSTO V) have not fulfilled the promise of the earlier studies. In GUSTO V patients were randomized to thrombolytic (reteplase) or the combination of half dose reteplase and abciximab. The combination was not superior to the thrombolytic alone. Nevertheless, there were reductions in secondary points including reinfarction. In ASSENT-S there were significantly fewer endpoints for the combination of abciximab plus thrombolytic (11.1 per cent versus 15.4 per cent) compared with thrombolytic and unfractionated heparin, but a similar benefit was achieved with low- molecular-weight heparin (enoxaparin) and thrombolytic: 11.4 per cent endpoints. There were fewer bleeding events with enoxaparin than with abciximab (major bleeds 3 per cent versus 4.4 per cent). Thus the glycoprotein Hb/IDas do not appear to offer any advantage over the combination of low-molecular-weight heparin and thrombolytic (TNKtPA). A combination ofTNKtPA and enoxaparin appears to provide the best combination of efficacy and safety based on the ASSENT-3 trial.

If the results of ASSENT-3 are confirmed in a separate study, the new standard of care for fibrinolysis will be aspirin plus a fibrinolytic agent plus antithrombin therapy with low-molecular-weight heparin (enoxaparin).

Primary angioplasty

In an attempt to overcome the limitations of fibrinolysis (bleeding hazards and delayed or incomplete reperfusion) studies of primary angioplasty have been undertaken. Primary angioplasty is defined as percutaneous coronary intervention (PCI) without concomitant fibrinolytic therapy. It requires a highly skilled interventional cardiology team with substantial experience of the procedure.

Patients are transferred as an emergency to the cardiac catheterization laboratory and angiography undertaken to establish coronary anatomy and the nature of the vessel occlusion. A flexible guidewire is then passed across the occluded lesion and balloon angioplasty (usually accompanied by stent implantation) performed, thereby restoring patency. Several moderate-sized comparative trials have demonstrated the feasibility of this approach, and in highly skilled centres the data suggest an improved outcome for primary angioplasty compared to conventional thrombolysis. The American College of Cardiology (**ACC**) and the American Heart Association (**AHA**) guidelines for the management of MI recommend primary PCI as an alternative to thrombolysis, provided it can be performed within 60 to 90 min of admission, and by individuals skilled in the procedure (those performing more than 75 cases per annum) and in a high-volume centre (more than 200 cases per annum). However, larger scale studies have been performed (GUSTO 2) and these reveal that the quality of the results achieved, in broad clinical practice, are not as high as those of very experienced interventional centres. In consequence, the differences in outcome between primary angioplasty and thrombolysis are less apparent in such large international comparisons. Nevertheless, primary angioplasty is effective in securing and maintaining coronary patency and avoids the intracerebral bleeding complications of thrombolysis. Randomized trials indicate that, in experienced centres, it is more effective in restoring patency and achieves better ventricular function, with trends towards improved clinical outcome (compared to thrombolysis). Particular gains are seen in haemodynamically compromised patients and those with cardiogenic shock. Thus:

- Primary percutaneous transluminal coronary angioplasty (**PCI**) is specifically indicated in individuals with a contraindication to thrombolytic therapy and in haemodynamically compromised patients.
- In highly experienced interventional centres primary **PCI** may provide an effective alternative to thrombolysis.

The choice of reperfusion strategy will clearly continue to depend upon available resources and the expertise of each centre. Unless primary angioplasty can be performed within approximately 1 h of hospital admission, the potential gains do not appear to outweigh the hazards when compared with thrombolysis.

Angioplasty combined with thrombolysis

The combination of angioplasty and thrombolytic therapy has proved disappointing in a number of trials, with a tendency to an increased risk of complications. Although many of these trials predate current instrumentation and drug therapy, the routine combination of angioplasty and thrombolysis is not recommended.

Rescue angioplasty

Patients in whom thrombolysis fails to achieve reperfusion may benefit from 'rescue' angioplasty. Such patients can be identified by the failure to resolve ST-segment elevation, in combination with persistent clinical features of ischaemia, with or without haemodynamic compromise. Limited experience from relatively small randomized trials suggests a trend towards an improved benefit from rescue angioplasty.

Coronary artery bypass surgery

In the acute phase of myocardial infarction the role of coronary artery bypass grafting (**CABG**) is limited to those patients with acute mechanical complications, such as ventricular septal defect or mitral regurgitation due to papillary muscle rupture. Unless such mechanical complications are present the hazards of acute bypass surgery are significantly increased compared to delayed revascularization in a stabilized patient. The Danish DANAMI study investigated the role of revascularization in those with ischaemia during the recovery phase of myocardial infarction. It suggested that, following infarction, individuals with symptomatic or electrocardiographic ischaemia on stress testing experience significant long-term benefit from surgical revascularization.

Later inhospital management

The main aims of later inhospital management are the:

- identification and treatment of acute complications of infarction;
- identification of patients at increased risk for subsequent cardiac events; and
- initiation of secondary prevention and rehabilitation.

The distinction between early treatment and later phase treatment is clearly arbitrary. Major complications may be apparent at the time of presentation and haemodynamic, arrhythmic, or ischaemic complications may be evident shortly thereafter. Nevertheless, in the period beyond the first 12 to 24 h it is appropriate to focus attention on the points listed above.

Identification and treatment of complications of infarction

Failure of reperfusion

Electrocardiographic markers of failed reperfusion are the persistence of ST-segment elevation together with clinical and haemodynamic features of continuing ischaemia. Continuous computed ST analysis allows the most accurate definition of ECG changes, but an approximation can be obtained with repeated 12-lead ECGs and measurement of ST-segment elevation.

- In those with successful reperfusion, ST segments decrease to less than 50 per cent of peak elevation within 60 min.

In addition, some patients exhibit reperfusion arrhythmias (ventricular tachycardia, idioventricular rhythm, and, rarely, ventricular fibrillation). Such arrhythmias are more common in the presence of marked ischaemia and prompt reperfusion within 60 to 90 min of occlusion.

The most effective treatment for failed reperfusion has not yet been validated in large-scale clinical trials. However in those without successful reperfusion:

- rescue angioplasty is feasible, consisting of mechanical recanalization of the occluded vessel with percutaneous intervention, often accompanied by stent implantation.

This strategy achieves an 'open artery' and may be associated with improved mechanical function and improved longer term prognosis.

Repeat thrombolysis

A thrombolytic agent may fail to achieve recanal*iza*tion as a result of an extensive organized thrombus (crosslinked fibrin), platelet-rich thrombi, and mechanical obstruction to flow due to intraplaque haemorrhage. In addition, among patients treated with streptokinase, previous exposure to a streptococcus or to streptokinase can induce an antibody response that can block at least half of the 1.5 million unit standard dose of streptokinase. Thus, previous exposure to streptokinase or known antistreptococcal antibodies are indications to use an alternative thrombolytic in the first instance. Feasibility studies have been undertaken of partial- or full-dose alteplase following (unsuccessful) streptokinase, but large-scale outcome trials are needed to establish the safety and efficacy of this strategy.

Cardiogenic shock, left ventricular dysfunction, and heart failure

Cardiogenic shock

In cardiogenic shock mechanical contractile abnormalities of the left ventricle or acute haemodynamic complications (papillary muscle rupture or ventricular septal defect) lead to reduced blood pressure and impaired tissue perfusion. Clinically, the condition is recognized by a systolic blood pressure of less 90 mmHg together with impaired tissue flow, as reflected by oliguria, impaired cerebral function, and peripheral vasoconstriction. Between 5 and 20 per cent of those patients admitted to hospital with acute MI demonstrate cardiogenic shock. There is evidence that its frequency has been reduced by thrombolytic therapy and primary PCI. The mortality rate when cardiogenic shock complicates an acute coronary event is in excess of 70 per cent if acute revascular *iza*tion is not possible.

Time delay is critically important in the management of cardiogenic shock: mortality rises progressively if more than 2 h have elapsed since its onset. Treatment aims to improve the recovery of acutely ischaemic myocardium (mechanical and surgical revascular *iza*tion) and to support the circulation with a combination of inotropes, vasodilators, and loop diuretics. Evidence suggests that the most important treatment may be to reopen the infarct-related artery with either thrombolysis or primary angioplasty. Once cardiogenic shock has developed observational studies of primary angioplasty have demonstrated improved outcome (PAMI trial). In addition, the SHOCK trial has demonstrated that aggressive treatment with intra-aortic balloon pumping (**IABP**) followed by surgical revascular*iza*tion may also significantly reduce mortality.

Aside from attempts to induce reperfusion, management of the patient with cardiogenic shock after myocardial infarction traditionally includes inotropes. Dopamine is commonly used, initially at a low 'renal dose' (1–5 μg/kg per min) that activates dopaminergic receptors (but also has an effect on the circulation), but if necessary at higher doses of 5 to 20 μg/kg per min that have positive inotropic and chronotropic effects. In doses above 20 μg/kg per min there is activation of a-adrenoceptors with undesirable peripheral vasoconstriction and a decline in renal perfusion. Dobutamine acts mainly as a b1-adrenoceptor agonist and is used in the range of 2 to 40 μg/kg per min. Phosphodiesterase inhibitors have both inotropic and vasodilator effects and, although they have produced favourable haemodynamic responses, the studies conducted have not shown an improvement in outcome.

The management of pulmonary oedema consists of opiates (to relieve distress and to reduce vascular resistance), oxygen, vasodilators, and diuretics. Vasodilators (including nitrates, salbutamol, and sodium nitroprusside) reduce venous and pulmonary arterial pressure, but tachycardia may be a limiting feature and their use is

limited in those who are profoundly hypotensive. Loop diuretics are employed in bolus intravenous doses or by infusion.

Left ventricular dysfunction and heart failure

Large-scale trials of angiotensin-converting enzyme (ACE) inhibitors have been conducted in patients with left ventricular dysfunction and those with clinical and radiological features of heart failure (see Chapter 15.5.3). Clear evidence demonstrates the improved short- and long-term outcome with ACE inhibitors in patients with heart failure and those with asymptomatic left ventricular dysfunction.

- In patients with left ventricular dysfunction or heart failure, ACE inhibitors improve the short- and long-term prognosis.

Caution must be exercised with the introduction of ACE inhibitors in patients with intravascular volume depletion: they can cause hypotension. ACE inhibition should commence with very small doses (for example, 6.25 mg of captopril) with dosages increased progressively in conjunction with clinical monitoring. They can provoke deterioration in renal function in patients with renal artery stenosis, which is not uncommon in those with atheromatous coronary disease. Hence, it is important to check serum electrolytes and creatinine during follow-up. Angiotensin receptor blockers appear to provide similar benefits to those seen with ACE inhibitors (ELITE 2 study), but most evidence exists for ACE inhibition.

Arrhythmias

A wide variety of arrhythmias can be seen in the context of acute myocardial infarction and its treatment. In the early days of coronary-care units, great emphasis was placed on the treatment of even minor rhythm disturbance. This is now thought to have been misplaced: antiarrhythmic agents are almost invariably negatively inotropic and they may also be proarrhythmic in the context of acute coronary ischaemia. An overview of randomized trials into the use of prophylactic lidocaine (lignocaine) showed that it increased mortality. Ventricular fibrillation should be treated with DC cardioversion, and treatment with lidocaine or other antiarrhythmics (for example, amiodarone) reserved for those who have had ventricular fibrillation or another symptomatic arrhythmia (see Chapter 15.6 for details of the diagnosis and treatment of arrhythmias).

Heart block

Heart block of any degree can occur after acute myocardial infarction. It is more common with inferior than anterior infarction because the right coronary artery supplies the atrioventricular node, and also because vagal reflexes are more likely from this area. It is often transient, and does not necessarily imply a large infarct, except when it occurs with anterior infarction, in which case the prognosis is grave. Temporary pacing is justified when bradycardia compromises the circulation, but not advocated 'prophylactically' for a first- or second-degree block.

Ventricular septal defect, papillary muscle rupture, and myocardial rupture

Rupture of the interventricular septum occurs in up to 3 per cent of acute infarctions and is responsible for about 5 per cent of deaths due to myocardial infarction. Rupture in the apical area may complicate anterior infarction and in the basal inferior area may complicate inferior infarction. Clinically, the condition is associated with the development of a new pansystolic murmur and clinical features of a left to right shunt with increased pulmonary congestion. Surgery should be undertaken as soon as possible: the outlook for those who are not operated upon is very bleak, few survive. However, a very few patients with small shunts survive the acute phase, but they may suffer the later consequences of the shunt.

Papillary muscle rupture occurs as a result of acute ischaemic damage due to obstruction of either the left anterior descending or circumflex coronary arteries. It causes the abrupt onset of severe mitral regurgitation and accounts for 5 per cent of deaths after acute MI. The complication generally occurs within the first week after infarction and may be recognized as the abrupt onset of acute pulmonary oedema. It is often accompanied by a new systolic murmur, but when the left atrial pressure rises acutely the murmur may be insignificant. The management is acute surgical repair with or without revascular *iza*tion (for further discussion of acute mitral regurgitation, see Chapter 15.7).

In the patient who deteriorates haemodynamically after myocardial infarction—with hypotension, pulmonary oedema, or both—it is important to consider the possibility of a ventricular septal defect or acute mitral regurgitation. However, it can be impossible to distinguish between the two on clinical grounds. Both classically produce a new pansystolic murmur, and although differences between the murmurs have been described, these are not robust enough to discriminate with certainty in the individual case. Acute mitral regurgitation is best diagnosed by echocardiography, but transthoracic echocardiography may be unable to detect a ventricular septal defect in a reliable manner. Transoesophageal echocardiography is better, as is the use of a contrast-enhanced technique. If unavailable, an alternative approach is to pass a flow-directed pulmonary catheter and take blood samples from the pulmonary artery, right ventricle, and right atrium. A step up in oxygen tension between the right atrium and the pulmonary artery indicates the presence of a left to right shunt and confirms the diagnosis of a ventricular septal defect.

Myocardial rupture may follow acute infarction, usually involving the free wall of the left ventricle. It is responsible for approximately 10 per cent of all deaths in acute MI. Half of the ruptures occur within the first week, and 90 per cent within 2 weeks. The location of rupture is usually within the infarcted area, but may be at the junction with adjacent normal myocardium. In most cases death is immediate and due to electromechanical dissociation. The patient is unresponsive to resuscitation measures but, rarely, with subacute rupture, patients can be supported until surgical repair is performed. The diagnosis is made on clinical and echocardiographic criteria with assessment for possible cardiac tamponade (see Chapter 15.9). In some patients, partial rupture of the free wall can result in the late development of a false aneurysm.

Left ventricular thrombus

A left ventricular thrombus can be detected using echocardiography in up to 40 per cent of patients with acute anterior MI. The thrombus is usually located at the apex in association with a dyskinetic or aneurysmal section of myocardium with impaired contractile function. The thrombus may be large and is associated with risks of embol*iza*tion (in 15 to 20 per cent of cases). Anticoagulation with heparin followed by warfarin is advised in patients with extensive infarction and those in whom apical aneurysms or mural thrombi are detected. Both thrombolysis and surgical repair have been successfully conducted. However, there is no clear evidence that either strategy is superior (provided there is no evidence of embol*iza*tion).

Pericarditis

Pericarditis is a frequent complication of transmural myocardial infarction and may be manifest clinically as a pericardial friction rub accompanied by pleuritic chest pain. A small pericardial effusion may be detected using echocardiography. Dressler's syndrome is associated with pericarditis between 2 weeks and 3 months after acute infarction and has an autoimmune basis, often accompanied by pleural and pericardial effusions. It is managed with salicylates or non-steroidal anti-inflammatory agents. The frequency of both pericarditis and Dressler's syndrome is reduced with acute reperfusion (see Chapter 15.9 for further discussion).

Shoulder hand syndrome

This is a syndrome of rheumatic pain in the left shoulder, with restricted movement, which can occur in the weeks after myocardial infarction. The pathogenesis is unknown. It is treated symptomatically and usually resolves spontaneously.

An integrated approach to the management of ST-segment-elevation MI

Management of the at-risk patient

Secondary prevention measures in patients with documented coronary artery disease reduce the frequency of subsequent infarction (aspirin, lipid lowering, ACE inhibitors, cessation of smoking, treatment of hypertension). Preventive strategies in those at risk of subsequent infarction can reduce the frequency of both MI and sudden cardiac death.

Prehospital management

In a patient with suspected acute infarction prehospital management aims to treat acute arrhythmic complications, including ventricular fibrillation and other forms of cardiac arrest, to provide analgesia and oxygen, and to minimize delays to reperfusion. Prehospital thrombolysis may be given where transfer times to hospital exceed 30 min, and appropriate facilities exist with trained paramedic crews.

Early inhospital management

Initial assessment involves the identification of those with clear-cut evidence of infarction (based on clinical and diagnostic ECG criteria). Such patients require immediate triage to reperfusion therapy (thrombolysis with a fibrinolytic agent plus an antiplatelet agent or primary PCI (Table 5). The remaining patients in whom the diagnosis of MI is suspected but the ECG criteria are not diagnostic should be managed in an intensive-care setting (in the Emergency Department or CCU) with repeat ECG evaluation at 30-min intervals (or ST-segment analysis). Cardiac enzymes may be elevated when the index episode of pain occurs more than 6 h prior to the obtained blood sample. Such patients may be resolved into those with evidence of non-ST elevation infarction (ECG and enzyme or troponin elevation) and those with unstable angina (T-wave inversion, ST-segment depression, or transient ST-segment elevation, without elevated cardiac troponins). Among those with minor or non-specific ECG changes and no enzyme elevation, re-evaluation should take place for alternative diagnoses, and stress testing performed subsequently to detect underlying coronary artery disease (Fig. 1 and Fig. 3).

Management of the later inhospital phase

During this phase the management of complications, initiation of secondary prevention, and early cardiac rehabilitation should take place. In high-risk patients (those with recurrent acute ischaemia or those with failure of ST-segment resolution and continuing pain) emergency angiography and possible revascular *iza*tion can be performed in appropriately equipped centres (Fig. 6).

Regular clinical and electrocardiographic assessments are required during the recovery phase to detect acute mechanical and arrhythmic complications, and to identify impaired contractile function in patients who will benefit from ACE inhibitor treatment. ACE inhibitor treatment is indicated in those with overt heart failure in the acute phase. Based on the HOPE trial, patients with documented vascular disease benefit substantially from ACE inhibition (ramipril 10 mg). Cardiovascular deaths are reduced from 8.1 per cent to 6.1 per cent and myocardial infarction from 12.3 per cent to 9.9 per cent (relative risk reductions 0.73 and 0.80 respectively, p <0.001 in both instances). Treating 1000 patients with ramipiril for 4 years prevents approximately 150 cardiovascular events in 70 patients. Thus, ACE inhibition is indicated for those with vascular disease irrespective of whether there is evidence of overt heart failure or impaired LV function in acute phase. Prior to discharge, patients also require assessment for lipid-lowering therapy (current evidence suggests that all patients with MI will benefit unless their total cholesterol concentration is below 4.8 mmol/l or their low-density lipoprotein (LDL) concentration is below 3.0 mmol/l). There is evidence to support management of diabetes with glucose and insulin during the in-hospital and early post-hospital phase (see Chapter 12.12.1).

All patients will benefit from smoking cessation and the management of hypertension (systolic pressure to less than 140 mmHg). Dietary advice is required for those with a basal metabolic index (**BMI**) above 25 kg/m^2.

Summary of secondary prevention measures in those with unstable angina and myocardial infarction

Following an acute coronary syndrome, patients require dietary and lifestyle advice including the support necessary to discontinue smoking (including nicotine replacement therapy). Lipids should be measured within the first 24 h of admission and evidence supports the use of lipid-lowering therapy with statins in almost all patients, excepting those with very low LDL or total cholesterol levels. Based on data from the HOPE study, individuals with documented coronary artery disease have reduced long-term risks of death and myocardial infarction if maintained on ACE inhibition. In addition, such patients may require antianginal therapy and all should receive long-term, low-dose aspirin.

Non-pharmacological interventions

Evidence supports the following non-pharmacological interventions in secondary prevention:

- cessation of smoking (including the avoidance of passive smoking);
- dietary modification;
- exercise;
- rehabilitation; and
- management of obesity.

Modification of high-risk conditions

Trial evidence supports therapeutic interventions to modify the following conditions:

- hyperlipidaemia;
- left ventricular dysfunction and heart failure;
- diabetes mellitus;
- hypertension.

Pharmacological interventions

Evidence (summarized in Table 6 and Table 7) supports the following therapies to reduce the risk of subsequent cardiovascular events:

- antiplatelet therapy (usually aspirin in a dose of 75 mg/day);
- b-blockers in those without contraindications;
- lipid lowering with 3-hydroxy-3-methylglutaryl coenzyme A (**HMG CoA**) reductase inhibitors (statins);
- ACE inhibitors in those with left ventricular dysfunction and heart failure, and based on the results of the HOPE study, in other patients with vascular disease (Table 6).

Anticoagulants

These are indicated in those with high risks of embolism due to left ventricular or atrial thrombus. There is evidence to support the use of anticoagulants in post-MI patients but no definitive evidence that such treatment is superior to aspirin therapy.

Hormone replacement therapy (HRT)

HRT is associated with a reduced risk of coronary heart disease in observational studies, but in the only randomized study (HERS) it resulted in no overall reduction in the risk of non-fatal MI or CHD death.

Calcium-channel blockers

An overview of data from 19 000 patients based on all randomized trials of acute infarction and unstable angina suggests that the available calcium-channel blockers are unlikely to reduce the rate of subsequent infarct development, infarct size, or subsequent infarction. They may, however, have indications for the relief of angina (especially heart-rate lowering calcium antagonists).

Antiarrhythmic agents

A review of the effects of antiarrhythmic agents (with the exception of b-blockers) does not demonstrate a beneficial impact on mortality.

15.4.2.4 Percutaneous interventional cardiac procedures

Edward D. Folland

Introduction

The birth of interventional vascular medicine is generally credited to Charles Dotter, a radiologist from Portland, Oregon, who in 1964 first dared to relieve atherosclerotic stenosis of a patient's femoral artery by passage of a percutaneously introduced dilator. Although Dr Dotter had a few notable successes, which were widely publicized in the lay press, the scientific community scorned him. His radical concept lay dormant until a decade later when Andreas Gruentzig, a young German radiologist studying in Zurich, revived it. Dr Gruentzig was convinced that percutaneous dilatation of atherosclerotic stenosis was a sound concept and proposed that Dotter's solid dilator be replaced by a catheter with an inflatable cylindrical balloon at its tip. Using catheters he created in his own kitchen, he proceeded carefully and logically in applying his technique first to animal models, then to human peripheral vessels, and finally in 1977 to his ultimate goal, the human coronary artery. News of Gruentzig's percutaneous transluminal coronary angioplasty (**PTCA**) was quickly embraced by the medical community, and the era of percutaneous coronary intervention (**PCI**) was born. This chapter will deal with percutaneous approaches to treating coronary, valvular, and congenital heart disease.

Percutaneous coronary intervention

Percutaneous coronary intervention or PCI is the current general term applied to a variety of percutaneous, catheter-based procedures that accomplish revascularization either by angioplasty (enlargement of a vessel lumen by modification of plaque structure), stenting (deployment of an internal armature or stent), atherectomy (removal or ablation of plaque), or thrombectomy (removal of thrombus). Several different devices have been developed to perform these procedures. The interventional cardiologist chooses among these approaches to best suit the particular requirements of each individual patient.

Indications

The indications for percutaneous revascularization have expanded dramatically during the past 25 years. In the early days of PTCA it was indicated for subtotal, proximal occlusions of single vessels in patients with chronic, stable angina pectoris who had failed medical therapy. As experience grew and equipment improved, patients with unstable angina, total occlusions, bypass grafts, multivessel disease, and acute myocardial infarction were added to the list. Currently, the most common single indication for PCI is acute coronary syndrome (unstable angina or acute myocardial infarction).

PCI has traditionally been performed only in hospitals having cardiac surgical backup. However, as the procedure has become safer and the need for emergency bypass surgery less common (currently under 1 per cent of all cases), it has become more common, particularly in Europe, for these procedures to be performed in facilities where surgical backup is not on-site. Likewise, all patients undergoing PCI were once required to be potential candidates for bypass surgery in case of failure of the percutaneous procedure. Now some patients who are poor surgical candidates may undergo salvage intervention as their best or only avenue for revascularization. The choice of initial treatment (pharmacological, interventional, or surgical) for patients with each of the above coronary syndromes has been guided by evidence from a number of randomized clinical trials and will be treated in more detail in the later section headed 'Outcomes'.

Devices

Balloon angioplasty

Balloon angioplasty is the traditional, basic technique of coronary intervention, although it is now uncommonly employed as a stand-alone treatment. Nevertheless, it is fundamental to the deployment of coronary stents, which are currently the most widely utilized of the interventional devices. The equipment for angioplasty is displayed in Fig. 1 and consists of a coaxial array of guiding catheter, balloon catheter, and steerable guidewire. The procedure is accomplished by first engaging the left or right coronary orifice with the tip of the guiding catheter to access the vessel containing the target lesion and to provide backup support during advancement of the guidewire and balloon across the lesion (Fig. 2(a)). Next, the guidewire is advanced through the guide catheter into the appropriate vessel and across the lesion to be treated. Typical guidewires are 14-thousandths of an inch in diameter (about 0.36 mm) and have a flexible spiral coil tip that can be directed by rotating its proximal end outside the body. The balloon catheter is then advanced over the guidewire until the deflated balloon lies across the target lesion. Finally, the balloon is inflated with a solution of dilute contrast medium to a pressure sufficient to expand the cylindrical balloon to its nominal manufactured diameter (Fig. 2(b)). The balloon size is selected to match the estimated diameter of the nearest segment of normal vessel and the length of the target lesion. Sometimes intravascular ultrasound is used to assist in this choice. The balloon is then withdrawn and the result assessed by angiography and, occasionally, by ultrasound (Fig. 2(c)).

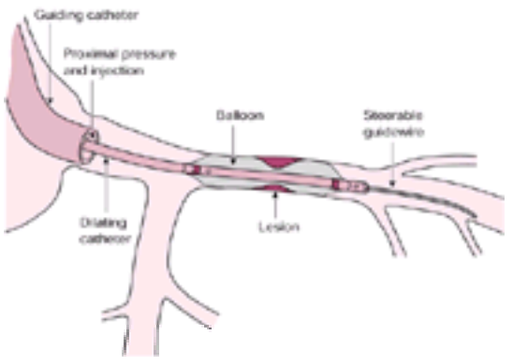

Fig. 1 Balloon angioplasty. The guiding catheter gives access to the coronary artery and provides a platform against which the dilating apparatus can be advanced. The steerable guidewire is passed down the vessel being treated and provides a rail over which the balloon catheter can be advanced. Once centred on the atherosclerotic lesion, the balloon is inflated under pressure to dilate the narrowed segment of artery.

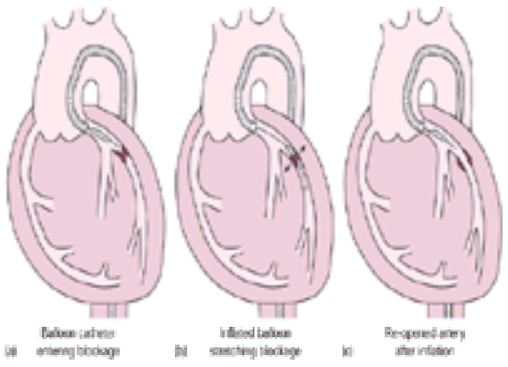

Fig. 2 A typical lesion before (a), during (b), and after (c) balloon angioplasty.

Traditional angioplasty now finds its chief application in deployment of balloon expandable stents. However, angioplasty may serve as a stand-alone interventional technique for the treatment of lesions of small vessels (less than 2.5 mm in diameter) and lesions located far distally or beyond tortuous segments where more rigid devices such as stents cannot reach. In experienced hands, with appropriate case selection, the initial success rate of balloon angioplasty should exceed 95 per cent. Abrupt closure of the vessel might be expected in about 3 per cent of cases (usually due to dissection), but the majority of these can be corrected by deployment of a stent, resulting in a need for emergency bypass surgery in less than 1 per cent of cases. The clinical consequence of vessel closure is often insufficient to justify surgery in vessels too small or distal for stenting.

The technology of guide, balloon, and guidewire systems has advanced to the point where few locations in the coronary anatomy are inaccessible. Totally occluded vessels can usually be successfully crossed with appropriate manipulation of the right guidewire, enabling successful angioplasty. The success rate for angioplasty of totally occluded vessels depends upon the age, length, and composition (thrombus versus plaque) of the occlusion; it is well over 90 per cent in cases of acute thrombotic occlusion, and over 50 per cent in cases of chronic occlusion (longer than 3 months).

The chief disadvantage of balloon angioplasty is the phenomenon of restenosis, which will be discussed in more detail later in this chapter, and which spurred the development of newer devices in the hope of circumventing restenosis.

Stenting

Stenting has become the intervention of choice in approximately 90 per cent of cases undergoing PCI. The term 'stent' is believed to originally derive from the name of an eighteenth-century British dentist who devised a compound for creating impressions of human teeth. A modern-day vascular stent is actually an armature, or internal skeleton, for restoring and maintaining the cylindrical structure of a diseased vessel. Most stents are made from a thin-walled, stainless-steel tube in which slots have been carved. The slotted tube is then mounted securely on a deflated angioplasty balloon and deployed at the target lesion of the coronary artery by inflating the balloon at high pressure with dilute contrast medium. When the balloon is deflated the stent remains expanded against the vessel wall, its slots stretched into diamond-shaped apertures (Fig. 3). Approximately 20 per cent of the vessel wall is covered by metal, the remainder being an intra-strut aperture. This accounts for the surprisingly high patency of side branches following stent deployment, and the ability to access these side branches when necessary for further intervention. A variation of the slotted-tube stent is a balloon-deployed coiled wire. Many recent stent designs are hybrids, which incorporate desirable properties of both the slotted-tube and coiled-wire designs.

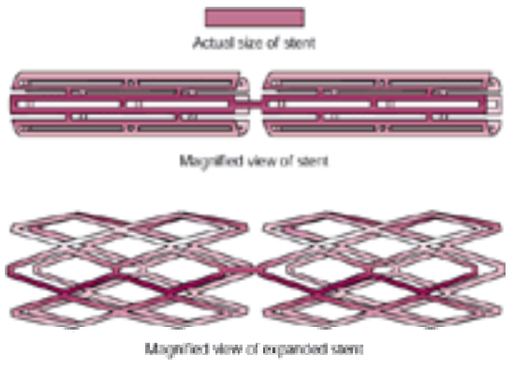

Fig. 3 A balloon-deployed coronary artery stent before (a) and after (b) deployment.

A somewhat different approach to stenting is the self-deploying, coiled-wire stent called the Wallstent. A coiled wire made from nitinol or another alloy with shape-retaining characteristics is compressed into a tubular delivery sheath, which is advanced over a guidewire across the target lesion. Once in its proper position the sheath is drawn back, allowing the stent to expand to its original size and shape (Fig. 4). As with slotted-tube stents, pre- or postdeployment dilation with a balloon may be necessary depending upon the nature of the lesion treated and the device used. Although it is one of the original stent designs, the self-expanding stent is used less commonly for coronary artery applications, but still finds use in many peripheral vascular cases.

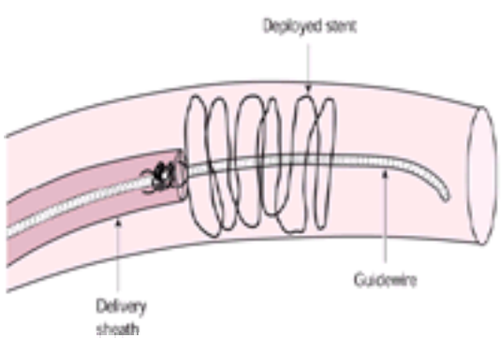

Fig. 4 A self-deploying coil stent. The stent unfurls as its delivery (containment) sheath is pulled back.

Stents have gained remarkable popularity mainly for three reasons. First, immediate complications are reduced because abrupt closure of the vessel due to dissection is less likely, emphasized by the fact that a stent is the best treatment for a balloon-induced dissection. Second, the immediate result is better in terms of the diameter and smoothness of the lumen, which turns out to be of more than cosmetic value because the early gain in lumen size relates directly to the late outcome. Finally, stents have been demonstrated in randomized clinical trials to be effective in reducing the likelihood of late restenosis.

However, stents do have some disadvantages, which include their propensity to subacute thrombosis, the persistence of some degree of restenosis (depending upon the size of the vessel and length of the lesion), and the fact that they cannot be deployed under some circumstances. Subacute thrombosis, a complication unique to stents, usually occurs within 10 days after stent deployment. By contrast to restenosis, which is a gradual phenomenon, stent thrombosis is usually sudden,

presenting as acute myocardial infarction and requiring emergency revascularization, usually by balloon angioplasty. The likelihood of subacute thrombosis has been reduced to less than 3 per cent by antiplatelet therapy with a combination of aspirin and clopidogrel or ticlopidine.

Directional coronary atherectomy

Directional coronary atherectomy (**DCA**) is achieved with a device illustrated in Fig. 5, which utilizes a rotating cylindrical blade that is advanced across an open aperture near the tip of a cone-shaped, guidewire-directed catheter. Opposite the aperture is an eccentric balloon, which when inflated compresses plaque of the opposite vessel wall into the aperture, where it is cut away by the rotating blade and pushed into the nose cone. The direction of the aperture can be rotated so that slices of plaque are removed in a radial fashion by multiple cuts taken at different locations around the circumference of the vessel. The catheter can then be withdrawn and the excised plaque removed from the nose cone. The catheter may be reintroduced, if necessary, for more atherectomy.

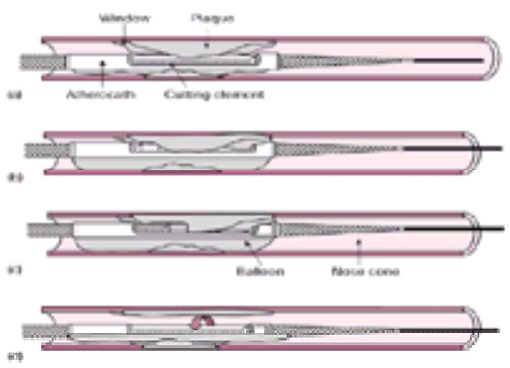

Fig. 5 Directional coronary atherectomy. The rotating cylindrical blade is advanced across the window of the housing and cuts away plaque, packing it into the nose cone.

Although DCA was originally devised with the hope of reducing the incidence of restenosis, it has failed to outperform balloon angioplasty in most circumstances. It has therefore assumed the role of a 'niche' technology, which is useful in particular situations such as very eccentric proximal lesions, and lesions involving the ostia of major side branches. Removal of plaque at branch points seems to reduce the likelihood of plaque shifting from one branch to another as the respective lesions are dilated with balloons or stents. DCA has the disadvantage of requiring a rather large, stiff device, limiting its application to proximal lesions of large vessels. Furthermore, the removal of plaque seems to have surprisingly little effect on restenosis. DCA is currently employed in less than 5 per cent of interventional cases.

Rotational ablation (Rotablator)

Rotational ablation (Rotablator) is a method of pulverizing plaque into particles smaller than the size of a capillary, which wash away with the circulating blood. This process is accomplished by means of a diamond-studded burr, which rotates at approximately 150 000 revolutions per min (Fig. 6) and is advanced along a guidewire into the plaque. The diamond studs on the forward face of the olive-shaped burr selectively cut into hard substances such as plaque and calcium, sparing the soft surface of normal tissue. During rotational atherectomy a vasodilating solution is infused into the artery proximal to the burr to prevent spasm and to maintain maximal coronary flow, which carries away particulate debris. Burrs are manufactured in sizes ranging from 1.5 mm to 2.5 mm in diameter. Atherectomy often requires the use of two or three burrs of progressively larger size until an adequate lumen size is achieved. Although occasionally used as a stand-alone procedure, rotational ablation is usually employed to 'debulk' lesions prior to final dilatation with a balloon or stent.

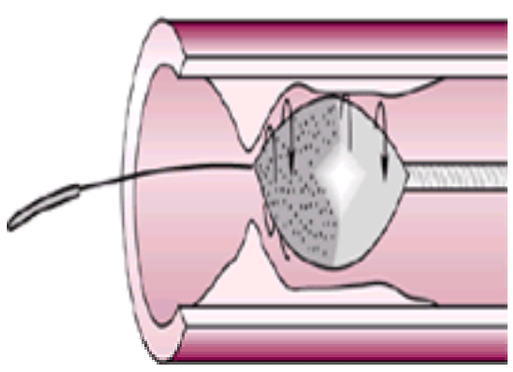

Fig. 6 Rotational atherectomy. The rotating burr pulverizes plaque as it is advanced over the guidewire into the lesion.

Like directional atherectomy, rotational ablation was originally conceived as a potential solution to the problem of postintervention restenosis. Unfortunately, it too has failed to outperform balloon angioplasty in this regard and has also assumed the role of a 'niche' device for special situations. It is most commonly used to treat restenosis within previously deployed stents, but it also finds application in the treatment of heavily calcified lesions that do not respond well to balloons and stents. It is also useful in treating diffuse, osteal, and bifurcating lesions. The frequency with which rotational ablation is employed varies by operator, but averages 5 to 10 per cent of most centres' cases.

Rotational ablation has the disadvantage of being a relatively expensive addition to other interventional modalities. It is unable to adequately increase the lumen of large vessels, and is contraindicated in lesions containing thrombus. Due to its tendency to transiently decrease contractility during the ablation process, it is also relatively contraindicated in patients whose left ventricular function is severely impaired.

Cutting balloon

The cutting balloon has several tiny longitudinally mounted blades which become erect when the balloon is inflated and create linear cuts along the vessel wall. This balloon is preferred by many cardiologists for initial treatment of stent restenosis. Its use is often followed by brachytherapy in order to reduce further the likelihood of another episode of stent restenosis.

Brachytherapy

The local, catheter based delivery of beta or gamma radiation is currently considered the best method for prevention of recurrent episodes of stent restenosis. Radiation is delivered with the assistance of a radiation therapist after initial treatment of stent restenosis with a cutting balloon, Rotablator, or conventional balloon. The benefit of brachytherapy appears to be limited to treatment of stent restenosis. It is not recommended following initial deployment of a stent. Brachytherapy also prolongs the period of risk for subacute thrombosis, making it necessary to treat patients with both aspirin and clopidogrel for at least 6 months following treatment.

Drug eluting stents

Polymer coated stents can be used locally to deliver drugs which inhibit the vessel's proliferative response to injury and therefore reduce the likelihood of stent restenosis. Drugs which have shown promise in preliminary trials include sirolimus (Rapamycin), taxol (and its derivative paclitaxel), and actinomycin.

Other devices

Distal protection devices are methods of capturing and collecting thrombus and other debris that may embolize distally from the target lesion during the use of many of the interventional tools mentioned above. They may be particularly beneficial during the treatment of old, degenerated vein grafts in which distal embolization is especially common.

Excimer laser coronary atherectomy (**ELCA**) employs a guidewire-directed fibreoptic catheter to deliver bursts of excimer laser energy to the plaque. Disintegrated plaque washes away in the circulation. However, ELCA has also failed to solve the restenosis problem, is used uncommonly at most centres, but remains the sole surviving member of a number of laser applications that have been tried and failed over the past 25 years. It finds its most frequent application in treatment of osteal lesions, stent restenosis, and diffuse calcified disease. Due to limitations of fibre size it is usually followed by balloon or stent treatment.

The transcutaneous excision catheter (**TEC**) device was developed at approximately the same time as directional coronary atherectomy and employs a rotating conical blade, which cuts away plaque and clot as it is advanced over a guidewire. The resulting debris is sucked back through the catheter into a reservoir outside the body. Although originally developed as an atherectomy device, it has found its chief application in treating clot-laden lesions. Nevertheless, it has not gained wide usage. More recently devised approaches to clot removal are the AngioJet and Excisor devices. The AngioJet uses the Venturi effect from a high-velocity jet of water, which draws thrombus into a window near the tip of a guidewire-directed catheter and propels it into a reservoir. The Excisor employs a helical screw at the end of a catheter, which breaks up the clot so that it can be withdrawn through the catheter. Both these devices currently find their chief application in the treatment of degenerated and clot-laden vein-graft lesions.

Complications

Percutaneous coronary intervention exposes the patient to all the potential complications of cardiac catheterization presented in Chapter 15.3.6. In addition, it carries the risk of other complications unique to interventional procedures. Most of these complications stem from four general processes, which account for most of the adverse outcomes from coronary artery intervention: abrupt closure, distal embolization, subacute stent thrombosis, and restenosis. When considering PCI for a patient, it is important to weigh the likelihood of these adverse outcomes against the expected chance of adverse events without intervention. The approximate frequencies of various specific complications from percutaneous coronary intervention are listed in Table 1. As in diagnostic catheterization, the likelihood of these complications is also dependent upon patient characteristics and operator skill.

Abrupt closure and distal embolization

Abrupt closure and distal embolization account for most of the immediate complications of PCI, especially acute myocardial infarction and emergency coronary artery bypass surgery. Dissection, spasm, and thrombosis are the leading causes of abrupt closure. The availability of stents has reduced the need for emergency bypass surgery to less than 1 per cent, because these are an effective treatment for acute dissection in most cases. Nevertheless, dissection sometimes extends with the addition of each stent, and occasionally the stent itself can be the cause of dissection at one of its edges. Acute thrombosis may occur in spite of routine prophylactic treatment with heparin and aspirin: glycoprotein IIb and IIIa inhibitors may stop this process and are often given prophylactically, especially in high-risk cases. Incomplete stent deployment seems to be a leading cause of thrombotic occlusion.

Distal embolization is surprisingly uncommon, except when patients have acute coronary syndromes or visible thrombus. It is especially troublesome for patients with degenerated or thrombus-laden vein grafts. Embolization may result in discrete occlusion of branch vessels or the phenomenon called 'no reflow', which is manifest by reduced flow without identifiable occlusion and thought to be due to capillary plugging from showers of microemboli.

In any case, either abrupt closure or no reflow often results in some degree of myocardial infarction. The frequency of this complication is a matter of how it is defined. Non-Q-wave infarction indicated only by a rise of creatine kinase enzyme is more common than Q-wave infarction.

Subacute thrombosis

Subacute thrombosis is a complication unique to stents, which occurs between 2 and 10 days following intervention and is manifest by acute myocardial infarction. It is a medical emergency that should be managed in a fashion similar to spontaneous acute infarction. Emergency reperfusion by balloon angioplasty is usually preferred, unless a catheterization laboratory is unavailable, in which case thrombolytic therapy is recommended. In the early days of stenting this complication occurred in over 3 per cent of cases in spite of vigorous anticoagulation including intravenous heparin and warfarin. This treatment required several days of hospital stay for the initiation of warfarin therapy and delayed the widespread acceptance of stenting. However, once the current treatment consisting of oral antiplatelet agents was proven to be superior, the length of hospital stay and local bleeding complications were reduced, and the use of stents grew rapidly. Subacute thrombosis now occurs in approximately 1 to 3 per cent of cases.

Restenosis

Restenosis remains the 'Achilles heel' of coronary intervention. In patients undergoing balloon angioplasty the likelihood of restenosis at 6 months following intervention is between 30 and 50 per cent if defined by angiographic stenosis of 50 per cent or greater, and approximately 25 per cent if defined by the clinical recurrence of symptoms. The use of stents has reduced the angiographic rate of restenosis to approximately 25 per cent and the clinical rate to as little as 10 per cent. The risk of restenosis varies depending upon the individual circumstances of each case: factors associated with restenosis include long lesions, small vessels, and suboptimal initial results.

Restenosis typically presents clinically as exertional angina at 1 to 6 months following intervention: if it is not present at 6 months, it is unlikely to occur. It is a gradual phenomenon, caused by the proliferation and migration of smooth muscle cells into the lumen of the treated vessel. Stents have been effective in reducing restenosis because they eliminate elastic recoil and generally result in a large lumen. However, smooth muscle cell migration is triggered by any form of vascular injury and takes place after stenting as well as other interventions. Attempts at reducing restenosis by pharmacological and mechanical means other than stenting have been largely unsuccessful. Brachytherapy, described above, is successful in reducing smooth muscle cell proliferation following repeat intervention. Other promising approaches under investigation include local gene therapy and local drug therapy delivered by coated stents or 'leaky' balloons.

Outcomes

Chronic stable angina

Randomized clinical trials have shown that patients with single- and double-vessel disease experience a more rapid and complete resolution of symptoms, and a greater improvement in treadmill exercise performance, when treated by balloon angioplasty rather than by pharmacological therapy for chronic stable angina pectoris. However, this comes at the price of a greater likelihood of repeat intervention or bypass surgery at 6 months, largely due to the need to treat restenosis. Nevertheless, the rate of bypass surgery becomes equal in both groups by 3 years.

When compared to coronary bypass surgery, angioplasty provides similar relief of symptoms and similar rates of mortality and myocardial infarction at 5 years' follow-up, with the exception of diabetic patients who have somewhat better 5-year survival rates when treated surgically. Otherwise, the main difference between patient groups randomly assigned to surgery or angioplasty is that repeat catheterization or revascularization is less frequent for those having surgery. Again, this difference is largely due to the effect of restenosis in the angioplasty group. Few of the interventionally treated patients in these trials received stents, so the likelihood of repeat procedures might be expected to be less using current devices.

Unstable angina

The choice between initial aggressive treatment (catheterization and revascularization) and initial conservative treatment (medical therapy with catheterization and revascularization only for those who have continued evidence of ischaemia) for patients with unstable angina has been controversial. However, one of the most recent

studies favours an aggressive approach to these patients.

Acute myocardial infarction

Percutaneous intervention has been shown to be an effective treatment for acute myocardial infarction, both as a salvage procedure after failed thrombolytic therapy and as a direct, initial approach to reperfusion. Randomized trials have shown that direct intervention is superior to initial thrombolytic therapy when performed in centres with expert interventionists and catheterization facilities that are available around the clock. In the general community setting this advantage has not yet been proven. In any case, direct PCI is the treatment of choice for patients in whom thrombolytic therapy is contraindicated and for patients who are haemodynamically unstable.

Economic considerations

The cost of equipment and supplies for percutaneous coronary procedures may become a limiting factor, particularly in developing countries and in healthcare systems with stringent budgets. Most catheters, guidewires, and other supplies are intended for one-time use. Expendable supplies alone cost approximately £500 ($US 800) for a simple balloon angioplasty procedure. That cost may be multiplied severalfold as multiple stents and Rotablator burrs are added to the list. Nevertheless, the cost of a single percutaneous revascularization procedure usually remains less than that of a comparable coronary bypass operation. However, when the added cost of repeat percutaneous revascularizations necessitated by restenosis is considered, the price difference between the two therapeutic approaches narrows.

Percutaneous balloon valvuloplasty

Allain Cribier of France developed the treatment of valvular stenosis by means of balloon catheters in the 1980s. The clinical utility of the procedure depends upon the valve treated and the age of the patient.

Mitral stenosis

Balloon valvuloplasty of the mitral valve has become the treatment of choice for selected patients with rheumatic mitral stenosis. The concept is similar to the aortic valvuloplasty illustrated in Fig. 7. The most common approach to the mitral valve is via trans-septal puncture of the left atrium from percutaneous access of the right femoral vein. After passing a stiff guidewire with a curved soft tip across the mitral valve, an appropriately sized balloon is centred on the valve and inflated with dilute contrast medium, tearing open the fused commissures and allowing the valve to open more normally. A dumbbell-shaped balloon, named after Dr Inoue, is often utilized, preventing the balloon from slipping off the valve during inflation. Clinical improvement, complications, and durability of the outcome from balloon mitral valvuloplasty have been shown to be comparable to surgical commissurotomy in appropriately selected patients. To be a candidate for balloon mitral valvuloplasty a patient must have no evidence of thrombus in the left atrium. Other features which auger poorly include immobility of the valve leaflets, severe calcification, thickening of the chordae tendineae, and more than mild regurgitation.

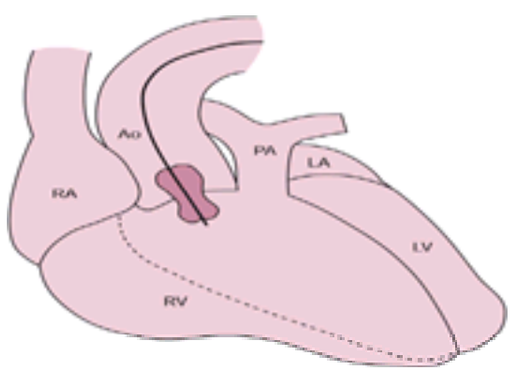

Fig. 7 Percutaneous balloon aortic valvuloplasty. The balloon is centred on the stenotic valve and inflated to tear open the fused commissures.

Aortic stenosis

Experience with balloon valvuloplasty for patients with aortic stenosis has been disappointing, largely due to an almost universal tendency for the stenosis to recur within 1 year. Consequently, the procedure is now performed only under unusual circumstances. It is occasionally used as a bridge to later surgery for patients who are initially too ill to safely undergo valve replacement. It is also sometimes performed for the temporary palliation of patients who are not candidates for valve replacement. In addition, it has a role for children with congenital aortic stenosis, where temporary treatment by valvuloplasty may allow the child to complete growth before requiring surgical valve replacement.

Pulmonic stenosis

Balloon valvuloplasty is the treatment of choice for patients with pulmonary stenosis. The majority are children whose valves respond well to this treatment. The advantage of avoiding surgery outweighs the moderate tendency for restenosis of these valves.

Percutaneous closure of cardiac defects

Atrial septal defects and patent ductus arteriosus can be closed percutaneously with catheter-delivered devices. One such device called a clamshell has been used for this purpose for a number of years, but has not yet gained wide acceptance.

15.4.2.5 Coronary artery bypass grafting

A. J. Ritchie and L. M. Shapiro

Introduction

Coronary artery bypass grafting (CABG) is one of the most effective therapeutic surgical interventions that can be undertaken. It can reliably be performed with a mortality of 1 to 3 per cent in complex groups of high risk patients, providing sustained and proven relief from the symptoms of angina, and high quality, event-free survival in up to 80 per cent of patients 10 years later. It is a unique procedure that has to be immediately effective if the patient is to survive: there is no room for recovery and rest of the organ as in almost all other forms of surgery. The role of CABG in the treatment if ischaemic heart disease is constantly evolving. Over the past decade, advances in all fields of cardiovascular medicine and surgery have taken place at an astonishing pace. This continues, such that discerning the role of the changing therapeutic options requires continuous reassessment. The purpose of this chapter is to define the role of CABG as it currently stands, discuss issues of particular relevance to physicians, to outline work currently under study, and to delineate likely future developments.

Historical perspectives of CABG

Cardiac surgery is the youngest surgical specialty. The earliest attempts by surgeons to treat ischaemic heart disease were aimed at avoiding operating on the heart altogether, for example endeavours to control the symptoms of angina by denervation with alcohol and phenol injections. Subsequently, it was claimed that 80 per cent of patients could have their angina abolished if the thyroid gland was removed, but the price was obvious—profound hypothyroidism.

In the early part of the twentieth century efforts were made to address the root cause, occlusive coronary artery disease, by indirect attempts at revascularization. These took the forms of attaching omentum to the heart, or inducing a pericarditis and inflammatory response. More directly, arterialization of the coronary sinus was achieved by connecting a vein graft from the aorta. In 1946, Vineberg implanted the bleeding end of the left internal mammary artery into the left ventricular wall.

Seminal to the development of modern cardiac surgery were technological advances that gave surgeons the time and opportunity to construct direct aortocoronary artery bypass grafts with the expectation of a successful outcome. These came in the form of cardiopulmonary bypass circuits and angiography, which allowed the identification and targeting of the epicardial arteries. Saphenous vein bypass conduits attached directly to coronary arteries by Johnson and Favaloro made direct coronary revascularization possible and this became achievable in routine operations, associated with low mortality and morbidity, and which were applicable to the vast majority of patients. They offered substantial benefits over previous therapeutic modalities for intractable angina pectoris. CABG passed from being possible to achievable.

Questions then arose about the applicability and affordability of CABG when compared to medical treatment, which was also evolving at the same time. The most important clinical trials that had a bearing on this were conducted in the 1970s and 1980s. The Veterans Administration Coronary Artery Surgery Study and the European Coronary Surgery Study were multicentre studies examining the efficacy of CABG versus medical management in different clinical situations. These landmark studies each had problems controlling variables and could not compensate for important improvements in treatment within each group and cross over from medical to surgical groups. In addition, different types of patient were enrolled in the various studies, making comparison between them difficult. However, in essence, they showed that surgery provided better relief of symptoms, improved functional capacity, and reduced the incidence of fatal myocardial infarction. They demonstrated that patients with left main stem and/or significant flow obstructing lesions in all three major coronary arteries (triple vessel disease) enjoyed a significant prognostic benefit compared with medical treatment. Those with impaired ventricular function benefited likewise from surgery. Hence, these flawed but crucial studies led to the development of broad clinical indications for CABG. These indications, together with others that are widely accepted in clinical practice, are summarized in Table 1.

The objectives of CABG

Rapid revascularization of ischaemic myocardium, no matter how achieved, dramatically improves outcome and survival. Complete reversibility of the changes that occur due to ischaemia can be achieved when perfusion is restored, providing the rational basis for thrombolytic therapy and mechanical revascularization, whether achieved by balloon angioplasty or CABG. The simplistic aim is to rematch oxygen supply with demand. However, recent studies indicate that where there is disease at the microvascular level, then epicardial revascularization alone is likely to be only of partial benefit. Advances in medical therapy that reduce mortality in ischaemic heart disease, such as aspirin, b blockade, aggressive treatment of hyperlipidaemia by HMG CoA reductase inhibition, and angiotensin-converting enzyme (ACE) inhibition were not available at the time of the early CABG versus medical trials outlined previously. These are likely to affect the microvasculature in addition to effects on disease of the main epicardial (coronary) arteries. We are therefore moving into an era where the control of risk factors may lead not only to a slowing of the progression of coronary disease, but even to its regression. This has major implications for defining the modern role of CABG, but the core objectives of mechanical revascularization remain the same:

1. revascularization of ischaemic areas of myocardium;
2. relief of anginal symptoms;
3. prolongation of patient survival;
4. prevention of myocardial infarction;
5. preservation of cardiac function;
6. improvement of quality of life, for example exercise tolerance.

The broad indications for CABG are to control symptoms where medication has failed and the patient remains unacceptably incapacitated by pain, and to improve prognosis when this is possible. Increased survival after coronary artery bypass surgery is seen in the following groups: left main stem stenosis, triple vessel disease, double vessel disease with left ventricular impairment, and left ventricular aneurysm.

The standard CABG operation

This involves the use of the left internal mammary artery and saphenous vein obtained from the leg as bypass conduits via a median sternotomy incision. The patient is then fully heparinized and cardiopulmonary bypass instituted, usually by cannulation of the ascending aorta and right atrium. When it is difficult to access these vessels safely, then femoral artery and vein cannulation provide a satisfactory alternative. The cardiopulmonary bypass machine provides continuous or pulsatile flow, oxygenates and removes carbon dioxide, and regulates the temperature of the blood. This leaves the heart isolated, allowing the operation to proceed. A range of techniques is then employed to reduce or stop heart movement and allow the construction of anastomoses. Inevitably these compromise the circulation to the heart and create myocardial ischaemia, creating a time limit within which the surgery must be completed. As directed by the angiogram, and in the knowledge that incomplete revascularization is a risk factor for premature death or recurrent angina, all technically suitable coronary arteries are bypassed distal to occlusive lesions. Where diffuse disease exists, or there is no lumen, an endarterectomy can be performed. As many bypass grafts as necessary can be constructed from available conduits using 'jump' grafts, but the usual number is three or four in patients with triple vessel disease. At the end of the procedure the patient is weaned from

cardiopulmonary bypass and returned to the intensive care unit.

Perioperative morbidity

Following a standard CABG procedure the patient must recover from the effects of cardioplegia and cardiopulmonary bypass as much as from the operation per se. The use of cardioplegia rarely causes perioperative myocardial infarction or more diffuse global myocardial ischaemia, thought to be due to reperfusion injury and resulting in myocardial stunning. This can result in a low cardiac output state, seen particularly in patients with impaired ventricular function or evolving infarction. Although this occurs in less than 2 per cent of cases, the changing case mix of the population undergoing cardiac surgery is resulting in operations on older, sicker, and higher risk patients (Table 2), such that these problems are likely to become more common. Several strategies are under investigation to improve cardioprotection, but in general the risk of complications rises with prolonged ischaemia and cardiopulmonary bypass times and in older patients; they are rare in routine elective cases.

The use of cardiopulmonary bypass results in local and systemic complications as outlined in Table 3. The most common form of arrhthymia after CABG is atrial fibrillation, occurring in up to 30 per cent of cases. This often delays patient discharge and carries extra risks for the patient, despite its usually transient nature. Ventricular arrhymias are much less frequently seen, but potentially much more serious, and usually indicate ongoing ischaemia.

Transient but diffuse cerebral injury resulting in short term memory and concentration loss are detectable by neurobehavioural comparison pre- and postsurgery in most patients undergoing CABG. By contrast, stroke is very rare, affecting less than 1 per cent of cases. Damage to other organs, in particular the development of acute renal failure, can follow cardiopulmonary bypass and the occurrence of a low output state.

Medical treatment and longer-term complications of patients who have undergone CABG

Routine medication in the immediate and long term almost always includes lifelong aspirin or other antiplatelet agent. There is little place for the use of warfarin, except in those patients who have undergone endarterectomy. Medications to control hypercholesterolaemia (statins) and hypertension (b blockers and ACE inhibitors) are increasingly being associated with improved survival and are usually lifelong treatments.

The patient has to recover from the operation before CABG can achieve its long-term goals. In the vast majority of cases there are no complications, when ambulation and return to exercise occurs within days. Initial stiffness and muscular aches can be expected, but there is no reason to advise against exercise or resumption of sexual activities for any specified period of time. By far the most frequent complaint that patients make is in relation to the saphenous vein harvest site. The ankle has a tendency to swell and the wound may be inflamed. This usually subsides quickly with rest and elevation. The increasing use of radial artery for conduits is associated with quickly healing, trouble-free wounds. A dull ache or burning pain in the chest can be associated with mammary artery harvest but usually recedes after 2 to 3 months.

Driving, riding bicycles, or other activities that put similar tensions on the chest should not be undertaken until the sternal base has a solid union, usually 6 to 8 weeks postoperatively. It is normally expected that patients who are working up until the time of their operation will be fit to resume work at 2 months postoperatively, although those employed in hard physical labour should be advised to recommence this carefully.

Other complications that can develop in the medium and long term are very rare. Postcardiotomy syndrome (Dressler's syndrome) presents as pain in the chest, which may be similar to angina but is associated with a pericardial friction rub and relieved by non-steroidal anti-inflammatory agents. Return of angina is the most sinister symptom, requiring further investigation and usually due to incomplete revascularization or occlusion of a bypass conduit. In diabetics this may be due to microvascular disease, the operation being conducted to confer prognostic benefit rather than relief of angina as its main aim.

Mortality

CABG is currently performed in over 1000 per million population in the United States and 300 to 700 per million population in Europe and Australia. It is the most documented and assessed operation ever performed. In the United Kingdom, mortality for first time CABG that includes elective and emergency cases has remained constant at 2 to 3 per cent over the last decade, with comparable figures in the United States. These data do not yet take account of risk stratification, the different nature, increased complexity, and age of patients currently referred, but there is clearly a range of outcomes, from less than 1 per cent mortality for a routine elective case to up to 10 per cent for rescue from acute percutaneous transluminal coronary angioplasty (PTCA) dissection.

Non-standard CABG procedures

Prior to the introduction of percutaneous transluminal coronary angioplasty (PTCA), CABG resulted in longer survival and better quality of life for patients with multivessel disease compared to medical treatment alone. Technological advances in PTCA and stenting now offer strategies in this group. The Bypass and Angioplasty Investigation (BARI) trial, a 5-year prospective comparison of CABG and PTCA in patients with multivessel disease, found no statistically significant difference in survival between the two groups (except for diabetic patients). However, the rate of reintervention or revascularization was 42 per cent in the PTCA group, compared with only 3 per cent in the CABG group, with 31 per cent of patients initially undergoing PTCA ultimately receiving CABG.

Standard CABG still has a major role to play in patients with multivessel disease, yet the invasive, expensive, and time-consuming nature of the operation are unattractive to physician and patient alike. While much has been done to limit the deleterious effects of cardiopulmonary bypass, reports in the last decade have continued to highlight the morbidity and mortality associated with its use. The introduction of PTCA has been seen as a way of avoiding these problems altogether and resulted in a dramatic shift of treatment paradigms, as well as driving new technical developments in surgery.

Total arterial revascularization

Cardiac surgeons no longer dispute the use of the left internal mammary artery as the choice for revascularizing the left anterior descending artery, pioneered in 1968. Critics doubted its ability to deliver enough flow and worried about morbidity associated with its harvest, particularly in diabetic patients. However, the use of single as well as double internal mammary artery grafts instead of saphenous vein has been convincingly demonstrated to improve survival and reduce recurrent angina and infarction without adding to morbidity or mortality. The outcome for the patient is longer survival and higher quality of life where revascularization is maintained by continued patency.

In the past, the issue of conduit patency was not accorded primary importance because progression of disease distal to the original site of anastamosis was thought to be the major determinant of outcome. However, this view has changed with appreciation of the time-related failure of saphenous veins due to accelerated atherosclerosis and the advent of a new era of medical interventions (aggressive lipid lowering strategies etc.). These may prevent progression of disease and stabilize acute plaque fissure, or even lead to disease regression, meaning that the long-term patency of the conduit becomes the major determinant of success or failure of CABG. The current trend in CABG is therefore to utilize a range of arterial conduits with similar biological properties, for example radial artery, gastroepiploic artery. Increased use of total arterial revascularization in combination with control of risk factors is likely to reduce significantly the requirement for redo CABG, with its attendant risk for the patient and cost to society.

Off pump coronary artery bypass

The initial work in coronary artery bypass grafting was done in an era before cardiopulmonary bypass was established. In 1967, Kolessov performed grafts to left anterior descending and circumflex through a left thoracotomy without bypass, and various reports over the following 7 years demonstrated the safety of off pump CABG in large, single centre cohorts of patients. However, the introduction and refinement of cardiopulmonary bypass made an extraordinary difference to our ability to provide definitive surgical management. Additionally, dramatic improvements in survival at and beyond surgery came with advances in cardioplegia, allowing a dry operative field and a protected myocardium. Such was the rapid advance in these technologies that the original method of CABG was abandoned, but off pump techniques are now being used again.

Minimal access CABG procedures, conducted through minimally invasive incisions, are capable of producing effective and long lasting anastomosis off pump in single vessel disease. The main shortcomings of this approach are the limited number of vessels that can be bypassed, that is primarily the left internal mammary to left

anterior descending arteries, and morbidity from minithoracotomy wounds. It is likely to be applicable to less than 10 per cent of the overall patient population, but because of the significant reintervention rate following PTCA and the associated problem of in-stent stenosis, the off bypass and minimal access CABG procedure has immense potential and may revolutionize coronary revascularization in a large group of patients.

Minimally invasive procedures in cardiology and surgery can have significant advantages for both patients and institutions: reduced recovery time, reduced requirement for intensive care, and shorter hospital stay. Costs can potentially be reduced in the short and long term, with quicker return to normal life. These procedures are patient and industry driven: audit data is disseminated on the internet, and many patients in the United States and Europe now actively seek off pump CABG procedures. Well-designed, randomized, prospective, controlled trials are needed in this area.

The future for CABG

The last decade has seen marked and rapid advances across all aspects of medical and surgical management of ischaemic heart disease, making it difficult to discern the optimal treatment strategy. Innovation in CABG surgery is likely to utilize total arterial conduits in short operations, possibly done without the use of cardiopulmonary bypass. It remains to be seen in whom these advances are best applicable, and how affordable they are in competition with percutaneous interventional techniques. However, single episode, short duration operations with unrivalled long-term patency provided by arterial conduits and backed up by preventative cariological medications are likely to be cheaper and more efficacious than currently available interventional alternatives.

15.4.2.6 The impact of coronary heart disease on life and work

M. C. Petch

Introduction

Coronary heart disease is common and lethal (Table 1 and Table 2). In developed countries, heart attacks account for about a quarter of all deaths. Death is usually sudden. These facts are well known and have a profound influence on attitudes towards the victims of heart disease. Employers are reluctant to take back people who have lost time off work as a result of a heart attack. Spouses become overprotective. The survivors are acutely aware that they have received an intimation of their mortality; some fail to cope. The first manifestation of coronary heart disease, which is usually chest pain, prompts re-evaluation of the remainder of life and work. The spectre of cardiac pain and death hangs over many a middle-aged man, including employers, politicians, public health physicians, journalists, and others in positions of influence. In most developed countries there is therefore public pressure to prevent the development of coronary disease (primary prevention), to prevent a recurrence (secondary prevention), and to put in place measures which will reduce the risk of harm to the individual and others in the event of sudden incapacity/death of a worker in a 'safety-critical' job.

Women are not of course immune, but coronary heart disease does tend to strike later, often after usual retirement age. Nevertheless the impact of coronary heart disease can be as devastating: older women are often the most important carers in a family. Whilst there are minor differences between the sexes in the presentation and management of coronary heart disease, the comments in this chapter should be taken to apply to both sexes.

Life before coronary heart disease

Most people do not think about their health until it goes wrong. With advancing years people become aware that their contemporaries are suffering from mortal diseases. They then belatedly begin to look at their own lifestyle. Many believe the results of the latest research quoted in the press and attempt to adapt their habits by increasing their intake of vitamin E, or fish oil, or red wine, or by reducing the amount of coffee and animal fat that they consume, or by undergoing stress counselling, or by purchasing an exercise machine which they never use. Then along comes a new report which sets another fashion.

There are a few public health issues on which the medical profession can speak with authority. Cigarette smoking is the prime example. Doctors, nurses, and other health-care professionals have a duty to discourage this habit by example and by persuasion. No other habit enjoys such powerful evidence that mandates a lifestyle change. Regular exercise is to be commended. A prudent diet is capable of different interpretations, but the old adage 'a little of what you fancy does you good' dates back many generations to a time when coronary heart disease was much less common. Food can be one of life's great pleasures. The current political ambition to change national lifestyles is not heeded by those most at risk and has never been clearly shown to have lasting benefit.

A sensible compromise for most societies is to prevent smoking, encourage exercise, promote the sale of fruit, vegetables, and so on, and to reduce the availability of 'junk' foods in shops and workplace canteens, but not to go to such lengths that people feel guilt when faced with a delicious steak. The fact that this Epicurean attitude is shared by most doctors makes it all the more persuasive. The use of drugs such as aspirin and statins to reduce the risk of a coronary event can likewise only be justified in those individuals whose risk is especially high, as judged by their family history and other risk factors.

Health screening is another controversial topic. In (over)developed societies screening services have become very popular and assessment of cardiovascular risk in businessmen is a useful source of income for some clinics. Certainly the measurement of blood pressure can be supported and, in some circumstances, the estimation of serum lipids. Beyond that the advice that may be offered boils down to common sense—don't smoke, take more exercise, eat less.

Occasionally health screening can create extreme anxiety, for example when an electrocardiogram or exercise test suggests silent coronary disease. These investigations can only be justified when the individual is aware of the possible outcomes of screening and/or is in a safety-critical job.

Life and work with coronary heart disease

The risk of sudden disability and death through ventricular fibrillation is the major factor affecting work capacity amongst victims of coronary heart disease. The risk is greatest in the early days following the development of symptoms and in those with most myocardial damage.

Common sense and experience (i.e. clinical judgement) remain the best tools for assessing an individual's fitness to resume his life and work following the development of coronary heart disease. The onset of cardiac pain, or change in the nature of pain in someone with known ischaemic heart disease, should prompt rapid evaluation. Stable angina pectoris, preferably confirmed by exercise testing, usually requires no change in lifestyle: modern drug therapy is very effective and often comprises just aspirin, glyceryl trinitrate, and a statin. Unstable angina or myocardial infarction is a different matter and necessitates hospital admission, with further investigation. Even then clinical judgement remains the basis for advice about lifestyle changes, supplemented by 'non-invasive' tests.

The presence of myocardial failure and/or significant areas of ischaemia are the principal determinants of prognosis. The former may be identified by history, clinical examination, chest radiography, and echocardiography; the latter by the development of angina and electrocardiographic ST-segment shift on exercise testing. An exercise test may also reveal cardiovascular incapacity in other ways, for instance exhaustion, inappropriate heart rate and blood pressure responses, and arrhythmia.

Following myocardial infarction or unstable angina, assessment of prognosis along the lines outlined above is recommended: those with no complications and good exercise tolerance may return to work in about 4 weeks. This applies particularly to younger individuals whose employers need have little hesitation in taking them back to their former job, perhaps part-time initially. A few will take longer to recover, and some will need a change of job.

Limitation of working capacity and the risk of sudden incapacity can both be well judged in populations by specialist opinion, aided by the results of 'non-invasive' tests. However, the progression of coronary disease can be unpredictable, and individuals judged to be at low risk from further cardiovascular events can suffer recurrences. This difference between the individual and the population is not well understood by employers and employees and can be a source of misunderstanding and confusion. Nevertheless, individual exceptions do not invalidate the principles on which recommendations for individuals are made.

Coronary angioplasty/stenting

Patients with persistent angina, or those with a very abnormal exercise response, should undergo coronary arteriography with a view to myocardial revascularization. Coronary angioplasty is nowadays straightforward, safe, and effective in relieving angina. Resumption of normal activities, including work, is normally possible a few days afterwards. Recurrent angina is much less common with the more widespread use of stents, but it remains a problem in 10 to 20 per cent of patients and hence

regulatory authorities remain cautious about those individuals whose performance might be compromised by a return of cardiac pain.

Coronary artery bypass grafting

Coronary artery bypass grafting is also remarkably safe, with most centres reporting mortality rates of less than 1 per cent for elective operations. Recovery is rapid and most patients resume work within 2 to 3 months of surgery. Most are relieved of their angina. Patients who were able to work before surgery should generally be able to do so afterwards, and restrictions that may have been appropriate previously should no longer be relevant. However, since surgery is a dramatic event, it may prompt overprotective attitudes amongst family members, friends, employers, or even medical advisers. Many individuals who could and should return to work fail to do so for this reason, rather than because of continuing incapacity. No special restrictions are usually necessary after return to work. Coronary graft stenosis and occlusion leads to recurrence of angina at a rate of about 4 per cent per annum. This is generally less severe than previously but will affect long-term occupational planning. Unfortunately, waiting times for coronary arteriography and bypass surgery in some countries (such as the United Kingdom) are very long, so that many patients do not return to work.

Rehabilitation programmes

Rehabilitation programmes are now well established in many hospitals and communities. These enable patients to make a full physical and psychological recovery following a cardiac event such as myocardial infarction or coronary artery bypass grafting. An acceptable exercise response is a prerequisite for enrolment into a rehabilitation programme. The participants are thus the fittest survivors, selected for physical retraining on the strength of their satisfactory performance on the treadmill. Definite measures of benefit, such as reduction in recurrent myocardial infarction or death, are lacking.

However, the fashion for cardiac rehabilitation is undeniable and seems to owe much to the enthusiasm of the participants—patients and staff alike. This may be a comment on modern cardiology with its mechanistic approach, haste, and failure to recognize the psychological effects of heart attacks, with concomitant need for lifestyle advice. Sex, for example, is rarely discussed except in rehabilitation classes, yet for many patients it is a burning issue. The mechanistic view is that the physical effort required is equivalent to two flights of stairs or stage 3 of the Bruce protocol. The psychological aspects are probably better dealt with in a rehabilitation class (or perhaps the bar afterwards). With health-care budgets always under pressure, it is reasonable to suggest that the demand for rehabilitation might perhaps best be satisfied on a voluntary basis, and that scarce resources may be better directed elsewhere, for example towards the drug budget, where outcome benefits are measurable.

Risk evaluation: the 1 per cent rule

Workers whose sudden incapacity would place themselves and others at risk are described as being in 'safety-critical' jobs. The traditional approach to this dilemma was to exclude anyone with heart disease from working in such an environment. This may still be appropriate in certain occupations where any increased risk of incapacity is unacceptable: drivers of mainline passenger trains and captains of ocean-going vessels are two current examples. This blanket exclusion is patently unfair to some, and may waste the skills and experience of a valued employee. Also, no individual is totally free of risk of an incapacitating event, so a few accidents as a result of sudden illness are inevitable in apparently normal people. A better approach is therefore to define what level of risk is acceptable, and then decide whether the medical condition places that individual within the predetermined limits of acceptability. This has the great merit of objectivity and is a well-tried engineering practice.

The Civil Aviation Authority was the first to adopt this approach with what is now known as the '1 per cent rule'. Aircraft engineers have always recognized that a disaster may occur as a result of component failure, and have recommended design and safety features so that the risk of failure is 'extremely improbable' ($1/10^{-9}$ flying hours). This approximates to a risk of an incapacitating event in a pilot of 1 per cent per annum if a number of assumptions are made. A pilot with a medical condition may therefore be regarded as a component of aircraft safety and hold a licence if his risk of a cardiovascular event is comparable, that is, his risk is no greater than his peers or other parts of the aircraft.

There are a number of difficulties in applying the approach described above in other situations and in other industries. First, who decides an acceptable level? Second, the epidemiological data in cardiovascular medicine generally describe events such as death or heart attack, which may not be the relevant parameter. Heart attacks are a rare cause of road traffic accidents; more commonly the driver is found in his vehicle on the verge, 'slumped over the wheel with the engine still running'. Death may have been sudden in epidemiological terms, but it was not instantaneous; the victim had sufficient warning to pull over to the side of the road. Third, some incapacitating events, neurocardiogenic syncope for example, are clearly relevant to many safety-critical jobs, and yet there are scant data on which to base an objective decision. Fourth, cardiovascular event rates have fallen since the 1 per cent rule was formulated.

Risk evaluation: exercise testing

The data on exercise testing in coronary heart disease are the best established for evaluating the risk of incapacity in employees in safety-critical jobs, for example vocational driving. The guidelines relating to vocational drivers were developed in the United Kingdom and adapted by a Task Force of the European Society of Cardiology. They are now being applied more widely to other groups of workers whose occupation may involve an element of risk to themselves or others should that individual suffer cardiovascular collapse.

The protocol for which most information is available is that described by Bruce. He and Fisher examined strategies for risk evaluation of sudden cardiac incapacitation in men in occupations affecting public safety: 2373 men with clinically manifest coronary artery disease who had undergone exercise evaluation were followed up for a mean of 61 months; 300 sudden cardiac incapacitations (cardiac arrest or sudden cardiac death) occurred. Exercise testing in all age groups defined low- and high-risk populations with annual incapacitation rates of 1 and 3 per cent, respectively. The former were those who could reach stage 3 of the Bruce protocol with no chest pain, attain 85 per cent of age-predicted maximal heart rate, and manifest less than 1 mm of ischaemic ST-segment depression. A similar message came from the study of 4083 medically treated patients in the Coronary Artery Surgical Study registry. The 32 per cent of patients who could exercise into stage 3 of the Bruce protocol with less than 1 mm ST-segment depression on ECG (10 METS) had an annual mortality of 1 per cent or less. By contrast, the annual mortality rate of the 730 patients with 2 mm or greater ST depression was 3.6 per cent, ranging from 5.6 per cent for those patients achieving stage 1 or less of exercise to 2.0 per cent for those patients achieving stage 3. The study also confirmed the overriding prognostic importance of left ventricular function and the poor survival of patients with heart failure. An ability to exceed stage 3 of the Bruce protocol with less than 2 mm of ST-segment depression is the best criterion for identifying a population with an annual risk of death of less than 2 per cent.

Driving

Since decisions concerning fitness to drive should be objective and evidence-based whenever possible, a similar approach to that described for pilots is being adopted. An attempt is also being made to be consistent, so that all forms of illness that might cause sudden incapacity should be considered in comparable manner. One condition for which good data are available is epilepsy. Currently the agreed, annual, acceptable levels of risk in the United Kingdom are 2 per cent for vocational drivers and 20 per cent for ordinary drivers: a driver's licence entitlement can be determined by reference to well-validated tables of risk, for example following a head injury. Risks for drivers with cardiovascular disorders are less easy to quantify because of the poor relationship between the presence of the disease process and the risk of incapacity. However, some drivers with heart disease can be identified as being at an increased risk of an incapacitating event, and attempts are being made in the transport industry and elsewhere to provide objective criteria, which will be applicable across a range of disease processes.

The '2 per cent rule' may prove to be the correct criterion for vocational drivers and other workers in similar occupations who suffer from cardiovascular disorders. Society already accepts drivers with vocational licences up to the age of 80 years, by which time their annual risk of a cardiovascular event is 4 per cent. If the assumption is made that half of the events are incapacitating then the acceptable risk accords with the epilepsy criteria, so those drivers whose annual risk of a cardiovascular event is 4 per cent (or death 2 per cent) or greater should not be entitled to hold a vocational licence.

For ordinary drivers a 20 per cent annual risk also seems reasonable for cardiovascular disorders; such level of risk is in accord with existing guidelines, for instance shortly after a heart attack. Ordinary driving may be resumed 1 month after a cardiac event provided that the driver does not suffer from angina which may be provoked at the wheel. Vocational driving may be permitted at 6 weeks, subject to a satisfactory outcome from non-invasive testing. In the United Kingdom, ordinary driving licence holders do not need to notify the Driver and Vehicle Licensing Agency (**DVLA**), Swansea if they have made a good recovery and have no continuing disability, but vocational drivers must notify the DVLA. Insurance companies vary in their requirements, but most policies are temporarily invalidated by illness.

Special circumstances

Toxic substances

Work involving exposure to certain hazardous substances may aggravate pre-existing coronary heart disease and careful consideration should be given to patients who are returning to jobs involving exposure to chemical vapours and fumes. Methylene chloride, a main ingredient of many commonly used paint removers, is rapidly metabolized to carbon monoxide in the body and, in poorly ventilated work areas, blood levels of carboxyhaemoglobin can become elevated enough to precipitate angina or even myocardial infarction. A blood carboxyhaemoglobin level of 2 to 4 per cent has been shown to be associated with impairment of cardiovascular function in patients with angina pectoris. The World Health Organization recommends a maximum carboxyhaemoglobin level of 5 per cent for healthy industrial workers and a maximum of 2.5 per cent for susceptible persons in the general population exposed to ambient air pollution: this level may also be applied to workers whose jobs entail specific exposure to carbon monoxide, such as car park attendants and furnace workers. To ensure that the 2.5 per cent carboxyhaemoglobin level is not exceeded, the ambient carbon monoxide concentration should not be higher than 10 ppm over an 8-h working day: equivalent to exposure to the current occupational exposure standard (50 ppm) for no more than 30 min. Occupational exposure to carbon disulphide in the viscose rayon manufacturing industry is a recognized causal factor of coronary heart disease but the mechanism remains unclear.

Reports of sudden death from angina are well recognized in dynamite workers, particularly after a period of 36 to 72 h away from work and following re-exposure, an effect almost certainly related to direct action of nitroglycerine on the blood vessels of the heart or peripheral circulation. Persons with clinical evidence of coronary heart disease should avoid occupational exposure to these substances.

Solvents, such as trichloroethylene or 1,1,1-trichloroethane, may cause sudden death in workers receiving heavy exposure in poorly ventilated workplaces. The chlorofluorocarbon CFC-113 has been implicated in sudden cardiac deaths and CFC-22 has been reported to cause arrhythmias. Some industrial workers will need proper assessment of their workplace by an occupational physician and occupational hygienist so that they can be advised on their suitability for work handling chlorinated hydrocarbon solvents or involving exposure to gases.

There are no formal medical requirements for workers who have to enter confined spaces where there may be hazards of oxygen deficiency or a build up of toxic gases. Those with heart disease or severe hypertension may need to be excluded. Certain occupations may require the use of special breathing apparatus either routinely (e.g. asbestos-removal workers), or in emergencies (e.g. water workers handling chlorine cylinders). The additional cardiorespiratory effort required whilst wearing a respirator, combined with the general physical exertion that may be required, usually means that people with a previous history of coronary heart disease are excluded from such work.

Hot conditions

Working in hot conditions may prove difficult for some patients with heart disease. High ambient temperatures or significant heat radiation from hot surfaces or liquid metal, added to the physical strain of heavy work, will produce quite profound vasodilatation of muscle and skin vessels. Compensatory vascular and cardiac reactions to maintain central blood pressure may be inadequate and lead to reduced cerebral or coronary artery blood flow. The resulting weakness or giddiness could prove dangerous. Since many cardioactive drugs have vasodilating and negative inotropic actions, some reduction in dosage may be necessary.

Cold conditions

Cold is a notorious trigger of myocardial ischaemia and caution must therefore be exercised for individuals who suffer from coronary heart disease. Impaired circulation to the limbs will result in an increased risk of claudication, risk of damage to skin (frostbite), and poor recovery from accidental injury to skin and deeper structures.

Stress

The idea that psychological stress has a role in the aetiology of coronary heart disease is a persistent one, owing much to the work of Friedman and his colleagues who suggested that hectic work patterns marked by long hours, competitiveness, time urgency, and aggression (so-called type A behaviour) may predispose to the development of coronary heart disease. The results of other epidemiological and clinical studies have been conflicting, much of the difficulty arising from the criteria for identifying a type A personality. The idea that a stressful incident may trigger a heart attack is also well embedded in Western culture. Some studies have shown a relationship, for example after earthquakes. But generally psychological stress is not regarded as sufficient provocation to form the basis of a legal settlement. Such stress may, however, on occasion provoke angina in susceptible individuals. Patients and their relatives can almost invariably point to a stressful incident prior to a heart attack and may fail to appreciate that life is a series of stressful incidents, heart attacks are extremely common, and coincidences are inevitable. The only trigger of a heart attack that has withstood critical scrutiny (and legal cross-examination) so far is sudden unaccustomed vigorous effort within 2 h of the attack.

Travel

Following a cardiac event such as myocardial infarction, individuals should convalesce at home and not travel far for 4 to 6 weeks. Those with no evidence of continuing myocardial ischaemia or heart failure can then travel freely within their own country for pleasure, for example a holiday. Business and overseas travel is more problematical because the physical and psychological demands are greater. Additional difficulties for the overseas traveller include the uncertain provision of coronary care facilities in some countries and the justifiable reluctance of insurance companies to provide health cover. Such travel is best deferred until 3 months have elapsed and any necessary further investigations and treatment have been carried out to ensure cardiovascular fitness.

Overseas travel for those with continuing cardiovascular unfitness need not be ruled out. Utilizing the airport services for disabled travellers can ease a passenger through customs, passport control, and so on, at major airports. Modern aircraft can be very comfortable. The cabins are kept at a pressure equivalent to 2000 m so that those with angina are not likely to experience an attack. Businessmen with continuing cardiac disorders may therefore fly to Europe, North America, and other countries with good coronary care services with very little risk. But flights in unpressurized aircraft, work in undeveloped countries or in remote areas of the world, and work in a hostile environment (both climatic and political) are best avoided.

Aircrew are subject to guidelines drawn up by the Joint Aviation Authorities. In the United Kingdom the regulatory agency is the Civil Aviation Authority, whose advice should always be sought.

Cardiac deaths are uncommon in trekkers or workers at high altitude (2440 to 4570 m.). The increase in cardiac output at altitude will exacerbate symptoms in those who already experience symptoms at sea level, but asymptomatic individuals with coronary heart disease are unlikely to be at special risk.

Implanted devices

Cardiac pacemakers are generally implanted into older patients who have idiopathic degeneration of their conduction system. However, both heart block and sinoatrial disorder are well-recognized complications of coronary heart disease. Single- and dual-chamber (VVI and DDD in most) pacemakers are rarely subject to electromagnetic interference and no modification of lifestyle is necessary, with the exception that the device can trigger alarms at airports and elsewhere.

The implantable cardioverter defibrillator (**ICD**) has the capacity to detect and treat ventricular tachycardia and fibrillation, either by antitachycardia pacing or by a shock, in patients in whom a further cardiac arrest is anticipated. Both shock and arrhythmia are potentially incapacitating. In North America and Europe, patients with ICDs have restrictions placed upon them, for example driving. They commonly have severe underlying heart disease and may well not be able to work, but if they can do so, then this should be in an environment that is free from electromagnetic interference. There has been one report of ICD malfunction in the vicinity of an electronic antitheft surveillance system.

There has been considerable interest in the possibility that mobile telephones might interfere with pacemakers and ICDs. Studies have shown that this is a theoretical possibility and that reprogramming of a pacemaker can be achieved under exceptional circumstances if the telephone is held close (less than 20 cm) to the pacemaker. In practice no clinically significant interference has yet been reported, but individuals are advised to use the hand and ear furthest from the pacemaker

and not to 'dial' with the telephone near to the pacemaker.

Seafarers

The Merchant Shipping (Medical Examination) Regulations in the United Kingdom currently state that any manifestation of ischaemic heart disease renders the individual permanently unfit to return to sea. This regulation has been in force since 1983 and applies to all those seafarers who serve in vessels registered in the United Kingdom above a certain size (a small coaster upwards). This does not necessarily apply to vessels registered in other countries. These regulations will almost certainly change, the likely outcome of current discussions being that acceptable levels of risk will be defined, both for the individual and for the job.

Retirement and end of life

Despite modern treatments some patients will experience multiple coronary events which eventually lead to extensive ventricular damage and persisting symptoms of fatigue and dyspnoea, with signs of heart failure. Such individuals should be warned of their limited prognosis. Some should be advised to retire, which is never an easy decision.

There is often a discrepancy between the symptoms and the objective cardiac data. Some patients—typically the overweight, smoking, manual worker in his forties, who has always enjoyed robust good health—appear to be very symptomatic despite good ventricular function and no evidence of myocardial ischaemia. A heart attack proves devastating. One explanation for this is the profound psychological disturbance that sometimes follows the development of cardiovascular disease. At the other extreme some patients seem well and active despite appalling ventricular function. As always, common sense has to override the results of investigations, but the latter group are still liable to experience sudden cardiac death, when apparently 'so well'.

Patients (with their partners if appropriate) should be given the opportunity of a frank discussion about their prognosis, but some would rather not know and that attitude should be respected. However, most need to put their affairs in order: what to say exactly is one of the most difficult problems in cardiology. The victim's quality of life may be excellent. There is no point in advising a restricted lifestyle or retirement. The only lifestyle trigger of a heart attack, namely sudden unexpected vigorous exercise, should be avoided. Otherwise, normal activities should continue, with the knowledge that the chance of successful resuscitation following a coronary event are greater in developed countries, in fact better in most of Europe and North America than the United Kingdom.

Early retirement on grounds of ill health following a heart attack is sometimes seen as an attractive option. However, most permanent sickness policies contain a clause which states that benefit will only be payable if the subscriber is 'totally unable to follow his former occupation', which is often not the case after a heart attack or coronary artery bypass grafting. Advice about retirement should only be given after due consideration and a review of the job description.

15.5.1 Pharmacological management of heart failure

J. K. Aronson

There are three aims in treating heart failure: if possible, to remove causative factors and so reverse the condition; otherwise, to relieve symptoms and to improve survival. Examples of reversible causes include valvular disease, hypertension, anaemia, and hyperthyroidism. Symptomatic relief can be produced by the use of diuretics to relieve fluid retention, vasodilators to reduce the workload of the heart, and digitalis to increase cardiac contractility. Positive inotropic drugs other than digitalis (for example, inhibitors of phosphodiesterase type III) are not currently used in the long-term treatment of congestive heart failure, because they are associated with increased mortality. By contrast, reduction in mortality during long-term treatment of heart failure can be achieved with angiotensin-converting enzyme (**ACE**) inhibitors, spironolactone, beta-blockers, and the combination of hydralazine with a nitrate.

Mechanisms of action of drugs used to treat heart failure

The ways in which drugs affect the major pathophysiological abnormalities of heart failure are shown in Fig. 1, and a list of the drugs used is given in Table 1.

Fig. 1 The pathophysiology of cardiac failure and the sites and mechanisms of action of drugs used in its treatment. (Taken with permission from Grahame-Smith DG, Aronson JK (2001). *The Oxford textbook of clinical pharmacology and drug therapy*, 3rd edn. Oxford University Press, Oxford.)

The effects of heart failure and of some of the drugs used to treat it on the relation between cardiac output and ventricular end-diastolic pressure (the Frank–Starling curve) are shown in Fig. 2. In established heart failure the curve is displaced downwards. It may be possible to increase cardiac output (for example, by increased endogenous sympathetic drive), but that can only happen at the expense of an increased ventricular end-diastolic pressure, and eventually signs and symptoms of congestion occur. If cardiac output cannot be increased, the signs are of low output (for example in cardiogenic shock).

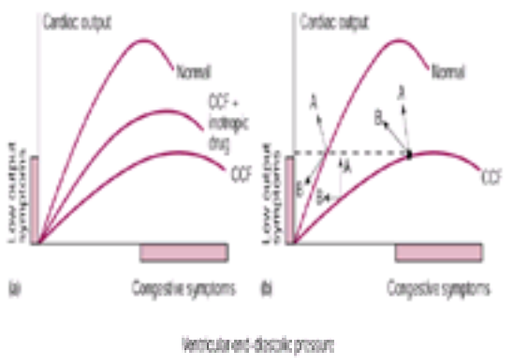

Fig. 2 The Frank–Starling curve, shown here as the relation between ventricular end-diastolic pressure and cardiac output. (a) The effect of positive inotropic drugs: inotropic drugs increase the cardiac output for any given value of end-diastolic pressure. (b) The effects of vasodilators: the effects of vasodilators depend on whether they are predominantly arterial vasodilators (A: for example hydralazine) or mixed vasodilators (B: for example ACE inhibitors). ((a) Adapted with permission from Mason DT (1973). *American Journal of Cardiology* **32**, 437–48. (b) Adapted with permission from Braunwald E (1980). *Heart disease*, p. 548. WB Saunders, Philadelphia.)

Diuretics

Sodium and water retention occur in heart failure through a combination of mechanisms, including reduced renal blood flow, increased ADH secretion, and increased renin secretion, leading to increased secretion of angiotensin and aldosterone. Diuretics reduce the body sodium and water content. Their sites of action in the renal tubule are shown in Fig. 3.

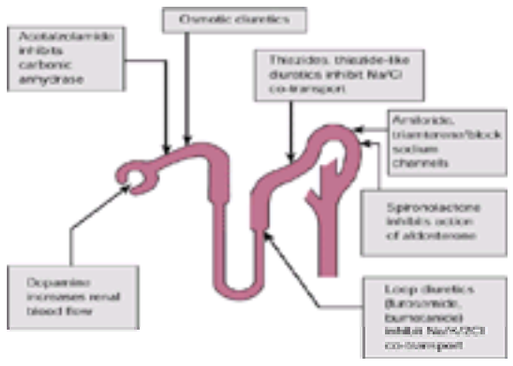

Fig. 3 The sites of action of diuretics in the nephron (Taken with permission from Grahame-Smith DG, Aronson JK (2001). *The Oxford textbook of clinical pharmacology and drug therapy*, 3rd edn. Oxford University Press, Oxford.)

The loop diuretics furosemide and bumetanide inhibit sodium and chloride reabsorption in the ascending limb of the loop of Henle, with a resulting increase in sodium excretion and a reduction in free-water clearance. They do this by inhibiting Na/K/2Cl cotransport. In addition potassium secretion in the distal convoluted tubule is increased, because of the exchange of potassium for sodium under the influence of aldosterone and an increased intraluminal sodium concentration. Note, however, that the effects of furosemide and bumetanide in the treatment of acute left ventricular failure occur more quickly than would be expected from the rate of onset of their diuretic actions; vasodilator effects may be involved in their acute actions.

The thiazide diuretics act by inhibiting sodium and chloride reabsorption in the distal convoluted tubule of the nephron, resulting in increased sodium and free-water clearance. The molecular mechanism of this effect is through the inhibition of a Na/Cl cotransport system. A secondary effect is the loss of potassium by increased secretion in the distal tubule in response to the increased intraluminal sodium concentration.

Spironolactone and its active metabolite canrenone are aldosterone receptor antagonists; they counteract the effects of hyperaldosteronism that can occur from heart failure itself, and as a secondary response to the natriuresis produced by other diuretics. In a low dosage (25 mg/day) spironolactone reduces mortality in congestive heart failure, presumably by inhibiting the effects of aldosterone, circulating concentrations of which are markedly increased in heart failure. Other potassium-sparing diuretics (amiloride and triamterene) do not interfere with the action of aldosterone; instead they inhibit sodium channels in the distal tubule. They are used only as potassium-sparing diuretics and have not been shown to affect mortality.

The effect of diuretics on the Frank–Starling curve is to lower the ventricular end-diastolic pressure.

ACE inhibitors and angiotensin receptor antagonists

ACE inhibitors, which reduce mortality in chronic heart failure, reduce the production of angiotensin II and prevent the breakdown of bradykinin, both of which are mediated by the angiotensin-converting enzyme (ACE). They are mixed arteriolar/venular vasodilators, mostly by their action on angiotensin production. Because angiotensin causes aldosterone release, the ACE inhibitors also reduce aldosterone production, which reduces sodium retention, leading to reduced blood volume and a fall in cardiac preload.

The ACE inhibitors do not completely prevent the effects of angiotensin on the myocardium, because some angiotensin II is produced by the action of a convertase that is not inhibited by ACE inhibitors. Angiotensin II receptor antagonists, which are selective for angiotensin II type 1 receptors, act beyond this point and prevent the effects of angiotensin II at its site of action. They do not affect the production of bradykinin.

b-Adrenoceptor antagonists

In chronic heart failure, particularly in patients with milder disease, the risk of sudden death is increased; b-blockers reduce that risk through an antiarrhythmic action. They also mitigate the effects of catecholamines, which are produced in excess due to increased sympathetic nervous system activity in heart failure. In some patients there is poor ventricular relaxation during diastole, which can be obviated by b-blockers. However, great care must be taken, because their negative inotropic effect can lead to worsening of heart failure. In addition to being a b-blocker, carvedilol is an a $_1$-adrenoceptor antagonist and therefore also a vasodilator.

Positive inotropic drugs

Positive inotropic drugs increase cardiac output at any given value of ventricular end-diastolic pressure, thus shifting the Frank–Starling curve upwards. Of drugs with positive inotropic effects only the cardiac glycosides are currently used in the long-term treatment of congestive heart failure. They act by inhibiting sodium transport out of cells, through inhibition of the Na+/K+ pump enzyme Na+/K+-ATPase. The resultant increase in the intracellular sodium concentration leads to altered calcium flux via the Na+/Ca2+ exchange mechanism, and thus to an increased intracellular calcium concentration. This leads to increased contractility through excitation–contraction coupling. The long-term use of other positive inotropic drugs increases mortality in heart failure; digoxin does not.

Other vasodilators

Vasodilators reduce the workload of the heart by dilating arterioles or venules, or both. Dilatation of arterioles results in a reduction in cardiac afterload; dilatation of venules results in a reduction in cardiac preload. A pure reduction in afterload increases the cardiac output at a given ventricular end-diastolic pressure, while a pure reduction in preload reduces the ventricular end-diastolic pressure and hence the cardiac output along the Frank–Starling curve. In practice, vasodilators cause both these effects. This is because a reduction in arterial resistance (reduction in afterload) increases ventricular emptying (which in turn reduces preload), and venous dilatation (reduction in preload) reduces ventricular volume (which in turn reduces afterload). In both cases cardiac output increases and ventricular end-diastolic pressure falls. However, the extent to which these two effects occur depends on whether the vasodilator acts predominantly on arterioles or venules. For example, nitrates are mixed vasodilators, but the venous element predominates, reducing filling pressure. The effects of different vasodilators on arterioles and venules are shown in Table 2.

Clinical pharmacology of drugs used to treat heart failure

Diuretics

All the thiazide diuretics are well absorbed and excreted unchanged by the kidney. They have a slow onset and long duration of action, with half-lives of about 8 to 12 h, and are given once a day. Hypokalaemia, hyponatraemia, and dehydration are their most important adverse effects, and hypomagnesaemia can also occur. Hypokalaemia due to thiazide diuretics potentiates the effects of cardiac glycosides and can cause ventricular arrhythmias, such as *torsade de pointes*, in patients taking antiarrhythmic drugs that prolong the QT interval. Hypercalcaemia can occur in susceptible patients, due to reduced urinary calcium excretion. Hyperglycaemia occurs but is usually not of clinical importance, although occasionally diabetes mellitus may be precipitated in a susceptible patient; increased doses of oral hypoglycaemic drugs may be required in diabetics. Hyperuricaemia occurs, but acute gout is uncommon. Erectile impotence can occur in men. Thiazide diuretics reduce the clearance of lithium by the kidney; lithium dosages should be halved initially and adjusted with careful serum concentration monitoring.

In contrast to the thiazide diuretics, furosemide and bumetanide have a rapid onset and short duration of action (about 6 to 8 h), with half-lives of between 1 and 2 h. Bumetanide is well absorbed after oral administration, but furosemide is not, and its absorption may be slowed in patients with congestive heart failure. For this reason patients who do not respond to oral furosemide should be given intravenous furosemide or oral bumetanide instead. Despite their short duration of action these drugs are usually given only once a day, partly to avoid night-time diuresis and partly because, at least in the case of furosemide, the kidney is refractory to further diuresis for about 8 h after an effective dose. If furosemide is given intravenously in doses of 80 mg or more it should be infused at a rate of 4 mg/min, partly to avoid ototoxicity and partly because it is more effective when infused slowly, for reasons that are not understood. The adverse effects and interactions of the loop

diuretics are similar to those of the thiazides, except that the loop diuretics are calciuric. Acute urinary retention can be precipitated by too rapid a diuresis in patients with prostatic hyperplasia. Encephalopathy can be precipitated in patients with hepatic insufficiency, particularly if hypokalaemia occurs. Rapid intravenous injection of high doses of furosemide can cause cochlear damage, which is usually reversible. Bumetanide can occasionally cause muscle cramps, independent of hypokalaemia.

Spironolactone is well absorbed. It has a short half-life (about 10 min) but is metabolized to the active compound canrenone (half-life 16 h), which is excreted by the kidney. Partly because of the long half-life of its metabolite, spironolactone has a long duration of action and its maximum effects develop over several days. Nausea and vomiting are common, but not with the low doses currently used to treat heart failure. Hyperkalaemia can occur and is dose-related. Gynaecomastia is common, even with low dosages, and is often painful. Other less frequent effects include menstrual disturbances, impotence, testicular atrophy, and peptic ulceration.

Amiloride is very poorly absorbed. It is almost completely excreted unchanged in the urine and has a half-life of 6 h. Triamterene is incompletely but fairly rapidly absorbed from the gastrointestinal tract. It is extensively metabolized before urinary excretion and its half-life is 2 h. It has variable biliary excretion. Both amiloride and triamterene commonly cause hyperkalaemia, dehydration, and hyponatraemia. The incidence of hyperkalaemia (about 5 per cent) is unaffected by the concurrent administration of potassium-depleting diuretics. Nausea and vomiting occur occasionally. Triamterene can cause crystalluria and rarely causes interstitial nephritis, particularly when it is used in combination with thiazide diuretics; renal prostaglandins may protect the kidney against this damage and this protection may be lost if patients also take non-steroidal anti-inflammatory drugs.

Angiotensin-converting enzyme inhibitors

The ACE inhibitors are variably absorbed: captopril and enalapril are well absorbed, ramipril is moderately well absorbed, and lisinopril is slowly and poorly absorbed (25 per cent or less); the absorption of captopril and enalapril is reduced to 50 per cent by food. Lisinopril is eliminated unchanged in the urine; captopril is 50 per cent excreted unchanged and 50 per cent metabolized to inactive compounds; and the other ACE inhibitors are prodrugs that are metabolized to active forms. The half-lives of the ACE inhibitors are long, because they bind to ACE in the plasma.

Hypotension can occur with ACE inhibitor overtreatment—particularly if the intravascular volume is depleted by concurrent diuretic therapy—and is most common after the first dose, which should therefore be low and taken whilst the patient is lying down. Cyclo-oxygenase inhibitors, such as indometacin, can reduce the hypotensive effects of the ACE inhibitors.

The ACE inhibitors can cause renal function impairment, particularly in those with renovascular disease and especially unilateral renal artery stenosis; this is because the perfusion pressure in the ischaemic kidney depends on the action of locally produced angiotensin. Proteinuria and the nephrotic syndrome are uncommon adverse effects; the latter is due to a membranous glomerulonephritis. ACE inhibitors inhibit the excretion of lithium.

The ACE inhibitors cause potassium retention by inhibiting aldosterone secretion, and potentiate the effects of other drugs that cause hyperkalaemia, for example, potassium-sparing diuretics or potassium chloride supplements.

Rashes are common (up to 10 per cent) and may be accompanied by fever and eosinophilia. Taste disturbance, which is usually transient, occurs in up to 5 per cent of patients. Cough is the commonest adverse effect requiring drug withdrawal. Angio-oedema occurs rarely. Although neutropenia is rare, it may progress to agranulocytosis.

b-Adrenoceptor antagonists (b-blockers)

Some properties of some commonly used b-blockers are shown in Table 3. Most are well absorbed; atenolol, nadolol, and sotalol, being relatively polar, are exceptions, at 50 per cent or less. During their first passage through the liver carvedilol, metoprolol, and propranolol are extensively metabolized to active compounds, which are excreted in the urine. Bisoprolol is 50 per cent metabolized, but without first-pass elimination. Atenolol and sotalol are mostly eliminated unchanged in the urine. Those b-blockers that are used to treat patients in heart failure (bisoprolol, carvedilol, and metoprolol) have durations of action that roughly correlate with their half-lives.

Blockade of b_2-adrenoceptors in the lungs in susceptible subjects can cause bronchoconstriction, which can lead to life-threatening acute severe asthma. Hence, non-selective b-blockers should not be given to asthmatics, and even relatively selective b-blockers should be used with caution, if at all, since none is completely devoid of some b_2-adrenoceptor antagonist activity.

b-Blockers have negative inotropic effects: careful dosage titration and monitoring of therapy is therefore important in patients in whom they are being used to treat heart failure. In patients with poor left ventricular function after myocardial infarction D-sotalol increased mortality from 3 to 5 per cent (the SWORD trial), probably because of cardiac arrhythmias secondary to prolongation of the QT interval.

Central nervous system effects (depression, hallucinations, sleep disturbances) are more common with lipophilic drugs, which enter the brain well (see Table 3). Peripheral vasoconstriction, resulting in Raynaud's phenomenon, which is particularly troublesome in cold weather, is a common complaint, the precise mechanism of which is still not understood.

If a b-blocker is to be withdrawn, this should be done slowly, since abrupt withdrawal can cause a rebound increase in anginal symptoms or frank myocardial infarction, possibly related to adaptive b-adrenoceptor supersensitivity in response to chronic blockade.

Carvedilol can cause postural hypotension because of its a-blocking action.

Drug interactions with b-blockers occur through a variety of mechanisms:

- The effects of insulin and oral hypoglycaemic drugs are potentiated by b-blockers, and hypoglycaemia can result. There is some evidence that this effect is more pronounced with non-cardioselective b-blockers. This interaction is distinct from the effect of b-blockers in blocking the peripheral clinical response to hypoglycaemia, except for sweating, which is a sympathetic nervous function not served by catecholamines.
- Cimetidine inhibits the first-pass metabolism of propranolol and metoprolol and the metabolism of bisoprolol.
- When b-blockers and verapamil are used concurrently there is an increased incidence of bradyarrhythmias and an increased risk of heart failure. There have also been reports of asystole attributed to the use of the combination.
- Sotalol should not be used in combination with other antiarrhythmic drugs that prolong the QT interval (for example, amiodarone, disopyramide, procainamide, quinidine), nor with the antimalarial drug halofantrine, which does the same.
- Monitoring the plasma digoxin concentration during carvedilol therapy is recommended, since carvedilol has been reported to increase plasma digoxin concentrations.

Cardiac glycosides

Digoxin is moderately well absorbed from tablets (about 67 per cent) and better from elixir (80 per cent) and encapsulated elixir (more than 90 per cent). It is mostly eliminated unchanged by the kidneys, with a half-life of about 40 h when renal function is normal, increasing to about 5 days in complete anuria. Dosages must therefore be reduced in renal insufficiency (see below). It has a fast onset of action after oral administration so that intravenous administration is rarely justified; intramuscular injection is painful and causes muscle necrosis and should be avoided.

Digitoxin, in contrast, is almost completely absorbed after oral administration, has a long half-life (about 5 days), and is eliminated by hepatic metabolism. This makes its effects less predictable than those of digoxin, because hepatic metabolism is more variable than renal excretion. However, some prefer it to digoxin, particularly when there is severe renal insufficiency. There are no advantages to using other cardiac glycosides (such as ouabain, acylated forms of digoxin, gitoformate, gitoxin, k-strophanthin, pengitoxin, and proscillaridin).

The adverse effects of the cardiac glycosides are dose-related. Common non-cardiac effects include: anorexia, nausea, vomiting, and diarrhoea; confusion and acute

psychiatric disturbances, particularly in old people; and visual disturbances (photophobia, blurring of vision, disturbances of colour vision). Virtually any cardiac arrhythmia can occur, the commonest being ventricular and supraventricular ectopic arrhythmias. Atrioventricular nodal conduction can be impaired, leading to heart block. The combination of an ectopic arrhythmia and heart block (for example, paroxysmal supraventricular tachycardia with block) is particularly suggestive of glycoside toxicity. Bradycardia occurs occasionally, but is often simply an effect of parasympathetic stimulation in a resting patient without glycoside intoxication.

The adverse effects of cardiac glycosides are enhanced by electrolyte disturbances, especially: hypokalaemia, hypercalcaemia, and hypomagnesaemia; hypoxia and acidosis; hypothyroidism; and old age (due to increased tissue sensitivity).

Drug interactions are common with digoxin. Hypokalaemia due to other drugs (for example diuretics) markedly enhances its effects and should be avoided. Drugs that inhibit P-glycoprotein, which mediates the renal tubular secretion of digoxin, increase plasma digoxin concentrations and the risk of toxicity; these include amiodarone, ciclosporin, quinidine, spironolactone, and many of the calcium channel blockers, notably verapamil. Quinidine also alters the tissue distribution of digoxin and reduces its non-renal clearance; this combination is better avoided. The antibiotics erythromycin, clarithromycin, and tetracycline increase the oral systemic availability of digoxin by inhibiting its breakdown by intestinal bacteria, mainly *Eubacterium glenum.* The metabolism of digitoxin is increased via enzyme induction by drugs such as rifampicin and barbiturates.

Cardiac glycoside plasma concentrations should be carefully monitored. This can be of value in individualizing therapy, in monitoring compliance, and in diagnosing digitalis toxicity. It is worth measuring the plasma (or serum) concentration during the initial stages of therapy to ensure that a reasonable target concentration has been achieved (1.0 to 2.0 nmol/l for digoxin, 10 to 20 nmol/l for digitoxin). A cautious increase in dosage is justifiable if there is still a poor response to treatment, but the risk of toxicity starts to rise markedly at plasma concentrations above 2.0 and 20 nmol/l respectively. If there are subsequent changes in the patient's condition, for example renal insufficiency in a patient taking digoxin, measurement of the plasma concentration may help in readjusting dosages. Toxicity is highly likely at plasma concentrations above 3.0 nmol/l (digoxin) or 30 nmol/l (digitoxin); at concentrations below 1.5 or 15 nmol/l respectively, toxicity is unlikely. However, toxicity can occur even with low concentrations and should particularly be suspected if there is hypokalaemia. Certain factors besides potassium depletion increase the risk of digitalis toxicity at a given plasma concentration (see above); these alter the interpretation of the plasma concentration and lower the threshold of suspicion of toxicity.

Other vasodilators

Hydralazine

Hydralazine is well absorbed and extensively metabolized, principally by acetylation. This has a bimodal distribution in the general population, but the half-life of hydralazine (about 4 h) does not differ much between people who are slow and fast acetylators. This is because acetylation occurs mainly during the first passage through the liver, hence the subsequent rate of clearance is not appreciably related to the rate of acetylation; however, patients who are slow acetylators are exposed to more of the parent compound.

Palpitation and tachycardia, nausea, vomiting, diarrhoea, and postural hypotension are all common adverse effects. An arthropathy resembling rheumatoid arthritis or a syndrome similar to that of systemic lupus erythematosus (so-called lupus-like syndrome) can occur with dosages over 200 mg/day, especially in those who are slow acetylators. Hydralazine-induced lupus is more common in patients with the HLA phenotype DR4.

Nitrates

In contrast to glyceryl trinitrate, which is completely metabolized in the liver after oral administration and cannot therefore be given orally, isosorbide dinitrate is absorbed from the gut and extensively metabolized to its active metabolites: especially isosorbide mononitrate, which is itself metabolized. Isosorbide dinitrate and isosorbide mononitrate are therefore active after oral administration, the half-life of isosorbide dinitrate being 1 h and that of isosorbide mononitrate being 4 h, which rate-limits the kinetics of isosorbide dinitrate.

Vasodilatation can cause throbbing headache, sinus tachycardia, and hypotension. Tolerance to the actions of the nitrates occurs with prolonged administration, for example if transdermal patches are left on the skin continuously, or if modified-release formulations are taken without a long enough gap between doses. This can be minimized or avoided by removing the patch for a few hours each day (for example, overnight) or by leaving at least 14 h between the night-time dose of a modified-release formulation and the next morning's dose. The mechanism of this tolerance is not known, but hypotheses include depletion of tissue sulphydryl groups (causing reduced transformation of organic nitrates to nitric oxide), desensitization of guanylyl cyclase, increased vascular production of superoxide anions, changes in plasma volume, and increased production of vasopressin. An attractive theory is that chronic vasodilatation in response to nitric oxide causes a compensatory increased production of the vasoconstrictor endothelin via activation of the renin–angiotensin system.

Patients who take sildenafil concurrently with a nitrate may experience profound hypotension; this combination should be avoided.

Angiotensin receptor antagonists

Candesartan esters are rapidly and completely de-esterified during absorption to candesartan, the systemic availability of which is low, and which is partly metabolized and partly excreted in the bile. Irbesartan is rapidly and completely absorbed and subject to only slight presystemic metabolism; it is metabolized by glucuronidation and oxidation by CYP2C9. Losartan is well absorbed but is subject to extensive presystemic metabolism by CYP2C9 and CYP3A4—one metabolite is active, and is inactivated by further metabolism. The metabolites are excreted in the bile and systemic availability is doubled in patients with liver disease. Valsartan has a systemic availability of about 0.25, which is reduced to about 0.15 by food. It is mostly excreted in the bile. The half-lives of these drugs or their active metabolites range from 6 to 12 h.

As with the ACE inhibitors, hypotension can occur with overtreatment, particularly if the intravascular volume is depleted by concurrent diuretic therapy. Similarly, the angiotensin receptor antagonists should be used with caution in patients with renal insufficiency, since they can cause impairment of renal function, particularly in those with renovascular disease. Hyperkalaemia can occur, but is uncommon. Angio-oedema is rare. Because they do not affect kinins the angiotensin receptor antagonists do not cause cough.

Practical management of heart failure

Acute left ventricular failure

Acute left ventricular failure producing pulmonary oedema is a medical emergency, requiring treatment with oxygen, morphine or diamorphine, a loop diuretic, and vasodilators if required.

Oxygen should be given in a high concentration by face-mask or nasal cannulae. Furosemide 40 mg, or bumetanide 1 mg, is given intravenously (**IV**), followed by 10 mg of morphine IV, via the same needle. If there is a poor response to this regimen, the dose of morphine is repeated and a higher dose of diuretic given. Intravenous vasodilators should be used in patients with severe left ventricular failure, for example glyceryl trinitrate or isosorbide dinitrate, but glyceryl trinitrate can be given sublingually (0.5 mg) or by transdermal patch (5 mg) as a stop-gap. Such treatment should ideally be monitored with the measurement of pulmonary artery wedge pressure using a Swan–Ganz catheter, but this may not be practicable, in which case careful monitoring of the systemic blood pressure is necessary to avoid a systolic pressure below 95 mmHg. Glyceryl trinitrate is given as an IV infusion through a syringe pump in a dosage of 10 to 200 µg/min—starting with no more than 10 µg/min, increasing as necessary, and monitoring the response. The dose of isosorbide dinitrate by IV infusion is between 2 and 10 mg/h.

Cardiac glycosides can also be used in the treatment of acute left ventricular failure, particularly when this is associated with fast atrial fibrillation. However, they increase the risk of cardiac arrhythmias after myocardial infarction.

In the rare circumstance of acute left ventricular failure due to acute severe hypertension, the blood pressure should be lowered rapidly (see Chapter 15.16.3).

Acute left ventricular failure due to iatrogenic fluid overload can be prevented by the use of a loop diuretic. For example, during blood transfusion in a patient with chronic anaemia and therefore a normal intravascular volume, furosemide 20 mg IV should be given immediately before each unit of blood, which should be infused

as slowly as possible.

Chronic heart failure

Diagnosis on the basis of symptoms and signs, assisted where possible by echocardiography, should be made as soon as possible, because of the improvement in prognosis promised by ACE inhibitors and spironolactone; such therapy should be begun as early as possible. Information on left ventricular function is immensely helpful in assessing severity, appropriate treatment, response, and prognosis. Appropriate action is indicated if a primary cause is selectively correctable, unsuspected aortic valve disease in the elderly being a common example.

A drug history is essential. Non-steroidal anti-inflammatory drugs cause sodium retention and can tip patients into heart failure. Many calcium channel blockers are negatively inotropic, and short-acting calcium blockers increase the risk of heart failure and should be avoided. Some antiarrhythmic agents are negatively inotropic. Most b-blockers (outside of their careful use, as described below) can be deleterious. Tricyclic antidepressants are best avoided.

Salt intake should be moderated. Hypertension must be treated, and ACE inhibitors can relieve both heart failure and hypertension. It is important that plasma electrolytes, urea, and creatinine be measured, so that renal function can be monitored during treatment.

Assuming that drug therapy is indicated and there is left ventricular dysfunction, then, although diuretics may bring symptomatic relief, an ACE inhibitor should also be used. These two drug categories are now the mainstay of therapy and can be supplemented by spironolactone, which also reduces mortality. In severe cases or when ACE inhibitors are contraindicated or poorly tolerated, there is a case for further vasodilator therapy with hydralazine plus isosorbide dinitrate or mononitrate. Cardiac glycosides as positive inotropic agents still have a place.

It is not yet known whether different types of heart failure require different types of pharmacological management. Currently there is not enough evidence to guide the selection of therapy in different patients, and choices among different types of drugs are generally made on the basis of contraindications and adverse effects rather than positive indications.

Diuretics

The choice of diuretic depends on the severity of heart failure. In mild heart failure a thiazide or thiazide-like diuretic is sufficient (see Table 1). The most commonly used of these diuretics in the United Kingdom are bendroflumethiazide (5 to 10 mg once daily, orally) and cyclopenthiazide (0.5 to 1.0 mg once daily, orally), but there is no particular advantage in using one thiazide rather than another.

Oral loop diuretics are used in cases of more severe heart failure; for example, furosemide 40 to 160 mg once daily or bumetanide 1 to 5 mg once daily. If there is a poor response to either a thiazide or a loop diuretic, the two types can be combined.

In the Randomized Aldactone Evaluation Study (**RALES**), 822 patients were randomly assigned to receive spironolactone 25 mg/day and 841 to receive placebo. There were significantly fewer deaths in the spironolactone group (284 versus 386), with fewer deaths from progressive heart failure and fewer sudden deaths from cardiac causes. There was also a reduced frequency of hospital admission for worsening heart failure and a significant improvement in the symptoms of heart failure. Most of the patients were taking an ACE inhibitor. Spironolactone 25 mg/day should be given routinely to all patients with congestive heart failure.

In using potassium-wasting diuretics care should be taken to avoid hypokalaemia, especially in old people and in patients taking cardiac glycosides. In patients who are also taking an ACE inhibitor and even a low dose of spironolactone, extra measures to conserve potassium are generally unnecessary. It is not known whether higher doses of spironolactone than 25 mg/day are also associated with a beneficial effect on mortality. If extra potassium-sparing is required it is probably wise to use potassium chloride supplements (to repair depletion) or another potassium-sparing diuretic (amiloride or triamterene) (to prevent further depletion).

ACE inhibitors

ACE inhibitors are now widely considered to be the first-line treatment for chronic heart failure, in combination with a diuretic. Several large studies have shown they improve symptoms and reduce morbidity and mortality in patients with left ventricular dysfunction. A systematic review of 32 randomized, controlled clinical trials in symptomatic heart failure showed that ACE inhibitors reduced mortality by 28 per cent, independent of the ACE inhibitor used. Treatment with an ACE inhibitor also reduced the number and duration of hospital admissions. There was a reduction in mortality of about 8 per cent in patients with asymptomatic heart failure (but see the results of the HOPE study mentioned below).

When starting treatment with an ACE inhibitor in a patient who is already taking a diuretic, particularly a high-efficacy (so-called 'high ceiling') loop diuretic, care must be taken not to cause serious hypotension. If a patient is in severe heart failure and taking a large dosage of a loop diuretic, or is hypovolaemic, or has hyponatraemia (plasma sodium concentration of 130 mmol/l or less), has renal impairment, is taking other vasodilator therapy, or is frail and elderly, it is wise to admit them to hospital for initiation of therapy. Diuretics should be stopped for 24 h, a low dose of a short-acting ACE inhibitor (preferably captopril) should be given, blood pressure should be monitored both when the patient is lying and standing, and the dosage of the ACE inhibitor should only be increased when one is satisfied that serious hypotension has not occurred. If the systolic blood pressure is less than 100 mmHg, if there is clinical heart failure, and if diuretic therapy has already been given, it is unlikely that ACE inhibitor therapy will be tolerated, but each case must be taken on its merits.

Despite all these cautions, it is possible to start some patients on an ACE inhibitor in the community. Diuretics should be stopped for at least 24 h; the first low dose should preferably be given in an environment in which blood pressure monitoring is possible; and the dosage should be increased very gradually.

The effects of ACE inhibitors in the treatment of heart failure are dose-related. The recommended maximal doses are those that have been shown to be efficacious and set as limits beyond which toxicity, namely hypotension, becomes a frequent and unacceptable problem. Thus, the maximal dose for captopril is 50 mg three times a day, for enalapril 20 mg/day, and for lisinopril 20 mg/day. Of these, the author prefers enalapril, which has a longer duration of action than captopril and is better absorbed than lisinopril. However, since the publication of the results of the Heart Outcomes Prevention Evaluation (**HOPE**) study, ramipril has become more widely used. In this study 9297 high-risk patients (aged 55 or over), with vascular disease or diabetes plus one other cardiovascular risk factor and who were not known to have a low ejection fraction or heart failure, were randomly assigned to receive ramipril (10 mg/day) or placebo. Ramipril reduced the death rates from cardiovascular causes (relative risk 0.74), myocardial infarction (0.80), stroke (0.68), death from any cause (0.84), revascularization procedures (0.85), cardiac arrest (0.63), heart failure (0.77), and complications related to diabetes (0.84).

b-Adrenoceptor antagonists (b-blockers)

Despite much evidence that b-blockers are beneficial in patients with chronic heart failure, particularly in preventing sudden death in patients with mild or moderate disease, there is understandable reluctance to use them, because of the risk of worsening heart failure through impaired myocardial contractility. Certainly they should not be used in patients with severe heart failure (New York Heart Association class IV); indeed, in patients with severe heart failure the b-blocker xamoterol increases mortality. However, if b-blockers are used in patients with milder forms of heart failure, and in very low initial doses with very gradual dosage increases, the evidence is that they are relatively safe and reduce all-cause mortality (risk ratio about 0.7) and cardiac deaths (risk ratio about 0.6). As yet, however, there is no evidence about their efficacy in direct comparison with ACE inhibitors and spironolactone, nor information about whether the combination of a b-blocker with such drugs produces further increases in benefit. Current trials are comparing different b-blockers with each other and b-blockers with ACE inhibitors. It is not known whether digoxin can mitigate the negative inotropic effect of b-blockers in patients with chronic heart failure (although one would expect it to do so), nor how such a combination would affect mortality.

In my view, b-blocker therapy should currently be initiated only by a specialist in hospital. It should be limited to patients with moderate heart failure at worst, despite optimal doses of diuretics, an ACE inhibitor, spironolactone, and digoxin, if indicated. For carvedilol the initial dose should be 3.125 mg and the patient should be observed for a few hours after the first dose. If there is no evidence of worsening heart function 3.125 mg can be given twice daily for 2 weeks, after which a further dosage increase to 6.25 mg twice daily can be attempted. The dosage can be further increased, no more often than every 2 weeks, to a maximum of 50 mg twice daily, and at each stage the patient should be carefully monitored for a few hours after the first dose for evidence of worsening cardiac function. Daily monitoring of body weight is also important, and if a patient's weight increases by 2 kg or more they should report to their doctor; an increase in the dosage of diuretic may help in such cases. The corresponding initial and maximum doses of other b-blockers of proven efficacy in heart failure are: bisoprolol 1.25 mg/day and 10 mg/day;

metoprolol 12.5 mg/day and 200 mg/day. The class III antiarrhythmic drug D-sotalol increases mortality after myocardial infarction, suggesting that the racemic form DL-sotalol, which also has b-blocking activity, should be avoided in such patients.

Cardiac glycosides

The positive inotropic effects of cardiac glycosides can be useful in reducing symptoms (mainly breathlessness) in patients already taking diuretics and ACE inhibitors. However, the beneficial effect is small and digoxin does not reduce mortality during long-term therapy. However, it does have a small effect in reducing hospital admission rates; there is also evidence that heart function deteriorates in about 25 per cent of patients after withdrawal, so there may still be a role for digoxin in a few patients who need extra symptomatic relief. It is also the drug of choice for treating atrial fibrillation in patients with congestive heart failure. Set against this is the difficulty in using it properly and the high risk of toxicity, particularly in older people, who have poor renal function and are prone to hypokalaemia, particularly if they are also taking diuretics.

Cardiac glycosides should not be used, or are ineffective, in the following conditions:

- left ventricular outflow obstruction (for example, aortic stenosis, hypertrophic obstructive cardiomyopathy), since they increase the force of contraction against a fixed obstruction;
- constrictive pericarditis, for an analogous reason;
- chronic cor pulmonale, because of reduced efficacy and an increased risk of toxicity, perhaps secondary to hypoxia and acidosis;
- hyperthyroidism, because of reduced efficacy and an increased risk of toxicity, although they may be useful in addition to a b-adrenoceptor antagonist in patients with atrial fibrillation and to some extent protect the heart against the negative inotropic effects of b-blockers;
- arrhythmias associated with accessory conduction pathways (for example Wolff–Parkinson–White syndrome), since they impair conduction through the normal conducting pathways without affecting the accessory pathways.

Digoxin is given orally in an initial loading dose of 15 µg/kg, preferably in three divided doses at 6-hour intervals, monitoring for evidence of toxicity (for example, cardiac arrhythmias or symptoms of nausea and vomiting) before the second and third doses. In severe renal insufficiency the initial loading dose should be reduced to 12 µg/kg and increased only in the face of a plasma concentration below the target range (see above). The subsequent maintenance dose should be based on renal function, as shown in Table 4. In patients with atrial fibrillation, in whom the response to digoxin can be easily measured by counting the ventricular rate, an extra dose of 5 µg/kg (in other words, a total loading dose of 20 µg/kg) can be given if necessary; in that case the daily maintenance dose should be increased proportionately. There is no advantage in giving digoxin intravenously; moreover, intramuscular injection is painful and causes muscle necrosis. If digoxin has to be given parenterally in a patient who cannot swallow, it should be infused intravenously over no less than 30 min to avoid the acute hypertension that can occur during rapid intravenous administration. Monitoring therapy by plasma concentration measurement is discussed above.

Other vasodilators

The combination of hydralazine (300 mg/day) with a nitrate (isosorbide dinitrate 160 mg/day) has beneficial haemodynamic effects, improves symptoms, and also reduces mortality, although not as markedly as ACE inhibitors. This combination is also less well tolerated than ACE inhibitors. It should be reserved for patients in whom renovascular disease militates against the use of ACE inhibitors and angiotensin receptor antagonists. It has been suggested that the addition of hydralazine and a nitrate to ACE inhibitor therapy should improve mortality even further, but this hypothesis has not yet been tested in a large clinical trial.

Short-acting calcium channel blockers increase cardiovascular mortality in patients with coronary heart disease and should be avoided in long-term treatment. Modified-release formulations of short-acting calcium blockers and long-acting drugs (such as amlodipine) seem to be safe in this regard, but there is as yet no evidence that they reduce mortality in patients with chronic heart failure. Amlodipine may delay the time to and reduce the number of admissions to hospital in connection with ventricular arrhythmias. However, there is currently no place for the use of calcium blockers in patients with congestive heart failure, except in the treatment of associated conditions such as hypertension or angina pectoris.

Alpha-blockers, such as prazosin, neither improve symptoms nor reduce mortality in chronic heart failure; they should not be used.

Angiotensin receptor antagonists

In patients who cannot tolerate ACE inhibitors because of adverse effects, such as cough or renal insufficiency, angiotensin receptor antagonists seem a logical alternative, and they are certainly better tolerated than ACE inhibitors. However, although there is some evidence that angiotensin receptor antagonists improve symptoms in congestive heart failure, there is currently no evidence that they are better than ACE inhibitors at reducing mortality. There is some early evidence that a combination of an ACE inhibitor with an angiotensin receptor antagonist may be more efficacious than either alone, but this hypothesis awaits proper testing. Until further information becomes available, angiotensin receptor antagonists should be reserved for patients who cannot tolerate ACE inhibitors. Typical once-daily doses are: candesartan 4 to 16 mg; irbesartan 75 to 300 mg; losartan 25 to 100 mg; and valsartan 40 to 160 mg.

Other positive inotropic drugs

Other positive inotropic drugs, including the phosphodiesterase inhibitors (such as amrinone, milrinone, and vesnarinone), ibopamine, and intermittent intravenous dobutamine, all increase mortality during long-term treatment of congestive heart failure and should not be used. However, there is evidence that short-term intravenous milrinone for a few weeks can help achieve haemodynamic stability and tide suitable patients over to heart transplantation. Milrinone has also been used to help wean patients off cardiopulmonary bypass.

Other antiarrhythmic drugs

If sudden death in chronic heart failure is due to cardiac arrhythmias, one would expect other antiarrhythmic drugs to be beneficial. However, the results of the few available studies of the class III antiarrhythmic drug amiodarone are not impressive. In one trial amiodarone 300 mg/day produced a small reduction in mortality, but this has not been confirmed. Some of the data suggest that amiodarone may be more beneficial in patients with non-ischaemic heart failure, but it should currently be reserved for patients with identified ventricular arrhythmias. Class I antiarrhythmic drugs increase mortality after myocardial infarction and should be avoided.

Anticoagulants

There is an increased risk of venous thrombosis in immobile patients who have severe heart failure and have swollen legs due to oedema. Prophylactic anticoagulation is therefore advisable, using either an oral anticoagulant (for example, warfarin) or low-dose subcutaneous heparin. Other patients with cardiomyopathy, severe left ventricular dilatation, or demonstrable intracardiac thrombus on echocardiography should be given anticoagulants to prevent systemic emboli. These issues are discussed in Chapter 15.5.2.

Monitoring therapy in heart failure

Drug therapy in heart failure should be monitored for evidence of therapeutic efficacy and drug toxicity.

Fluid and electrolyte balance and the response to diuretics should be monitored by body weight and serum electrolyte measurements. Potassium depletion can occur, even in patients taking potassium-sparing drugs (ACE inhibitors, angiotensin receptor antagonists, and spironolactone), in which case potassium chloride should be given to replace any deficit and additional amiloride or triamterene to prevent further potassium loss.

Renal function should be monitored before giving an ACE inhibitor or angiotensin receptor antagonist during the first few days or weeks of therapy, and whenever the dosage is increased. Worsening renal function will dictate dosage reduction or drug withdrawal.

Blood pressure should be measured at each visit. It will often fall after the first dose of an ACE inhibitor but will usually improve thereafter.

Serum or plasma digoxin concentration measurement is discussed above.

During anticoagulant therapy with warfarin the target International Normalized Ratio (**INR**) is 2.0 to 2.5 for the prevention of deep vein thrombosis, 2.5 to 3.0 for patients with atrial fibrillation, dilated cardiomyopathy, or mural thrombosis, and 3.5 for recurrent deep vein thrombosis or pulmonary embolism and in patients with prosthetic heart valves.

15.5.2Therapeutic anticoagulation in atrial fibrillation and heart failure

David Keeling

Atrial fibrillation

Atrial fibrillation is present in 5 per cent of the population over 65 years of age and in 10 per cent of those over 70 years. It increases the risk of stroke fivefold and is present in 15 per cent of all stroke patients. The overall risk of ischaemic stroke in atrial fibrillation without rheumatic heart disease is about 5 per cent per year, but this can be modified by other risk factors. The risk increases with age: those over 75 years old are at high risk; by contrast, those less than 65 years old with no other risk factors have a risk of stroke of 1 per cent per year. Other factors that increase the risk of stoke in atrial fibrillation have been well characterized (Table 1). It is not clear for how long one must successfully treat patients with hypertension before their risk of stroke decreases, and pending further studies treated hypertension should still be regarded as a major risk factor.

Warfarin decreases the risk of ischaemic stroke in atrial fibrillation by 68 per cent, compared with a reduction of approximately 21 per cent with aspirin. The risk of ischaemic stroke has to be balanced against the risk of intracranial haemorrhage on anticoagulant therapy. The risk of intracranial haemorrhage on warfarin is approximately 0.5 per cent per year, and although this increases with age, so does the risk of ischaemic stroke.

Long-term oral anticoagulation should be considered for those patients with atrial fibrillation who are at high risk of stroke. They should receive warfarin if they are over 75 years old or have one or more of the major risk factors in Table 1 and no contraindication. Oral anticoagulation is recommended instead of aspirin because of the large absolute risk reduction: when the risk of stroke is 7.5 per cent per annum only 20 patients need to be treated for 1 year to prevent a stroke. Patients between 65 and 75 years are at greater risk than those less than 65 years: if they have additional minor risk factors such as diabetes or coronary artery disease, they too should be offered warfarin. Patients between 65 and 75 years of age with no other risk factors and those less than 65 years old with only minor risk factors are at intermediate risk and the choice of oral anticoagulation or aspirin will be significantly affected by patient preference. Those less than 65 years old with no risk factors should receive aspirin (Table 2).

For warfarin the target INR should be 2.5 (range 2.0 to 3.0): lower intensity anticoagulation is not effective and higher intensity increases the risk of bleeding. For those on aspirin it is unnecessary to give more than 75 mg /day.

Anticoagulation after an acute ischaemic stroke should be delayed until most of the deficit has resolved, or for 2 weeks in the case of severe strokes.

Oral anticoagulation should be given for 3 weeks before elective cardioversion of patients who have been in atrial fibrillation for more than 48 h and continued until sinus rhythm has been maintained for 4 weeks. It is not needed if atrial fibrillation has lasted for less than 48 h.

Heart failure

The trials of oral anticoagulation (with high target INRs) after myocardial infarction showed reductions in recurrent myocardial infarction, ischaemic stroke, and all-cause mortality similar to those observed with aspirin. However, aspirin is recommended for long-term therapy in preference to warfarin because of its safety. Warfarin is given to survivors of myocardial infarction at high risk of systemic embolization because of severe left ventricular dysfunction, congestive heart failure, mobile mural thrombus, or atrial fibrillation. In these cases the target INR is 2.5 (target range 2.0 to 3.0). Although it is not clear if this lower intensity protects as effectively against vascular disease, aspirin is not given concurrently because of the increased risk of bleeding. Warfarin should also be considered in congestive heart failure due to causes other than myocardial infarction to reduce the high risk of thromboembolism.

15.5.3Cardiac rehabilitation

Andrew J. S. Coats

Introduction

Cardiac rehabilitation constitutes the use of pharmacological and non-pharmacological treatment modalities to restore a patient to premorbid health, outlook, and activity. It is more than treating a disease: it is the systematic attempt to correct all factors limiting a subject from full participation in the healthy aspects of their predisease lifestyle.

The conventional four phases of rehabilitation constitute: the early interventions during hospital stay (phase 1); followed by the first 6 weeks after discharge (phase 2); then full participation in sport, work, and family life over the next 6 to 12 months (phase 3); and, last, the maintenance of the new healthier condition and lifestyle (phase 4). Secondary prevention of cardiovascular disease by the full use of available techniques is an important part of rehabilitation. The components of a successful cardiac rehabilitation programme, which needs to be well monitored and adequately staffed with a multidisciplinary team, are listed in Table 1.

It has been established that cardiac rehabilitation can increase quality of life, exercise capacity, and the chance of return to work in patients recovering from a myocardial infarction. Meta-analyses of published randomized controlled trials of cardiac rehabilitation programmes which include a structured exercise training component have shown that these are able to produce an approximately 25 per cent reduction in mortality. Rehabilitation programmes also give an opportunity for the effective implementation of secondary preventive measures to reduce the risk of subsequent cardiovascular events.

Rehabilitation in special populations

The benefits and risks of taking part in a cardiac rehabilitation programme after a myocardial infarction depend on the prior morbidity and prognosis of the individual. The lower the cardiovascular risk, and the better the exercise tolerance and state of health of the patient at the start, the lower the chance of any adverse events occurring during rehabilitation. However, such low-risk patients may have relatively little to gain from the programme if their degree of fitness and motivation are already high. By contrast, patients at a higher risk of reinfarction, or with a lower level of motivation and exercise tolerance, may achieve more substantial benefit. However, there is a tendency for rehabilitation to be offered to the lower risk younger patient rather than the higher risk older patient with more medical problems. But given the benefits that can be achieved in those at high risk, special procedures should be instituted to make sure these patients receive rehabilitation services.

The elderly

There is often an effective age restriction for entry to many cardiac rehabilitation programmes, but, physiologically and medically, there is no reason for age *per se* to be a contraindication to rehabilitation. The risk factors for cardiovascular disease may differ in the elderly, with dys- and hyperlipidaemias being quantitatively less important and systolic blood pressure being more important, but it can still be advantageous to identify and reduce these risk factors. Exercise tolerance is more markedly impaired at the outset, but it can be increased by training even in the very elderly. Other diseases frequently coexist in the elderly, and they are more likely to be taking multiple medications, to have a poorer memory, and to have less adequate social support networks for their greater needs. These and many other factors make rehabilitation programmes with an exercise component more problematic and associated with a higher rate of complications. This does not mean, however, that elderly patients should not be encouraged to participate.

The elderly are likely to need a longer and gentler introduction to rehabilitation, more frequent and prolonged contact throughout the programme, and closer attention from medical staff. They will often present with other non-cardiac problems, requiring assistance from various medical specialties and paramedical staff and social workers. It is wise to involve all relevant parties in the rehabilitation visits of the elderly patient, so that no conflict of advice ensues about, for example, activities and lifestyle. However, the benefits of recruiting elderly patients can be very great, enabling them to achieve a greater degree of independence and avoiding the need for long-term residential care.

Rehabilitation in those with specific cardiac conditions

Angina

Continuing angina frequently prevents a patient from participating in a formal rehabilitation programme. In some, participation can be delayed until completion of further investigation and revascularization procedures, but there remain many patients with persistent angina in whom revascularization procedures are either impossible or incompletely successful. These patients may gain benefit in terms of secondary prevention and in improving exercise tolerance by participating in a rehabilitation programme. There is good evidence for a modest antianginal effect of physical training, and risk factor reduction is of considerable importance for angina sufferers. Training in the presence of exercise-induced angina may also promote the development of new collateral vessels to the myocardium.

Heart failure

In the past, heart failure was frequently listed as an absolute contraindication to participation in cardiac rehabilitation. Whilst active myocarditis or acute heart failure with congestion remain contraindications to exercise training, research over the last decade has shown that carefully selected patients with stable chronic heart failure can achieve significant and worthwhile benefits from exercise training. This is now an important area in cardiac rehabilitation research.

Like the situation for the elderly, those with heart failure are significantly limited and in need of considerable medical care. They are also likely to benefit substantially from even modest improvements in their ability to perform exercise, as many daily tasks will stress them to close to their cardiopulmonary exercise reserve. These patients are frequently well motivated and co-operate fully with the rehabilitation programme. Several practical difficulties arise, however, including the need for closer supervision, more detailed preparticipation assessment, and a greater likelihood of complications including serious ventricular arrhythmia. Perhaps most importantly from a practical point of view, these patients may need a lifelong attachment to the programme for continuing benefit.

Research in specialist units has shown possible training benefits for patients with moderate and severe heart failure, provided their condition is stable. Improvements of between 20 and 25 per cent have been seen in exercise capacity, associated with reduced sympathetic tone, reduced breathlessness and exercise ventilation, and improved exercise haemodynamics. However, in each case the training exercise needs to be tailored specifically to the patient's reduced capacity. The level of exercise prescription may start at a very low level, such as 70 per cent of their existing maximal capacity for as little as 5 to 10 min a session. This is then gradually increased in duration and absolute intensity as the patient's maximal capacity increases.

It is recommended that patients with heart failure undergo cardiopulmonary exercise assessment in a specialist unit to establish accurately their exercise capacity prior to entry into a rehabilitation programme. Detailed evaluation is needed, such as the detection of ventricular arrhythmias either by 24-h ECG monitoring or on exercise testing. The presence of ventricular tachycardia is common in patients with moderate and severe heart failure, and may increase the risk during exercise. Whether these arrhythmias negate possible benefits of rehabilitation because of the risk of precipitating arrhythmias remains unknown.

P>No patient with heart failure should take part in an exercise programme in the presence of acute decompensation, such as with pulmonary or peripheral oedema, active myocarditis, or febrile illnesses. Although there is no lower limit on ejection fraction for the participation of those with heart failure, the patient must be

comfortable at rest and be able to exercise for 5 min at an exercise level of 2 **METS** (metabolic equivalents (of oxygen consumption)) or greater. A left ventricular ejection fraction of 20 per cent or less is still compatible with participation, and patients can still usefully participate when they are stable on a cardiac transplantation waiting list.

15.5.4 Cardiac transplantation and mechanical circulatory support

John H. Dark

Introduction

The basic surgical technique and the first clinical attempts at heart transplantation were described over 30 years ago, but poor results lead to a quiescent phase during the 1970s. This hiatus stimulated the development of a range of pumps intended to replace the function of the heart.

Effective immunosuppression, particularly with the introduction of ciclosporin A in 1981, enormously improved transplant results and there was a rapid expansion of activity over the next decade. This reached a plateau during the 1990s, with 3000 to 4000 heart transplants worldwide and up to 300 in the United Kingdom, although the total is now declining.

The size of the problem

The incidence of heart failure is increasing, not only because of an ageing population but also because of the longer survival of existing patients, benefiting from greatly improved medical management. In the United States, a conservative estimate is that 35 000 patients per year would benefit from cardiac replacement therapy, and enthusiasts put this figure above one million. By extrapolation, a figure of 5000 patients per year can be derived for the United Kingdom.

Transplantation brings with it unavoidable morbidity, both from immunosuppression and progressive graft failure, and long-term survival is limited. The limited number of donors means that it is only an option for a tiny proportion of those with congestive cardiac failure, and furthermore, transplantation is not always available when required, as demonstrated by a mortality rate of 15 to 40 per cent amongst those accepted on to transplant waiting lists. There is thus a huge need for an alternative to transplantation for patients with heart failure that is readily available, will provide an adequate cardiac output, and will have better long-term performance.

Mechanical circulatory support

Mechanical means of assisting or replacing the heart have evolved through short-term (days) postoperative support and medium-term (weeks to months) devices for 'bridge to transplant', to those on the verge of being accepted for long-term permanent implantation (Fig. 1).

Fig. 1 The Jarvik pump (by courtesy of Mr Steve Westaby).

Devices

Intra-aortic balloon pump

Counterpulsation with an intra-aortic balloon pump (**IABP**), usually placed via the femoral artery into the proximal descending aorta, was introduced in the late 1960s and is now used primarily for the short-term support of patients with postoperative low cardiac output or unresolved ischaemia. It is sometimes used as an adjunct to intravenous inotropes in potential transplant recipients who are deteriorating, but has no proven role except perhaps in those with ischaemic cardiomyopathy. The balloon pump has not found a role in the management of cardiogenic shock after myocardial infarction, unless there is a surgically remediable problem such as an acquired ventricular septal defect or papillary muscle rupture.

Centrifugal pumps

There are a number of paracorporeal pumps, developed as alternatives to roller pumps for cardiopulmonary bypass, that can be used for short-term circulatory support. Their use is limited to about 96 h, and there are significant problems with bleeding because of the need for partial heparinization. However, they are very inexpensive and have a role in support after cardiac surgery, or for assistance of the right ventricle.

Paracorporeal, pulsatile, ventricular assist devices

A variety of relatively simple, external, pneumatically powered pumps, connected to the heart with pipes traversing the skin, are available. The best known is the 'Thoratec' system, but others include the 'ABIOMED' pump, and in Europe, various forms of the 'Berlin' Heart. They can be used for either univentricular or biventricular support, for days or even weeks. The principal application is in 'bridging to transplant'. Morbidity and mortality is high, and complications include bleeding, thromboembolic events, and infection.

'Pusher-plate' implantable devices

This category includes the two most successful left ventricular assist devices, the 'Novacor' and the broadly similar 'HeartMate', which have the electrically powered pump lying deep to the abdominal wall. Connections are to the apex of the left ventricle and ascending aorta, with inflow and outflow valves. Power is supplied via a percutaneous cable and there is also a pipe to vent the air displaced with each beat. Transcutaneous transmission of electrical power is possible using induction

loops, but a reliable implantable expansion chamber to deal with the displaced air has yet to be perfected. Portable batteries and control systems have been developed for both devices to allow discharge of the patient from hospital. Some patients fitted with such a device have survived for several years.

The principal difference between these two pumps lies in their blood interface. In the Novacor there is a seamless polyurethane sac, which is rhythmically compressed by the pusher plate. Anticoagulation with both warfarin and antiplatelet agents is required. By contrast, the blood-contacting surfaces of the HeartMate are textured to encourage deposition of circulating cells. The resulting autologous tissue lining is resistant to thrombus formation and only aspirin is required.

Both these pumps are large and expensive—typically £50 000 for the implantable components, batteries, and controllers. They cannot be used in small adults and children, and there are risks of infection and thromboembolism. Typically, 40 per cent of patients fitted with the HeartMate will experience driveline infections, although these can be contained in the 'bridge to transplant' setting and do not preclude successful transplant. The Novacor may be more prone to thromboembolic complications: in one study, 17 per cent of 36 patients who had the device for more than a year had major emboli; in another group 24 strokes occurred in 36 patients treated for a mean of 200 days.

Implantable impeller pumps

The next stage in the evolution of mechanical support is represented by a variety of axial-flow pumps. These are electrically driven, but with much lower power requirements than their predecessors, and consist of a turbine, usually in a tube connecting the left ventricular apex with the aorta. There are no valves, and the whole of the moving parts are bathed in blood. The earliest reports are only just appearing, but these pumps, if laboratory reliability can be repeated in clinical practice, have considerable potential.

Aims of mechanical support

Apart from postoperative support, which will not be discussed further, there are three uses for mechanical pumps. The commonest is 'bridge to transplant', with the intention of stabilizing or improving a deteriorating patient until a transplant can be performed. In a small minority of patients, myocardial function improves to the extent that the device can be removed. This is termed 'bridge to recovery'. The longer term aim of all these devices, and particularly for the impeller pumps, is permanent implantation.

Bridge to transplant

Patients with heart failure who deteriorate rapidly may die before they can be transplanted, or they develop progressive end-organ failure that significantly worsens the outcome after transplantation. Mechanical pumps, principally the Thoratec device and the two implantable pusher-plate pumps, have been used in thousands of patients for periods of up to several years, before they eventually receive a transplant. Only 60 to 70 per cent of such patients will receive a transplant. Most of the remainder do not survive, either developing irreversible failure of other organs despite a good cardiac output, or succumbing to problems such as stroke, haemorrhage, or infection whilst on the pump.

The 1-year survival rate after transplantation for bridged patients is between 80 and 90 per cent, at least as good as for routine patients, and probably better than that for very sick patients who do not receive a pump but survive to transplant in a precarious state.

Many patients develop anti-HLA and other antibodies whilst on a pump, either as a result of multiple transfusions, or due to the inflammatory response that occurs secondary to prolonged exposure of the blood to foreign surfaces. This delays transplantation, sometimes for years, and makes the implantable systems and discharge home economically attractive despite the high initial cost.

Bridging does not result in more transplants, but biases the transplant population towards younger, sicker recipients, and away from older, more stable candidates. The costs are huge: sums of $300 000 to 400 000 per subsequent transplant have been quoted from centres in the United States. A cynical view is that it is a very expensive way of selecting a slightly different group of patients for transplantation, and it has not yet been adopted in the United Kingdom to any significant extent.

Bridge to recovery

The reduction in afterload when the left ventricle is completely decompressed by a mechanical pump results in shrinkage of the heart and an improved ejection fraction. In some patients this improvement is real (in other words, it is not just load-dependent), sustained, and the pump can eventually be removed. Such myocardial recovery occurs particularly after postpartum cardiomyopathy and in those supported for an acute myocarditis. However, recovery in idiopathic dilated cardiomyopathy can also result: an improvement in histological appearance is seen, with a more regular arrangement of myocytes accompanied by a reduction in their diameter to normal. Other markers of heart failure, such as levels of tumour necrosis factor-a (**TNF-a**) and anti-b-receptor antibodies, which may be involved in the aetiology of the cardiomyopathy, also improve.

Only a few patients recover to the point where transplantation is not needed, and such recovery is not always sustained. In the Berlin series, one of the largest, 7 out of 19 patients who had pumps removed had either died or had been transplanted within 12 months. The remaining 12 were alive 1 year after the device was removed. However, in the future, mechanical support combined with manoeuvres to reverse some of the causes of cardiomyopathy – control of inflammatory elements, reconstitution of b receptors – may be applicable to significant numbers of patients, avoiding the need for transplantation.

Permanent implantation

A number of patients have been sustained for years with various implantable, left-ventricular assist devices, and indeed such pumps were designed as an alternative to transplant. It is not known whether the current devices can be used in the very long term. A clinical trial of left-ventricular assist devices against medical treatment in patients deemed unsuitable for heart transplant (the REMATCH trial) reportED its results in November 2001. For these critically ill patients, there was a survival advantage in receiving an assist device but even for such patients the mortality at 2 years was 77 per cent. The implication is that the pusher plate type of pump used in this trial is not yet suitable for long-term implantation.

Cardiac transplantation

For a minority of patients with endstage cardiac failure, transplantation remains an excellent form of treatment. Crucial to a successful outcome are patient selection and donor management. Post-transplant, the avoidance of acute rejection, minimization of the side-effects of chronic immunosuppression, and steps to reduce late graft failure are important issues.

Patient selection

Almost all adults presenting for transplant will have either a dilated idiopathic or ischaemic cardiomyopathy. The latter predominates in older patients: other diagnoses in patients accepted for transplantation are shown in Table 1. Amongst children, dilated cardiomyopathy now exceeds congenital heart disease as a reason for transplantation. Young adults who underwent successful palliative procedures (such as Mustard or Senning operations for transposition of the great vessels) 20 or more years ago now need a transplant.

Regardless of the aetiology of the disease, referral for consideration for cardiac transplantation should only be made when conventional treatment, both medical and surgical, has been exhausted. Thus most patients with heart failure will have had the benefit of state-of-the-art medical therapy—angiotensin-converting enzyme inhibitors, b-blockade, diuretics including spironolactone, and often digoxin and amiodarone. Reversible ischaemia should be sought when there is coronary disease.

The outlook for patients with severe and deteriorating cardiac failure is clearly poor, indeed a proportion of these patients will either need urgent transplantation or a mechanical assist device. Consideration of the ambulant patient with controlled heart failure is more difficult: improvements in medical management have rendered obsolete many of the accepted markers of poor prognosis, and it has been suggested that transplantation only improves the 1-year survival rate of patients with the most severe heart failure.

Exercise testing with measurement of maximum oxygen uptake has been a useful objective test, with values below 14 ml/kg per min suggesting a 1-year survival rate of only 30 per cent. Its combination with other markers (Table 2) into a scoring system for likely survival has allowed the stratification of this group of patients, a system that has been validated both in North America and Europe.

Contraindications to transplantation

Careful screening of individuals with irreversible failure of other organs is essential and a list of standard exclusions is shown in Table 3. The absolute contraindications mainly relate to other life-threatening conditions that would not be reversed by the presence of a new heart. Active infection clearly has to be avoided in any patient who is about to be aggressively immunosuppressed. The relative contraindications are more difficult to judge, a good example being elevation of pulmonary vascular resistance. All patients with left-heart failure have some degree of pulmonary vasoconstriction and the chance of failure of the unprepared right ventricle of the donor heart, the risk of early death being correlated in a continuous fashion with the pulmonary vascular resistance or transpulmonary gradient. Higher values contribute the greatest risk but, of course, are more likely to be found in the sickest patients. An individual assessment has to be made in each case, considering not only the patient's need but also the best use of a limited number of donor organs.

Perioperative management

The cardiac donor

Although the heart continues to beat after brainstem death occurs, there is a progressive loss of homeostatic control. This includes hypotension with loss of vascular tone, compounded by a polyuria and hypothermia. Appropriate corrections include the administration of ADH analogues (usually intranasal **DDAVP**, 1-deamino-8-D-arginine vasopressin; desmopressin), intravenous fluids, and often peripheral vasoconstrictors as well.

The initial damage to the brain is usually intracerebral or subarachnoid haemorrhage, or head trauma. Positive serology for the human immunodeficiency virus (**HIV**) and hepatitis B, previous cardiac surgery, or a known history of ischaemic heart disease are contraindications to cardiac donation, as are prolonged periods of hypotension. Intravenous drug abuse (because of its association with HIV infection) is a contraindication, as is more than the occasional use of cocaine. Brainstem death following tricyclic antidepressant overdose or carbon monoxide poisoning is associated with specific damage to the heart and such donors would not usually be acceptable.

Older donors, into their fifties or even sixties, are acceptable if they have normal coronary arteries, but the use of such hearts is associated with a poorer long-term outcome since they are much less tolerant of longer ischaemic times. However, with falling mortality rates from trauma and an increasing demand for transplantation, donors are now more likely to be older and to die as a result of intracerebral haemorrhage, often being hypertensive with left ventricular hypertrophy and premature coronary artery disease.

Matching of recipient and donor

The donor should be blood-group compatible (but not necessarily identical) with the recipient, and size discrepancies of more than 20 to 30 per cent should be avoided. Although HLA matching, particularly for the DR antigens, may reduce rejection rates, time constraints make this impossible.

Some 5 to 10 per cent of recipients are presensitized to HLA antigens by blood transfusion, pregnancy, or a previous transplant. Moreover, preformed antibodies can cause immediate rejection, which is often fatal. Before a transplant is performed from a particular donor, recipient serum is tested against donor cells to exclude a positive or cytotoxic crossmatch in this group of patients.

The operation

After removal of the native heart, the standard implantation was, in the past, with anastomoses to the pulmonary artery, aorta, and cuffs of the left and right atrium. Whilst technically straightforward, this was somewhat clumsy and sometimes resulted in distortion of the interatrial septum. The standard approach now is to perform separate caval anastomoses, thus keeping the donor right atrium intact. Better right ventricular filling, fewer arrhythmias, and almost complete elimination of the need for permanent pacing has followed this modification.

Postoperative management is as for any other cardiac surgical procedure, with transfer from an intensive care unit to the recovery ward within a few days, and discharge from hospital after approximately 2 weeks.

Immunosuppression and rejection

A host's immune response is most vigorous early after the transplant and gradually diminishes with time. Immunosuppression is based principally on one of the calcineurin-inhibitor group of drugs, ciclosporin A or tacrolimus (FK506), in conjunction with corticosteroids and usually one other agent. There are few clinically important differences between the two calcineurin inhibitors: both are nephrotoxic and both have neurological side-effects, both require monitoring by measurement of trough drug levels. Tacrolimus does not cause the hirsuitism or gum hypertrophy seen with ciclosporin A and is therefore preferable in adolescents and females: it is, however, associated with a much higher rate of glucose intolerance.

Steroid treatment is initially with large intravenous doses of methylprednisolone, which is then converted to oral prednisolone, with dosage titrated down from 1 mg/kg to between 0.1 and 0.2 mg/kg over 2 to 4 weeks. Approximately 50 per cent of patients can be weaned off steroids entirely. However, in practice, continuation of a small dose (5–10 mg per day) allows lower doses of the other drugs with different toxicities to be tolerated.

The other component of so-called 'standard triple-drug regimens' is azathioprine in a dose of 1.5 to 2.5 mg/kg, adjusted against the white blood cell count. The principal side-effects are marrow toxicity and cholestatic jaundice, but azathioprine is effective, inexpensive, and easy to control. An alternative with broadly similar actions is mycophenolate mofetil (**MMF**). In comparative studies, patients treated with MMF have slightly lower rejection rates and there may be some reduction in the rate of progression of allograft vasculopathy (see below), but these advantages have not been translated into a demonstrable improvement in survival. Mycophenolate is much more expensive than azathioprine and its role in cardiac transplant patients has yet to be determined.

Monitoring rejection episodes

Acute rejection, a loss of the control of the immune response caused by drug therapy, leads to an infiltration of inflammatory cells and myocardial oedema. This causes diastolic rather than systolic dysfunction. Clinical signs may be sparse; a third sound, elevated filling pressures or atrial flutter, together with pyrexia and sometimes influenza-like symptoms can occur. The 'gold standard' for detecting rejection is transvenous endomyocardial biopsy, performed under local anaesthetic and radiological control. Non-invasive methods are not as sensitive or specific, although echocardiography may have a role in children. Biopsy is done weekly for the first month, then at decreasing intervals over the first year. Dense infiltrates with myocyte necrosis require augmented treatment, usually with intravenous steroids. Between 20 and 40 per cent of patients will have at least one such episode of acute rejection. Regular biopsies allow the titration of treatment against the histological picture, effectively tailoring therapy to the individual.

Infection after transplantation

The need for high levels of immunosuppression creates a substantial risk of infection, particularly during the first few months. Within the first few weeks this is typically bacterial (chest, urinary tract, intravenous catheters) and with commonplace rather than opportunistic organisms. Patients who receive augmented immunosuppression are at risk of fungal infections, of which aspergillosis is the most significant.

Cytomegalovirus (**CMV**) is the most important viral infection, occurring between 1 and 2 months' post-transplantation. This may be either a reactivation of a previous exposure (50 per cent of recipients are seropositive at the time of transplant), or acquired with the heart from a donor who was seropositive. For those at greatest risk, prophylaxis with oral ganciclovir has become routine. If an infection occurs with pyrexia, leucopenia, and organ involvement (for example, pneumonitis or gastritis), it

can be life-threatening and requires treatment with intravenous ganciclovir.

Patients with fever should be investigated aggressively to make a specific diagnosis, often with invasive means such as bronchoscopy. Except for life-threatening sepsis, empirical antibiotics should be avoided. Unusual, opportunistic organisms (for example, *Aspergillus* spp., *Pneumocystis carini*, and *Legionella* spp.) should all be considered.

For further discussion of infective complications after solid-organ transplantation, see Chapter 20.6.3 and chapters dedicated to particular pathogens.

Long-term complications

Despite excellent survival and functional rehabilitation, drug side-effects, the risks of continuous immunosuppression, and graft vasculopathy can lead to morbidity. The combination of these factors results in an attrition rate of 4 per cent per year after the first 12 months.

Side-effects of immunosuppressants

All the drugs used have relatively poor therapeutic profiles, and a degree of drug toxicity is almost invariable. For the calcineurin inhibitors (ciclosporin, tacrolimus) the most troublesome are hypertension and nephrotoxicity. Some 80 per cent of patients require an antihypertensive agent, with ACE inhibitors as the first choice, followed by nifedipine. Many other calcium-channel blockers interact with ciclosporin metabolism. Both ACE inhibitors and calcium-channel blockers may benefit graft vasculopathy.

Renal impairment is due to a combination of drug toxicity and pre-existing renal disease: by 10 years' post-transplant, between 5 and 10 per cent of patients need renal replacement therapy, but their prognosis is very poor.

Effects of chronic immunosuppression

The transplant patient remains at risk, diminishing with time, of opportunistic infections. Malignant change in the skin exposed to sunlight is very common, and appropriate precautions should be taken from the beginning.

Post-transplant lymphoproliferative disease (PTLD)

All immunosuppressants inhibit suppressor T cells, which usually exert immunological control over Epstein–Barr virus (**EBV**)-infected lymphocytes. Reduction of this control after transplantation may result in the proliferation of lymphocytes with a histological picture of B-cell 'lymphoma'. The clinical picture ranges from something akin to primary EBV infection (infectious mononucleosis) to a highly malignant, multifocal lymphoma. In most cases, reduction of immunosuppression results in restoration of control, and the 'lymphoma' is seen to shrink. Sometimes this is inadequate (or rejection of the heart occurs) and chemotherapy is required, when the outlook for the patient is much poorer.

PTLD affects about 2 per cent of transplant patient in the first year, and 1 per cent per year thereafter. It is much commoner (up to 40 per cent) if acquired as a primary infection from the donor organ. Use of polymerase chain reaction (**PCR**) technology to monitor viral load may have a role in predicting those at risk, and for allowing a pre-emptive reduction in immunosuppression.

Graft vasculopathy

There is continued immunological damage to the endothelium of the coronary arteries of the transplanted heart. (A similar process is seen in other solid-organ grafts.) Endothelial abnormalities can be detected as early as 6 weeks' post-transplant, and intravascular ultrasound (**IVUS**) can detect thickening of the subintimal layer over the first year. This process is accelerated in individuals with repeated rejection episodes and is worsened by hyperlipidaemia and hypertension. It is commoner in older donor hearts, even when free of disease at transplant. By 5 years, between 40 and 70 per cent of patients will have angiographically visible disease, and this is the commonest cause of death after the first year.

Control of risk factors, particularly hyperlipidaemia, is very important. The statin group of drugs are of proven benefit, and all adult patients with heart transplants should be given these agents (if tolerated).

Because the heart is denervated, clinical presentation is subtle. There is a spectrum of disease from exercise dyspnoea, through silent myocardial infarction, to sudden death. Detection is by surveillance angiography: non-invasive alternatives (for example, thallium scintigraphy and stress dobutamine echocardiography) have yet to prove themselves useful.

Treatment of established disease is unsatisfactory. Localized lesions may respond to angioplasty or coronary stenting, but graft vasculopathy is a diffuse process and restrictions to flow from small-vessel narrowing remain. The very occasional patient may require coronary grafting for a collection of proximal, focal lesions, but the only definitive treatment is retransplantation, which gives satisfactory results for carefully selected patients.

Results

Voluntary registries and publications from single institutions report a 1-year survival rate between 80 and 85 per cent, falling to 70 per cent at 5 years, and perhaps 50 per cent at 10 years (Fig. 2). Figures for a typical transplant programme may be a little worse. Rehabilitation is excellent, with 90 to 95 per cent of patients in **NYHA** (New York Heart Association) class I or II, although a disappointing proportion, perhaps only 20 per cent, return to work.

15.6 Cardiac arrhythmias

S. M. Cobbe and A. C. Rankin

General principles

Definition

The term cardiac arrhythmia (or dysrhythmia) is used to describe an abnormality of cardiac rhythm of any type. The spectrum of cardiac arrhythmias ranges from innocent extrasystoles to immediately life-threatening conditions such as asystole or ventricular fibrillation. Arrhythmias may occur in the absence of cardiac disease, but are more commonly associated with structural heart disease or external provocative factors.

Normal cardiac electrophysiology is discussed in Chapter 15.3.2. Abnormalities in cardiac impulse formation or propagation may give rise either to an abnormally slow heart rate (bradycardia) or fast heart rates (tachycardia).

Symptoms of cardiac arrhythmias

The symptoms produced by bradyarrhythmias depend on the extent of cardiac slowing. They may include sudden death, syncope (Stokes–Adams attacks), or dizziness (presyncope). Continuous bradycardia without asystolic pauses may produce symptoms of fatigue, lethargy, dyspnoea, or mental impairment.

The symptoms caused by tachyarrhythmias depend on a variety of factors including the heart rate, the difference between the rate during the arrhythmia and the preceding heart rate, the degree of irregularity of the rhythm, and the presence or absence of underlying cardiac disease. Symptoms of tachycardia include a feeling of rapid palpitation, angina or dyspnoea, syncope or sudden death. The differential diagnosis of palpitation and syncope is discussed in Chapter 15.2.3.

Investigation of arrhythmias

History taking must include a detailed description of the symptoms associated with the arrhythmia. Evidence should be sought for factors that may precipitate the arrhythmia (for instance, exercise, alcohol) and for the presence of underlying cardiac disease, in particular valvular heart disease, myocardial ischaemia/infarction, or congestive heart failure. Examination of the pulse will be unremarkable if the arrhythmia is intermittent. Physical examination for evidence of structural heart disease is essential. Further investigations to establish the presence of structural heart disease and to determine ventricular function may include 12-lead electrocardiography, chest radiography, echocardiography, exercise stress testing, and coronary arteriography.

Electrocardiography

The key to the successful diagnosis of cardiac arrhythmias is the systematic analysis of an electrocardiogram (**ECG**) of optimal quality obtained during the arrhythmia (Table 1). Ideally, this should comprise all 12 leads recorded on a multichannel recorder, which can allow the identification of P-waves in one lead while they may be absent or equivocal in another.

Ambulatory electrocardiography

Continuous monitoring is necessary for identification where arrhythmias are intermittent. This may involve monitoring in the cardiac care unit, particularly in the acute stages of myocardial infarction, or ambulatory (Holter) monitoring. Ambulatory electrocardiography is normally performed for periods of between 24 and 48 h using a portable recorder, which records every heartbeat on to magnetic tape or into solid-state memory. High-speed or automatic replay facilities enable the identification of intermittent arrhythmias, as well as the quantification of extrasystoles and assessment of parameters of heart rate variability.

Interpretation of recordings requires knowledge of possible artefacts, such as variations in tape speed in magnetic tape-based recorders, or movement artefact. It is important to allow for physiological variability in the sinus rate, also to appreciate that minor abnormalities such as extrasystoles or brief (3 to 4 beat) runs of supraventricular arrhythmias are usually of no significance. Ambulatory electrocardiographic recordings are of most value when they provide correlation between the patient's symptoms and the cardiac rhythm at that moment. Patients should therefore be issued with a diary card to report any symptoms suggestive of arrhythmia during the recording.

Conventional 24- to 48-h ambulatory electrocardiography is unlikely to yield useful results if the frequency of arrhythmic symptoms is less than every day or two. Alternative strategies include the use of a patient-activated recorder, which is applied and activated during symptoms, or an external or implanted 'loop' recorder. Loop recorders continually record the electrocardiographic signal, but only have sufficient buffer memory to retain a few minutes' data. In the event of symptoms, the patient activates the device, thus 'fixing' the previous few minutes' recording for analysis. Loop recorders are particularly useful in the diagnosis of infrequent brief, but disabling, symptoms, where the use of a patient-activated recorder is not feasible.

Cardiac electrophysiological study

More detailed investigation of cardiac arrhythmias is undertaken by invasive cardiac electrophysiological testing. Multipolar electrodes are inserted to record electrograms from the atrium, ventricle, His bundle, and commonly from the coronary sinus (Fig. 1). The site of conduction delays within the heart may be identified, or accessory pathways localized. Sustained arrhythmias may be initiated and terminated by extrastimuli (Fig. 2), and their pattern of activation in the heart studied in detail. Electrophysiological mapping is an essential part of radiofrequency ablation (see below).

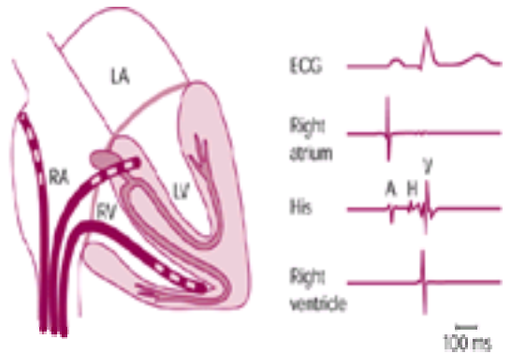

Fig. 1 Electrophysiological study. Illustration of lead placement (left). Quadripolar leads have been inserted from the femoral vein and the tips are shown positioned to allow recording and pacing from the high right atrium, the His bundle, and the right ventricular apex. Intracardiac electrograms (right) show recordings from atrium (A), His bundle (H), and right ventricle (V).

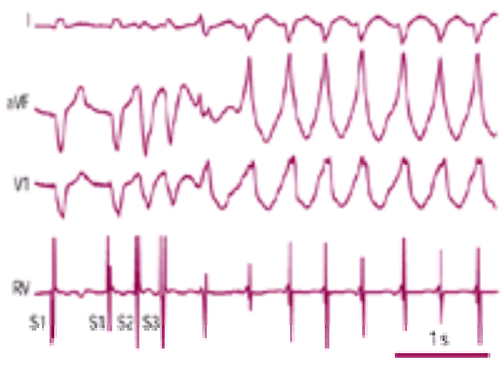

Fig. 2 Induction of ventricular tachycardia by programmed stimulation. Ventricular pacing stimuli (S1) at 100 beats per min are followed by two extra stimuli (S2, S3). Sustained monomorphic ventricular tachycardia is induced. Surface leads I, aVF, V_1, and the intracardiac electrogram from right ventricular apex (RV) are shown.

Bradycardias

Aetiology and mechanisms

Bradycardia is defined as a ventricular rate of less than 60 per min, and results from a reduction in the rate of normal sinus pacemaker activity, or from disturbances of atrioventricular (**AV**) conduction. Sinus bradycardia may be physiological—for example, during sleep, in athletes, and in young people. Pathological bradyarrhythmias can result from intrinsic degenerative disease of the sinus or atrioventricular node, or the conducting system. Changes may also be due to extraneous factors such as sympathetic withdrawal, vagal stimulation, drug effects, myocardial ischaemia/infarction, infiltration, or surgical trauma, also miscellaneous conditions such as hypothyroidism, hypothermia, jaundice, or raised intracranial pressure.

Specific disorders

Sinoatrial disease

Sinoatrial disease, often referred to as 'sick sinus syndrome', results in inappropriate sinus bradycardia, sinus pauses, or junctional rhythm (Fig. 3) in the absence of extrinsic factors. The condition is most commonly caused by idiopathic degeneration of the sinus nodal cells, particularly in the elderly, and is associated in about 20 per cent of cases with idiopathic bundle-branch fibrosis (see below). Occasionally, sinoatrial disease is caused by ischaemia due to obstruction of the right coronary artery. Conduction block may occur between the sinus node and the atrium (sinoatrial block), resulting in 'dropped' P-waves (Fig. 4). More prolonged suppression of sinus node activity results in periods of sinus arrest, which are terminated by an escape beat from the sinus node, atrioventricular junction, or ventricle (Fig. 5(a)). Where the sinus rate is permanently slower than the junctional rate, continuous AV junctional rhythm will be present. Patients with sinoatrial disease have an increased predisposition to atrial tachyarrhythmias (bradycardia/tachycardia syndrome), and prolonged pauses may follow termination of tachycardia (Fig. 5(b)).

Fig. 3 Sinus bradycardia. The heart rate is less than 40 beats/min, and the sinus rate is so slow that an escape junctional beat is seen (open circle), preceding the P-wave.

Fig. 4 Sinoatrial block. A pause occurred because of the absence of a P-wave (open arrow). The timing of the sinus beats, however, is not interrupted, indicating that the sinus node discharged but the impulse failed to excite the atria.

Fig. 5 Sinus arrest. (a) Pause of 4 s results from failure of the sinus node to discharge. (b) Termination of atrial fibrillation is followed by a sinus pause of 2.5 s due to sinus arrest in a patient with bradycardia/tachycardia syndrome.

Sinoatrial disease can cause symptomatic bradycardia, dizziness, or syncope, but may be asymptomatic. The diagnosis is normally made from 12-lead or ambulatory ECG recording. Investigation should focus on excluding extrinsic causes of bradycardia, and on demonstrating the correlation between bradycardia or pauses and symptoms.

Neurocardiogenic syncope

Conditions where patients suffer reflex-induced attacks of bradycardia or hypotension are described in Chapter 15.2.3.

Atrioventricular conduction disorders

Impairment of atrioventricular conduction may occur either within the atrioventricular node (intranodal) or within the His–Purkinje system (infranodal). Intranodal block is not associated with QRS abnormalities, while distal (infranodal) block is commonly associated with bundle-branch block.

First-degree atrioventricular block

The normal upper limit of the PR interval is 0.20 s, and if the value exceeds this then first-degree atrioventricular block is present (Fig. 6). A prolonged PR interval may be associated with bifascicular block (for example, right bundle-branch block plus left anterior hemiblock). This condition, termed trifascicular block, implies the presence of slowed conduction through the remaining fascicle.

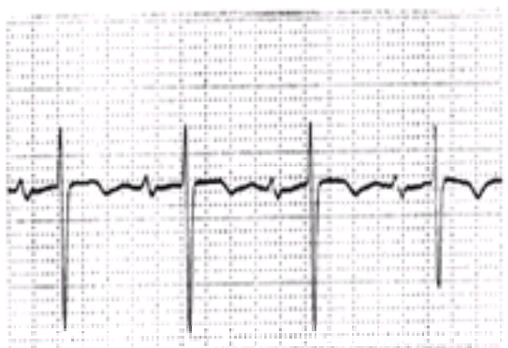

Fig. 6 First-degree heart block. The PR interval is prolonged (0.32 s).

Second-degree atrioventricular block

In second-degree atrioventricular block, there is intermittent failure of conduction from atrium to ventricle. In type I (Wenckebach) second-degree block, a characteristic pattern of increasing PR interval duration followed by a non-conducted P-wave is seen (Fig. 7). The QRS morphology is commonly normal. In type II second-degree AV block there is a sudden failure of conduction, without a preceding increase in the PR interval (Fig. 8). Regular non-conducted P-waves may result in high-degree block, with 2:1 or 3:1 conduction.

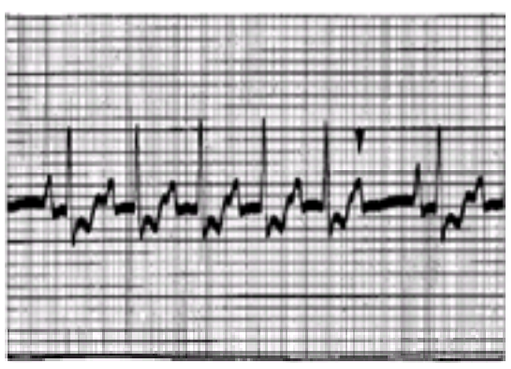

Fig. 7 Second-degree heart block, type I (Wenckebach). The PR interval progressively prolongs until there is a failure of conduction following a P-wave (arrow).

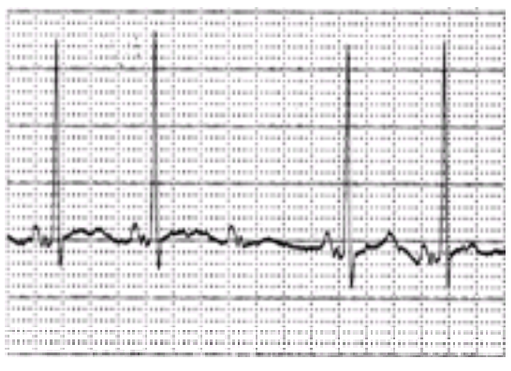

Fig. 8 Second-degree heart block type II. A non-conducted P-wave occurs without preceding prolongation of the PR interval.

Third-degree atrioventricular block

The characteristic feature of third-degree (complete) atrioventricular block is complete dissociation between atrial and ventricular activity (Fig. 9). The ventricular rate is regular and slower than the atrial rate. An escape rhythm arising above the bifurcation of the bundle of His will produce a narrow QRS morphology, commonly with a relatively rapid escape rhythm (50 to 60 per min). A more distal escape rhythm results in widened, bundle branch block morphology complexes with a slower escape rate (20 to 30 per min). When complete AV block coexists with atrial fibrillation, it is recognized by the presence of a slow, regular ventricular response.

Fig. 9 Third-degree (complete) heart block. Atrial activity does not conduct to the ventricles, and there is a regular escape rhythm of 35 beats per min.

High-degree AV block can be intermittent, and the resting ECG may be normal or only show evidence of mild conducting system disturbance such as first-degree AV block or bundle-branch block. If there is clinical suspicion, ambulatory ECG recording, for prolonged periods if necessary, is required to obtain evidence of higher degrees of AV block.

Aetiology of atrioventricular block

The causes of atrioventricular block are shown in Table 2: the commonest is idiopathic fibrosis of the His–Purkinje system, which occurs with increasing frequency from the seventh decade of life onwards, is associated with sinoatrial disease in up to 25 per cent of cases, and results in progressive impairment of atrioventricular conduction.

Atrioventricular block may occur acutely in myocardial infarction (Fig. 10). Inferior myocardial infarction predominantly affects atrioventricular nodal conduction by vagal overactivity, and possibly adenosine release from ischaemic myocardium. First-degree, type I (Wenckebach) second-degree block or third-degree atrioventricular block may occur, but these are commonly transient. Spontaneous recovery of normal conduction generally occurs within 7 to 10 days. By contrast, atrioventricular block secondary to anterior myocardial infarction is normally due to extensive infarction of the interventricular septum involving the left and right bundle branches after the division of the bundle of His. This may result in type II second-degree block or complete atrioventricular block, with a lower probability of recovery of normal conduction.

Fig. 10 Complete heart block in a patient with acute myocardial infarction. There is a narrow QRS-complex escape rhythm with ST segment elevation, ventricular rate 45 beats/min.

Any drug slowing atrioventricular conduction may potentially produce atrioventricular block. The risk is greater when such drugs are used in combination, the combination of intravenous verapamil in patients already receiving b-adrenoceptor blockers being particularly hazardous. Vagally mediated conduction disturbances occur as a physiological finding in highly trained athletes, or in neurocardiogenic syncope. Atrioventricular conduction disturbances arise in structural congenital heart disease such as endocardial cushion defects, but also as an isolated congenital abnormality, commonly in association with maternal systemic lupus erythematosus.

Management of bradycardias

The principal indications for active intervention in bradycardia are symptomatic (disturbances of consciousness, fatigue, lethargy, dyspnoea, or bradycardia-induced tachyarrhythmias) or prognostic (prevention of sudden cardiac death). Drugs interfering with sinoatrial or atrioventricular nodal function should be withdrawn if possible, although under certain circumstances (for example, tachybradycardia syndrome) it may be necessary to combine pacemaker implantation with continued drug therapy. Transient increases in sinus rate or the ventricular escape rate in complete atrioventricular block may be obtained with atropine or isoproterenol (isoprenaline). However, drug treatment is only of temporary value, and pacing is indicated for persistent bradycardia.

Management of specific disorders

Sinoatrial disease

Pacemaker implantation is indicated for the relief of symptoms (see below). Prognosis is not improved by pacemaker implantation in sinus nodal disease and thus pacemaker implantation in asymptomatic patients is not indicated.

Neurocardiogenic syncope

Patients with carotid sinus hypersensitivity and symptoms of presyncope or syncope should undergo permanent pacemaker implantation (see below). In vasovagal syndrome, the optimal treatment is uncertain: medical therapy with agents as diverse as a-agonists, b-blockers, vagolytic agents (disopyramide, hyoscine), ephedrine, or antidepressants is often tried, but the evidence base for the efficacy of drug therapy is weak, and spontaneous resolution of symptoms occurs in many patients.

Those whose symptoms persist despite drug therapy, particularly if bradycardia is a major component of the response to tilt-testing, are candidates for pacemaker implantation.

Atrioventricular conduction disturbances

First-degree AV block produces no symptoms and does not require treatment. The risk of progression from chronic bifascicular block to complete heart block is low, and patients with asymptomatic bifascicular block do not require prophylactic pacemaker implantation. The presence of trifascicular block implies advanced conducting system disease, and permanent pacing should be considered if there are symptoms or evidence of intermittent complete heart block.

Type I (Wenckebach) second-degree AV block is normally associated with a reliable subsidiary pacemaker and a low risk of progression to complete heart block. In the majority of instances active treatment is not necessary unless recurrent presyncope or syncope suggest the occurrence of an intermittent higher degree block, requiring consideration of pacemaker implantation. Type II second-degree AV block is generally indicative of extensive infranodal conduction abnormality, with a high risk of progression to complete AV block. Most authorities therefore recommend permanent pacemaker implantation even in the absence of symptoms. The presence of complete atrioventricular block, except in the context of an acutely reversible condition, should be regarded as an indication for permanent pacemaker implantation. This is urgent in cases where Stokes–Adams attacks are occurring, but even in asymptomatic patients the prognosis appears to be improved by permanent pacing. One exception to this general rule is congenital complete heart block, where the escape rhythm is often relatively fast (50 to 60 per min) with a narrow QRS morphology. Many patients remain asymptomatic well into adult life, although there is a small risk of syncope or sudden death. Pacemaker implantation should be considered if there are symptoms, or if the ventricular rate on ambulatory recording remains persistently below 50 beats/min, or in patients over 40 years of age.

Temporary pacemaker implantation is indicated where frequent Stokes–Adams attacks are occurring, or where the conduction disturbance is likely to be transient such as in cases of drug intoxication or inferior myocardial infarction. In the latter case, even the presence of complete heart block may be associated with an adequate ventricular rate and pacing need only be undertaken if there is haemodynamic compromise. Temporary pacing can only be used for a few days, owing to the risk of introducing infection along the electrode track.

Prognosis

The prognosis of patients with complete atrioventricular block having Stokes–Adams attacks is poor without pacemaker implantation, and is improved markedly by permanent pacing. Following pacing, the prognosis will depend on the nature and extent of underlying cardiac disease.

Asystole

The term asystole is used when the electrocardiogram shows a complete cessation of both atrial and ventricular activity: this appearance may be mimicked by disconnected ECG cables or other artefacts, but since asystole causes cardiac arrest the distinction is usually obvious. The management of asystole is discussed in Chapter 16.3.

Pacemaker therapy

Basic principles

The basis of pacemaker therapy is the local depolarization of the myocardium by an electric current passed through an electrode in contact with the heart (atrium or ventricle). Activation of the remainder of the atria or ventricles occurs by direct cell-to-cell conduction. The minimum current necessary to stimulate the heart during diastole is known as the pacing *threshold*. Pacemaker systems normally comprise one or more intracardiac catheter *electrodes*, introduced into the heart via the venous system, and a *pulse generator*, which contains the circuitry for generating and timing the pacing stimulus, as well as for sensing spontaneous cardiac depolarizations. The pacing stimulus is delivered between the active pole at the tip of the electrode catheter and an indifferent electrode. This is sited either on the same electrode catheter 1 to 2 cm proximal to the tip (bipolar pacing), or utilizes the can of the implanted pulse generator (unipolar pacing). An essential prerequisite for satisfactory pacing is that the electrode maintains a stable electrical contact with the myocardium. This is most likely to occur when the endocardial surface is trabeculated rather than smooth, and for this reason the standard sites for endocardial atrial and ventricular pacing are the right atrial appendage and the right ventricular apex, respectively (Fig. 11).

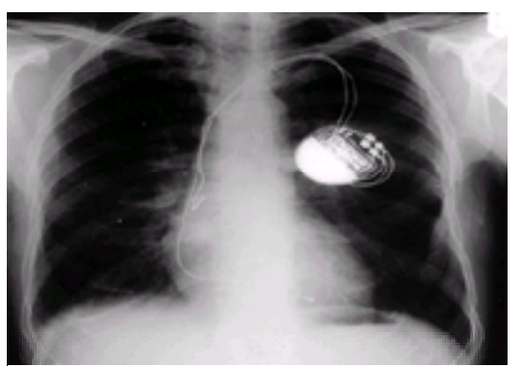

Fig. 11 Dual-chamber permanent pacemaker. Chest radiograph showing the pacemaker generator (in a subcutaneous pocket in the pectoral region) which is connected to electrodes that pass via the left subclavian vein and superior vena cava to the heart. The tips of the electrodes are in the right atrial appendage and the right ventricular apex.

The pulse generator is sited externally for temporary pacing. For permanent pacing, it is usually implanted deep to the subcutaneous fat layer in the prepectoral region (Fig. 11). The generator contains a timer set to deliver pacing stimuli at a preset *pulse interval* (for example, 1000 ms). The amplitude and duration of the pacing stimulus (*pulse width*) are usually set at nominal values (for example, 5 volts, 1 ms), but are adjustable and can be reduced to prolong the life of the battery, providing there is a sufficient safety margin between the pulse generator output and the pacing threshold. Most pulse generators are powered by lithium batteries and have a life of approximately 5 to 7 years, after which the generator is replaced. Pacemakers normally operate in the *demand* mode, whereby if spontaneous activation of the cardiac chamber is sensed via the electrode, the delivery of a pacing stimulus is *inhibited,* and the timer circuit of the generator is reset. Pacing in the *fixed rate* mode results in the delivery of stimuli regardless of the spontaneous activity of the chamber being paced.

Temporary ventricular pacing

Facilities for radiographic screening, continuous electrocardiographic monitoring, and defibrillation are necessary for the performance of temporary ventricular pacing. The temporary pacing electrode is introduced under aseptic conditions via an intravascular sheath inserted into the subclavian, internal jugular, or femoral vein and passed under radiographic control to the right atrium. The electrode tip is advanced across the tricuspid valve and impacted as distally as possible at the right ventricular apex. Non-sustained ventricular tachycardia, or occasionally ventricular fibrillation, may occur during catheter manipulation. Once the electrode is in an acceptable site, pacing is initiated, and the minimum output necessary to achieve stable ventricular capture is determined. The pacing threshold should normally be less than 1 volt, at a pulse width of between 0.5 and 2 ms. If the pacing threshold is unsatisfactory, the electrode is repositioned until an acceptable site is found. Care should be taken to determine that the electrode is stable by asking the patient to take deep breaths or to cough while pacing at threshold. The electrode is then secured at the site of insertion and the pulse generator set to an output of at least 3 volts above the pacing threshold.

Permanent pacemaker implantation

The technique of permanent pacemaker implantation is essentially similar to that of temporary pacing, except that the electrodes are much more flexible to minimize the risk of late myocardial perforation, and they are stiffened by a stylet during manipulation. Insertion is normally via the left subclavian or cephalic vein. Once the

electrode is in a satisfactory position, it is secured and connected to the implanted pulse generator. The rate, output voltage, pulse width, and other pacemaker functions can be modified non-invasively by means of telemetry via a transmitter/receiver placed on the skin over the pulse generator.

Pacing mode selection

The nomenclature used to describe pacing mode is given in Table 3, and electrocardiographic examples of the principal pacing modes are given in Fig. 12. Atrial demand (AAI) pacing is used for sinoatrial disease in the absence of atrioventricular block. Ventricular pacing (VVI) is the simplest and technically easiest mode of pacing, and is required for atrioventricular conduction disturbances. However, VVI pacing does not permit atrioventricular synchrony or an increase in pacing rate in response to an increase in sinus (atrial) rate. Dual-chamber (DDD) pacemakers have electrodes in both the right atrium and ventricle. If the sinus cycle length is greater than the pulse interval, atrial demand pacing occurs. Following the atrial stimulus, a programmable atrioventricular delay commences. If no spontaneous ventricular depolarization is sensed before the end of this interval, a pacing stimulus is delivered via the ventricular electrode. If the sinus cycle length is shorter than the pulse interval, no atrial stimulus is given, but the atrioventricular delay is *triggered*, followed by spontaneous or paced ventricular activation. By this means, the ventricular rate tracks the atrial rate up to a programmable maximum, allowing the heart to increase its rate in a physiological manner in response to metabolic demand. An alternative, and simpler, approach to achieve a rate response is the use of an activity sensor such as an accelerometer in the pulse generator. Such devices detect bodily movement and increase the pacing rate according to a programmable algorithm. Rate response can be utilized in either single- or dual-chamber pacemakers, and is designated by the suffix 'R' (e.g. AAIR, VVIR, DDDR).

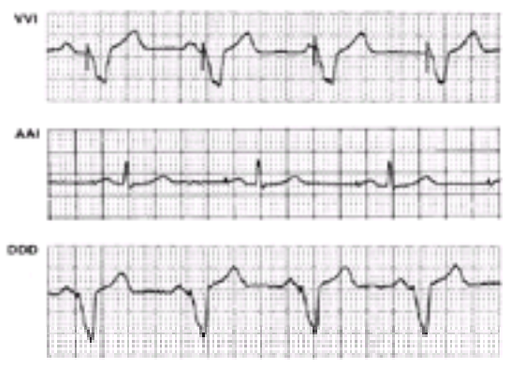

Fig. 12 Permanent pacemaker modes. Ventricular demand pacing, VVI (upper) with broad-complex ventricular complexes following the stimulus. Dissociated atrial activity can be seen. Atrial demand pacing, AAI (middle) with low amplitude bipolar pacing spike preceding the P-waves. Dual-chamber pacemaker, DDD (lower) with paced ventricular complexes following each P-wave (atrial tracking).

The advantage of dual-chamber (DDD) pacing over VVI pacing lies in the maintenance of atrioventricular synchrony and rate responsiveness, but this is achieved at the expense of increased complexity, complications, and cost. Observational studies have suggested that dual-chamber pacing reduces the risk of atrial fibrillation by virtue of pacing the atrium and avoiding retrograde atrial activation via the atrioventricular node. Additional suggested benefits include a lower incidence of the pacemaker syndrome (see below) and reduction in the risks of stroke, heart failure, and death. However, two recent large-scale randomized trials comparing DDD with VVI(R) pacing have failed to substantiate important prognostic or symptomatic benefits from DDD pacing, at least during follow-up periods of up to 3 years.

Complications

Complications of temporary or permanent pacemaker implantation include those of central venous cannulation (for instance, pneumothorax), perforation of the heart by the electrode tip leading to pericardial effusion and cardiac tamponade, and macroscopic or microscopic displacement of the electrode resulting in an increase in the pacing threshold or failure to capture. A chest radiograph should always be taken after pacemaker insertion to exclude pneumothorax and to confirm that the electrode position is satisfactory.

Permanent pacing may be complicated by the development of infection around the pulse generator, or by mechanical erosion of the generator through the skin. Once infection is established, or the skin is breached, it is almost never possible to eradicate infection with antibiotics: removal and replacement of the pacing system is required. Following electrode implantation, oedema and inflammation around the electrode tip result in a steady rise in the pacing threshold over the first few weeks. This may occasionally result in an increase of the pacing threshold such that capture is lost (Fig. 13(a)), although the process is normally mild and self-limiting. Demand pacemakers require an adequate intracardiac signal to recognize activation of the chamber in question, in order to inhibit output. If the intracardiac signal is of insufficient amplitude the pacing stimulus will not be suppressed (*undersensing*), resulting in inappropriate pacemaker firing (Fig. 13(b)). This phenomenon is commoner in atrial pacing, owing to the lower amplitude of atrial compared with ventricular electrograms. Alternatively, detection of extraneous electrical activity (for example, skeletal muscle activity) via the pacing electrode can result in inappropriate inhibition of the pacemaker output (*oversensing*) (Fig. 13(c)). Oversensing is commoner with unipolar than bipolar pacing modes because of the inclusion of the pulse generator can in the electrical circuit, and its proximity to the pectoral muscles. For the same reason, unipolar pacemaker systems are more prone to the problem of local skeletal muscle stimulation. Damage to the conductor or insulation of the pacing electrode may occur due to trauma at the site of ligation or to compression between the clavicle and first rib. This may result in oversensing, skeletal muscle stimulation, or to short-circuiting leading to premature battery depletion.

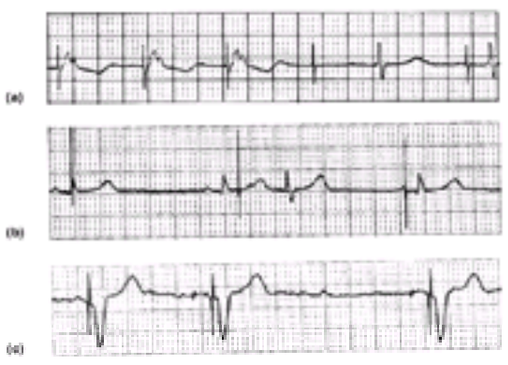

Fig. 13 Pacemaker malfunction. (a) Failure to capture. The fourth stimulus fails to capture the ventricle. (b) Undersensing. The atrial pacemaker has failed to sense the preceding atrial activity and therefore delivered the second stimulus. This has captured the atrium, with the P-wave in the ST segment, and subsequent conduction to the ventricle. (c) Oversensing. This dual-chamber pacemaker has sensed an electrical artefact through the ventricular lead and as a result has suppressed ventricular pacing, with the absence of ventricular activation following the third P-wave.

Patients receiving atrial demand (AAI) pacemakers may subsequently develop atrioventricular block, resulting in a recurrence of syncope and requiring upgrade of the pacing system to a dual-chamber (DDD) unit. A proportion of patients with ventricular demand (VVI) pacemakers, particularly those with sinoatrial rather than atrioventricular disease, will manifest retrograde ventriculoatrial conduction during ventricular pacing. This sometimes causes symptoms of fatigue, dizziness, or hypotension ('pacemaker syndrome'), which are associated with the presence of atrial cannon waves occurring as a result of simultaneous atrial and ventricular contraction. Upgrade of the system to a dual-chamber unit is necessary if symptoms are troublesome.

Follow-up

Patients with permanent pacemakers require follow-up by a pacemaker clinic. As well as detection of the complications described above, the function of such a clinic

is to assess the status of the pulse generator battery, and to maximize its life by programming the pulse generator output to the minimum consistent with a satisfactory safety margin. The design of pulse generators and the battery characteristics normally allow prediction of the expected replacement date several months if not years ahead. However, premature battery depletion or pacemaker failure does occur, and patients should therefore be assessed at least annually by the clinic. It must be borne in mind that many patients who have long-standing heart block treated by permanent pacing have no underlying cardiac rhythm, and that failure of the pacing system for whatever reason may be fatal.

Tachycardias

Mechanisms of arrhythmogenesis

The exact electrophysiological mechanism responsible for tachyarrhythmias is not known in all cases. There is a complex interaction between an underlying substrate such as previous myocardial infarction, a triggering event such as an extrasystole, and modulating influences, of which sympathetic stimulation and myocardial ischaemia are the most important. The principal mechanisms responsible for tachyarrhythmias are those of abnormal automaticity, triggered activity, and re-entry (Fig. 14).

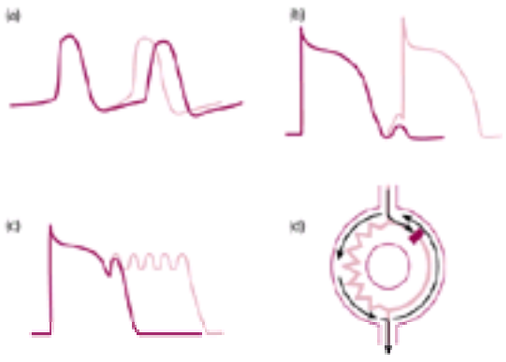

Fig. 14 Mechanisms of arrhythmia. (a) Increased automaticity. (b) Triggered activity due to early after-depolarizations. (c) Triggered activity due to delayed after-depolarizations. (d) Re-entry circuit. See text for details.

Automaticity

Abnormal automaticity is defined as an inappropriate increase in the rate of discharge of a tissue that has physiological pacemaker properties (namely, sinus node, atrioventricular node, or Purkinje fibres) (Fig. 14(a)). Such abnormalities are most commonly seen in the presence of ischaemia, sympathetic stimulation, or drug toxicity, especially digoxin. Automatic tachycardias are characterized by an absence of initiation by extrasystoles, either spontaneously or during electrophysiological testing.

Triggered activity

The term 'triggered activity' is used to define the appearance of automaticity immediately associated with a preceding action potential, and can be induced *in vitro* in tissues that do not demonstrate physiological automaticity. Two characteristic forms of depolarization may cause triggered activity:

1. *Early after-depolarizations* occur during the plateau phase of the action potential, prior to repolarization (Fig. 14(b)), and are more evident at slow heart rates, particularly in the presence of hypokalaemia and hypomagnesaemia. Mutations in cardiac Na^+ or K^+ channels, or drugs that prolong myocardial repolarization by inhibiting one or more components of the outward potassium current I_k (for example, class IA and class III antiarrhythmics, tricyclic antidepressants, antihistamines, organophosphorous insecticides, and many others) predispose to the appearance of early after-depolarizations *in vitro*. These changes are associated with the congenital and acquired long QT syndromes and the arrhythmia *torsade de pointes* (see below).
2. *Delayed after-depolarizations* are small subthreshold depolarizations occurring after full repolarization of the action potential (Fig. 14(c)). Their amplitude is increased by tachycardia or intracellular calcium overload, and may reach a level at which a spontaneous action potential is generated, potentially initiating a sustained tachycardia. Delayed after-depolarizations can be induced experimentally by digitalis overload, and are the likely mechanism of digitoxic arrhythmias.

Re-entry

The majority of the clinically important sustained tachycardias, whether of atrial, junctional, or ventricular origin, appear to arise on the basis of re-entry. The establishment of a re-entry tachycardia requires the presence of a potential circuit comprising two limbs with different refractoriness and conduction properties (Fig. 14(d)). A premature beat can be conducted in one limb of the circuit, but the other limb may still be refractory, resulting in unidirectional conduction block. If conduction is sufficiently slow, the tissue distal to the site of block in the refractory limb will have regained excitability before the arrival of the depolarizing wavefront, and can conduct the activity retrogradely. This results in reactivation of the initial conducting pathway and thus a circus movement tachycardia is established. Macro re-entry is defined as the occurrence of a re-entry circuit over a large area of the heart, such as in the presence of an accessory pathway (Fig. 15(a)). Micro re-entry occurs in a relatively small area of the heart, for example at the border zone of an old myocardial infarction, where effective conduction velocity is markedly slowed (Fig. 15(b)). The characteristic feature of a re-entrant tachycardia is that an appropriately timed extrastimulus can induce unidirectional block and initiate the arrhythmia. The tachycardia may be terminated by extrastimuli that depolarize the tissue ahead of the circulating wave front and thus interrupt the circus movement.

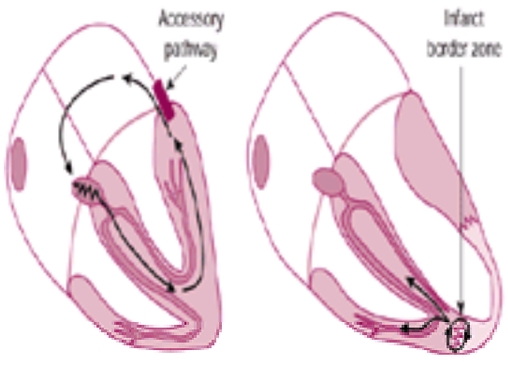

Fig. 15 Clinical examples of re-entry tachycardias. (a) Macro re-entry circuit involving an accessory pathway, which results in atrioventricular re-entry tachycardia. (b) Micro re-entry circuit at the border zone of a myocardial infarction.

Management of tachyarrhythmias

Differential diagnosis of tachycardias

The first and most important step in the diagnosis and management of tachycardias is to determine whether the arrhythmia arises within the atria and/or atrioventricular junction, or from the ventricles. An essential element in the differential diagnosis is to distinguish between tachycardias with normal QRS-complex

morphology and duration ('narrow-complex tachycardias'), and those where the QRS complexes are abnormal in morphology and increased in duration ('wide-complex tachycardias').

Narrow-complex tachycardias

Narrow-complex tachycardias arise through mechanisms that result in ventricular activation via the atrioventricular node and His–Purkinje system and therefore show normal QRS morphology and duration (£0.12 s) during tachycardia. The principal narrow-complex tachycardias and their characteristic ECG features are listed in Table 4. Careful study of all leads of the electrocardiogram is necessary to identify the presence of retrograde P-waves. Atrial flutter waves are most commonly evident in the inferior limb leads or in lead V1. Transient nterruption of atrioventricular nodal conduction by vagal stimulation or intravenous adenosine is of particular value in revealing the tachycardia mechanism. Atrial tachyarrhythmias will not normally be terminated by adenosine, but an increase in AV block reveals the underlying atrial tachyarrhythmia. By contrast, tachycardias utilizing the atrioventricular junction as part of the re-entry circuit will be terminated by transient AV block.

Wide-complex tachycardias

Few areas in cardiology cause more difficulty, or result in more mismanagement, than the diagnosis of wide-complex tachycardias. Whilst it is safe to assume that virtually all narrow-complex tachycardias have a supraventricular origin, wide-complex tachycardias (QRS duration ³0.12 s) may arise either from the ventricle or from supraventricular mechanisms, the latter occurring if there is pre-existing bundle-branch block in sinus rhythm or if functional bundle-branch block (aberration) occurs as a result of the tachycardia. An additional cause is activation of the ventricles via an accessory pathway. The electrocardiographic features of wide-complex tachycardias are described in Table 5.

Difficulties in diagnosis and management most commonly arise when ventricular tachycardia is not recognized and is misdiagnosed as 'SVT with aberration'. This usually happens as a result of a number of failings and misconceptions, the commonest being that the clinical context is not considered:

1. *The age of the patient*: middle-aged or elderly individuals presenting with a recent history of wide-complex tachycardia, and who give a history of myocardial infarction or congestive heart failure, are more likely to have ventricular than supraventricular tachycardia. Ventricular tachycardia can also arise in young patients.
2. *The haemodynamic status of the patient*: it is often assumed that ventricular tachycardia should cause haemodynamic collapse, whereas patients may in fact be haemodynamically stable if the rate is not excessively fast or if underlying cardiac function is good. Conversely, supraventricular tachycardias may cause syncope, hypotension, or shock if sufficiently rapid.
3. *The nature of the episodes of palpitation*: it is often not appreciated that ventricular tachycardia can present with a typical history of paroxysmal self-terminating episodes, just as in the case of supraventricular tachycardia.

In addition to attention to the history and 12-lead ECG, which must be analysed carefully during tachycardia, the response to transient AV nodal blockade with adenosine will assist considerably in diagnosis in many patients (Table 6). The importance of making a correct diagnosis in wide-complex tachycardia is twofold. First, inappropriate acute therapy of the tachyarrhythmia can be avoided. In particular, the use of verapamil in ventricular tachycardia misdiagnosed as supraventricular tachycardia is associated with a high risk of haemodynamic collapse as a result of the negative inotropic effect of verapamil, coupled with its lack of efficacy in terminating ventricular tachycardia. Adenosine is a safer diagnostic aid. Second, the correct diagnosis has prognostic implications. Although any wide-complex tachycardia can be terminated effectively by cardioversion, if the original arrhythmia has been misdiagnosed then the adverse prognostic significance of ventricular tachycardia will be overlooked. Appropriate investigation and long-term management may not be instituted.

Objectives of therapy

Many cardiac arrhythmias are benign and require no intervention. The main indications for treatment are the relief of symptoms, prevention of complications such as myocardial ischaemia, cardiac failure, or embolism, or an attempt to prevent arrhythmic sudden death. Precipitating factors such as myocardial ischaemia/infarction, infection, thyrotoxicosis, alcohol, electrolyte disorders, or drug toxicity must be sought and treated if possible. The type of therapy used will commonly be influenced by the presence of underlying structural heart disease such as myocardial ischaemia/infarction or left ventricular impairment.

Antiarrhythmic drug therapy

All antiarrhythmic drugs have potentially serious side-effects. They may worsen existing arrhythmias or produce new, possibly life-threatening ones (proarrhythmia), and the possibility of a proarrhythmic response should be borne in mind as part of the risk–benefit assessment whenever such drugs are prescribed. No classification exists that provides an accurate predication of the efficacy of a given drug for a given arrhythmia, thus therapy is initiated partly on the basis of trial and error, supported if necessary by more detailed investigation such as ambulatory ECG monitoring or cardiac electrophysiological testing.

The Vaughan Williams classification is based on the effects of anti-arrhythmic drugs in isolated tissue. The effects of the major classes of antiarrhythmic drug activity at the tissue level, and the associated electrocardiographic changes, are listed in Table 7. Individual drugs are described in Table 8.

Class I activity

Class I antiarrhythmic drugs act by inhibiting the rapid inward sodium current and have local anaesthetic activity. Class Ia agents (for example, quinidine, procainamide, and disopyramide) increase the action potential duration and have intermediate effects on the onset and recovery kinetics of the sodium channel and hence on intracardiac conduction. Class Ib agents (for example, lidocaine and mexiletine) shorten the cardiac action potential duration and have very rapid offset kinetics that result in minimal slowing of normal intracardiac conduction. Class Ic drugs (for example, flecainide and propafenone) have no major effect on action potential duration, but produce the most long-lasting effect on cardiac sodium channel kinetics and the most marked slowing of intracardiac conduction.

Class II activity

Class II activity is defined as antagonism of the arrhythmogenic effects of catecholamines. The commonest agents in this class are the competitive b-adrenoceptor blockers. Other agents such as propafenone have a weak b-receptor blocking activity, while amiodarone (see below) exhibits a non-competitive sympatholytic effect.

Class III activity

The class III mode of antiarrhythmic activity comprises lengthening of the cardiac action potential duration and hence of the effective refractory period. Drugs in this class possess a broad spectrum of activity against atrial, supraventricular, and ventricular arrhythmias. Currently available class III agents act by inhibiting the rapid component of the outward potassium current I_{kr}. Dofetilide and ibutilide are examples of drugs with 'pure' class III antiarrhythmic actions. Sotalol is a non-selective b-adrenoceptor antagonist that also possesses class III activity. Amiodarone possesses antiarrhythmic activity in all four Vaughan Williams classes.

Class IV activity

Class IV drugs (for example, verapamil and diltiazem) reduce the inward calcium current I_{Ca} in sinoatrial and atrioventricular nodal tissues. They are used to prevent or interrupt re-entry arrhythmias involving the atrioventricular node (for example, atrioventricular nodal re-entry tachycardia), or to slow the ventricular response in atrial fibrillation or flutter. The dihydropyridine calcium antagonists such as nifedipine have no antiarrhythmic action.

Digoxin

The antiarrhythmic activity of digoxin is not explained within the Vaughan Williams classification. Although its inotropic actions are based on inhibition of cardiac Na^+K^+ATPase, the antiarrhythmic activity appears to be mediated predominantly through vagal stimulation. Digoxin is used to slow ventricular rate in atrial fibrillation.

Adenosine

Adenosine, a naturally occurring purine nucleoside, is used pharmacologically to produce transient slowing or block of the sinus node or atrioventricular node, and is effective for the termination of re-entry arrhythmias involving the atrioventricular node. Adenosine is of particular value in view of its extremely short plasma half-life (about 2 s), which confers safety. It must be administered by rapid intravenous bolus injection, using incremental doses from 3 to 12 mg, to achieve the desired therapeutic effect.

Non-pharmacological therapy

Physical manoeuvres

Tachycardias involving the atrioventricular node may be terminated by manoeuvres that produce transient vagal stimulation, and patients with recurrent supraventricular tachycardias should be taught to perform these techniques in order to abort attacks and avoid the need for hospital treatment. The Valsalva manoeuvre, performed in the supine position, is the most effective technique.

Antitachycardia pacing

Re-entry tachycardias may be terminated by the delivery of appropriately timed extrastimuli that depolarize part of the re-entry circuit prior to the arrival of the wave front and interrupt the arrhythmia. Simple overdrive pacing can be effective in the termination of atrial flutter, AV nodal re-entry, AV (orthodromic) re-entry tachycardia, or sustained ventricular tachycardia (Fig. 16). The cardiac chamber in question is paced for brief periods at a rate just above that of the tachycardia, for example 6 to 12 beats, with repeated attempts sometimes necessary at gradually increasing rates. Overdrive atrial or ventricular pacing may result in degeneration into atrial and ventricular fibrillation, respectively, hence facilities for defibrillation must be available. Implantable antitachycardia pacing facilities are incorporated into implantable cardioverter-defibrillators (see below).

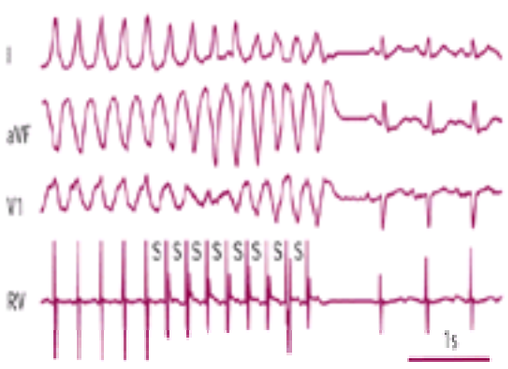

Fig. 16 Termination of ventricular tachycardia by overdrive ventricular pacing. During ventricular tachycardia a burst of eight stimuli (S) results in termination of the tachycardia and resumption of normal sinus rhythm. Surface leads I, aVF, V_1, and intracardiac electrograms from the right ventricular apex (RV) are shown.

External cardioversion/defibrillation

R-wave synchronized, direct current cardioversion under general anaesthesia or deep sedation is the most effective and immediate means of terminating sustained tachycardias, and is commonly used in the termination of atrial flutter, atrial fibrillation, or sustained ventricular tachycardia (Fig. 17). Although atrial flutter may respond to low-energy cardioversion (50 to 100 joules), the other arrhythmias normally require energies of 100 to 360 joules for termination. The use of non-synchronized DC shock in the termination of ventricular fibrillation is discussed in Chapter 16.3.

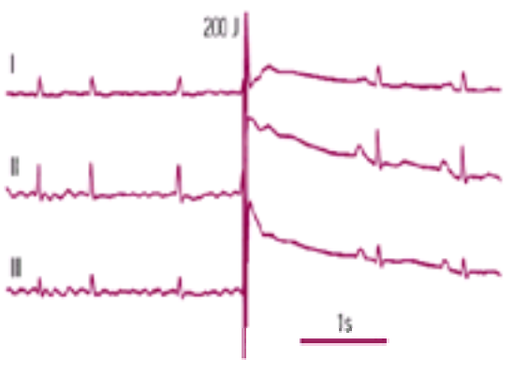

Fig. 17 Synchronized DC cardioversion of atrial fibrillation. A direct current shock, 200 joules, is delivered during atrial fibrillation to coincide with the R-wave of the QRS complex. This shock terminates the arrhythmia with restoration of normal sinus rhythm.

Internal cardioversion

Failure of external cardioversion of atrial fibrillation occurs in a significant proportion of patients as a result of various factors, including increased transthoracic impedance due to obesity, prolonged atrial fibrillation, left ventricular dysfunction, and left atrial dilatation. Internal cardioversion can still be achieved in a proportion of these patients. The procedure involves the introduction of specialized electrode catheters that permit DC-shock delivery between electrodes in the right atrium and the pulmonary artery or coronary sinus, providing a current field that achieves depolarization of both atria.

Implantable cardiovertor-defibrillators

Patients identified as being at high risk of sudden cardiac death, owing to a history of spontaneous or inducible sustained ventricular arrhythmias or out-of-hospital cardiac arrest, may be treated with an implantable cardioverter-defibrillator (**ICD**). However, these devices are expensive, complex, and require regular specialist follow-up. A transvenous rate-sensing/-shocking electrode is introduced via the subclavian vein to the right ventricular apex, with the generator implanted in the pectoral region (Fig. 18). The shock is delivered between the intracardiac shocking electrode and the generator can. Some devices also include a right atrial electrode to sense atrial activation. This improves the distinction between sinus or atrial tachyarrhythmias and ventricular tachycardia, and reduces the risk of an inappropriate shock being delivered. ICDs can be programmed to deliver initial antitachycardia ventricular pacing for slower tachycardias, with shock delivery available for faster rates or if pace-termination fails.

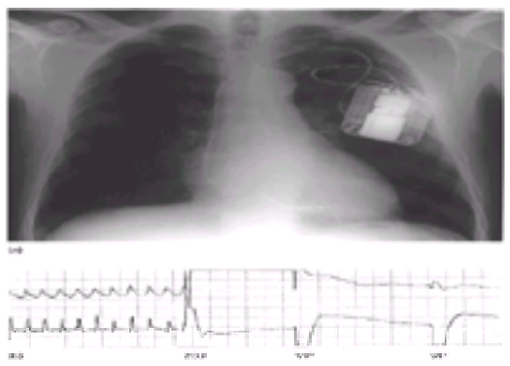

Fig. 18 Implantable cardioverter-defibrillator (ICD). (a) Chest radiograph showing the ICD generator in the left pectoral region, connected to a lead which passes via the left subclavian vein and superior vena cava to the heart. The tip of the lead is in the right ventricular apex. Cardiac rhythm is sensed from the electrodes at the tip of the lead, and shocks can be delivered between the metal casing of the generator and the right ventricular coil (thickened portion of lead). (b) Discharge from an ICD. A rapid polymorphic ventricular tachycardia is terminated by a 20-joule shock from the device. Electrograms shown are retrieved from the memory of the device, upper tracings from the shocking circuit (generator can to ventricular coil) and lower tracings from the sensing circuit (bipolar electrodes at the tip of the catheter in the right ventricle. The shock is followed by ventricular pacing (**VP**).

Implantable atrial defibrillators have been developed for use in those patients with frequent paroxysmal atrial fibrillation, but the value of these has not been fully evaluated.

Radiofrequency ablation

Selective ablation of part of a re-entry circuit, an arrhythmic focus, or of the atrioventricular node is used increasingly in the management of troublesome arrhythmias, and offers the opportunity of curative treatment. Radiofrequency energy is delivered between the tip of an intracardiac electrode positioned at the appropriate site and an indifferent surface electrode placed over the scapula. The energy produces a localized necrotic lesion 2 to 3 mm in diameter, which results in local conduction block. The success of the procedure depends on the accuracy of the placement of the lesion in relation to the re-entry circuit or arrhythmic focus. Current indications for radiofrequency ablation are listed in Table 9, and specific issues are discussed below in relation to individual arrhythmias.

Arrhythmia surgery

The 'Maze' procedure for atrial fibrillation involves creating a series of linear incisions in the left and right atria, which are then sutured, creating lines of conduction block. This prevents the development of atrial re-entry circuits while permitting atrioventricular conduction. Surgical management of recurrent ventricular tachycardia by mapping and resection of the re-entry circuit is occasionally performed, but is being superceded by ablation or ICD therapy.

Individual arrhythmias

Extrasystoles

The term extrasystole is used to describe a premature beat arising from a focus other than the sinus node. Extrasystoles are also described as premature beats, premature contractions, premature depolarizations, or ectopic beats.

Atrial extrasystoles

Atrial extrasystoles are recognized by a premature P-wave of different morphology from the sinus P-wave (Fig. 19(a)), which can be hidden within the ST segment or T wave of the preceding sinus beat. Premature atrial extrasystoles that occur before full recovery of the atrioventricular node will be followed by prolongation of the PR interval, or, if sufficiently premature, complete failure of conduction (Fig. 19(b)). Non-conducted atrial extrasystoles must be distinguished from sinus arrest or second-degree atrioventricular block.

Fig. 19 Atrial extrasystoles. (a) An atrial extrasystole, with an abnormal P-wave at the end of the preceding T wave, occurs following a sinus beat. (b) Blocked atrial extrasystoles. In the same patient, atrial extrasystoles occur following each sinus beat. They are earlier than those in (a), and the AV node is refractory because of the proximity of the atrial extrasystoles to the preceding beat, and conduction is blocked.

Atrial extrasystoles are a common finding in healthy people, particularly with increasing age, but are more frequent in the presence of increased atrial pressure or stretch such as in cardiac failure or chronic mitral valve disease. Patients should be reassured that the arrhythmia is benign and that drug treatment is rarely necessary. If treatment is required on symptomatic grounds, b-adrenergic blockers may be used, but class I antiarrhythmic drugs should be avoided in view of their proarrhythmic risk.

Junctional extrasystoles

Junctional extrasystoles are identified by the appearance of a premature, normal QRS complex in the absence of a preceding atrial extrasystole. The atria as well as the ventricles may be activated, resulting in an inverted P-wave simultaneous with the QRS complex, or inscribed within the ST segment. The significance and management of junctional extrasystoles are similar to those of atrial extrasystoles.

Ventricular extrasystoles

Ventricular extrasystoles are identified by the appearance of a bizarre, wide QRS complex not preceded by a P-wave (Fig. 20). There is commonly ST segment depression and T wave inversion. Ventricular extrasystoles may be intermittent, or occur with a fixed association to the preceding normal beats, that is 1:2, 1:3 (bigeminy or trigeminy). Where extrasystoles are of differing morphologies, the terms 'multifocal' or 'multiform' are used.

Fig. 20 Ventricular extrasystole (open circle). No retrograde atrial activation occurs, and the P-wave sequence is undisturbed (arrowed).

Ventricular extrasystoles occur in otherwise normal hearts, but are found particularly in the presence of structural heart disease. They occur commonly in the acute phase of myocardial infarction, but are also seen in the postinfarction phase, and in the presence of severe left ventricular hypertrophy or dysfunction of whatever cause. Extrasystoles may produce symptoms that require treatment in a minority of cases. The safest option is b-blockade.

Atrial arrhythmias

Atrial fibrillation

Atrial fibrillation is the commonest sustained tachycardia. The underlying mechanism is thought to be re-entry in most instances, with multiple wavelets (probably a minimum of six) circulating through the atria. Studies of patients with frequent paroxysmal 'lone' atrial fibrillation suggest that the arrhythmia may be triggered by one or more rapidly discharging foci, which are commonly situated in the pulmonary veins. Such patients often have frequent premature 'P-on-T' atrial extrasystoles on ambulatory ECG monitoring. Recent experimental and clinical studies have helped to explain the long-standing clinical observation that the longer the duration of atrial fibrillation, the more difficult it is to restore and maintain sinus rhythm ('atrial fibrillation begets atrial fibrillation'). Rapid atrial activation induces a process of electrical remodelling, resulting in shortening of the atrial refractory period and loss of the normal lengthening of the atrial refractory period at slower heart rates. The initial mechanism is thought to be intracellular Ca^{2+} overload, although more prolonged atrial tachyarrhythmias result in downregulation of Ca^{2+} entry and de-differentiation of atrial myocytes towards a fetal phenotype. Preliminary clinical data suggest that atrial electrical remodelling is reversible following cardioversion. The possibility exists that short-term treatment after cardioversion, during the period of regression of atrial electrical remodelling, could have long-term benefits in the prevention of relapse.

The characteristic ECG findings in atrial fibrillation of recent onset are of rapid, irregular 'f' waves at a rate of 350 to 600/min. These are associated with an irregular ventricular response because of variable conduction through the AV node (Fig. 21). With increasing duration of chronic atrial fibrillation, the amplitude of the 'f' waves diminishes until they are no longer visible. Under these circumstances, atrial fibrillation is diagnosed by the absence of P-waves and the irregular ventricular response (Fig. 21(b)).

Fig. 21 Atrial fibrillation. (a) Coarse atrial fibrillation of recent onset. (b) Fine atrial fibrillation in a patient with long-standing valvular disease. Surface V_1 leads are shown.

Clinical features of atrial fibrillation

The prevalence of atrial fibrillation increases with advancing age and may be as high as 5 per cent in the elderly. There are numerous causes of the arrhythmia (Table 10), but in many instances no obvious aetiological factor can be identified, and the individual is described as having 'lone' atrial fibrillation. Atrial fibrillation carries adverse prognostic significance, due in part to its association with organic heart disease. In addition, atrial fibrillation is an important risk factor for the development of stroke and systemic embolism as a result of stasis and thrombus formation in the left atrium. The risk of stroke is particularly high in patients with mitral stenosis or mitral valve replacement and chronic atrial fibrillation. The thromboembolic risk in non-rheumatic atrial fibrillation is related to age, previous left ventricular dysfunction, hypertension, and diabetes mellitus (Table 11).

Atrial fibrillation results in loss of the atrial contribution to left ventricular filling, which results in a modest reduction in cardiac output. In the presence of impaired ventricular function this can result in a worsening of heart failure. More commonly, symptoms and impairment of left ventricular function ('tachycardiomyopathy') arise as a result of a rapid uncontrolled ventricular rate. In addition, uncontrolled atrial fibrillation can cause further impairment of ventricular filling in mitral stenosis and conditions associated with left ventricular diastolic dysfunction, or the development of angina in patients with coexisting coronary artery disease.

Atrial fibrillation is classified into three patterns: paroxysmal, persistent, or permanent. In paroxysmal atrial fibrillation, spontaneously terminating attacks of palpitation last anything from a few seconds to a few days. The ventricular rate is often rapid and the patient may be severely symptomatic. The term 'persistent atrial fibrillation' is used to describe instances where the arrhythmia is not self-terminating, but where sinus rhythm can be restored by electrical or pharmacological cardioversion. In paroxysmal and persistent atrial fibrillation, the objectives of therapy are the restoration and maintenance of sinus rhythm. Permanent atrial fibrillation describes the situation where restoration of sinus rhythm is no longer possible, and the principal objective of therapy is control of the ventricular rate. At this stage, the ventricular rate is often slower and the patient may be unaware of the irregular pulse or of palpitations.

Management of atrial fibrillation

The management of a patient in atrial fibrillation depends upon the duration of the episode, the presence of organic heart disease, and any precipitating factors. Atrial fibrillation of recent onset (for example, less than 12 h) may terminate spontaneously. If fibrillation is persistent, an attempt to restore sinus rhythm should be made unless the arrhythmia is obviously long-standing or is associated with advanced organic heart disease. Underlying precipitating factors such as thyrotoxicosis should be corrected before attempting cardioversion. Chemical cardioversion may be achieved with class Ia, Ic, or III agents. Class Ia agents accelerate the ventricular rate by virtue of their anticholinergic action on the AV node and must be used in combination with digoxin. Traditionally, the commonest agent used was quinidine (1–2 g/day), but use of this drug has declined with the increasing recognition of adverse effects, in particular the risk of *torsade de pointes*. For patients without significant underlying heart disease, the current drugs of choice are the class 1c agents (for example, flecainide 2 mg/kg intravenously over 30 min). Class III drugs are somewhat less effective but are safer in the presence of left ventricular dysfunction or ischaemic heart disease. Options include sotalol (1.5 mg/kg intravenously over 30 min) or amiodarone (300 mg intravenously over 30 min followed by 1200 mg per 24 h until cardioversion). The pure class III agent ibutilide is approved for this indication in the United States. Normally, only one drug should be tried in any individual patient. If drug therapy fails, direct current cardioversion is commonly

effective.

Following successful cardioversion, or in the presence of paroxysmal atrial fibrillation, prophylactic therapy should be considered, particularly if multiple episodes have occurred. No drug is entirely satisfactory. Quinidine, the traditional mainstay of prophylaxis, increases mortality and is best avoided. Class 1c agents (flecainide or propafenone) are effective and safe in the absence of underlying ischaemia or left ventricular dysfunction. Sotalol (80 to 160 mg twice daily) is also effective and well tolerated. A randomized clinical trial comparing amiodarone, sotalol, and propafenone in the prophylaxis of atrial fibrillation showed amiodarone to be clearly superior to the other two drugs in the prevention of recurrent fibrillation following DC cardioversion. However, the side-effect profile is such that it is rarely indicated for long-term use unless the arrhythmia is troublesome and fails to respond to other drugs.

In permanent atrial fibrillation, restoration of sinus rhythm is not feasible or is unsuccessful and chronic management involves control of ventricular rate. The mainstay of treatment is digoxin, at a dose titrated to achieve adequate slowing in the ventricular rate at rest, with therapeutic plasma concentrations. Despite adequate rate control at rest, patients with atrial fibrillation commonly have an uncontrolled heart rate on exercise. Control of rate response with additional atrioventricular nodal blocking drugs such as verapamil or b-blockers does not improve exercise tolerance in the short term, but improved rate control reduces the risk of development of tachycardiomyopathy and chronic heart failure. Rate control is especially important if the duration of diastole is critical, as in mitral stenosis or ischaemic heart disease.

If drug therapy fails to control paroxysmal atrial fibrillation, particularly in the absence of underlying heart disease, consideration should be given to the possibility of a focal mechanism, which may be amenable to radiofrequency ablation. Atrioventricular nodal ablation and implantation of a permanent pacemaker may be indicated if such treatment fails, or in the case of permanent atrial fibrillation with uncontrolled ventricular rate. Ablation and pacing may improve symptoms and function, but it is wise to defer therapy if possible in view of the irreversible nature of the procedure and the need for lifelong permanent pacing. Furthermore, many patients with paroxysmal atrial fibrillation revert into permanent atrial fibrillation with a marked improvement in symptoms.

Prophylaxis against thromboembolism should be considered in all patients in atrial fibrillation. Cardioversion may be associated with embolism, hence patients who are scheduled to have elective chemical or electrical cardioversion should ideally be treated with warfarin for up to 4 weeks before admission. If the arrhythmia is known to have started within the previous 24 h, intravenous heparin for 24 to 48 h is acceptable. Once warfarin has been started, it should be continued for a minimum of 4 weeks after cardioversion since atrial mechanical function recovers slowly and there is a high risk of recurrent fibrillation.

Chronic anticoagulation with warfarin is indicated in patients in atrial fibrillation with mitral stenosis or regurgitation. Recent studies have shown that patients with non-rheumatic atrial fibrillation will also benefit from prophylaxis against thromboembolism. Meta-analysis of these trials shows that warfarin anticoagulation with a target range for the International normalized ratio (**INR**) of between 2.0 and 3.0 reduces the risk of thromboembolic events by about 60 per cent. Aspirin is a significantly less-effective alternative, achieving a risk reduction of around 20 per cent. The choice of antithrombotic prophylaxis depends on balancing the risk of thromboembolism (Table 11) against the risk of haemorrhagic complications, as well as the local facilities for anticoagulant control.

Atrial flutter

Atrial flutter is caused by a macro re-entrant circuit in the right atrium (Fig. 22), which produces a typical electrocardiographic 'saw tooth' pattern of atrial activity with a rate close to 300/min (Fig. 23). In the common form of the arrhythmia, flutter waves are negative in leads II, III, and aVF and positive in lead V1. Atrial flutter may be associated with either a regular or irregular ventricular response. Flutter with 2:1 atrioventricular conduction produces a regular tachycardia of 150/min and should always be considered in the differential diagnosis of a regular, narrow-QRS tachycardia of this rate. Occasionally, flutter occurs with 1:1 atrioventricular conduction producing a ventricular rate approaching 300/min. The flutter waves may not be seen easily with faster ventricular rates, and transient slowing of AV conduction may be necessary to make the diagnosis (Fig. 23).

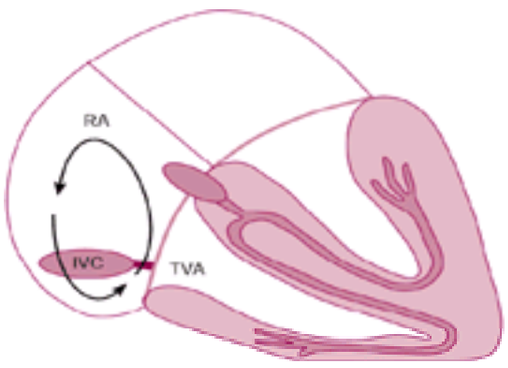

Fig. 22 Mechanism of atrial flutter. Typical atrial flutter results from a counter-clockwise re-entry circuit in the right atrium. The isthmus between the tricuspid valve annulus (**TVA**) and inferior vena cava (**IVC**) forms a critical part of this circuit, and linear ablation to create block can prevent recurrent atrial flutter.

Fig. 23 Atrial flutter with 1:1 AV conduction (above), 2:1 conduction (middle), and following adenosine administration (below) (6 mg intravenous injection 10 s previously).

The underlying causes of atrial flutter are the same as those of atrial fibrillation (Table 10). Although atrial flutter may last for many months or occasionally years, it usually degenerates into chronic atrial fibrillation unless cardioversion is undertaken. Atrial flutter also carries a risk of thromboembolism, and anticoagulation is indicated before and after cardioversion as for atrial fibrillation.

It is important to attempt to terminate atrial flutter since the ventricular rate is often poorly controlled by atrioventricular nodal blocking drugs. Termination may be achieved by chemical or electrical cardioversion as described above for atrial fibrillation. Bursts of atrial overdrive pacing at a rate approximately 10 per cent above the atrial flutter rate are also used: this may restore sinus rhythm or precipitate atrial fibrillation. Prophylaxis against atrial flutter is undertaken using the same agents as in paroxysmal atrial fibrillation, indeed the conditions often coexist and patients may manifest either flutter or fibrillation at different times.

Curative treatment of atrial flutter by radiofrequency ablation can be achieved by creating a line of conduction block between the tricuspid valve annulus and the inferior vena cava. This interrupts the isthmus through which the re-entry circuit must pass (Fig. 22).

Atrial tachycardia

Atrial tachycardia usually results in an atrial rate between 120 and 250/min. As in atrial flutter, there may be a degree of AV block, although 1:1 AV conduction may occur. The ECG shows regular P-waves which do not show the same 'saw tooth' appearance as in atrial flutter (Fig. 24). Atrial tachycardia may occur as a result of sinus node re-entry, when sudden paroxysms of tachycardia with a normal P-wave morphology will arise. Automatic atrial tachycardia manifests an abnormal P-wave morphology, commonly with a longer PR interval. The rate characteristically accelerates or 'warms up' before reaching a rate of 125 to 200/min. This arrhythmia is not started or terminated by atrial extrasystoles. Atrial tachycardia with atrioventricular conduction block is a manifestation of digitalis toxicity. Multifocal atrial tachycardia, in which rapid, irregular P-waves of three or four different morphologies are seen, may occur in severely ill elderly patients or in association with acute exacerbation of pulmonary disease.

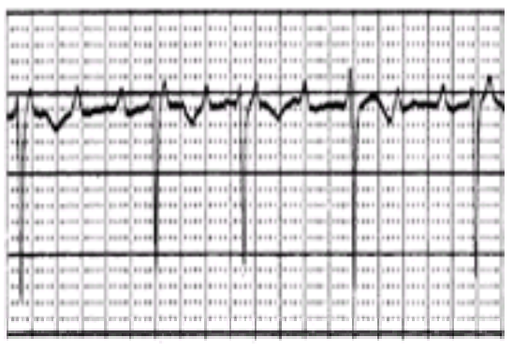

Fig. 24 Atrial tachycardia, with variable AV conduction. Lead V_1.

The approach to management is identical to that of atrial fibrillation. Focal atrial tachycardia can be treated by radiofrequency ablation.

Junctional re-entry tachycardias

The majority of regular narrow-complex tachycardias are junctional re-entry tachycardias, which involve the atrioventricular node in the re-entry circuit. Correct recognition of these arrhythmias has achieved additional importance with the development of effective curative measures.

Atrioventricular nodal re-entry tachycardia

This is the commonest cause of paroxysmal re-entry tachycardia manifesting regular, normal QRS complexes. The basis of the arrhythmia is the presence of two functionally distinct pathways in the region of the atrioventricular node (Fig. 25). The 'fast' pathway conducts more rapidly, but has a longer refractory period. The 'slow' pathway has slower conduction properties but a shorter refractory period. During sinus rhythm, atrioventricular nodal conduction occurs via the fast pathway with a normal PR interval (Fig. 25(a)). If a sufficiently premature atrial extrasystole arises, conduction in the fast pathway is blocked, but slow pathway conduction may continue, resulting in an abrupt increase in the AH interval as recorded in the His–bundle electrogram and corresponding to an increased PR interval on the surface ECG. Conduction down the slow pathway may be sufficiently tardy to allow the fast pathway to recover excitability before activation reaches the distal end of the pathways, allowing retrograde activation to occur via the fast pathway (Fig. 25(b)). The stage is then set for a re-entry circuit with anterograde conduction via the slow pathway and retrograde conduction via the fast pathway ('slow/fast atrioventricular nodal re-entry') (Fig. 25(c)). The arrhythmia circuit is functionally distinct from the atria and ventricles, which may be perturbed by extrastimuli without interruption of the tachycardia. Characteristically, anterograde activation of the ventricles and retrograde activation of the atria occur virtually simultaneously, resulting in the P-wave being 'buried' within the QRS complex, or producing a very small distortion of the terminal QRS, which requires careful comparison with the ECG during sinus rhythm (Fig. 26). The tachycardia is readily initiated by atrial premature stimulation, and terminated by appropriately timed extrastimuli or by overdrive pacing.

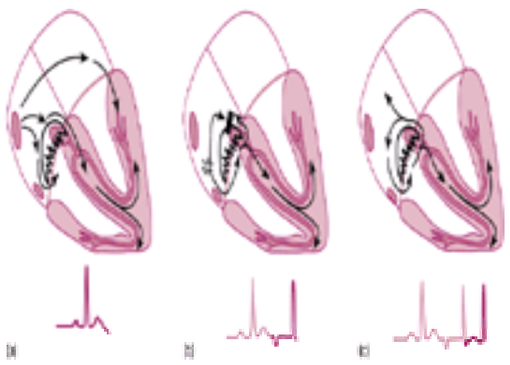

Fig. 25 Atrioventricular nodal re-entry tachycardia. Mechanism of initiation by atrial extrasystole. See text for details.

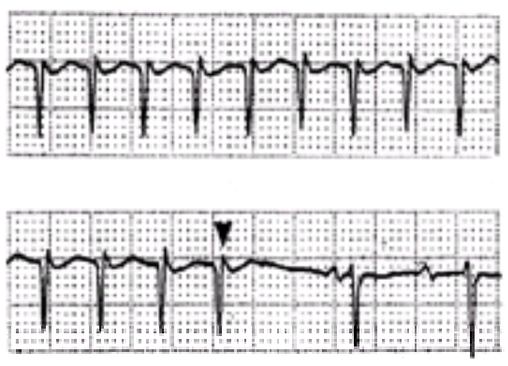

Fig. 26 Atrioventricular nodal re-entrant tachycardia. Rapid narrow-complex tachycardia with no apparent P-waves (upper) responding to 6 mg adenosine with restoration of sinus rhythm (lower). Close inspection reveals a positive deflection of the terminal QRS during tachycardia (arrow) which is absent during sinus rhythm. This is due to retrograde atrial activity coincident with ventricular activation. Lead V_1.

A less common variant of atrioventricular nodal tachycardia may arise where anterograde conduction during tachycardia is via the fast pathway with retrograde conduction via the slow pathway ('fast/slow atrioventricular nodal re-entry'). Under these circumstances, the atrium is activated well after the QRS complex, characteristically producing an inverted P' wave with the RP' interval greater than the P'R interval during tachycardia (Fig. 27). Occasionally, slow/fast and fast/slow tachycardias may coexist in the same patient.

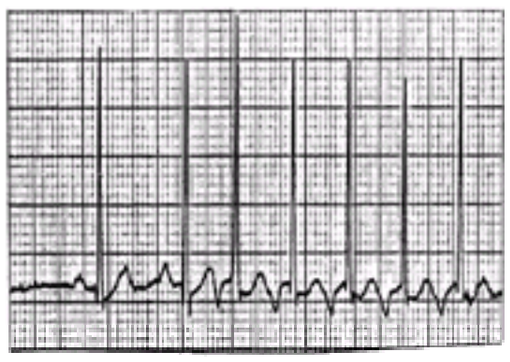

Fig. 27 Atypical atrioventricular nodal re-entry tachycardia (long RP'). Inverted P-waves precede the QRS complex during tachycardia (compare with preceding sinus beats).

Atrioventricular nodal re-entry tachycardia commonly presents for the first time in childhood or adolescence, although it may appear at any age. The natural history is of episodic paroxysmal tachycardia. Attacks occur at random intervals, although clustering of attacks may occur interposed with periods of relative freedom from symptoms. Atrioventricular nodal re-entry tachycardia has no specific association with other organic heart disease. Palpitations are normally well tolerated unless the tachycardia is particularly rapid, prolonged, or if the patient has other heart disease.

Management

Termination of an attack of atrioventricular nodal re-entry tachycardia is achieved by producing a transient AV nodal block. This may be achieved by vagotonic manoeuvres, by intravenous verapamil (5 to 10 mg), or by intravenous adenosine (3 to 12 mg) (Fig. 26). Drug prophylaxis of AV nodal re-entry tachycardia is undertaken with b-blockers, a combined b-blocker/class III agent such as sotalol, or with atrioventricular nodal blocking drugs such as verapamil or digoxin. Curative treatment of AV nodal re-entry tachycardia is readily achieved by ablation and is indicated if patients are refractory to drugs, intolerant of side-effects, or unwilling to take long-term medication. Radiofrequency energy is delivered to the 'slow' pathway, which lies between the compact atrioventricular node and the tricuspid annulus. Ablation at this site is normally curative but carries a small risk (1 to 2 per cent) of inducing complete heart block.

Pre-excitation syndromes (Wolff–Parkinson–White syndrome)

The term 'pre-excitation' refers to the premature activation of the ventricle via one or more accessory pathways that bypass the normal atrioventricular node and His–Purkinje system. The commonest of the pre-excitation syndromes is the Wolff–Parkinson–White syndrome, in which accessory pathways with electrophysiological properties of normal myocardium may lie at any point in the atrioventricular ring, the commonest sites being in the left free wall and the posteroseptal region. The characteristic electrocardiographic appearance is of early activation of the myocardium adjacent to the ventricular insertion of the accessory pathway (Fig. 28(a)). There is no atrioventricular delay, hence the PR interval is shortened, but slow intraventricular conduction results in slurred initiation of the QRS complex (the delta wave) (Fig. 29), although the remainder of the ventricle is excited via the normal His–Purkinje system. The ECG appearances of a delta wave occur in approximately 1.5 per 1000 of the population, but many individuals never experience paroxysmal tachycardias. The degree of pre-excitation during sinus rhythm is variable: it may be *intermittent* if the refractory period of the accessory pathway is close to the sinus cycle length (Fig. 29), or *inapparent* if the delta wave is obscured due to rapid AV nodal conduction. In such instances, transient slowing of AV nodal conduction (for example, by adenosine) will enhance the proportion of the ventricle excited by the accessory pathway and reveal pre-excitation.

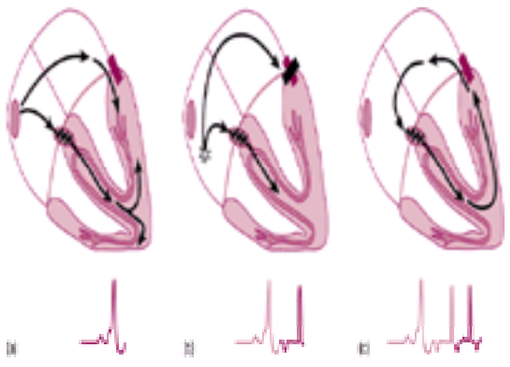

Fig. 28 Atrioventricular re-entry tachycardia. Mechanism of initiation by atrial extrasystole. See text for details.

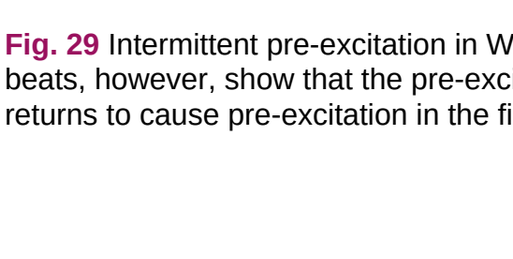

Fig. 29 Intermittent pre-excitation in Wolff–Parkinson–White syndrome. The first two beats show the characteristic short PR interval and delta wave. The middle two beats, however, show that the pre-excitation was intermittent. The pathway has become refractory, with normal PR interval and QRS morphology. Pathway conduction returns to cause pre-excitation in the final two beats.

In many instances, accessory pathways conduct only in the retrograde (ventriculoatrial) direction, and do not cause ventricular pre-excitation. Such pathways are termed *concealed*, since there is no clue to their presence on the resting ECG. These patients are not at risk of pre-excited atrial fibrillation (see below), but either overt or concealed accessory pathways can lead to episodes of atrioventricular re-entry tachycardia.

Atrioventricular re-entry tachycardia

The mechanism of orthodromic tachycardia, the common form of atrioventricular re-entry tachycardia, is illustrated in Fig. 28. A premature atrial extrasystole may find the accessory pathway refractory, but be conducted through the atrioventricular node to the ventricles (Fig. 28(b)). If sufficient delay has occurred by the time the ventricular insertion of the accessory pathway is depolarized, the pathway will have recovered excitability and allow retrograde activation from the ventricle to atrium, with the establishment of a re-entry circuit (Fig. 28(c)). Since the circuit involves activation of the ventricles via the His–Purkinje system, the QRS morphology during re-entry tachycardia is normal, unless a rate-related, bundle-branch block develops. Retrograde atrial activation can be identified by the presence of a characteristic

inverted P' wave early in the ST segment, an important diagnostic feature of atrioventricular tachycardia (Table 7, Fig. 30).

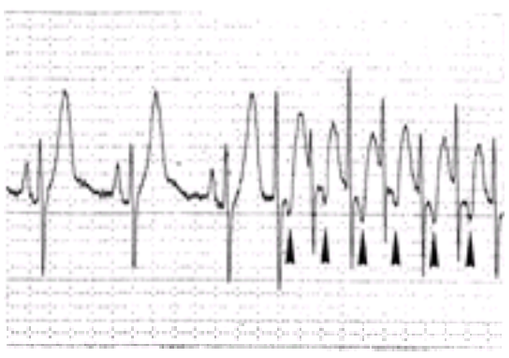

Fig. 30 Initiation of atrioventricular re-entry tachycardia. The third sinus beat is followed by the onset of narrow-complex tachycardia, initiated by an atrial extrasystole (obscured by T-wave). Retrograde atrial activation, with inverted P-waves in the ST segment (arrows), are seen during tachycardia.

Antidromic tachycardia

A rarer form of atrioventricular tachycardia has anterograde conduction via the accessory pathway and retrograde conduction via the atrioventricular node (antidromic tachycardia). The QRS morphology of this tachycardia is grossly abnormal with appearances dependent upon the site of insertion of the accessory pathway.

Other forms of pre-excitation include the Mahaim pathway, a direct atrioventricular or atriofasicular connection with slow conduction properties typical of AV nodal tissue. Evidence for direct atrionodal pathways associated with a short PR interval but no delta wave (Lown–Ganong–Levine syndrome) remains controversial and has not been established histologically.

Pre-excited atrial fibrillation

The major prognostic concern in Wolff–Parkinson–White syndrome is pre-excited atrial fibrillation. Conduction via an accessory pathway with a short refractory period, bypassing the normal AV nodal slowing, results in very rapid ventricular conduction that may degenerate into ventricular fibrillation (Fig. 31). The degree of pre-excitation during atrial fibrillation varies, giving a characteristic pattern of an irregular ventricular response with QRS morphology ranging from normal to fully pre-excited.

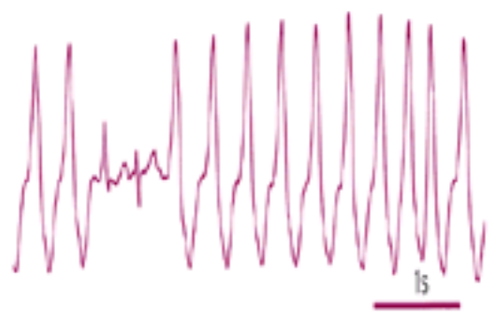

Fig. 31 Pre-excited atrial fibrillation. Conduction via an accessory pathway results in an irregular wide-complex tachycardia. The third and fourth beats show less pre-excitation, with activation mainly through the normal conducting system, with more normal QRS-complex morphology. Lead V_1.

Patients with symptomatic Wolff–Parkinson–White syndrome should be evaluated carefully for the risk of pre-excited atrial fibrillation. If pre-excitation is intermittent, this is commonly associated with a long accessory-pathway refractory period and a low risk of life-threatening tachycardias. Disappearance of the delta wave in response to administration of a class Ia or Ic antiarrhythmic drug also suggests a low risk. The risk of sudden death due to rapid pre-excited atrial fibrillation is very low among patients who have not had any symptomatic tachycardias, but is higher in symptomatic patients, particularly if episodes of pre-excited atrial fibrillation have been documented. Risk can be assessed by analysis of the shortest pre-excited RR intervals during spontaneous or induced episodes of pre-excited atrial fibrillation, a value of less than 250 ms identifying a higher risk group. Patients who have experienced atrial fibrillation with relatively slow ventricular rates are unlikely to develop faster ventricular responses subsequently. The general tendency is for accessory pathway conduction to become slower with increasing age, and spontaneous disappearance of conduction is well documented.

Management of patients with accessory pathways

Orthodromic re-entry tachycardia may be terminated by AV nodal blocking manoeuvres such as vagal stimulation, verapamil, or adenosine. Pre-excited atrial fibrillation requires particular care, since digoxin or verapamil may paradoxically accelerate the ventricular rate and are contraindicated. Electrical cardioversion is indicated in the presence of severe haemodynamic disturbance. Where patients are stable, agents such as intravenous flecainide, sotalol, or amiodarone, which both slow anterograde conduction through the accessory pathway and also restore sinus rhythm, are used. Drug prophylaxis is used to minimize the risk of recurrent orthodromic re-entry tachycardia or atrial fibrillation. Drugs acting only on the AV node, such as verapamil, are less effective than agents having additional action on the accessory pathway such as flecainide and sotalol. Although amiodarone is effective, its use is not desirable in otherwise fit young people who may require long-term drug therapy.

Patients with symptomatic Wolff–Parkinson–White syndrome are increasingly offered radiofrequency ablation as first-line therapy. This approach abolishes the risk of pre-excited atrial fibrillation as well as preventing further attacks of atrioventricular re-entry tachycardia. Careful electrode mapping of the atrioventricular annulus is necessary to identify the accessory pathway, the site at which the interval between the atrial and ventricular electrograms is at a minimum, ideally with a discrete accessory pathway potential between the signals. Passage of the radiofrequency current results in the disappearance of accessory pathway conduction within a few seconds (Fig. 32). The success rate of ablation varies according to the location of the pathway, but is usually over 90 per cent in experienced hands.

Fig. 32 Radiofrequency ablation of an accessory pathway. The patient had Wolff–Parkinson–White syndrome with evidence of ventricular pre-excitation on the surface electrogram during sinus rhythm (short PR interval, delta wave). One beat after switching on the radiofrequency (**RF**) current the QRS becomes normal, indicating successful ablation of the accessory pathway. This was a left-sided accessory pathway, as shown by the short interval between left atrial and left ventricular activation recorded from the coronary sinus (**CS**). This interval is prolonged following ablation of the pathway. Surface leads I, V_1, and intracardiac electrograms from CS and mapping catheter (**Map**) are shown.

Radiofrequency ablation is indicated in patients with tachycardias due to concealed accessory pathways if they are not well controlled on drugs, intolerant of side-effects, or unwilling to take long-term medication. Localization of the accessory pathway is performed as described above, except that mapping is performed during ventricular pacing or during stable atrioventricular tachycardia, and the earliest site of retrograde atrial activation at the atrioventricular annulus is the site of ablation.

Ventricular tachyarrhythmias

Definitions

Ventricular tachycardia is defined as the presence of three or more consecutive ventricular beats at a rate of 120 per min or greater. Ventricular tachycardia is considered *sustained* if an individual salvo lasts for 30 s or more, and *non-sustained* if the duration is between 3 beats and 30 s. *Monomorphic* ventricular tachycardia demonstrates a consistent QRS morphology during each paroxysm, although patients may have paroxysms of monomorphic ventricular tachycardia of different morphologies at different times. *Polymorphic* ventricular tachycardia demonstrates a constantly changing QRS morphology, often without discrete QRS complexes. Polymorphic ventricular tachycardia may degenerate into ventricular fibrillation and the electrocardiographic distinction between the two is difficult. *Torsade de pointes* is a characteristic type of polymorphic ventricular tachycardia with a typical undulating variation in QRS morphology as a result of variation in axis. The term is reserved for the arrhythmias arising in association with QT interval prolongation.

Sustained monomorphic ventricular tachycardia

Aetiology

Sustained monomorphic ventricular tachycardia commonly occurs in the presence of structural heart disease, but also arises in structurally normal hearts. It rarely occurs in the acute phase of myocardial infarction, but may be seen in the subacute phase (>48 h), or may arise many years after the index infarction, particularly in association with left ventricular dilatation and aneurysm formation. The arrhythmia also occurs in other conditions associated with ventricular dilatation or fibrosis such as dilated cardiomyopathy, hypertrophic cardiomyopathy, or previous ventriculotomy (for example, following repair of Fallot's tetralogy). Sustained monomorphic tachycardia can occur as a proarrhythmic response to antiarrhythmic drugs, particularly class I agents.

Although ventricular tachycardia normally occurs in individuals with overt heart disease, it is also seen in young, apparently healthy, subjects. Arrhythmogenic right ventricular cardiomyopathy (dysplasia) is an autosomal dominant condition associated with replacement of the right ventricular free wall with fat and fibrous tissue. These patients may have no symptoms or signs of cardiac disease, but typical ECG changes (T wave inversion in the right precordial leads) are associated with variable degrees of dilatation of the right ventricle demonstrated on echocardiography or magnetic resonance imaging. There remains a minority of patients with documented ventricular tachycardia in whom no structural heart disease is evident on clinical, ECG, or echocardiographic examination. The tachycardia may arise from the outflow tract of the right or, rarely, left ventricle, or from one of the fascicles of the left bundle branch.

ECG characteristics

The presence of atrioventricular dissociation is a particularly important feature to seek in a wide-complex tachycardia as it makes the diagnosis of ventricular tachycardia virtually certain (Table 8, Fig. 33(a)). A careful search for P-waves perturbing the QRS complex or T-waves is necessary, ideally using multichannel recordings. Occasionally, a fortuitously timed P-wave allows the development of a capture beat of normal QRS morphology without interrupting the tachycardia. A fusion beat occurs when activation of the ventricle is partly via the normal His–Purkinje system and partly from the tachycardia focus (Fig. 33(b)). Fusion and capture beats are diagnostic of ventricular tachycardia, but are commonly present only if the ventricular rate is relatively slow. Where dissociated P-wave activity cannot be recognized with certainty on the surface ECG, direct recording of atrial activity by an oesophageal or right atrial electrogram may aid the diagnosis. Although atrioventricular dissociation is diagnostic of ventricular tachycardia, it is not invariable. Retrograde ventriculoatrial conduction may occur, giving either 1:1 conduction or higher degrees of block (Fig. 33(c)).

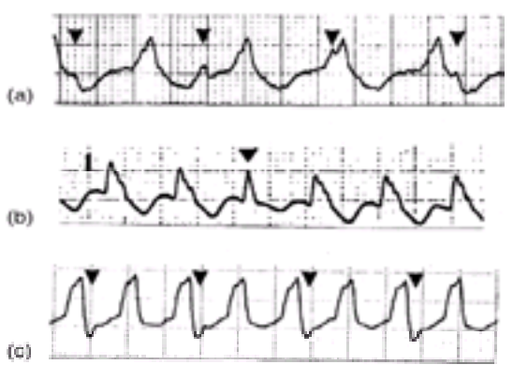

Fig. 33 Sustained monomorphic ventricular tachycardia. (a) Ventricular tachycardia with atrioventricular dissociation. P-waves (arrowed) are seen to have no relationship to the ventricular activation. Lead V_1. (b) Ventricular tachycardia with fusion beat (arrow). Lead V_1. (c) Ventricular tachycardia with 2:1 ventriculoatrial conduction. Lead III. Inverted P-waves (arrows) follow every second ventricular complex.

The QRS duration in ventricular tachycardia is commonly greater than 0.12 s, and values greater than 0.14 s are particularly suggestive of ventricular tachycardia. Although the QRS morphology may superficially resemble left or right bundle-branch block, the morphology is commonly atypical (Table 8). Ventricular tachycardia arising from the right ventricular free wall has a left bundle-branch block-like pattern, whilst left ventricular free wall tachycardias show right bundle-branch block morphology. The presence of concordant positive or negative QRS complexes across the chest leads is suggestive of ventricular tachycardia, as is the existence of extreme axis deviation.

Acute management of ventricular tachycardia

Rapid ventricular tachycardia may present with cardiac arrest, syncope, shock, anginal chest pain, or left ventricular failure, but slower tachycardias in patients with good cardiac function may be well tolerated.

Sustained ventricular tachycardia is a medical emergency. If the patient is pulseless or unconscious, immediate DC cardioversion is necessary. If the patient is conscious but hypotensive, urgent DC cardioversion under general anaesthesia or deep sedation is used. Haemodynamically tolerated tachycardias may be terminated by drug therapy. The commonest agent used is intravenous lidocaine (lignocaine) 100 mg, repeated if necessary after 5 min. Sotalol 1.5 mg/kg intravenously is more effective, but its use is restricted by its negative inotropic action. Second-line drugs for the termination of ventricular tachycardia include procainamide, disopyramide and amiodarone. Amiodarone normally has a slow onset of action but may be effective if the tachycardia is well tolerated. Flecainide is

contraindicated in view of the risk of developing incessant tachycardia. All antiarrhythmic drugs have significant negative inotropic actions that may further impair the haemodynamic status of the patient if sinus rhythm is not restored. For this reason, no more than one antiarrhythmic drug should normally be given before recourse to alternative therapy, usually DC cardioversion. Overdrive termination of ventricular tachycardia following insertion of a temporary pacing lead may be effective (Fig. 16), particularly if the tachycardia is relatively slow. Facilities for cardioversion must be available in view of the risk of acceleration or degeneration into ventricular fibrillation.

Prophylaxis of ventricular tachycardia

Ventricular tachycardia is a potentially life-threatening condition. Unless the acute episode was clearly precipitated by some transient or reversible factor, there is a high probability of recurrent attacks, which may result in sudden death rather than a sustained tachycardia. The 3-year cardiac survival rate varies from 80 per cent in patients in whom arrhythmia induction is suppressed by antiarrhythmic drug therapy, to 40 per cent in those in whom no effect of suppression is achieved and/or empirical therapy is used.

Clinical evaluation of the patient after restoration of sinus rhythm should be supported by electrocardiography, echocardiography, and/or radionuclide ventriculography. In those with ischaemic heart disease, exercise testing should be undertaken to identify the presence of reversible ischaemia, which may act as a trigger to ventricular tachycardia, and coronary arteriography to determine the extent of arterial disease. Particular attention should be paid to the possibility of right ventricular dysplasia in young patients.

Unless there is a clear precipitating factor such as drug toxicity, electrolyte abnormality, or acute ischaemia, patients who have had documented ventricular tachycardia require antiarrhythmic prophylaxis. The most reliable form of prophylaxis against arrhythmic sudden death or recurrent sustained ventricular tachycardia is provided by the implantable cardioverter-defibrillator (Fig. 18). The Antiarrhythmics versus Implantable Defibrillators Trial (**AVID**) showed defibrillators to be superior in preventing death from any cause, in comparison to drug therapy with amiodarone or sotalol in patients resuscitated from ventricular fibrillation or ventricular tachycardia causing haemodynamic compromise (Fig. 34). Those with non-sustained ventricular tachycardia (see below) and left ventricular dysfunction, in whom sustained tachycardia can be induced at electrophysiological testing, also have a better survival with defibrillator implantation compared with drug therapy. Indeed, the indications for such treatment are expanding to include a wide range of patients with sustained or non-sustained ventricular tachyarrhythmias who are at risk of sudden death.

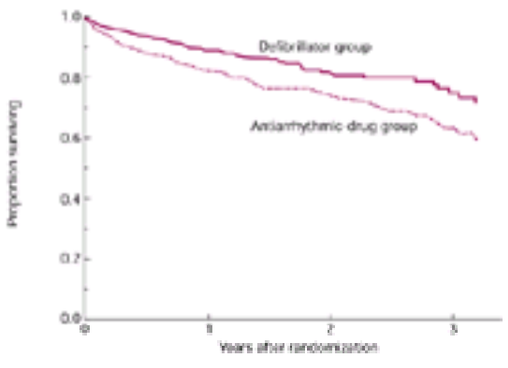

Fig. 34 Improved survival with the implantable cardioverter defibrillator compared to antiarrhythmic drugs in patients resuscitated from near-fatal ventricular arrhythmia. (Taken with permission from the AVID investigators (1997). *New England Journal of Medicine* **337**, 1576. Copyright 1997, Massachusetts Medical Society. All rights reserved).

In view of the cost and complexity of implantable defibrillator therapy, it is not affordable in all countries, and not appropriate for patients with advanced congestive heart failure or other conditions with a severely limited prognosis. Medical therapy is necessary for many patients, but is limited by a relative lack of randomized, controlled-trial evidence. Beta-adrenoceptor blockers have been shown to reduce the risk of sudden death in unselected survivors of myocardial infarction, and to be comparable to conventional antiarrhythmic agents in the prevention of recurrent ventricular tachyarrhythmias. Since b-adrenoceptor blockers are now shown to be of prognostic benefit even in the presence of severe left ventricular dysfunction, they should be used routinely in the prophylaxis of ventricular tachycardia if tolerated. Of the conventional antiarrhythmic agents, there is evidence that the class III drugs sotalol and amiodarone are superior to class I antiarrhythmic agents, which should no longer be used for this indication. However, sotalol and amiodarone have not been tested against placebo or conventional b-adrenoceptor blockers in randomized trials, although observational studies suggest they are of benefit in the prevention of arrhythmic death.

The efficacy of any given antiarrhythmic drug cannot be predicted, thus it is necessary to demonstrate antiarrhythmic drug efficacy and to exclude proarrhythmic responses in each patient. If episodes of ventricular tachycardia, sustained or non-sustained, are occurring frequently, it is sufficient to administer antiarrhythmic drugs under continuous electrocardiographic monitoring, and to demonstrate that salvoes of tachycardia have been completely suppressed. If episodes of ventricular tachycardia are infrequent, cardiac electrophysiological testing is indicated. The initial objective of such testing is to initiate a tachycardia of similar rate and QRS morphology to the spontaneous arrhythmia (Fig. 2): drug therapy is then administered and a repeat study is undertaken once stable plasma levels of the drug have been achieved. Suppression of inducibility of the tachycardia is associated with a reduced risk of arrhythmia recurrence and an improved prognosis in comparison with patients whose arrhythmia is not suppressed. Even if ventricular tachycardia is still inducible, the presence of marked slowing (increase in cycle length greater than 100 ms) associated with good haemodynamic tolerance appears to indicate a good long-term prognosis.

Radiofrequency ablation is used in the management of ventricular tachycardia, particularly in right ventricular outflow tract or fascicular tachycardia. Location and ablation of critical areas of slow conduction in ventricular tachycardias due to previous myocardial infarction are feasible but technically difficult, with lower rates of success than for other types of ablation.

Direct surgical management of recurrent ventricular tachycardia involves aneurysmectomy, endocardial mapping, and resection of the subendocardial area containing the micro re-entry circuit. The indications for surgery have been reduced considerably since the advent of the implantable cardioverter-defibrillator, since the surgical mortality is up to 10 to 15 per cent, compared with 0.5 per cent for defibrillator implantation. Where medically intractable ventricular tachyarrhythmias are associated with very poor left ventricular function, the only possible therapeutic option is cardiac transplantation.

Non-sustained ventricular tachycardia

Clinical features

The mechanism and causes of non-sustained ventricular tachycardia (Fig. 35) are similar to those of sustained ventricular tachycardia. There is often slight variation in the RR interval, particularly if the salvo involves only a few beats. Short salvoes of non-sustained ventricular tachycardia are often asymptomatic; more prolonged episodes may result in dizziness or presyncope, and occasionally in syncope. Apart from the instances where non-sustained ventricular tachycardia produces troublesome symptoms, the major clinical significance of the arrhythmia is as a risk marker for sustained ventricular tachycardia or sudden cardiac death. However, long-term follow-up of patients with non-sustained ventricular tachycardia in the absence of structural heart disease has indicated a good prognosis with no excess risk, although non-sustained ventricular tachycardia recorded by ambulatory ECG monitoring in the convalescent phase or after remote myocardial infarction is an independent risk factor for subsequent sudden cardiac death, especially if it is associated with impaired left ventricular function. The risk of arrhythmic death is particularly high if sustained ventricular tachycardia can be initiated in these patients by electrophysiological testing. Non-sustained ventricular tachycardia is also an adverse prognostic feature in patients with hypertrophic cardiomyopathy. Asymptomatic non-sustained ventricular tachycardia is commonly recorded in patients with advanced congestive heart failure: it is associated with an increased risk of cardiac death, but not selectively of sudden death.

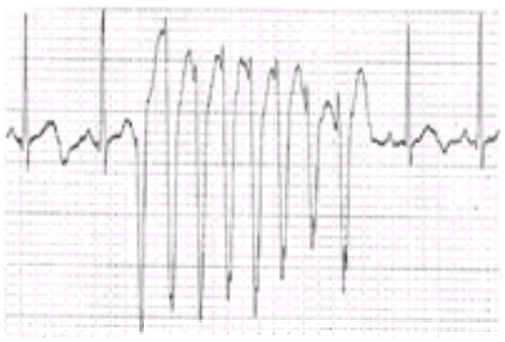

Fig. 35 Non-sustained ventricular tachycardia.

Management

The management of non-sustained ventricular tachycardia involves the identification of underlying organic heart disease, as described in the section on sustained monomorphic ventricular tachycardia. Patients should be evaluated non-invasively by echocardiography or radionuclide ventriculography. If no significant organic heart disease is present, and the patient is asymptomatic, no treatment is indicated. Treatment of symptoms in the absence of significant heart disease should be with b-blockers in the first instance to minimize the risk of proarrhythmic reactions. Calcium-channel blockers are effective occasionally and may be tried. Failing these, sotalol or a class I agent may be necessary.

Patients with structural heart disease but well-preserved ventricular function and a normal signal-averaged electrocardiogram are at low risk of sustained ventricular tachycardia and may be treated empirically with b-blockers. If non-sustained ventricular tachycardia is associated with impaired ventricular function, there is likely to be a substrate for sustained ventricular tachyarrhythmias. Patients in whom sustained ventricular tachycardia or fibrillation is inducible have an improved survival following defibrillator implantation compared with patients treated medically.

Low-dose amiodarone therapy has been recommended in the management of patients with hypertrophic cardiomyopathy and non-sustained ventricular tachycardia, although the evidence for its efficacy is based on comparison with historical controls rather than on a randomized prospective study.

Accelerated idioventricular rhythm

The term 'accelerated idioventricular rhythm' is used to describe a continuous ventricular rhythm with a rate less than 120/min. Idioventricular rhythm commonly occurs in the setting of acute myocardial infarction and appears to be a marker of successful thrombolytic therapy. No active treatment is necessary.

Polymorphic ventricular tachycardia

Polymorphic ventricular tachycardia is an unstable rhythm with varying QRS morphology. It is most commonly seen in the acute phase of myocardial infarction and is due to unstable re-entry circuits. As such, it commonly undergoes spontaneous termination, although it may degenerate into ventricular fibrillation. If episodes of polymorphic ventricular tachycardia are frequent in the early hours of myocardial infarction, they can be suppressed by intravenous lidocaine (lignocaine). However, short, infrequent episodes are commonly left untreated.

The Brugada syndrome is an autosomal dominant condition due to a mutation of one of the genes encoding the rapid sodium channel (SCN5a), causing partial inactivation. There is an unusual pattern of variable ST-segment elevation and partial right bundle-branch block in the right precordial leads, associated with a risk of polymorphic ventricular tachycardia and sudden death.

Torsade de pointes and the long QT syndromes

ECG characteristics

Torsade de pointes is an atypical ventricular tachycardia characterized by a continuously varying QRS axis ('twisting of points') (Fig. 36). Episodes of *torsade de pointes* are commonly repetitive and normally self-terminating, although they may degenerate into ventricular fibrillation. Paroxysms of *torsade de pointes* are associated in the preceding beats with evidence of marked QT prolongation, and frequently with morphological abnormalities of the T-waves such as T–U fusion, gross increases in T-wave amplitude, or T-wave alternans. Paroxysms of *torsade de pointes* in the congenital syndromes are often associated with increases in sinus rate, while in the acquired syndromes a slowing of the heart rate, and in particular a postextrasystolic pause, is often associated with initiation of the arrhythmia. This produces a characteristic 'short–long–short' sequence of initiation (Fig. 36). The combination of QT interval prolongation during sinus rhythm with intermittent *torsade de pointes* is described as the long QT syndrome.

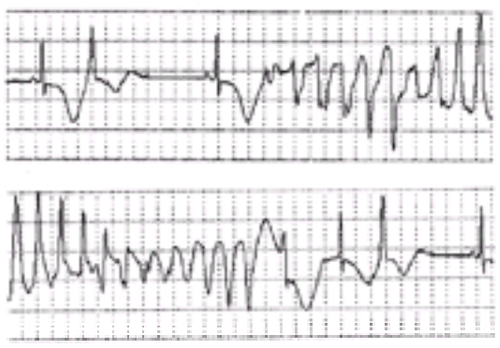

Fig. 36 *Torsade de pointes*. Note the marked QT interval prolongation in the sinus beats. Ambulatory monitoring recording is shown (continuous tracing).

Congenital long QT syndromes

The underlying arrhythmic mechanisms in the congenital syndromes involve mutations in genes encoding proteins in the ion channels conducting either the inward sodium current I_{Na}, or the rapid or slowly inactivating components of the outward potassium current (I_{kr} and I_{ks}, respectively). Multiple mutations have been described and the long QT syndromes are subclassified according to the underlying gene defect (Table 12). All the currently recognized subgroups show an autosomal dominant mode of inheritance. Lengthening of ventricular repolarization, and hence of the QT interval, occurs as a result either of increased duration of current flow via I_{Na}, or inhibition of outward current flow via I_{kr} or I_{ks}. The arrhythmias have characteristics consistent with triggered activity. A variety of congenital long QT syndrome phenotypes have been identified. In the Jervell–Lange–Nielsen syndrome, the long QT gene disorder is inherited as an autosomal dominant, but neural deafness as an autosomal recessive. The other long QT syndromes are not associated with deafness. Sporadic cases of idiopathic, presumed congenital long QT syndrome have been reported.

Attacks of *torsade de pointes* in the congenital syndromes are commonly associated with sympathetic stimulation such as exercise, waking, or fright. Paroxysms may produce syncope, which if prolonged may be complicated by convulsion, leading to misdiagnosis as epilepsy. A family history of recurrent syncope or sudden death

may be obtained. Sinus bradycardia is commonly seen in these syndromes.

Acquired long QT syndromes

Many drugs and other factors predispose to the development of the acquired long QT syndrome (Table 13). Although class Ia and III antiarrhythmic drugs are best known for this complication, it is important to recognize that a very large number of non-cardiac drugs inhibit the outward potassium current I_{kr}, and may cause significant lengthening of the QT interval singly or in combination. Episodes of *torsade de pointes* often occur as a result of a combination of factors, including prolongation of the QT interval in association with bradycardia or pauses, hypokalaemia, and hypomagnesaemia. All of these predispose to early after-depolarizations *in vitro* and this mechanism appears to be the likely cause of *torsade de pointes* in the acquired syndromes. It is increasingly recognized that there is a genetic predisposition to the development of acquired long QT syndrome in the face of predisposing factors, leading to the concept that patients developing acquired long QT syndrome have reduced 'repolarization reserve' as a result of a *forme fruste* of the congenital syndrome.

Acute management of torsade de pointes

The common clinical presentation is of recurrent dizziness or syncope, and the condition may easily be misdiagnosed as self-terminating polymorphic ventricular tachycardia or ventricular fibrillation unless the characteristic morphology of *torsade de pointes* and the associated QT interval prolongation is recognized. It is essential to discontinue predisposing drugs or other agents and to avoid empirical antiarrhythmic drug therapy, which may worsen the arrhythmia. Individual paroxysms of *torsade de pointes* are normally self-limiting, but if they are persistent, cardiac arrest will occur and emergency defibrillation is necessary. Intravenous magnesium sulphate (8 mmol over 10–15 min, repeated if necessary) is a safe and effective emergency measure for the prevention of recurrent paroxysms of tachycardia. If *torsade de pointes* is associated with bradycardia and pauses, the heart rate should be increased to between 90 and 100/min by atrial or ventricular pacing or isoproterenol (isoprenaline) infusion. Hypokalaemia should be sought and corrected if necessary.

Long-term management of long QT syndromes

The prognosis of untreated congenital long QT syndrome is poor, with a high incidence of sudden death in childhood. Patients with the congenital long QT syndrome presenting with attacks of syncope are initially treated with high-dose b-blockade for example, propranolol. If this is unsuccessful, selective high left stellate ganglionectomy has been employed successfully. Permanent pacing at rates of 70 to 80/min, in combination with b-blockers, may also be effective in reducing symptoms. Defibrillator implantation is necessary for resistant cases, and is commonly used as first-line therapy if episodes of *torsade de pointes* have resulted in cardiac arrest. Retrospective data from the International Registry have indicated that the 15-year survival in patients following their first episode of *torsade de pointes* has been improved from 50 per cent in untreated cases to 90 per cent following treatment with b-blockade and/or left stellate ganglionectomy. The prognosis of the acquired long QT syndromes are excellent, provided the underlying predisposing factors are identified and avoided.

Ventricular fibrillation

Ventricular fibrillation is defined as a chaotic, disorganized arrhythmia with no identifiable QRS complexes (Fig. 37). The mechanism is of multiple, unstable re-entry circuits. The electrocardiographic pattern depends on the duration of fibrillation: recent-onset fibrillation is described as 'coarse', with a peak-to-peak amplitude of around 1 mV (1 cm); with increasing duration of cardiac arrest, the amplitude of ventricular fibrillation diminishes and 'fine' ventricular fibrillation is less likely to be amenable to successful electrical defibrillation.

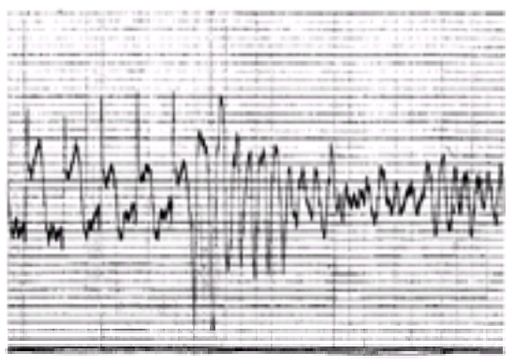

Fig. 37 Ventricular fibrillation complicating acute myocardial infarction. The arrhythmia is initiated by an 'R on T' ventricular extrasystole.

Ventricular fibrillation may represent the endpoint of cardiac disease of many aetiologies. Fibrillation may occur during acute myocardial ischaemia, and is the principal cause of death in the first 2 hours following acute myocardial infarction (Fig. 37). Ventricular fibrillation during myocardial infarction is subdivided into primary, occurring without warning in an otherwise stable patient, and secondary, where fibrillation occurs in the context of left ventricular failure and cardiogenic shock. In acute myocardial infarction, ventricular fibrillation is often initiated by an R on T extrasystole. Ventricular fibrillation occurring in chronic heart disease is most commonly a result of degeneration of rapid ventricular tachycardia, whose causes have been described above. Rarer causes of fibrillation are listed in Table 14.

Ventricular fibrillation is rarely self-terminating, and normally causes cardiac arrest with the rapid onset of pulselessness, unconsciousness, and apnoea. The management of cardiac arrest due to ventricular fibrillation is discussed in Chapter 16.3.

Management of survivors of ventricular fibrillation

Patients who survive an episode of ventricular fibrillation should be assessed carefully to determine the risk of recurrence. If ventricular fibrillation has occurred in the first few hours of a typical Q-wave myocardial infarction, the risk of recurrent cardiac arrest is low, and no specific prophylactic therapy other than conventional postinfarction b-blockade is indicated. In many instances ventricular fibrillation arises as a result of acute ischaemia in patients with known, extensive heart disease who have not sustained an acute infarction. These patients remain at high risk of recurrent ventricular fibrillation, and should be evaluated fully by exercise testing and coronary arteriography with a view to revascularization. Patients may sustain a cardiac arrest without any preceding chest pain, but in the presence of a known risk factor for ventricular tachycardia such as previous myocardial infarction. In these individuals, it is likely that ventricular fibrillation arose as a result of degeneration of rapid ventricular tachycardia. These patients are at risk of further cardiac arrest, and are managed with an implantable cardioverter-defibrillator or antiarrhythmic therapy as discussed in the section on ventricular tachycardia.

15.7 Valve disease

D. G. Gibson

Mitral stenosis

Aetiology

Chronic rheumatic heart disease is much the commonest cause of mitral stenosis, though there are a number of other well defined conditions in which blood flow across the mitral valve is limited to a variable extent.

1. Congenital mitral stenosis is a rare condition with thick, rolled leaflets and short chordae, with the spaces between them obliterated. The papillary muscles may be abnormally inserted, either directly from the free wall of the ventricle or from the septum. In parachute mitral valve, there is only one papillary muscle. Congenital mitral stenosis may be associated with left ventricular outflow obstruction, hypoplasia of the left ventricular cavity and the aorta, or endocardial fibroelastosis.
2. A calcified mitral valve ring may rarely cause mild mitral stenosis.
3. In infective endocarditis, bulky vegetations may occasionally interfere with transmitral flow.
4. Nodular rheumatoid arthritis may be associated with thickening of the valve cusps, but true mitral stenosis does not occur.
5. In systemic lupus erythematosus, treatment of Libman–Sachs endocarditis with steroids has led to fibrosis of the cusps with commissural fusion.
6. The combination of ostium secundum atrial septal defect and rheumatic mitral stenosis, Lutembacher syndrome, is probably fortuitous.

Rheumatic mitral stenosis

Incidence

The incidence of rheumatic mitral stenosis parallels that of acute rheumatic fever (see Chapter 15.10.1). It is thus much commoner, and presents earlier, in the Middle East, the Indian sub-continent, and the Far East than in the West.

Pathology

Rheumatic mitral stenosis is due to distortion of the normal mitral valve anatomy with fusion of the commissures. The cusps themselves become vascularized, thickened, and frequently develop thrombus on their atrial surfaces. The chordae become thickened and fused, and the papillary muscles scarred. Finally, the cusps may become calcified. The left ventricle is usually normal or small in pure mitral stenosis, but occasionally dilates. The left atrium is characteristically enlarged with scarring and disruption of muscle fibres. Mural thrombosis is common, particularly on the free wall just above the posterior mitral valve cusp (McCallum's patch). In long-standing cases, calcification of the left atrial wall may develop in plaques on its endocardial surface. In the lungs, the changes of pulmonary venous congestion, pulmonary hypertension, and haemosiderosis develop. These lead to dilatation and hypertrophy of the right ventricle with functional tricuspid regurgitation.

Pathophysiology

The main disturbance in mitral stenosis is due to left ventricular filling. When mitral valve area falls to around 2.5 cm^2, peak early diastolic ventricular filling rate falls and diastasis is lost. This does not matter at rest when the heart rate is slow and filling period relatively long, but during exercise as the heart rate increases, flow is maintained only by a pressure drop between atrium and ventricle. With a smaller valve area, a pressure drop is present at rest, and mean left atrial pressure rises. Patients with symptomatic mitral stenosis have a valve area of 0.75 to 1.25 cm^2, and a pressure drop as high as 20 to 30 mmHg across the valve during diastole. Cardiac output falls and pulmonary vascular resistance usually increases.

The subvalvular apparatus may interfere with left ventricular filling by restricting wall movement, so reducing stroke volume and increasing left atrial pressure in the absence of any diastolic pressure drop across the valve itself. Left ventricular cavity size, usually normal in young patients, may increase in the middle aged or elderly, and end-diastolic pressure may rise. A number of factors contribute to such left ventricular disease, including restriction of filling, coronary emboli, and distortion of the septum by right ventricular hypertrophy and overload. In addition, disturbed filling interferes in some way with systolic function, since after successful surgery cavity size usually falls, particularly at end-systole, as stroke volume increases.

Chronic left atrial hypertension causes a corresponding rise in pulmonary capillary pressure; clinical evidence of pulmonary congestion appears when it reaches around 25 mmHg. Further lung disease may be caused by active pulmonary hypertension, repeated pulmonary emboli or chest infections, haemosiderosis, or even bone formation.

Clinical features

Symptoms

The symptoms of mitral stenosis usually appear insidiously, and may have been present for several years before the patient seeks medical attention. They may be apparent within 3 or 4 years of the attack of acute rheumatic fever, or be delayed by up to 50 years. Less frequently, their onset is abrupt with an attack of acute pulmonary oedema, systemic embolism, or the onset of atrial fibrillation.

The commonest manifestation of mitral stenosis is a reduction in exercise tolerance by breathlessness, or less frequently, by fatigue or palpitation in patients in atrial fibrillation. Later in the disease, nocturnal dyspnoea occurs, though florid acute pulmonary oedema has become uncommon. Recurrent chest infections or winter bronchitis are very characteristic; the resulting infected pulmonary oedema responds poorly to antibiotics, and often leads to fluid retention and haemoptysis. Occasionally, massive or recurrent haemoptysis may be the presenting or only symptom of mitral stenosis. Systemic embolism from the left atrium is common in untreated mitral stenosis, particularly when atrial fibrillation is present. Any organ may be affected, but the commonest sites are cerebral, coronary, splenic, renal, mesenteric, or the arteries of the limbs. Salt and water retention is common in untreated mitral stenosis, and leads to peripheral oedema, ascites, pulmonary oedema, and pleural effusion.

Physical examination

Prolonged low cardiac output leads to weight loss and a malar flush.

The character of the pulse is normal, although its amplitude may be decreased and the rhythm irregular due to atrial fibrillation. The arterial pulses should always be checked in view of the possibility of previous arterial emboli.

The venous pressure is usually normal unless tricuspid regurgitation is present. An 'a' wave in the venous pulse of a patient with what appears to be pure mitral stenosis should always raise the possibility of additional tricuspid stenosis or severe pulmonary hypertension.

Palpation of the precordium at the apex may reveal a palpable first sound, previously called a 'tapping apex', and less frequently, a palpable opening snap. It may also be possible to feel pulmonary valve closure at the base of the heart if severe pulmonary hypertension is present. A left parasternal heave is usually due to right ventricular hypertrophy caused by pulmonary hypertension, but may also be due to tricuspid regurgitation, or increased prominence of a normal right ventricle secondary to an enlarged left atrium. In pure mitral stenosis, a sustained apex beat is unusual, but may be seen when the right ventricle is very considerably enlarged or more commonly, because of coexistent left ventricular disease.

On auscultation at the apex, the classic findings are a loud first sound, preceded by a presystolic murmur if the patient is in sinus rhythm, an opening snap, and a mid-diastolic murmur. A loud first sound is less specific for rheumatic mitral stenosis than a palpable one, since it also occurs in high cardiac output states, such as hyperthyroidism. A soft or absent first sound in mitral stenosis strongly suggests that the anterior cusp of the mitral valve is calcified or immobile. An opening snap is a very characteristic physical sign. It is usually loudest at the lower left sternal edge, less commonly the apex or the base. It is a sign of a pliable anterior cusp, and is absent if the valve structure is severely disorganized. The mid-diastolic murmur starts after the opening snap; it is low pitched and persists for a variable period throughout diastole. If the mitral stenosis is mild, the murmur is short, but if the murmur lasts throughout diastole at a normal ventricular rate, then the degree of stenosis is likely to be at least moderately severe. When the rate is rapid due to atrial fibrillation, the murmur may no longer be audible, although in these circumstances, the diagnosis can be suspected from the palpable first sound. However, there are some patients in whom no mid-diastolic murmur is audible even when the heart rate is controlled: so-called 'silent' mitral stenosis. These patients frequently either have severe pulmonary hypertension or a very disorganized and immobile mitral valve.

Investigations

Chest radiography (Fig. 1)

Fig. 1 Chest radiograph from a patient with pure mitral stenosis. Heart size is normal, but the left atrial appendage is enlarged. The upper lobe vessels are dilated and there are Kerley lines at both bases.

Heart size may be normal or increased. Selective enlargement of the left atrium is the commonest radiographic abnormality, 'selective' implying that the degree of enlargement is proportionately greater than that of the heart shadow as a whole. It appears on the penetrated posteroanterior film as a double outline on the right side of the heart shadow, with elevation of the left main bronchus, and enlargement of the left atrial appendix which forms that part of the left heart border just below the main pulmonary artery. Mitral valve calcification may be visible on the posteroanterior film just to the left of the spine.

In the lung fields, the upper lobe veins may be dilated with the patient in the erect position, indicating that left atrial pressure is raised. The size of the main pulmonary

artery can be increased due to pulmonary hypertension. Upper lobe blood diversion occurs when pulmonary vascular resistance is greatly increased: this can be recognized from decreased prominence of the vessels to the lower zones, while those to the upper zones are normal or increased. Pulmonary oedema occurs when the left atrial pressure reaches approximately 25 to 30 mmHg. It gives rise to lymphatic (Kerley B) lines in the lower zones, basal pleural effusions, generalized hazy shadowing, and finally, obvious interstitial oedema. Pulmonary haemosiderosis is due to long-standing pulmonary congestion. Bone formation, appearing as dense nodules of a few millimetres in diameter, is rarely seen.

ECG

The ECG is not very informative in mitral stenosis. Atrial fibrillation can be confirmed. If the patient is in sinus rhythm, then left atrial hypertrophy causes a bifid P wave in lead II and a dominant negative deflection in V1. ECG evidence of right atrial hypertrophy suggests tricuspid stenosis in addition to mitral stenosis. The electrical axis is usually vertical: right ventricular hypertrophy, if severe, is shown by a dominant R wave in V1.

Echocardiography

On M-mode echocardiography (Fig. 2) the mid-diastolic closure rate of the anterior cusp of the mitral valve is less than 50 mm/s in mild mitral stenosis and 0 to 20 mm/s in severe disease. Cusp fusion causes forward rather than backward movement of the posterior cusp during diastole.

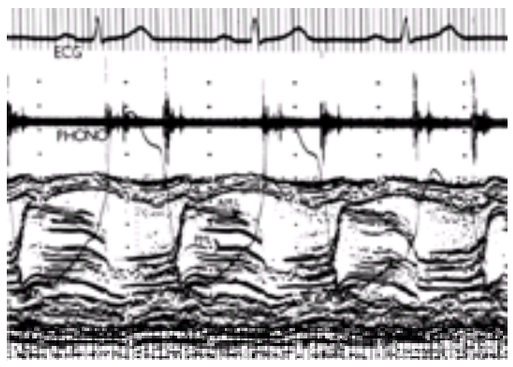

Fig. 2 M-mode echocardiogram from a patient with mitral stenosis. The anterior cusp (AML) is thickened, and its diastolic closure rate is reduced. The posterior leaflet (PML) moves forward during diastole. There is an opening snap on the phonocardiogram, coinciding with maximum forward motion of the anterior cusp.

On cross-sectional echocardiography the mobility of the anterior cusp is reduced, particularly near its tip (Fig. 3(a)). Valve area can be estimated semiquantitatively from the parasternal minor axis view (Fig. 3(b)), provided that the cusps are not calcified. The degree of subvalve involvement can be assessed and occasionally atrial thrombus can be detected (Fig. 4).

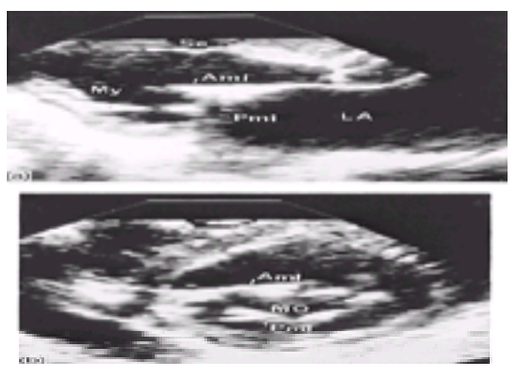

Fig. 3 (a) Two-dimensional echocardiogram from a patient with mitral valve disease; parasternal long-axis view taken in mid-diastole. The anterior cusp (Aml) of the mitral valve is thickened, and fails to open normally. LA, left atrium; Se, septum; My, myocardial echoes; whose intensity is increased due to scarring of the subvalve apparatus; Pml, posterior mitral leaflet. (b) Two-dimensional echocardiogram. Rheumatic mitral valve disease, parasternal minor-axis view during mid-diastole, at the level of the mitral valve orifice (MO), anterior cusp of the mitral valve (AML), and posterior mitral leaflet (Pml).

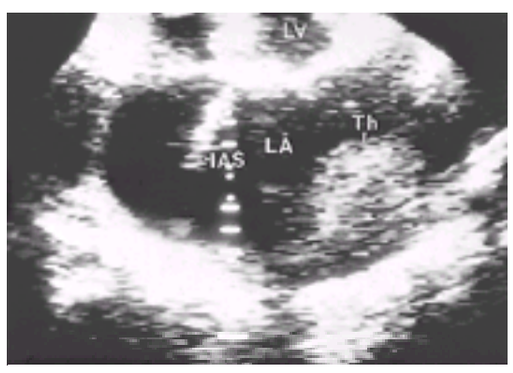

Fig. 4 Left atrial thrombus (Th) in a patient with mitral valve disease. LA, left atrium; LV, left ventricle; IAS, interatrial septum. The left atrium is considerably enlarged.

The diastolic pressure drop across the valve can be estimated by cross-continuous-wave Doppler. Peak right ventricular pressure is derived from the systolic velocity of tricuspid regurgitation. The aortic and tricuspid valves can also be checked.

Transoesophageal echocardiography is particularly useful for demonstrating thrombus in the body of the left atrium or in the left atrial appendix. Spontaneous contrast within the left atrial cavity is probably due to stasis resulting from a combination of atrial fibrillation, low forward flow, and increased cavity size. It indicates an increased risk of thrombus formation. Finally, the degree of thickening and calcification of the cusps and the extent to which the subvalve apparatus is involved can be assessed particularly well by this approach.

Cardiac catheterization

This is rarely necessary, either to make the diagnosis or to assess severity. It is performed only to determine the state of the coronary arteries in older patients and as a prelude to balloon valvuloplasty, or very occasionally in patients in whom diagnostic echocardiograms cannot be obtained.

Diagnosis

The diagnosis of mitral stenosis is usually straightforward on the basis of history, physical signs, and chest radiography, and can rapidly be confirmed by

echocardiography. When the ventricular rate is rapid, the diastolic murmur may be inaudible, but becomes apparent when the ventricular rate is controlled by digoxin. Silent mitral stenosis may mimic primary pulmonary hypertension, but the correct diagnosis is easily made by echocardiography. Mild mitral stenosis should be suspected as a source of systemic emboli and as a cause of unexplained atrial fibrillation, particularly in the elderly.

Differential diagnosis

1. Left atrial myxoma (see Chapter 15.11.1);
2. cor triatriatum (see Chapter 15.13);
3. pulmonary veno-occlusive disease (see Section 15.15.2); or
4. Austin–Flint murmur (see Aortic regurgitation section, below).

Treatment

Medical

In patients under 30 years of age, longer in some cases, penicillin prophylaxis against further attacks of acute rheumatic fever should be given (see Chapter 15.10.1 for further discussion).

Atrial fibrillation should be treated with a digitalis preparation to control ventricular rate. Anticoagulant therapy must be given to reduce the risk of systemic embolism to all patients with atrial fibrillation, unless there are very strong contraindications. It is also advisable to give anticoagulants to patients in sinus rhythm with mitral stenosis, particularly the middle aged and elderly: the incidence of embolism is significant, especially if they go into atrial fibrillation. The risk of embolism is particularly high when a patient with atrial fibrillation not receiving anticoagulants is admitted to hospital with a rapid heart rate and pulmonary oedema. In this situation intravenous heparin should be given until therapeutic anticoagulation with an oral agent is established.

Fluid retention associated with mitral stenosis responds well to treatment with diuretics. Chest infections should be treated promptly with appropriate antibiotics, and patients should be given a supply of antibiotic to take prophylactically at the start of a head cold. A diuretic is also useful because chest infections often precipitate, or may be precipitated by, fluid retention.

In all patients with valvular heart disease, prophylactic antibiotics should be given for all dental manipulations and other potentially septic hazards (see Chapter 15.10.2).

Mitral valvuloplasty

Rheumatic mitral stenosis results from fusion of the commissures between the two mitral cusps, which is susceptible to rupture by inflating a catheter-mounted balloon across the valve orifice (Fig. 5). Mitral valvuloplasty has the great advantage over surgery of avoiding thoracotomy. A catheter is introduced through the inferior vena cava to the right atrium. The atrial septum is crossed, and the catheter stabilized across the mitral valve, usually by a guidewire passed out through the aortic valve. The balloon itself may be single, often with a waist; less commonly, two balloons are placed simultaneously across the orifice. The balloon is inflated to a predetermined size for 20 s.

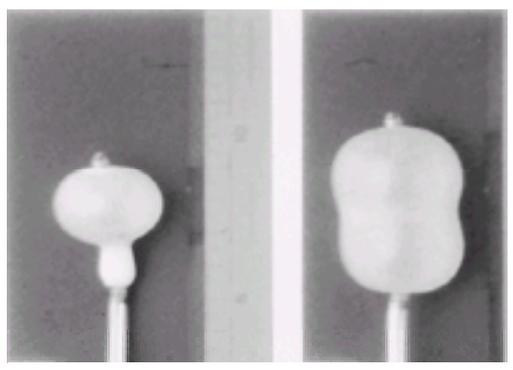

Fig. 5 The Inoue balloon catheter, as used for mitral valvuloplasty, partially (left) and completely (right) inflated.

Not all patients are suitable for valvuloplasty. It is unsatisfactory in those with calcified and immobile valve cusps, who constitute the majority with mitral stenosis in the developed world. There should be no more than minimal regurgitation. Ideally, the cusps should be thin and mobile, without calcification in the commissures, shortening of the chordae, or scarring of the papillary muscles. Clot in the left atrial appendix must have been excluded by transoesophageal echocardiography. In appropriately selected patients, valvuloplasty gives a satisfactory fall in transmitral pressure drop, maintained in the short and medium term. Mitral regurgitation may be provoked, sometimes severe enough to require valve replacement on an elective or even an emergency basis. The majority of patients are left with a small ASD at the site of passage of the catheter, but this is not of any haemodynamic significance.

Mitral surgery

Surgical procedures available include mitral valvotomy, open or closed, and mitral valve replacement. The choice of operation depends on the anatomy of the mitral valve determined on the basis of the physical signs and the echocardiogram, the age of the patient, and the surgical resources available.

Closed mitral valvotomy is a relatively simple procedure in terms of the resources that are required, although a satisfactory result presupposes considerable experience with the operation, experience that is now becoming rare in the developed world. It is particularly suitable in a Third World country, where the major radiographic and expensive disposables necessary for balloon valvuloplasty are not available. It is most effective in a young patient, in sinus rhythm, with evidence of a mobile anterior cusp. It can be regarded as a form of beating heart surgery, and when performed with intraoperative transoesophageal echocardiographic monitoring is particularly effective. Symptom-free follow-up of 40 years or more regularly occurs after this procedure.

Open valvotomy requires cardiopulmonary bypass but allows a more complete procedure to be undertaken, and in particular the subvalvular apparatus can be inspected and adherent chordae divided. If the results of valvotomy are found to be unsatisfactory, it is possible to proceed to valve replacement at the same operation. In general, significant mitral regurgitation is a contraindication to a conservative procedure; although the early results of repair may be excellent, replacement is usually necessary within 5 years.

Valve replacement is necessary when the valve cusps are greatly thickened or calcified. This operation should not be considered in patents in whom the haemodynamic disturbance caused by the valve disease is mild, since the prosthesis causes a resting diastolic pressure drop across it, as well as interfering with systolic and diastolic left ventricular function.

Indications for interventional procedures

It is difficult to lay down hard and fast indications for intervention in patients with mitral stenosis. If the clinical and echocardiographic evidence suggests that valvuloplasty is feasible, then the presence of definite limitation of exercise tolerance is an adequate indication, particularly in a young person. It may also be used in patients with asymptomatic but well developed mitral stenosis before pregnancy. Open valvotomy should be considered if there is any significant contraindication to valvuloplasty. Closed valvotomy is unfortunately no longer available in most developed countries, but it remains a most attractive possibility where medical and surgical resources are limited. In avoiding the use of either radiographic screening or cardiopulmonary bypass, it may be an attractive option for the patient who

develops acute pulmonary oedema during pregnancy, provided that local surgical expertise is available.

If valve replacement is likely to be required, then limitation of exercise tolerance should be more severe. In individual patients the decision is not usually difficult when there has been definite progression of symptoms. It is not often necessary to advise operation in a patient with normal exercise tolerance. Unless it is due to coronary artery disease, the presence of left ventricular dilatation is not a contraindication to operation, however severe it may appear to be in terms of increased cavity size or reduced amplitude of wall motion. The same applies to pulmonary hypertension, which is not a contraindication, since it increases the benefits of operation to a greater extent than the risks.

Prognosis

In the absence of surgical treatment, mitral stenosis is usually a progressive disease, although the rate is unpredictable. Unfavourable features include a gradual increase in the severity of the valve disease with disorganization of its structure and superimposed calcification, an increase in pulmonary resistance, and the development of functional tricuspid valve disease, with chronic elevation of the venous pressure leading to cardiac cirrhosis and impaired liver function.

Surgical treatment has considerably improved the prognosis, although conservative mitral surgery does not prevent progression of the rheumatic process, nor does it reduce the risk of infective endocarditis. It has also become clear that the life of biological mitral valve substitutes, particularly the porcine xenograft, is limited to no more than 10 years in the majority of patients above the age of 21, and considerably less than this in children. These valves should thus be confined to the very elderly, and to young women who wish to undertake pregnancy, knowing that repeat surgery will be needed. There are minor differences in haemodynamics between the different types of mechanical valve substitutes, but in individual cases, these are of little consequence.

Mixed mitral valve disease

Mixed mitral valve disease is nearly always rheumatic in origin. The mitral regurgitation is not usually severe in terms of the volume load that it imposes on the left ventricle, though the increased stroke volume increases the diastolic pressure drop across the valve. In general, it occurs in older patients than pure mitral stenosis, and the valve is more disorganized. It is more likely to be calcified with limited cusp mobility and scarred subvalve apparatus. The symptoms are similar. On examination, a pansystolic murmur is evident along with the mid-diastolic murmur. The first sound is not palpable or accentuated. The pansystolic murmur is usually loudest towards the axilla, reflecting the frequent scarring and retraction of the posterior cusp. Chest radiography (Fig. 6) may show more advanced changes than in pure mitral stenosis, and in particular, the left atrium may be very large indeed. ECG is unhelpful. Echocardiogram is likely to show thickened cusps whose motion is reduced as well as mitral regurgitation. Valvuloplasty or conservative surgery are both unsatisfactory, and when symptoms merit, mitral replacement is usually required.

Fig. 6 Chest radiograph from a patient with mixed mitral valve disease, showing gross cardiac enlargement, due mainly to dilation of the left atrium.

Mitral regurgitation

Aetiology

There are many causes of mitral regurgitation. Any of the components of the mitral valve apparatus may be involved (Table 1).

Degenerative mitral valve disease is the commonest condition to affect the cusps. It has been described under a number of other names, based either on its pathology or on its clinical features: degenerative mitral valve disease, mucinous or myxomatous degeneration, or floppy or ballooning mitral valve. It is a non-inflammatory process partially or completely affecting either cusp. Cusp area is increased, causing folding and upward doming into the left atrium during systole. The chordae may become elongated, tortuous, and thinned, predisposing to chordal rupture. Ulceration of the cusps may predispose to thrombosis on their surface and infective endocarditis. Ring circumference may increase. The papillary muscles are normal. Histologically, the centre of the cusp—the fibrosa—is abnormal, with large areas in which collagen bundles are fragmented or absent altogether, and a dense layer of laminated collagen forms on the atrial surface. There is no evidence of vascularization or of inflammatory cells in the absence of secondary infective endocarditis.

The cause of sporadic cases of floppy mitral valve is unknown. However, similar appearances may complicate Marfan's syndrome, pseudoxanthoma elasticum, Ehlers–Danos syndrome, and osteogenesis imperfecta. The incidence of the sporadic condition tends to rise with age, and individual case histories suggest that it can be a very benign and chronic process.

Infective endocarditis is a major cause of symptomatic mitral regurgitation (see Chapter 15.10.2).

Systemic lupus erythematosus can affect both mitral and aortic valves, causing thickening of the cusps and the appearance of sterile vegetations (Libman–Sachs endocarditis). Their appearance and severity fluctuates in individual patients, and does not correlate with other markers of activity of the underlying disease. They rarely give rise to significant haemodynamic disturbance, but may predispose to emboli and to infective endocarditis.

Pathophysiology

Pure mitral regurgitation increases left ventricular output. Since the pressure in the left atrium is lower than that in the aorta, the net force opposing left ventricular ejection is reduced, and stroke volume may be up to three times normal. Ejection begins almost immediately after the start of left ventricular contraction, and by the time the aortic valve opens, up to one-quarter of the stroke volume may already have entered the left atrium. Left atrial pressures are therefore increased, with the V or systolic wave sometimes reaching 50 to 60 mmHg. These high pressures shorten the phase of isovolumic relaxation and greatly increase the velocity of early diastolic left ventricular filling, thus causing the third heart sound. When mitral regurgitation is very severe indeed, left ventricular and left atrial pressure may equalize at mid-ejection. Left ventricular end-diastolic cavity size is not greatly increased, particularly when the history is short, but end-systolic size is considerably smaller than normal due to the low force opposing ejection. Resting left ventricular output is maintained by a sinus tachycardia that is nearly always present when mitral regurgitation is severe.

Clinical features

The clinical picture of pure mitral regurgitation depends on the underlying pathology, the severity of regurgitation, and whether or not the left ventricle is diseased. Different clinical patterns will be described separately, recognizing that they overlap and that the relation between the clinical picture and the underlying aetiology is not fixed.

Ruptured chordae tendineae

Ruptured chorda is a complication of degenerative mitral valve disease and often causes severe mitral regurgitation. It usually occurs spontaneously but may be caused by infective endocarditis. A murmur may have been heard in the past, often many years previously, and described at the time as 'innocent' or 'benign'. The onset of symptoms is usually gradual, but in a minority may be so sudden that patients are able to describe exactly what they were doing at the time. In such cases the symptoms are most severe at their onset, improving over the next few weeks as the ventricle adapts to the volume load. However, even in this more compensated phase, exercise tolerance may be severely limited by breathlessness or fatigue. When the regurgitation is only moderately severe, it can be tolerated remarkably well for many years with minimal symptoms. However, the most severe cases can present in intractable pulmonary oedema, requiring immediate intermittent positive-pressure ventilation.

Physical examination

Patients are usually in sinus rhythm until late in the course of the disease when mitral regurgitation is non-rheumatic. Sinus tachycardia is frequent, and the pulse 'jerky', implying that its amplitude is normal although the upstroke is rapid. The venous pressure is normal unless severe pulmonary hypertension or associated tricuspid regurgitation is present.

The precordial impulse at the apex is prominent and sustained, and may be double due to a palpable third sound. A systolic thrill may also be present. A left parasternal heave reflects systolic expansion of the left atrium rather than right ventricular hypertrophy.

On auscultation, the first sound is normal or reduced in intensity. The most prominent findings are a loud pansystolic murmur and a third heart sound. The third sound may be rather more high-pitched than that associated with left ventricular disease, reflecting the high early diastolic inflow velocity, and may be confused with the second sound. The murmur may thus be mistimed. This mistake can be avoided by starting auscultation at the base of the heart, where the true second sound can be appreciated, and 'inching' the stethoscope towards the apex, when the second heart sound can be heard to bury itself in the murmur as the third sound appears. If the mitral regurgitation is so severe as to cause left atrial and left ventricular pressures to equalize before the end of systole, the murmur stops early. In the most severe cases, presenting with acute pulmonary oedema and shock, the mitral valve is effectively absent and there may be no murmur at all. Unlike rheumatic mitral regurgitation, the position at which the amplitude of the murmur appears maximal is variable: it may be at the apex, down the left sternal edge, at the back, to the left of the spine, or even the top of the head.

Investigations

Chest radiography

The radiographic picture reflects the haemodynamic disturbance (Fig. 7). Overall heart size is normal or only moderately enlarged, with selective enlargement of the left atrium, though not to the same extent as in rheumatic mitral valve disease. The pulmonary vasculature reflects the increase in mean left atrial pressure. A chest radiograph taken soon after the onset of severe mitral regurgitation may show pulmonary oedema with a normal-sized heart. If the condition is severe and long-standing, considerable cardiac enlargement develops due to secondary left ventricular disease.

Fig. 7 Chest radiograph showing acute pulmonary oedema due to acute mitral regurgitation resulting from ruptured chordae tendineae.

ECG

The ECG usually shows sinus rhythm with only moderate left ventricular hypertrophy. There may, in addition, be evidence of left atrial hypertrophy. Frequent ventricular ectopic beats are characteristic of mild or moderate mitral regurgitation.

Echocardiography

M-mode echocardiography may show cusp prolapse, with cusp remnants visible in the left atrium during systole. The amplitude of left ventricular wall motion is increased. Initially the end-systolic cavity dimension is small, but it gets larger as the left ventricle adapts, increasing progressively when irreversible left ventricular disease supervenes.

Cross-sectional echocardiography confirms the presence of very active left ventricular wall motion. It allows a clearer view of the extent of systolic cusp prolapse into the left atrium, and the affected cusp is identified more reliably.

Continuous wave Doppler confirms the presence and timing of regurgitation, (Fig. 8) and the jet can be mapped within the left atrium by colour flow. Apparent jet area, whether or not normalized to left atrial cavity size, has proved a disappointing measure of the severity of the regurgitation.

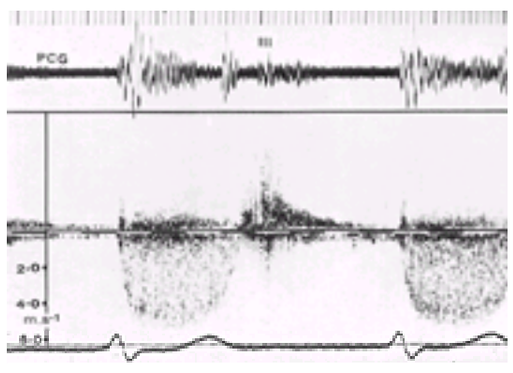

Fig. 8 Doppler cardiogram from a patient with pure mitral regurgitation, showing regurgitant flow as a downward deflection during systole. Diastolic flow velocity pattern is normal, with peak velocity coinciding with the third heart sound (III) on the phonocardiogram (PCG).

Transoesophageal echo may give more information about valve anatomy, allowing ruptured chordae and small vegetations to be seen in detail. Severe regurgitation causes retrograde flow in the pulmonary veins.

Cardiac catheterization

This is not usually necessary to make the diagnosis when the clinical features and echocardiography are typical, though many surgeons require views of the coronary arteries in older patients when planning operation.

Functional mitral regurgitation

Normal mitral closure depends on the integrity of the myocardium as well as that of the valve apparatus itself. In part, the position of the cusps during systole is maintained by contraction of the papillary muscles as the left ventricular cavity gets smaller. This mechanism can be disturbed in a number of ways. The papillary muscles themselves may be affected by ischaemic or other left ventricular disease, so that their ability to contract is impaired. If left ventricular cavity size is greatly increased, the relation between wall movement and papillary muscle shortening becomes abnormal. In hypertrophic cardiomyopathy (see Chapter 15.8.2), the greatly hypertrophied papillary muscles and abnormal cavity shape may contribute to the characteristic forward movement of the whole mitral valve apparatus during systole. Loss of support for the mitral ring itself may occur due to impairment of the function of circumferentially arranged myocardium at the base of the heart.

The term functional mitral regurgitation thus represents the combination of the regurgitation itself, a structurally intact valve apparatus, and left ventricular disease, usually cavity dilatation. It may also be referred to as papillary muscle dysfunction, although this mechanism has not been confirmed directly in humans.

The mitral regurgitation itself is usually mild, though in a minority it may be as severe as that due to ruptured chorda. However, even when mild it may last more than 500 ms, particularly when left bundle branch block is present, so that it limits the time available for ventricular filling when the heart rate is rapid. The clinical picture is therefore usually dominated by impaired left ventricular function. The presence of mitral regurgitation is demonstrated by either a late or a pansystolic murmur, which often varies in its intensity and timing from day to day, and which becomes softer with successful treatment as cavity size and left ventricular diastolic pressures fall.

Echocardiography shows a large cavity with poor wall movement, quite different from the picture seen in severe organic mitral regurgitation. The mitral regurgitation itself can be detected by continuous wave and colour flow Doppler. Cardiac catheterization confirms the presence of a raised left atrial pressure, secondary to a corresponding elevation of the left ventricular end-diastolic pressure. Left ventricular angiography shows a dilated and poorly functioning left ventricle with reflux of contrast into the left atrium, where it tends to accumulate due to poor forward flow. Coronary artery disease as the underlying cause can only be confirmed or excluded by coronary arteriography.

Ruptured papillary muscle

This is a rare and catastrophic complication of acute myocardial infarction, and is quite different from chordal rupture. Papillary muscle rupture is usually complete, though less commonly a single head may be involved. Rupture usually occurs 2 to 5 days after the infarct, and is rarely associated with survival for more than 24 h without very prompt surgical intervention. Whether partial or complete, papillary muscle rupture causes very severe mitral regurgitation, occurring on top of left ventricular impairment caused by the infarct itself. A pansystolic murmur may sometimes be audible at the apex. Death is due to cardiogenic shock and pulmonary oedema.

Partial rupture occurs rather later after the infarct than complete rupture, but similarly causes a striking deterioration in clinical state, along with the development of a pansystolic murmur. The posteromedial papillary muscle is involved more frequently than the anterolateral, both by partial and complete rupture. Since patients are likely to be ventilated, papillary muscle rupture is best diagnosed by transoesophageal echo (Fig. 9), which shows a very active left ventricle and an abnormally mobile mitral valve. The condition requires emergency mitral valve replacement, but even when this can be achieved the prognosis is much worse than that after chordal rupture due to associated left ventricular disease.

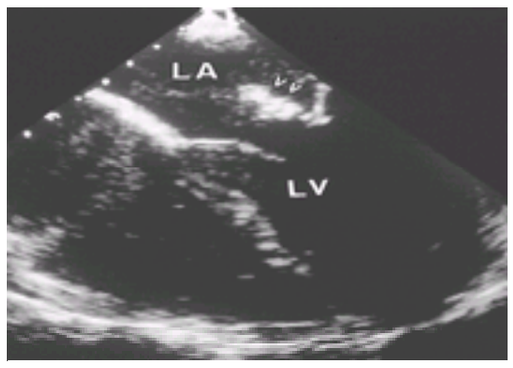

Fig. 9 Transoesophageal cross-section echocardiogram from a patient presenting with ruptured papillary muscle 48 h after acute myocardial infarction. Note the abnormal mobility of the papillary muscle head (indicated by arrows) attached to the anterior mitral valve cusp. LA, left atrium; LV, left ventricle.

Mitral prolapse

Mitral prolapse consists of systolic displacement of one or both mitral valve cusps into the left atrial cavity by 2 mm or more from the line joining the hinge points of the cusps as shown by cross-sectional echocardiography. There may or may not be associated thickening of the cusps themselves. The mid-systolic click occurs as the valve cusps move abruptly backwards into the left atrium during systole (Fig. 10).

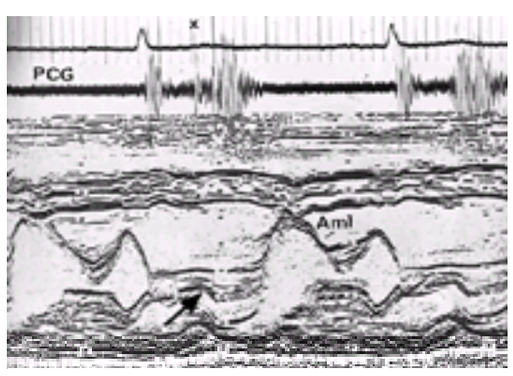

Fig. 10 Mitral valve prolapse, M-mode echocardiogram. Mid-systolic prolapse occurs, marked by the arrow. This is associated with a mid-systolic click (x) and late systolic murmur on the phonocardiogram (PCG).

The incidence of mitral prolapse, diagnosed on these strict criteria, is less than 2 to 3 per cent in a normal population. In the past, when the diagnosis was made on M-mode alone, or other less specific criteria, a much higher incidence was claimed, approaching 25 per cent in some populations. The majority of well documented

cases occur on the basis of mild degenerative mitral valve disease.

From the point of view of clinical manifestations, the main determining factor is the extent to which the margins of the cusps remain apposed during systole, that is, on the extent of secondary mitral regurgitation. It is usually insignificant and unrecognized until a mid-systolic click or late systolic murmur are heard at routine examination. Indeed, in the absence of both the diagnosis may be questioned.

In the past, it was thought that the condition was associated with non-specific chest pain, potentially life-threatening arrhythmias, and cerebral embolism. There is no good evidence for any of these clinical associations. However, mitral prolapse does predispose to infective endocarditis, so that antibiotic prophylaxis is essential. In addition, over the long term, simple mitral prolapse may gradually progress to more severe mitral regurgitation, either by chordal stretching or rupture, particularly when there is evidence of cusp thickening. This type of mitral valve disease is common in Marfan's syndrome and other connective tissue diseases.

Endomyocardial fibrosis

Endomyocardial fibrosis causes fibrosis of the endocardium and underlying myocardium of either or both ventricles. It also involves the papillary muscles, and thus causes secondary mitral regurgitation. It is common in Uganda and surrounding countries in East Africa, where it accounts for approximately 10 per cent of hospital admissions with heart disease, and also in Nigeria in West Africa. It occurs less commonly in south India and Sri Lanka. Occasionally, it is seen in European individuals who have lived in affected areas and very rarely in those who have never been to the tropics.

When the right ventricle is involved, fibrosis starts at the apex and spreads upwards towards the tricuspid valve, involving the papillary muscles and chordae, but sparing the outflow tract. In the left ventricle, the inflow tract, apex, and lower part of the outflow tract are usually involved, and also the posterior mitral valve cusp and its papillary muscle. In both ventricles there is involvement of the underlying myocardium and mural thrombosis. The result is atrioventricular valve regurgitation, an abnormally stiff ventricle, and very high atrial pressures.

The aetiology is unknown, but it does not appear to be related to rheumatic fever or any vector-borne virus, although the incidence increases with malnutrition.

The clinical picture is of progressive mitral or tricuspid insufficiency of insidious onset, together with restriction of ventricular filling by subendocardial scarring. When the tricuspid valve is mainly involved, there is gross fluid retention, whereas mitral or combined involvement leads to pulmonary oedema. Emboli from the right or left ventricle are common.

Medical treatment consists of high doses of diuretic and vasodilators, preferably an ACE inhibitor, if valvular regurgitation is severe. Decortication of the ventricular cavities may be possible surgically, along with replacement of mitral or tricuspid valve.

Mitral ring calcification

Heavy calcification of the mitral valve ring is a disease of the elderly, and is particularly common in women. Although it appears to be a degenerative condition, it occurs more frequently with left ventricular hypertrophy. It does not usually cause symptoms, and is detected incidentally by calcification in the mitral ring on chest radiography or on echocardiography. The central fibrous body may also be involved, with calcium spreading down the anterior cusp. However, the condition is not totally benign. The valve is a potential source of platelet emboli, and a focus for infective endocarditis. Approximately half the patients have abnormalities of conduction, including high-grade atrioventricular block, sinus node disease, or bundle branch block. Mild mitral regurgitation is common, but rarely is it severe enough to need valve replacement. Very occasionally the condition has been reported as causing mitral stenosis, with a diastolic pressure drop of up to 20 mmHg.

In the absence of complications, no treatment is required other than low-dose aspirin and prophylaxis against infective endocarditis. Complications are treated on their own merits.

Diagnosis of mitral regurgitation

The diagnosis of mitral regurgitation is usually straightforward on the basis of the physical signs, with a pansystolic murmur and third heart sound when it is haemodynamically significant, and a late systolic murmur when it is due to mitral prolapse and mild. Cardiac enlargement and pulmonary congestion on chest radiography reflect the extent both of the regurgitation itself and of associated left ventricular disease. Echocardiography is invaluable in assessing such cases. Abnormalities of mitral valve anatomy can be detected and associated abnormalities of left ventricular function quantified, whether due to volume overload or associated ventricular disease.

Difficulties in diagnosis may arise when mitral regurgitation is of acute origin and very severe. Patients may present with pulmonary oedema of sudden and unexplained onset with a chest radiograph showing a normal-sized heart shadow. Echocardiography demonstrates very active left ventricular wall movement, showing that the poor peripheral blood flow is due to valvular regurgitation rather than left ventricular disease, and in addition, one or both mitral valve cusps may be abnormally mobile, usually as the result of chordal or papillary muscle rupture. However, the Doppler echocardiogram may be atypical, showing an abbreviated regurgitant flow signal of low velocity reflecting near equalization of ventricular and atrial pressures. Such low blood velocities make colour flow Doppler particularly misleading.

In patients who present with more typical signs, the main diagnostic problem is to decide the relative contributions of valvular regurgitation and left ventricular disease to the overall clinical state. In such cases, intrinsic disease of the mitral valve apparatus suggests that ventricular disease is secondary to long-standing regurgitation, while normal mitral valve anatomy suggests the reverse.

Differential diagnosis

1. Ventricular septal defect (see Chapter 15.13).
2. Aortic valve disease—The ejection systolic murmur of aortic valve disease is frequently audible at the apex, where it may be louder than at the base, and have a slightly different quality. However, this is not an adequate basis for diagnosing additional mitral regurgitation and it is essential to establish that the timing of the murmur is pansystolic, either from its relation to the second heart sound, or in aortic regurgitation, from its relation to the start of the early diastolic murmur.
3. Tricuspid regurgitation—The pansystolic murmur of tricuspid regurgitation may be mistaken for that of mitral regurgitation, particularly when the right ventricle is greatly enlarged. The presence of tricuspid regurgitation can be suspected from an elevated venous pressure with systolic waves, and confirmed by Doppler echocardiography. In severe mitral regurgitation, however, additional tricuspid regurgitation may be present.

Treatment of mitral regurgitation

Mild or moderately severe mitral regurgitation is well tolerated and does not require treatment apart from prophylactic antibiotic for all dental manipulations and potentially septic hazards. If left ventricular size is increased either on chest radiograph or echocardiogram an ACE inhibitor should be added. Such patients should be followed up at annual intervals, since mitral regurgitation may be progressive, particularly when due to degenerative disease.

When mitral regurgitation is functional and mild, treatment is again medical and that of the underlying left ventricular disease. However, in a minority of patients with severe ischaemic ventricular disease, a more aggressive surgical approach may be warranted. Mitral regurgitation due to hypertrophic cardiomyopathy does not require specific treatment.

Severe mitral regurgitation, which causes significant symptoms in spite of medical treatment, is best managed by mitral valve surgery. This will involve either mitral valve replacement, or in suitable cases, mitral valve repair. The long-term prognosis following mitral repair is better than that after replacement, both with respect to survival and functional result. The exact reasons for the difference are not clear, but are probably because replacement involves insertion of a rigid mitral ring and section of the papillary muscles with very abnormal flow patterns into the ventricle. Mitral repair is thus to be preferred whenever possible, and in suitable cases can be recommended earlier in the course of the disease. It is particularly satisfactory with non-rheumatic regurgitation due to posterior cusp prolapse, and in an increasing number of patients with anterior cusp prolapse as surgical techniques develop.

The timing of operation is critical. After acute chordal rupture, it is often possible to treat the patients medically with rest, diuretics, and vasodilators for 1 to 2 weeks, while the left ventricle enlarges to compensate for the increased volume load. Clinical improvement may be striking, so that surgery becomes a less hazardous procedure than an emergency operation in the acute stage would have been. By contrast, those with a ruptured papillary muscle should undergo surgery at the earliest opportunity. Until this is possible, their pulmonary oedema is best treated by intermittent positive-pressure ventilation. Any benefit of pharmacological treatment or balloon counterpulsation is marginal at best, and probably only distracts attention from the main aim, which should be to get the patient to surgery as soon as possible.

The treatment of papillary muscle dysfunction is that of the underlying ventricular disease, with the particular aim of reducing the left ventricular diastolic pressures. In a minority of cases, hibernating myocardium will respond to vein grafting. Mitral valve replacement should be avoided whenever possible, since the deterioration in ventricular function caused by the valve replacement itself usually outweighs any benefit from correction of the regurgitation. A more promising approach is to insert an undersized mitral ring, leaving the mitral apparatus otherwise intact. This not only corrects the regurgitation but also may reduce basal left ventricular cavity size and thus systolic wall stress.

Aortic stenosis

Aortic stenosis represents a fixed obstruction to left ventricular ejection into the aorta. The obstruction is most commonly at the level of the valve itself, aortic valvar stenosis, but may also be immediately above the sinuses, supravalvar stenosis, or within the left ventricle, subvalvar stenosis.

Aetiology

Types of valvar aortic stenosis are summarized in Table 2. Valvar aortic stenosis is an important cause of cardiac disability, and though it is commonest in the elderly, it may present at any time of life. Congenital aortic stenosis, due to a valve with only a single commissure, is most frequent in infancy or childhood. Congenital bicuspid valve, consisting of fusion of one of the three commissures, is a much commoner abnormality. It may be detected as an incidental finding early in life, but does not usually give rise to significant haemodynamic abnormality unless it becomes calcified or involved by infective endocarditis. Rheumatic aortic stenosis develops as the result of commissural fusion in a tricuspid valve and may subsequently become calcified. Senile or degenerative aortic stenosis results from deposition of calcium in a tricuspid valve, initially on the aortic surface by a process similar to atherosclerosis. Calcification of a tricuspid valve is becoming an increasingly important cause of disability in the elderly. Very rarely, vegetations in infective endocarditis or lipid deposits in hyperlipidaemia may be bulky enough to cause significant left ventricular outflow tract obstruction.

Pathophysiology

Blood flow across a stenotic aortic valve causes a pressure drop between the left ventricular cavity and the aorta, which in symptomatic cases, may be greater than 60 mmHg at rest, and reach over 200 mmHg on exertion. Stroke work is therefore increased and left ventricular hypertrophy develops. Wall thickness increases although cavity size remains normal or even falls. A corresponding increase in the coronary vascular bed does not occur, predisposing to myocardial ischaemia, particularly in the subendocardial region. Hypertrophy, ischaemia, and associated fibrosis cause the diastolic stiffness of the myocardium to increase so that the end-diastolic pressure may rise causing pulmonary congestion. Increased left ventricular wall thickness also predisposes to ventricular arrhythmias. Late in the disease, when left ventricular involvement is severe, the cavity dilates and becomes more spherical. Calcification may spread from the aortic valve to the anterior cusp of the mitral valve or into the septum where it can involve the conducting system which runs nearby.

Aortic stenosis is most common in patients with a high incidence of ischaemic heart disease, so that obstructive coronary artery disease may contribute coincidentally to symptoms or impairment of left ventricular function.

Clinical features

Symptoms

The three characteristic clinical features of aortic stenosis are breathlessness, chest pain, and syncope.

Breathlessness in aortic stenosis is frequently associated with an elevated left ventricular end-diastolic pressure and occurs at first on exercise, but later at rest. Paroxysmal nocturnal dyspnoea and episodic pulmonary oedema—breathlessness persisting for 5 min or more after exercise—are both common in late stages of the disease and indicate the need for urgent treatment. The length of the history of breathlessness from its onset until it becomes severe is usually only of the order of 1 to 2 years, and thus considerably shorter than that in mitral stenosis.

Angina occurring in aortic stenosis is clinically indistinguishable from that due to coronary artery disease, which in many cases is the main cause. However, typical anginal pain can occur in patients in whom the large and medium-sized coronary arteries are normal. The mechanism for this is uncertain, but disproportion between muscle mass and coronary vascular bed, and the direct effects of abnormal myocardial relaxation in left ventricular hypertrophy are both likely to contribute.

There are several causes of syncope in aortic stenosis. In some patients it is clearly related to exertion and appears to be due to hypotension resulting from the combination of exercise-induced vasodilation and a fixed cardiac output. In other cases it results from transient complete atrioventricular block due to involvement of the atrioventricular node by calcification, carotid sinus hypersensitivity, or even from short periods of ventricular tachycardia or fibrillation.

Physical examination

The physical signs of well developed aortic stenosis are very characteristic.

1. The carotid pulse is slow rising with a reduced amplitude and an early notch on the upstroke, followed by a thrill.
2. The venous pressure is usually normal until late in the disease, but a small 'a' wave is frequently present. This cannot be taken as evidence of pulmonary hypertension, but appears to be related in some way to the presence of left ventricular hypertrophy (Bernheim 'a' wave).
3. The apex beat is sustained and is often double, due to an additional left atrial impulse.
4. On auscultation, the first sound is normal or soft, and may be preceded by a fourth heart sound. The second sound is single when the valve is calcified, due to lack of the aortic component. In younger patients with mobile valve cusps, aortic valve closure may be audible, but delayed, so that splitting of the second sound is reversed. When left ventricular disease is severe, pulmonary valve closure is accentuated. The characteristic ejection systolic murmur is maximal at the base of the heart, and is also audible over the right common carotid artery. It may seem longer than the ejection systolic murmur of, for example, anaemia or thyrotoxicosis because in aortic stenosis, ventricular systole is prolonged and aortic valve closure delayed. A soft early diastolic murmur is nearly always present, although this does not imply haemodynamically significant aortic regurgitation.

As ventricular disease progresses and stroke volume falls, these physical signs are modified. Pulse volume drops and loses its slow rising quality. The aortic murmur becomes shorter and softer, and a third heart sound and functional mitral regurgitation appear.

Investigations

Chest radiography

Heart size is normal in uncomplicated aortic stenosis. If it is increased, the underlying cause is likely to be unsuspected aortic regurgitation, left ventricular cavity dilatation, or very severe left ventricular hypertrophy, when the cavity may be normal in size, but the myocardium up to 50 mm thick. Increased left ventricular filling pressure may cause left atrial hypertension and thus dilatation of the upper lobe vessels as well as selective enlargement of the left atrium in the absence of organic mitral valve disease. The aortic root is nearly always dilated and the aortic valve calcified in older patients: this is best seen on the lateral chest radiograph or with screening.

ECG

The ECG characteristically shows changes of left ventricular hypertrophy, although it may be entirely normal, even in the presence of severe aortic stenosis. Left atrial hypertrophy is shown by a bifid P wave in lead II or a dominant negative deflection in V1. Conduction disturbances include left axis deviation, left bundle branch block, prolonged P–R interval, or complete heart block. Poor progression of R waves across the chest leads is common, and suggests septal hypertrophy rather than anterior myocardial infarction.

Echocardiography

Cross-sectional echocardiography demonstrates thickening and reduced mobility of the valve cusps. In young patients with a bicuspid valve, doming of the cusps during systole can be seen, while in older patients, a calcified aortic valve appears as an immobile mass (Fig. 11).

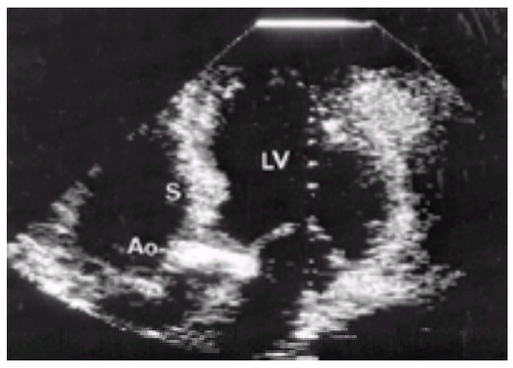

Fig. 11 Aortic stenosis, two-dimensional echocardiogram from apical four-chamber view, showing left ventricle (LV) and heavily calcified aortic valve (Ao). S, septum.

The pressure drop across the outflow tract can be reliably measured by continuous wave Doppler. Additional aortic regurgitation can also be detected. Left ventricular anatomy and function, both in terms of the extent of hypertrophy and cavity size and ejection fraction can be studied.

Transverse dimension and myocardial thickness can be measured by M-mode. Late in disease, the left ventricle becomes enlarged and its ejection fraction falls to values commonly seen in dilated cardiomyopathy.

Cardiac catheterization

The abnormal haemodynamics of aortic stenosis and associated left ventricular disease can usually be comprehensively demonstrated by echocardiography. The role of cardiac catheterization is thus to confirm the pressure drop across the valve in the minority of patients in whom this is not possible for technical reasons using continuous wave Doppler, and to display coronary artery anatomy.

Diagnosis

A complete diagnosis of aortic stenosis depends not only on establishing the anatomical abnormality, but also its severity and the degree of associated left ventricular disease. When cardiac output is normal, a peak pressure drop across the valve of greater than 60 mmHg indicates significant stenosis, and corresponds to a valve area of 0.9 cm^2 or less. The corresponding peak velocity, as measured by continuous wave Doppler is 4.0 m/s.

Mild aortic stenosis is associated with a normal carotid pulse and a short systolic murmur which stops well before the second sound, since a pressure difference between the left ventricular cavity and the aorta is present only during the first part of systole. In addition, both components of the second heart sound are audible and splitting is normal. An uncalcified bicuspid aortic valve causes mild stenosis, with an ejection click and systolic murmur, often followed by a short early diastolic murmur.

Left ventricular hypertrophy can be inferred from a sustained apical impulse with a palpable left atrial contraction. A raised left ventricular end-diastolic pressure can be deduced from accentuation of pulmonary valve closure, which forms the only component of the second sound and, in the late stages of the disease, a third heart sound. In such patients the stroke volume is low, the pressure drop across the valve falls, and significant stenosis may be associated with values of 30 to 40 mmHg. To allow for this, it is necessary to measure valve area.

Differential diagnosis

1. Hypertrophic cardiomyopathy—This can present with a history very similar to that of aortic stenosis. By contrast, the carotid pulse is normal or jerky rather than slow rising. The diagnosis is confirmed by echocardiography, which reveals a normal aortic valve and shows characteristic ventricular features (see Chapter 15.8.2).
2. Congestive cardiomyopathy—Patients with long-standing untreated aortic stenosis can present with severe breathlessness, a large heart on radiography, a small volume pulse with a normal upstroke, a third heart sound, and pansystolic murmur due to papillary muscle dysfunction. These features can all be found in congestive cardiomyopathy (see Chapter 15.8.2). In endstage aortic stenosis, the echocardiogram shows a calcified valve with a significant (more than 35 mmHg) pressure drop across it: in congestive cardiomyopathy it shows a dilated and poorly contractile ventricle, but the aortic valve is normal.
3. Fixed subaortic stenosis—This is usually discovered in asymptomatic children and young adults in whom a systolic murmur is detected on routine examination. An ejection click is absent, and a short early diastolic murmur usually heard. There is clinical and ECG evidence of left ventricular disease, which may be severe. The two-dimensional echocardiogram usually demonstrates the site and type of obstruction (see also Chapter 15.13).

Prognosis

The prognosis of symptomatic aortic stenosis is poor with a 50 per cent survival of only 1 to 2 years. Approximately half the deaths are due to relentless haemodynamic deterioration, and the remainder are 'sudden' and unexpected. The prognosis of asymptomatic but haemodynamically severe aortic stenosis is somewhat better. However, older patients with a peak velocity of 4 m/s or more across the aortic valve are likely to become symptomatic in a period of 2 years or less.

Exercise testing is as safe in aortic stenosis as it is in coronary artery disease, and using it a significant number of 'asymptomatic' patients can be shown to have reduced exercise tolerance. The truly asymptomatic patient, often below the age of 30 years, with normal ECG and without left ventricular hypertrophy or cavity dilatation on echocardiogram, can safely be watched. Regular follow-up of such patients is essential, and surgery should be considered with any evidence of deterioration.

Treatment

Medical treatment has little to offer in aortic stenosis: in mild cases it is unnecessary and in severe cases ineffective. However, it is essential that all patients with aortic stenosis, of whatever severity, have prophylactic antibiotic for any potentially septic hazard. Patients with severe left ventricular disease and fluid retention will benefit from a period of bed rest and treatment with a diuretic before operation is contemplated. ACE inhibitors are contraindicated.

Severe aortic stenosis requires intervention. Unfortunately, aortic balloon valvuloplasty, though satisfactory in infants and children, is either ineffective or harmful in adults in whom the cusps are calcified, and the procedure has been largely abandoned, even as a temporizing manoeuvre in very ill patients. Aortic valve

replacement for aortic stenosis is amongst the most effective of all surgical operations. In uncomplicated cases, it can be carried out with low mortality and morbidity, and should therefore be considered in all patients in whom the disease causes significant symptoms. It is likely to relieve breathlessness, angina, and syncope, whether due to ischaemic heart disease or to the aortic stenosis itself. Associated coronary artery disease is usually treated with bypass grafting at the same operation. Aortic valve replacement is also effective when significant aortic stenosis is complicated by severe left ventricular enlargement. Although the risks of surgery are greater, so are the benefits, and the remarkable improvement in symptoms and prognosis that may follow surgery for this combination of valve and ventricular disease is amongst the most gratifying in cardiology.

Mixed aortic valve disease

Mild to moderate aortic regurgitation often accompanies aortic stenosis, but does little to alter the overall clinical picture. The combination may result from a bicuspid aortic valve, chronic rheumatic heart disease, or be the result of conservative surgery or endocarditis on a stenotic valve. The main haemodynamic disturbance remains increased resistance to ejection rather than a volume load. In addition, superimposition of even a moderately increased stroke volume due to regurgitation on the small, stiff left ventricular cavity of pure aortic stenosis may lead to high filling pressures, left atrial enlargement, and even pulmonary hypertension. Breathlessness and chest pain thus remain the most prominent symptoms. The arterial pulse is bisferiens, with a notch half way up the upstroke, rather than slow rising. Atrial fibrillation usually points to a rheumatic basis; less commonly to high filling pressures in an incompliant cavity. The early diastolic murmur is audible down the left sternal edge. The extent of the volume load, the aortic pressure drop, and the presence or absence of rheumatic mitral involvement can all be determined by echocardiography. Treatment of symptomatic patients is likely to require valve replacement.

Aortic regurgitation

Aortic regurgitation increases stroke volume and when severe and uncorrected causes irreversible left ventricular disease. Its causes are summarized in Table 3.

Pathology

Chronic rheumatic involvement leads to a tricuspid valve whose cusps are thickened, with rolled edges and fused commissures. There may be superimposed calcification or thrombosis. Infective endocarditis may lead to cusp destruction or perforation and may spread to involve the sinus of Valsalva, the atrioventricular node and the interventricular septum, where abscess formation may occur. Organisms may also be carried to the anterior cusp of the mitral valve, where they cause 'jet lesions', localized aneurysms, or perforations. Dilatation of the aortic ring may cause aortic regurgitation with normal cusps. This can result from a 'flask-shaped' aneurysm of the ascending aorta, complicating Marfan's syndrome, or isolated medionecrosis. Syphilitic aortitis causes dilatation of the valve ring, with aneurysm formation of the ascending aorta and involvement of the coronary ostia. Dilatation of the ring may occur on its own or with connective tissue disease such as ankylosing spondylitis, rheumatoid arthritis, Reiter's syndrome, or relapsing polychondritis. Dissecting aneurysm involving the aortic root may separate the cusps from the valve ring; and the presence of a high ventricular septal defect or Fallot tetralogy may leave the cusps unsupported from below.

Pathophysiology

Aortic regurgitation is associated with an increase in left ventricular stroke volume and cavity size. Ventricular mass is therefore increased, but wall thickness is usually within normal limits. In moderately severe aortic regurgitation, the stroke volume is twice normal, and in severe cases, up to three or even four times normal. The characteristics of ejection are altered in that the end-diastolic pressure in the aorta is low, so that the resistance to ejection of blood by the left ventricle is reduced and ventricular systole is prolonged. These factors together with the large stroke volume, explain the characteristic rapid upstroke and large volume pulse. Peripheral vasodilatation also contributes to the large forward stroke volume. In long-standing cases, left ventricular cavity size increases out of proportion to the stroke volume, with loss of the normal myocardial architecture, so that the cavity becomes more spherical in shape; the walls become stiffer and the end-diastolic pressure increases.

Clinical features

Symptoms

Patients with aortic regurgitation remain asymptomatic for many years. When symptoms develop, they are those of left ventricular disease, with limitation of exercise tolerance by breathlessness or chest pain the most prominent one. Less commonly, the presenting symptom may be nocturnal dyspnoea, or an attack of acute pulmonary oedema. Retrosternal pain, aggravated by exertion, may develop in patients with aneurysms of the ascending aorta in whom the coronary arteries are normal. This seems to originate from the aortic root itself. Aortic dissection (see Chapter 15.14.1) may also cause severe central chest pain.

Physical signs

The physical signs of aortic regurgitation are characteristic.

1. The carotid pulse has a large amplitude and a rapid upstroke. Visible arterial pulsation in the neck (Corrigan's sign) excludes significant aortic stenosis. Other physical signs which depend on a large pulse volume and peripheral vasodilation include capillary pulsation, visible in the nail beds, and the de Musset sign, nodding of the head in time with the heart beat. The Durosiez sign, which is of greater clinical value, is elicited by compression of the femoral artery and listening proximally with the stethoscope for a diastolic murmur. It may be positive even when an aortic diastolic murmur is inaudible, and implies retrograde flow in the femoral artery due to aortic regurgitation that is at least moderately severe. The peripheral pulses should always be checked to exclude the presence of coarctation of the aorta.
2. The venous pressure is normal until late in the course of the disease, although the venous pulse may show a dominant 'a' wave (a Bernheim 'a').
3. The left ventricular impulse is sustained, indicating hypertrophy. A palpable 'a' wave is much less common than in aortic stenosis, and when present usually denotes additional left ventricular disease.
4. On auscultation, the characteristic finding is an early diastolic murmur, maximal down the left sternal edge. Less commonly it is loudest at the apex or even in the left axilla (the Cole–Cecil murmur). An ejection systolic murmur is nearly always present, due to the increased stroke volume, and not necessarily to additional stenosis. Aortic valve closure is usually inaudible, but P2 may be accentuated due to passive pulmonary hypertension. At the apex, a mid-diastolic murmur may be heard, indistinguishable from that of mitral stenosis (Austin–Flint murmur). This may continue throughout diastole, with presystolic accentuation and even a loud first heart sound, though the last is never palpable. With the development of ventricular disease, a soft mitral pansystolic murmur or a third sound may appear.

These classic signs of aortic regurgitation may be modified in a number of circumstances. If infective endocarditis has caused cusp perforation, then the early diastolic murmur may have a high-pitched musical quality, a 'seagull murmur'. In the presence of severe left ventricular disease, or less commonly, of rheumatic mitral stenosis or severe pulmonary hypertension, the collapsing pulse, and other evidence of aortic regurgitation may be lost, although the aortic diastolic murmur persists. It is worth noting, however, that Durosiez' sign frequently remains positive in these circumstances if the regurgitation is moderate or severe. In severe aortic regurgitation of rapid onset, usually due to infective endocarditis affecting the aortic valve, the patient presents with a low cardiac output state, normal or reduced pulse volume, and sinus tachycardia. On auscultation the main abnormality is a loud third sound, due to a very short period of forward flow across the mitral valve. A short early diastolic murmur may be audible. Durosiez' sign is usually positive.

Investigations

Chest radiography

Significant aortic regurgitation nearly always causes cardiac enlargement on chest radiography (Fig. 12). The aortic root is often dilated, but the aortic valve not necessarily calcified. The pulmonary vessels remain normal until severe left ventricular disease develops.

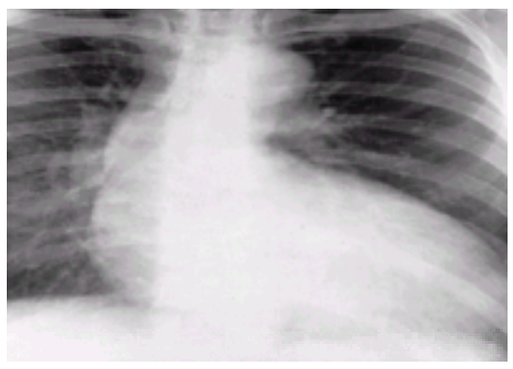

Fig. 12 Chest radiograph from a patient with chronic aortic regurgitation showing cardiac enlargement and dilation of the ascending aorta.

ECG

This usually shows left ventricular hypertrophy on voltage and T-wave criteria, with left atrial enlargement. The duration of the QRS complex increases and left bundle branch block may develop, indicating the presence of intrinsic left ventricular disease. A long P–R interval in association with aortic regurgitation is very suggestive of disease of the aortic root.

Echocardiography

The anatomy of the aortic valve and root can be determined. Dissection and aortic root abscesses can sometimes be detected; vegetations on the aortic valve are well. When infective endocarditis is suspected, transoesophageal echo may give further useful information, particularly if the P–R interval is prolonged. It is also the means of choice for demonstrating aortic root aneurysms. Colour flow Doppler allows the presence of regurgitation to be confirmed and a semiquantitative estimate made of its severity. Left ventricular cavity size is determined from the M-mode record (Fig. 13).

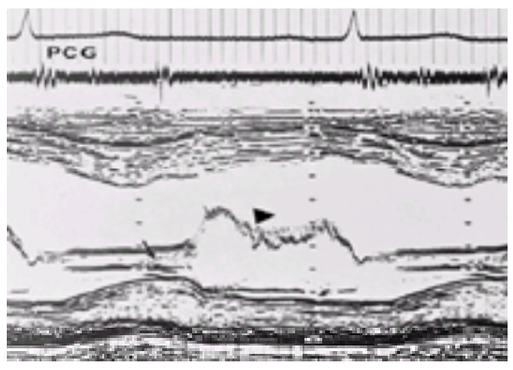

Fig. 13 Chronic aortic regurgitation. M-mode echocardiogram, showing dilatation of the left ventricular cavity; also 'flutter' on the anterior cusp of the mitral valve, marked by arrow, caused by the regurgitant aortic jet striking the cusp. PCG, phonocardiogram.

In acute aortic regurgitation, the mitral valve closes prematurely. This is the result of severe regurgitation into a relatively non-compliant left ventricle causing the cavity pressure to rise, closing the mitral valve in mid-diastole (Fig. 14). As ventricular diastolic pressure rises, the pressure drop from the aorta to the ventricle in diastole may fall to 20 mmHg or less, which is reflected in the continuous wave Doppler record across the valve in diastole. This is pathophysiologically significant, since the pressure difference between aorta and left ventricle during diastole supports coronary flow. Hence, as aortic regurgitation becomes more severe, coronary flow to a volume-loaded ventricle becomes progressively compromised.

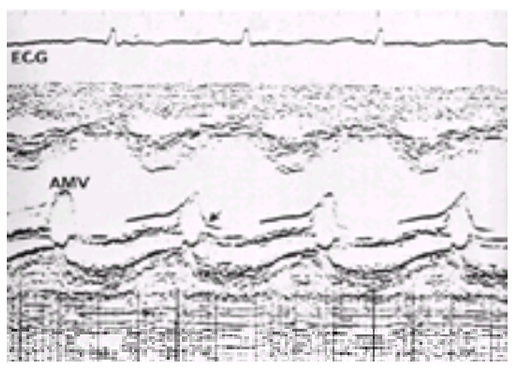

Fig. 14 M-mode echocardiogram showing premature mitral valve closure (arrow) in a patient with acute aortic regurgitation due to infective endocarditis.

Cardiac catheterization

It is not usually necessary to resort to cardiac catheterization to make the diagnosis of aortic regurgitation. Although an aortogram may give useful information, it should be avoided in seriously ill patients because radiographic contrast medium expands the plasma volume and depresses ventricular function. The anatomy of the aortic root is best demonstrated by MRI. Coronary arteriography is usually performed in older patients as a prelude to surgery, even in the absence of clinical evidence of significant coronary artery disease.

Diagnosis

As with aortic stenosis, it is not enough merely to establish the presence of aortic regurgitation; its severity must be estimated, and also the state of the left ventricle. In uncomplicated cases, the severity can be judged indirectly from the carotid pulse and from the heart size on chest radiography, but direct measurement of left ventricular cavity size and stroke volume by echocardiography, MRI, or angiography is more satisfactory. Left ventricular disease can be suspected clinically from accentuated pulmonary valve closure, and from chest radiography by the presence of pulmonary vascular congestion and inappropriate cardiac enlargement. However, left ventricular function is most satisfactorily assessed by direct measurement, the characteristic feature being enlargement of end-diastolic, and in particular, end-systolic cavity size out of proportion to stroke volume such that ejection fraction falls.

Acute aortic regurgitation may present difficulties in diagnosis when the classic physical signs are modified due to a low forward output. Echocardiography is particularly useful in making a definite diagnosis non-invasively, demonstrating aortic vegetations, a large left ventricular stroke volume, and premature mitral valve closure. It is also important to confirm or exclude other types of valve disease.

Coexistent aortic stenosis is often diagnosed on the basis of an ejection systolic murmur, but this does not constitute adequate evidence, and in order to confirm its

presence clinically, a bisferiens pulse should be present. Additional rheumatic mitral stenosis is best confirmed or excluded by echocardiography, although the presence of atrial fibrillation, a palpable first sound, or an opening snap makes its presence very likely on clinical grounds. Mitral regurgitation leads to an additional pansystolic murmur at the apex, which may sound continuous with the early diastolic murmur across the second sound. It is usually caused by a dilated valve ring in the absence of organic mitral valve disease, and thus indicates considerable left ventricular enlargement.

It is usually not necessary to establish the exact aetiology of aortic regurgitation, although it is important to exclude infection and look for the presence of disease of the aortic root and ascending aorta. This should be suspected if there is a history of chest pain that is not clearly anginal in nature, and also from excessive dilatation of the ascending aorta on chest radiography or a long P–R interval on ECG. Proximal aortic root diameter can be measured by echocardiography, and the anatomy of the whole aortic arch demonstrated by MRI.

Differential diagnosis

In the presence of severe pulmonary hypertension, the pulmonary artery may dilate, causing functional pulmonary regurgitation and a soft early diastolic murmur (Graham–Steell murmur). The carotid pulse is normal. Difficulty in diagnosis usually arises when the patient has mitral valve disease, pulmonary hypertension, and an early diastolic murmur. In these circumstances, aortic regurgitation may not necessarily cause an abnormal carotid pulse. In many cases, the differential diagnosis can only be made by Doppler echocardiography, but on clinical grounds, pulmonary incompetence is more likely when there is other evidence of severe pulmonary hypertension, and in particular, when chest radiography shows the main pulmonary artery to be appreciably dilated.

Aortic regurgitation should also be distinguished from other causes of aortic run-off (see Chapter 15.13):

1. persistent ductus arteriosus;
2. ruptured sinus of Valsalva aneurysm; and
3. coronary arteriovenous fistula.

These all cause an increase in pulse pressure, but a continuous rather than an early diastolic murmur down the left sternal edge.

Additional abnormalities that may give rise to confusion are the combination of aortic regurgitation and either mitral regurgitation or a ventricular septal defect. Here the combination of pansystolic and early diastolic murmurs may lead to a continuous quality.

Treatment

Chronic aortic regurgitation

Mild or moderately severe aortic regurgitation is well tolerated and requires no treatment other than prophylactic antibiotic to prevent infective endocarditis.

Severe aortic regurgitation in a symptomatic patient should be treated by aortic valve replacement.

In an asymptomatic patient with severe regurgitation, the decision is more difficult. Without treatment, the outlook is very favourable, with the clinical state remaining stable over many years. Premature operation should be avoided. The most reliable basis for recommending surgery is evidence of progression of disease, such as an increase in heart size on chest radiography, deterioration in the ECG, or an enlarging left ventricular cavity or aortic root on echocardiography. A policy of depending on the results of any single investigation or 'parameter', convenient as it may seem, is inflexible in practice and subject to the limited reproducibility of all cardiological measurements.

Prophylactic administration of nifedipine or ACE inhibitor has been shown to delay the necessity for operation by 2 to 3 years in asymptomatic patients with aortic regurgitation. Severe ventricular disease may become apparent over a period as short as 1 to 2 years, so patients being treated conservatively must be kept under regular review.

Acute aortic regurgitation

Acute aortic regurgitation is a surgical emergency. With a native valve, it is nearly always due to infective endocarditis, and blood cultures should be taken so that the organism can be isolated retrospectively, whilst antibiotics are started preoperatively.

One of the most useful criteria for emergency aortic valve replacement is premature mitral valve closure on the M-mode echocardiogram (Fig. 14). The aim should always be to transfer the patient as soon as possible to a centre capable of performing open heart surgery. As with mitral regurgitation, pharmacological treatment is usually a distraction, but intermittent positive-pressure ventilation is effective treatment for pulmonary oedema.

An increasing P–R interval is a sign of a septal abscess, and requires urgent pacemaker insertion, preferably before transfer, since bradycardia due to complete atrioventricular block can be fatal in severe aortic regurgitation. A prolonged preoperative course of antibiotics is contraindicated in such patients, since the valve is rarely sterilized, and the delay causes further deterioration in left ventricular function with a correspondingly poor outcome. The appearance of aortic regurgitation of any severity with acute dissection of the ascending aorta is also a very strong indication for surgery.

Acquired tricuspid valve disease

Tricuspid stenosis

Although functional tricuspid stenosis may occur with a large flow through the right heart such as occurs in an atrial septal defect, organic tricuspid stenosis is nearly always the result of chronic rheumatic heart disease. Rheumatic tricuspid stenosis virtually always coexists with rheumatic mitral valve disease, although its incidence is about one-tenth. The two conditions are similar both with respect to their pathology and to the functional disturbance that they cause. The valve cusps become thickened, and the commissures fused, so that the cross-sectional area of the orifice is reduced. The tricuspid subvalvar apparatus, though, is not usually involved, nor does calcification occur. The primary functional abnormality is obstruction to right ventricular filling associated with a diastolic pressure drop across the valve. In clinically severe tricuspid stenosis, however, this drop is smaller than it would be with clinically severe mitral stenosis, and is usually within the range of 3 to 10 mmHg. This causes a corresponding increase in right atrial pressure, which leads to ascites and peripheral oedema.

True acquired cusp fusion with severe tricuspid stenosis has recently been described in association with pacemaker catheters, when it presumably represents the effect of chronic trauma. Why it occurs so infrequently with simple pacing catheters, and whether its incidence will increase with the stiffer and more massive catheters needed for automatic implanted cardioverter devices is still not clear.

Clinical features

In patients with chronic rheumatic heart disease, the clinical problem is to recognize the presence of additional tricuspid stenosis in a patient known to have mitral and perhaps also aortic valve disease. This is not always possible on clinical grounds, but a number of indications may be sought. There are no specific findings in the history.

If the patient is in sinus rhythm, tricuspid stenosis is often associated with an 'a' wave in the venous pulse and with evidence of right atrial hypertrophy on ECG. These findings are unusual in the presence of pulmonary hypertension and mitral stenosis alone. The venous pulse is usually otherwise unremarkable.

On auscultation, a separate tricuspid mid-diastolic murmur may be audible. This is similar in timing to a mitral one, but it is higher in pitch, resembling an aortic diastolic murmur in this respect. It is maximal down the left sternal edge or in the epigastrium. A tricuspid opening snap may also be present; it is later than a mitral one and its timing with respect to pulmonary valve closure varies with respiration.

Investigations

Chest radiography may be suggestive, since right atrial enlargement causes the heart shadow to enlarge to the right of the midline. These appearances, however, are non-specific, and may be present with functional tricuspid regurgitation, or even a giant left atrium.

Echocardiography gives the diagnosis. Cross-sectional echocardiography shows doming of the tricuspid valve into the right ventricle during systole (Fig. 15) in the apical four-chamber view. The diastolic pressure drop can be estimated by continuous wave Doppler.

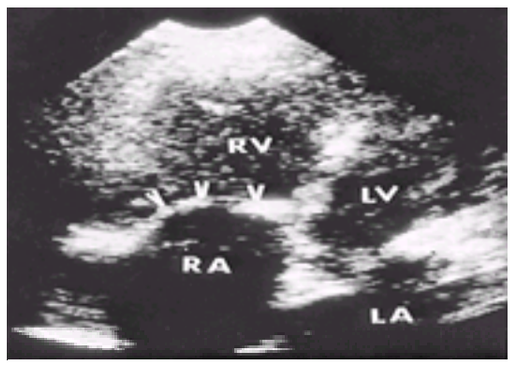

Fig. 15 Rheumatic tricuspid stenosis, apical four-chamber view showing doming and thickening of the tricuspid valve during diastole (arrows). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Cardiac catheterization is now rarely performed to diagnose tricuspid stenosis, but it may show a small diastolic pressure drop across the valve.

Cases of organic tricuspid stenosis may still reach operation for mitral or aortic valve disease without the diagnosis having been made. When they do so, the previously undiagnosed tricuspid stenosis may be unmasked by successful left-sided surgery, which allows cardiac output to increase. This causes a corresponding increase in the tricuspid diastolic pressure drop, which leads to salt and water retention, so that a patient thought to have had a satisfactory operation develops striking ascites or peripheral oedema afterwards.

Treatment

Medical treatment is not very satisfactory but consists of diuretic administration to control fluid retention. Prolonged administration of inappropriately large doses leads to potassium depletion. Definitive treatment is surgical, consisting of either valvotomy or repair at the time that the other valve lesions are dealt with. Isolated tricuspid stenosis, developing after mitral valve surgery, has been dealt with by balloon valvuloplasty. Tricuspid valve replacement is avoided whenever possible in view of the physiological significance on the right side of the heart of the diastolic pressure drop across all normally functioning prostheses. An additional procedure on the tricuspid valve increases the operative risk of mitral valve surgery, with greater postoperative incidence of jaundice and arrhythmias.

Tricuspid regurgitation

As with mitral regurgitation, a number of different pathological processes can cause tricuspid regurgitation (Table 4).

The tricuspid valve is much more liable to develop functional regurgitation than the mitral valve, and tricuspid regurgitation is often functional, occurring in association with dilatation of the right ventricular cavity. It is particularly common in patients with pulmonary hypertensive mitral valve disease, but may also occur with primary pulmonary hypertension, or in the terminal stages of many types of congenital heart disease, particularly those with a significant left to right shunt.

Severe, non-rheumatic tricuspid regurgitation is being increasingly recognized as occurring late after mitral valve replacement, in the absence of significant left-sided disease or pulmonary hypertension. Its cause is not clear, but there is no evidence of disease of the valve cusps or subvalve apparatus.

Organic tricuspid regurgitation may be congenital, as an isolated abnormality, or associated with the Ebstein anomaly. A cleft right-sided atrioventricular valve may also occur in ostium primum atrial septal defect. Acquired, organic tricuspid regurgitation may be rheumatic in origin, or result from infective endocarditis of a previously normal valve, which occurs particularly commonly in intravenous drug users. Right-sided endomyocardial fibrosis causes progressive obliteration of the right ventricular cavity with scarring and distortion of the tricuspid subvalvular apparatus.

Mid-systolic prolapse of the tricuspid valve can occur in exactly the same way as that of the mitral valve, and is common in Marfan's syndrome. Organic tricuspid regurgitation has been described as a long-term consequence of radiotherapy to the thorax, when it may be associated with features of pericardial constriction or restrictive myocardial disease, making its diagnosis difficult.

Clinical features

The clinical features of tricuspid regurgitation are those of severe and chronic elevation of the venous pressure, often in association with disease on the left side of the heart.

The symptoms are non-specific, although when tricuspid regurgitation supervenes in a patient with mitral stenosis, it is often associated with an increase in the prominence of fatigue as a factor limiting exercise tolerance instead of breathlessness. Symptoms may also be related to the development of oedema or ascites: hepatic enlargement may be associated with nausea and upper abdominal or epigastric pain aggravated by exercise.

The main physical sign of tricuspid regurgitation is a raised venous pressure with a prominent systolic wave, which is almost a *sine qua non* for the diagnosis. The mean venous pressure may be very high, greater than 15 cmHg, with pulsations visible in the retinal vessels or palpable in the femoral veins. The high venous pressure is also responsible for the protein-losing enteropathy that sometimes occurs in the same way as with constrictive pericarditis (see Chapter 15.9). In approximately two-thirds of patients, there is associated systolic expansile pulsation of the liver, which may be considerably enlarged and tender. In long-standing cases, hepatic fibrosis develops so that this physical sign disappears. The hepatic dysfunction may also cause mild jaundice, which with increased skin pigmentation can give these patients a very characteristic appearance.

In approximately one-third of cases, a tricuspid pansystolic murmur is present, audible down the left sternal edge. An increase in intensity during inspiration is difficult to demonstrate, so that the murmur is usually indistinguishable from that of functional mitral regurgitation.

Investigations

Chest radiographic findings depend mainly on other cardiac disease present, but, as with tricuspid stenosis, there may be enlargement of the heart shadow towards the right.

The ECG may show right atrial hypertrophy in isolated tricuspid regurgitation if the patient is in sinus rhythm, but otherwise is dominated by other cardiac disease present.

Echocardiography is the best way of making the diagnosis. Cusp disease, either rheumatic or 5-hydroxytryptamine (carcinoid, see later) induced, and right ventricular

function are assessed by the cross-sectional technique, while the extent of the regurgitation can be measured by continuous wave and colour flow Doppler. The nature and extent of left-sided disease and pulmonary hypertension can also be documented. Cardiac catheterization is rarely necessary either to make the diagnosis or assess its severity.

Treatment

Medical treatment with diuretics deals with associated fluid retention, and may even allow right ventricular cavity size to decrease, restoring competence to the tricuspid valve. Isolated tricuspid incompetence, unless very severe or accompanied by right ventricular disease, is reasonably well tolerated. Surgical treatment is avoided if possible. However, if regurgitation is very severe and fluid retention requires doses of diuretics large enough to cause significant metabolic consequences, then intervention may be considered. Unfortunately, repair and replacement of the tricuspid valve are unsatisfactory operations: the former does not usually control regurgitation and the latter leads to a very significant diastolic pressure drop between right atrium and right ventricle. In addition, the risks of surgery are high in these patients, and postoperative jaundice and renal failure are common.

When tricuspid regurgitation occurs in association with rheumatic heart disease involving the left side of the heart, it may subside spontaneously after the latter has been dealt with surgically, although there is a case for routine tricuspid valve plication or repair to prevent tricuspid regurgitation developing postoperatively.

Serotonin-induced heart disease

Increased levels of 5-hydroxytryptamine (**5HT**, serotonin) associated with metastatic carcinoid disease cause severe tricuspid and pulmonary regurgitation, and similar findings are associated with anorectic agents. Fenfluramine also causes 5HT release and thus has similar effects on the right-sided valves.

5HT is normally cleared by the lungs, so that in the absence of a right to left shunt, the left side of the heart is not usually affected in carcinoid disease. However, fenfluramine has been used in combination with phentermine, which blocks pulmonary uptake of 5HT, so that together these drugs can lead to involvement of the mitral and aortic valves as well.

The valves are thickened, with a glistening appearance, due to the deposition of plaques of fibrosis. Vascularization and cusp fusion do not occur. However, the cusps themselves become retracted, so that the dominant lesion is regurgitation through a central jet. Subendocardial thickening may also occur, so that the effects of reduced cavity compliance are superimposed on those of volume overload. On the left side of the heart, the regurgitation may be severe enough to require valve replacement.

Not all patients with carcinoid disease develop cardiac manifestations, but when they are present they may progress, even after removal of the tumour. In slowly progressive cases, tricuspid valve replacement has been successfully undertaken.

Pulmonary valve disease

Acquired pulmonary valve disease is unusual. The commonest form is that associated with severe pulmonary hypertension and dilatation of the pulmonary valve ring, causing mild regurgitation. This commonly occurs in association with pulmonary hypertensive mitral valve disease, causing a soft early diastolic murmur (the Graham–Steell murmur), but an identical picture may be present with severe pulmonary hypertension from any cause. Although the murmur itself is early diastolic in timing, there is no associated abnormality of the carotid pulse as would be expected in aortic regurgitation. Nevertheless, the differential diagnosis on clinical grounds can be difficult when mitral valve disease is severe. Mild pulmonary regurgitation is effectively a normal finding on colour flow Doppler; a more extensive jet in a patient with pulmonary hypertension being required to confirm the diagnosis. Aortic regurgitation can be confirmed or excluded by Doppler. Rheumatic pulmonary regurgitation is extremely rare, although it has been reported in populations living at high altitudes. However, even when present it contributes little to overall disability. Pulmonary regurgitation may also form part of the carcinoid syndrome, but its effect on the clinical picture is less than that of the tricuspid or left-sided valves. It may also be iatrogenic, following pulmonary valvotomy for pulmonary stenosis, when it contributes to the elevated venous pressure that can persist for a variable period after this operation. It is of no clinical consequence and requires no specific treatment.

Valve disease and pregnancy

For information of the effect of pregnancy on patients with valve disease, see Chapter 13.6.

Management of patients with valve prostheses

Many patients have received heart valve replacements over the past 40 years, with very significant improvement in their quality of life. However, although the haemodynamic performance of these prostheses is greatly superior to the diseased valves that they replaced, it is not normal, and survival with any valvular prosthesis is significantly less than that for age-matched normal individuals. Having a valve replacement should now be regarded as the commonest form of valve disease in Western society.

Valve prostheses can be mechanical or biological. Mechanical prostheses include the Starr–Edwards ball and cage prosthesis, which has the advantage of a 30-year follow-up and remarkable reliability; single tilting disc valves (Bjork–Shiley); but those inserted over the last 10 years are likely to be bileaflet (St Jude). The more modern types have a larger effective orifice area than the Starr–Edwards in relation to the size of their ring.

Biological prostheses usually consist of a plastic stent on which cusps made from some biological material are mounted. The cusps may be derived from porcine aortic valve or pericardium. More recently, unstented xenografts (e.g. the Toronto) have been used, where the aortic homograft is mounted on a ring of native aortic root. In the Ross operation, the patient's own pulmonary valve is inserted into the aortic position (pulmonary autograft) and replaced by an aortic homograft in the right ventricular outflow tract.

There are minor differences in performance between the various valve substitutes, but these are not of great clinical significance. Apart from the pulmonary autograft, all fall short of their natural counterpart *in vivo*. Under normal working conditions, pressure differences are present across mitral prostheses, which range from 4 to 5 mmHg for the Starr–Edwards to 2 to 4 mmHg for the others. In addition, all mitral valve substitutes have a rigid mitral ring which interferes with ventricular function. Apart from the autograft, and to a lesser extent the homograft, whose performance approximates to that of the native valve, systolic gradients across aortic prostheses are in the range 10 to 25 mmHg at rest, increasing on exercise.

The main factors guiding choice of valve prosthesis are durability and the likely incidence of thrombotic complications. Present operative mortality is in the region of 3 to 5 per cent for single valve replacement and approximately 10 per cent for double valve replacement. These values are higher if simultaneous coronary artery grafting is necessary. Long-term survival studies have shown that 10-year survival after single valve replacement is approximately 70 to 75 per cent, and after double valve replacement 50 to 65 per cent. For reoperation, mortality is higher, the exact figure depending on the circumstances in which surgery is performed.

Late complications of valve replacement

Thromboembolism

This is a major complication associated with all mechanical prostheses. Long-term anticoagulant therapy with a drug of the warfarin type is essential in all patients in whom these prostheses have been inserted, and even with satisfactory control (international normalized ratio, **INR**, between 3 and 4.5), an incidence of significant events including transient weakness, dysphasia, or visual disturbances of 1 to 2 per cent per annum can be expected. At the same time, anticoagulant therapy itself causes bleeding complications severe enough to require admission to hospital with an incidence of approximately 1 per cent per annum.

In a small minority of patients, emboli are frequent in spite of good anticoagulant control. Initially, such patients should be given an antiplatelet agent such a dipyridamole, and the anticoagulant dose adjusted accordingly. The possibility of some other cause for the neurological manifestations, such as cerebrovascular disease, must always be considered. However, frequent embolization may be associated with thrombosis of the prosthesis, and if this is proven beyond all question

and cannot be suppressed medically, reoperation and replacement with a biological prosthesis may be necessary.

The incidence of thromboembolic complications is much lower with biological prostheses, so that long-term anticoagulant therapy can be dispensed with in patients in sinus rhythm after aortic or mitral valve replacement. However, many surgeons recommend a short course of 2 to 3 months in such patients whilst suture lines become endothelialized. Patients with atrial fibrillation require standard long-term anticoagulant therapy.

In developing countries, mitral replacement may have to be performed in children under the age of 15 years, in whom biological valves are unsuitable. The use of a mechanical prosthesis might seem appropriate, but facilities for regular anticoagulant monitoring are not available, while uncontrolled administration of standard doses of warfarin is associated with unacceptable risk of haemorrhage. This therapeutic dilemma is, at present, unsolved.

Limited prosthetic function

In a minority of patients, valve replacement may give rise to severe haemodynamic disturbances, such that in extreme cases the condition of the patient may be worse after the operation than before. This usually arises when the valve ring or the ventricular cavity is very small, and a correspondingly small prosthesis was inserted. In the mitral position, resting diastolic pressure differences as high as 20 mmHg may be present, or of 50 mmHg across the aortic valve on this basis. A related problem is the insertion of a prosthesis that is too large, particularly of the ball and cage type. In the mitral position, the cage may impinge on the septum, and obstruct the left ventricular outflow tract, causing subaortic stenosis; whilst in the aortic position, obstruction may develop between the ball and the aorta. These complications are now avoided by the use of low-profile prostheses, such as the St Jude bileaflet prosthesis.

Infection

Patients with prostheses, mechanical or biological, are at greatly increased risk of infective endocarditis. The infecting organism may have been introduced at the time of operation, when it usually manifests within 2 months of surgery. Later infections are bloodborne. It is therefore essential that all patients receive full antibiotic prophylaxis immediately after surgery and subsequently for dental manipulations and other potentially septic hazards, rather than the single dose of single agent currently recommended for routine dental prophylaxis in those at lower risk (see Chapter 15.10.2).

Infective endocarditis is a very serious complication, and rarely responds to antibiotic therapy alone. A second valve replacement is nearly always required, often in a seriously ill patient in whom the valve ring may be infected and friable. The clinical features of endocarditis on a mechanical prosthesis differ very significantly from those on a native valve. Vegetations are uncommon. The infection is often confined to the tissue around the prosthesis, including the sewing ring, and may rot the sutures, so that the first manifestation is sudden death due to displacement of the valve to the aortic bifurcation. Partial dehiscence leads to severe regurgitation with a rocking prosthesis, demonstrable by simple screening or cross-sectional echocardiography. The main disturbance may be stenosis, due to ingrowth of infected clot. Abscess formation around the prostheses is particularly common in the aortic position, which may cause complete heart block or perforation to the right side of the heart. These difficulties are compounded by the acoustic properties of the mechanical valves themselves which limit the value of echocardiography. Para-aortic abscesses are well demonstrated by transoesophageal echo.

Prosthetic dysfunction

This is an important cause of morbidity in patients who have undergone valve replacement. There may be structural damage to the prosthesis itself, which is uncommon in mechanical valves, though occasional batches may undergo strut fracture due to metal fatigue, a well known example being the concavo-convex Bjork–Shiley valves inserted in the late 1970s.

Malfunction is much commoner with biological prostheses, when cusps may become calcified, perforated, or detached. Calcification of porcine bioprostheses regularly occurs within 1 to 2 years of insertion in children under the age of 15 years. This complication takes much longer to develop in the aortic homograft, usually 10 to 15 years. Once cusp degeneration has occurred, the valve should be regarded as unstable, since sudden cusp detachment or perforation can occur, and it is therefore inadvisable to adhere to haemodynamic guidelines appropriate to native valves when deciding on the timing of further surgery. It is an advantage of the homograft valve that sudden deterioration in haemodynamic function is much less common.

Mechanical prostheses are subject to thrombosis. This may take two forms. Deterioration in function may be insidious over a period of several months or years due to ingrowth of organized clot (pannus), usually from the atrial side (Fig. 16). This may be associated with an increased incidence of emboli in spite of adequate anticoagulant therapy. Alternatively, the prosthesis may clot acutely: this is particularly likely to occur with the Bjork–Shiley in the mitral position, and represents a surgical emergency. It can often be recognized clinically, the patient presenting with pulmonary oedema or in a low cardiac output state, and the closing click of the prosthesis no longer audible. Operation is required as soon as possible, since deterioration may occur within hours. If the condition of the patient is so poor as to preclude anaesthesia, then thrombolysis should be used, in spite of the risk of systemic embolism. Improvement may be expected within a few hours, when the thrombolysis can be neutralized and surgery undertaken.

Fig. 16 Thrombosed Star–Edwards prosthesis, removed at emergency operation.

Finally, paraprosthetic regurgitation may develop. In the aortic position, this may have been present since the original operation, because heavy calcification of the original valve extended into the valve ring. Paraprosthetic regurgitation that appears suddenly always raises the possibility that the prosthesis might have become infected. Mitral paraprosthetic regurgitation usually results from part of the valve sewing ring tearing away. Again, infection should always be considered, but regurgitation is well documented in its absence.

Recognizing prosthetic dysfunction

Stenosis or regurgitation associated with a prosthesis does not have the same physical signs as the corresponding lesion of the native valve. In general, it presents as deterioration in cardiac state, whose progress may be acute or chronic. The clinical picture is of 'heart failure'. On examination, the venous pressure is raised, the liver enlarged, and chest radiography shows that the heart has enlarged and pulmonary congestion appeared. When a mitral prosthesis is involved, there are characteristically no murmurs, other than those of tricuspid regurgitation; an aortic systolic murmur may be present, but its intensity and timing differs little from that of a normally functioning prosthesis. It is essential, therefore, that the possibility of a prosthesis-related complication is considered in all such patients in whom a diagnosis of 'heart failure' is entertained. The differential diagnosis is exacting, and requires echocardiography, Doppler, and possibly cardiac catheterization by an experienced operator. All patients presenting in this way should therefore be referred to a unit where these investigations can be performed reliably, and emergency surgery can be undertaken if necessary.

Haemolysis

All mechanical prostheses are associated with increased intravascular haemolysis. This rarely gives rise to clinical problems when the prosthesis is functioning

normally, and anaemia does not occur. The extent of haemolysis can be estimated from a peripheral blood film, which shows fragmented forms, from depression or absence of serum haptoglobin, and from an increase in lactate dehydrogenase levels.

Haemolysis may become significant with a normally functioning prosthesis when the patient has a compensated haemolytic state of some different aetiology, such as congenital spherocytosis or thalassaemia minor. In these circumstances, there is a risk of haemolysis becoming severe.

Mild paraprosthetic regurgitation whose severity is insufficient to give rise to any haemodynamic complications can cause clinically significant haemolysis. In such cases, it may be undesirable to expose the patient to the risk of reoperation, particularly if the original valve leak was due to some predictable cause such as heavy calcification of the valve bed, and so likely to recur. Provided that haemolysis is not severe, such patients can usually be treated medically on maintenance therapy with iron and folic acid. A requirement for transfusion, however, is a strong indication for reoperation.

Left ventricular disease

This is a major cause of morbidity and mortality after valve replacement. There is no single cause. In many patients, severe left ventricular disease was present preoperatively, and though some improvement frequently occurs with correction of the valve disease, function never returns to normal. Operation itself causes additional damage. Methods of myocardial preservation during the period of cardiopulmonary bypass have improved very considerably over the last 20 years with the general introduction of cold blood cardioplegia, but before then ischaemic arrest appears to have been associated with myocardial damage that may take several years to become manifest. A rigid prosthetic mitral ring invariably leads to abnormal function, and there is increasing evidence that section of the papillary muscles may have the same effect. Coronary emboli may arise from the prosthesis. Many patients are of an age to have additional coronary artery disease.

Whatever the cause, left ventricular disease after valve replacement presents its usual clinical features. There is progressive limitation of exercise tolerance and breathlessness due to reduction in cardiac output and pulmonary congestion. Venous pressure becomes raised, and the earliest clinical evidence may relate to right rather than left ventricular disease, with elevated venous pressure, fluid retention, and hepatic congestion. Auscultatory signs may be modified, and in particular third and fourth heart sounds are not audible in patients with mechanical mitral prostheses. Chest radiography shows an increase in heart size and pulmonary congestion. ECG may show Q waves, but their absence is of no significance.

The differential diagnosis of ventricular disease after valve replacement is prosthetic dysfunction, and it is essential that a correct diagnosis is established in any patient who fails to progress, or whose improvement after operation is not maintained. Echocardiography, transthoracic and transoesophageal, has proved of great value in such patients, since it allows the very active left ventricular wall motion that accompanies a paraprosthetic leak to be distinguished from the dilated cavity and poor shortening fraction of left ventricular disease. Continuous wave Doppler can be used to detect significant gradients across biological valves. However, unless the diagnosis is clear from non-invasive investigation, cardiac catheterization is required to settle the diagnosis beyond doubt.

The prognosis once clinically apparent left ventricular disease has developed is poor, usually being of the order of 1 to 2 years, so it is essential that no remediable cause is overlooked.

Follow-up of patients after valve replacement

Patients must be followed up after valve replacement for life. This must at least be at annual intervals, with regular chest radiography and ECG in an experienced clinic. Echocardiography should be performed early, not only to detect immediate postoperative complications such as a pericardial fluid collection, which can be potentially fatal if delayed tamponade occurs, but also to establish a baseline from which to detect future change. Deterioration must be detected early, and investigated in detail so that life-threatening complications are not missed. Dental prophylaxis is essential.

Valve disease and pregnancy

The circulatory changes associated with pregnancy modify the physiology of valve disease and thus its management. These changes are hormonally mediated, and result in an increase in cardiac output by 40 to 45 per cent above control values and a corresponding fall in peripheral resistance, maximal in the middle trimester. This elevation in cardiac output is mediated in approximately equal parts by increases in stroke volume and heart rate. The raised stroke volume, in particular, can lead to the development of a soft ejection systolic murmur, whose benign origin can normally be clarified by echocardiography, chest radiography being avoided where possible.

The effects of the circulatory changes of pregnancy on those of pre-existing valve disease are very predictable. Since the increase in cardiac output is brought about mainly by a fall in peripheral resistance, patients with valvular regurgitation do well. The main problems are with stenotic lesions. In mitral stenosis, the increased stroke volume and tachycardia combine to increase the diastolic pressure drop across the valve, thus predisposing to pulmonary oedema. Pulmonary oedema in a pregnant patient is a medical emergency, and prompt transfer to a surgical centre should be arranged if the symptoms are more than mild. Medical treatment with digoxin and b-blocking agents, aimed at slowing the heart rate, may be satisfactory, but surgery is often necessary. Mitral valve anatomy in young women is usually compatible with a conservative operation. Closed mitral valvotomy has a long and proven record, and is available if the surgical expertise is still available. In its absence balloon valvuloplasty, with appropriate screening to minimize radiation, is also satisfactory.

The combination of aortic stenosis and pregnancy is also difficult to manage, since an increase in the pressure drop across the valve combined with a fall in peripheral resistance is particularly liable to cause syncope as well as aggravating left ventricular disease, and leading to pulmonary oedema and death. Cardiopulmonary bypass for valve replacement during pregnancy is associated with a 20 to 30 per cent fetal loss, but there may be no alternative. In young female patients with mitral and particularly with aortic stenosis, therefore, there is a strong case for dealing with the valve lesion before pregnancy.

Prosthetic valves and pregnancy

Pregnancy

Clinical problems in pregnancy arise from the anticoagulant therapy needed for mechanical prostheses. Pregnancy is accompanied by an increase in coaguability and a decrease in fibrinolysis. Coumarin anticoagulants lead to an incidence of spontaneous abortion of approximately 30 per cent, particularly during the sixth to ninth weeks, while in the third trimester, they are associated with fetal haemorrhage and post-partum bleeding, even when the INR is well controlled. In the absence of large-scale trials, a commonly used regime is to give heparin for the first trimester, followed by warfarin until just before delivery, when heparin is substituted. Heparin does not cross the placenta, and can readily be discontinued or neutralized with protamine. There is recent evidence to suggest that the incidence of fetal abnormality is low if the warfarin dose can be maintained below 5 mg/day.

15.8.1

Myocarditis

Jay W. Mason

Introduction

Myocarditis is a disease that has captured the interest of clinicians and scientists. This interest is generated by its varied aetiology, its diagnostic and therapeutic challenges, the possibility that myocarditis may be the primary cause of dilated cardiomyopathy, and the availability of numerous, easily manipulated animal models of the disease.

Clinical features

Myocarditis affects young people. The average age of patients in the United States Myocarditis Treatment Trial was 42 years. There was a slight male predominance (62 per cent) in that trial, but other series have not demonstrated a sex predilection. The true incidence of myocarditis is unknown. Autopsy studies have reported up to a 3 per cent incidence, but varying histological criteria were used, and myocarditis may occur as an incidental complication of other fatal illnesses. About 10 per cent of patients with influenza infections have electrocardiographic abnormalities, but it is not know if these are the result of myocarditis. The incidence of fatal myocarditis was estimated in a retrospective review of United States Air Force recruits undergoing boot camp training. There were eight such deaths over 1 606 167 person days, which yields an estimate of 4/100 000 per year in people aged 17 to 28 years. This incidence is probably greater than would be expected in the general population in the United States, who would not be exposed to similar levels of intense exercise or high probability of transmission of viral illnesses.

In Europe and North America most cases of myocarditis present with congestive heart failure of unknown cause. In many cases there is a history of recent upper respiratory tract infection or of a 'flu-like' illness. This is followed by symptoms of cardiac decompensation, usually fatigue, breathlessness, and cough. Chest pain occurs in a substantial minority of patients. A small proportion of patients with myocarditis present with ventricular tachyarrhythmias and minimal or no cardiac dilatation. Typically, the duration of symptoms due to infection is brief, less than 1 month in approximately 50 per cent of patients and nearly always less than 1 year. Myocarditis should always be suspected when a patient presents with unexplained congestive heart failure with a rapid onset, especially if there is a viral prodrome.

Clinical examination typically reveals signs of cardiac failure. The ECG may show conduction abnormalities and ST/T-wave changes, or arrhythmias (atrial or ventricular). The chest radiograph shows cardiomegaly and pulmonary oedema. The echocardiogram reveals four-chamber dilatation and reduced contractility, and is notable for the fact that valvular disease is absent or minimal. Should coronary angiography be performed, the vessels are normal or show only minor abnormalities. The role of myocardial biopsy will be discussed later. CPK-MB elevation is common.

Although viruses are thought to be the most common cause of myocarditis, viral titres are rarely useful in diagnosis and treatment. Although the cardiotrophic enteroviruses, including echoviruses and coxsackieviruses, are the predominant aetiological agents, dozens of viruses have been implicated and many more, undoubtedly, cause myocarditis in humans. Thus, it is impractical to exclude all. In addition, patients usually present a substantial period of time after the viral infection has cleared, making it difficult or impossible to document an acute rise in titre. Knowledge of a specific virus, or any virus, as the cause in a given case of myocarditis has little, if any, therapeutic relevance. Even if virocidal therapy (which is not yet a proven treatment; see below) is being considered, negative titres for the common viral agents do not exclude a viral aetiology.

A small number of patients, perhaps about 10 per cent, present with a secondary form of myocarditis. These special presentations are discussed below.

Aetiology and pathogenesis Table 1)

The most common form of myocarditis in Europe and North America is known as lymphocytic myocarditis or non-specific lymphocytic myocarditis. Other frequently applied terms are viral or post-viral myocarditis, because an antecedent viral infection is common. Indeed, some experts believe that nearly all lymphocytic myocarditides are the result of viral infections, presumed to be subclinical in those patients with no awareness of a viral prodrome.

In animal models enteroviruses, such as coxsackie B3, can cause two phases of myocarditis. The first is the result of direct injury of myocytes by replicating virus and the resulting acute immune response. A delayed immune response brings about the second phase, and it is this which is thought to be the more common cause of overt congestive heart failure. The underlying mechanisms are complex and incompletely understood, but most hypotheses suggest that autoimmune phenomena play a major role. In some instances molecular mimicry may be involved, in which the similarity of a viral antigen to a myocardial protein triggers an autoimmune reaction. In others an autoimmune response to cellular proteins released during the viral replication phase may occur, and myosin has been implicated in this regard. Cytokines arising from immune activation and cellular necrosis probably play a role in some cases, bringing about further cellular damage. Although all of these mechanisms have been well delineated in murine models, they have not been proven to account for myocarditis in humans.

Myocarditis may result from a hypersensitivity reaction to a drug or other agent (see Table 1). In these cases eosinophils accompany the inflammatory lymphocytic infiltrate. A number of other specific causes of myocarditis, each with differing pathogenises and presentations, are discussed below.

Relationship to idiopathic dilated cardiomyopathy

Classic lymphocytic myocarditis usually resolves, with resultant improvement in cardiac function over weeks or months. In the United States Myocarditis Treatment Trial, the mean left ventricular ejection fraction improved during the year after initial presentation by more than 10 EF units (from 24 to 36 per cent; normal more than 55 per cent). However, residual cardiac dilatation and dysfunction were common, and mortality was high, reaching 55 per cent at 5 years. In those patients who do not recover fully, the ensuing clinical picture cannot be distinguished from that of idiopathic dilated cardiomyopathy. The possibility that myocarditis may occur without an obvious viral prodrome therefore raises the interesting possibility that viral myocarditis may be a common covert cause of idiopathic dilated cardiomyopathy. In the United States trial, only 10 per cent of patients with suspected myocarditis had positive biopsies. Hence, the fact that endomyocardial biopsy does not reveal myocarditis in patients with idiopathic dilated cardiomyopathy may be the result of timing of the biopsy. The lymphocytic infiltrate usually resolves spontaneously, and it may be that earlier biopsy might have detected myocarditis in a portion of the 90 per cent with negative biopsies. The presence of viral genomic material in a minority of these negative biopsies lends support to the viral aetiology hypothesis. Absence of viral genome in the rest of them does not eliminate post-viral autoimmune processes, proceeding despite complete viral clearing, as a possible aetiology.

Treatment of post-viral and non-specific lymphocytic myocarditis

As stated above, non-specific lymphocytic myocarditis is believed by most to have a viral aetiology, even in the absence of a clinically apparent viral prodrome. In the acute phase of viral myocarditis, the direct cytolytic effect of viral myocyte infection may lead to congestive heart failure, although this is uncommon. In this early phase, the immune response is likely, on balance, to be beneficial. Thus, antiviral therapy might be expected to be helpful, on theoretical grounds, but

immunosuppressive therapy would not. However, no antiviral therapies have been adequately tested in humans. Although hyperimmune globulin is thought to be effective on the basis of retrospective studies, its efficacy has not been proved in a prospective trial. In the second stage, thought to result from an adverse immune response to previous infection, immunosuppressive therapy has appeared to be beneficial in uncontrolled trials. However, no benefit was demonstrated in the United States Myocarditis Treatment Trial, the only prospective, randomized trial performed in patients with myocarditis defined histologically. In that trial the 'Dallas' criteria defined myocarditis histologically as a lymphocytic infiltrate with associated myocyte necrosis (Fig. 1). Treatment with prednisone combined with either cyclosporin or with azathioprine did not improve outcome, as defined by change in left ventricular ejection fraction.

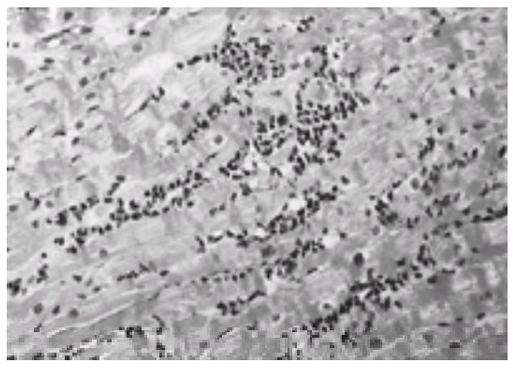

Fig. 1 An example of acute myocarditis, with lymphocytic infiltration adjacent to frayed myocytes.

An algorithm for the diagnosis and treatment of suspected myocarditis is shown in Fig. 2. Spontaneous improvement in left ventricular function can be anticipated in many patients with myocarditis. In most cases it is reasonable to use standard therapy for congestive heart failure, without performing a biopsy or administering steroids, and to observe the patient, using echocardiography to monitor left ventricular function. However, in patients who deteriorate, or who present in cardiogenic shock, an endomyocardial biopsy should be performed. If myocarditis is present, many would regard it as appropriate to administer immunosuppressive therapy, typically beginning with prednisone at 1.25 mg/kg per day, tapering to 0.15 mg/kg per day over 1 month. It must be admitted, however, that the efficacy of such treatment has not been proved.

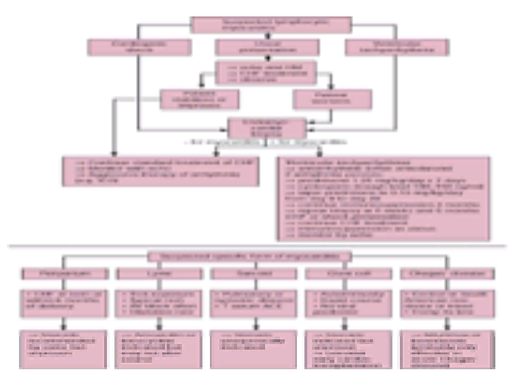

Fig. 2 Algorithm for diagnosis and treatment of suspected myocarditis. Abbrevations: CHF, congestive heart failure; ICD, implantable cardioverter device; ACE, angiotensin-converting enzyme; echo, echocardiogram; HM, Holter monitor.

Ventricular tachyarrhythmias

Lymphocytic myocarditis, with or without a viral prodrome, may present with ventricular tachyarrhythmias and little or no cardiac dilatation and dysfunction. An endomyocardial biopsy should be considered in all cases of ventricular tachycardia of recent onset if no aetiology is apparent, because the presence of myocarditis can substantially change treatment strategy. Since myocarditis is often a self-limiting disorder, the patient's risk of recurrent ventricular tachyarrhythmias may resolve, and it may be unnecessary to subject the patient to electrophysiological study and/or cardioverter-defibrillator implantation. If arrhythmia does not improve spontaneously, a trial of immunosuppressive therapy should be considered. In such cases it is difficult to know how long to continue with anti-arrhythmic drugs. The risks of ventricular arrhythmia should not be underestimated, but nor should those of long-term treatment with agents such as amiodarone. If 24-h ECG monitoring at 6 months shows no sinister abnormalities, then many would withdraw anti-arrhythmic treatment at that point, but others advocate repeat endomyocardial biopsy to document complete resolution of myocarditis before taking this step.

Specific forms of myocarditis

Peripartum myocarditis

Dilated cardiomyopathy developing during the last trimester of pregnancy or within 6 months of delivery is known as peripartum or postpartum cardiomyopathy (see also Chapter 13.6). In some series the dominant cause is myocarditis. When heart failure develops rapidly in the first few weeks after delivery, myocarditis is more likely to be found on endomyocardial biopsy than when the onset is insidious and delayed, and those with early, rapid onset are more likely to recover quickly and completely. While steroid therapy has been used and is recommended by some, its efficacy has not been proved, and spontaneous resolution of peripartum cardiomyopathy is well documented. The usual prohibition against future pregnancy has been debated; it is very clear that some women risk recurrent heart failure, while others do not. In those women in whom severe heart failure persists, cardiac transplantation is an appropriate therapy. After transplantation, successful pregnancies have occurred without recurrence of cardiomyopathy.

Lyme carditis (see Section 15.10 and Chapter 7.11.29)

Borrelia burgdorferi, a spirochaete, infects humans following *Ixodes* tick bites. Lyme disease, which results from this infection, has been reported in 48 of the 50 United States as well as in Europe and Asia. It is characterized by an erythema migrans rash and flu-like symptoms, followed by arthritis, carditis, and neurological disorders in some patients. Carditis is detected in approximately 8 per cent of cases. Both lymphocytic infiltration and the bacterium itself can be demonstrated by endomyocardial biopsy. The usual cardiac manifestation is varying degrees of atrioventricular block. Infrequently, cardiac dilatation occurs. Atrioventricular block is usually transient, though permanent complete heart block has been reported. The site of block appears to be the atrioventricular node in most cases, but block within the His bundle has been documented by electrophysiological study, and the common occurrence of intraventricular conduction delays suggests that bilateral bundle branch block may also occur. Temporary pacing is usually sufficient, though recovery of antegrade conduction may take a week or longer. Lyme carditis should be considered in any case of heart block of unknown cause, especially in young individuals.

Antibiotic therapy (see Chapter 7.11.29) is indicated in Lyme carditis, but it is not known if this alters the course of carditis and atrioventricular block.

Cardiac sarcoidosis

Less than 10 per cent of patients with pulmonary or systemic sarcoidosis have clinically manifest cardiac involvement, ranging from conduction disturbances and arrhythmias to cardiac dilatation. Endomyocardial biopsy reveals typical sarcoid granulomas. The most serious complications of cardiac sarcoidosis are complete heart block, ventricular tachyarrhythmias, and dilated cardiomyopathy. The relatively high incidence of sudden death in patients with sarcoidosis is thought to result from sudden complete heart block or ventricular fibrillation. Patients with sarcoidosis who develop significant conduction disease, arrhythmias, or congestive heart

failure should receive steroids. Occasionally, cardiac involvement will occur without detectable systemic manifestations of sarcoidosis. Thus, cardiac sarcoidosis is in the differential diagnosis of any undiagnosed ventricular arrhythmia, dilated cardiomyopathy, or atrioventricular block.

Giant cell myocarditis

Early recognition of this rapidly progressive form of myocarditis is required, as it has a prognosis considerably worse than that of non-specific lymphocytic myocarditis. The endomyocardial biopsy is distinguished by the presence of multinucleated giant cells and scattered lymphocytic infiltrates with eosinophils. The aetiology of giant cell myocarditis is unknown, but thought to be autoimmune, given its association with myasthenia gravis and other immune disorders, thymoma, and Crohn's disease. It should be suspected in patients, particularly those with a history of an autoimmune condition, who present with disease which progresses unusually rapidly, without viral prodrome, and who do not respond to standard therapy of congestive heart failure. Endomyocardial biopsy should be performed if giant cell myocarditis is suspected, because immunosuppressive therapy appears to be helpful, though not yet proved. Patients with giant cell myocarditis should be considered for early cardiac transplantation if they do not respond to therapy.

Chagas' disease (see Chapter 7.13.11)

Chagas' disease, caused by *Trypanosoma cruzi*, is the leading cause of myocarditis and dilated cardiomyopathy in some Central and South American countries, but uncommon in the United States. Overt acute myocarditis with congestive heart failure, arrhythmias, and conduction disease may develop, but cardiac involvement in early Chagas' disease is usually subclinical. Years later, chronic Chagas' disease may develop and may involve the heart. In the chronic phase, right bundle branch block and biventricular failure are present, and right heart failure predominates. Myocarditis occurs in both the acute and chronic phases, when immune mediation of myocyte injury is well documented. Antiprotozoal treatment with nifurtimox or benznidazole is beneficial in the acute phase. These agents are also indicated in the chronic phase, but, while they do reduce or eliminate serological immune markers of disease, it is not known if they improve outcome.

15.8.2 The cardiomyopathies: hypertrophic, dilated, restrictive, and right ventricular

William J. McKenna

Introduction

Heart muscle disease has traditionally been classified as idiopathic or specific. The former, termed the cardiomyopathies, are classified as hypertrophic, dilated, right ventricular, and restrictive. This descriptive classification is useful in relation to natural history, treatment, and prognosis, but recent discoveries of disease-causing mutations in genes encoding sarcomeric contractile proteins in hypertrophic, cytoskeletal proteins in dilated, and a desmosomal protein in right ventricular cardiomyopathy, all indicate that developing knowledge of aetiology/pathogenesis will ultimately require a new classification of the 'idiopathic cardiomyopathies'. The term specific heart muscle disease incorporates myocardial involvement as part of a systemic disease (such as sarcoidosis, systemic hypertension) or when the mechanism of myocardial damage is recognized (such as ischaemia).

Hypertrophic cardiomyopathy

Definition

Hypertrophic cardiomyopathy is defined clinically as an idiopathic heart muscle disorder that is characterized by a hypertrophied and non-dilated left ventricle in the absence of a cardiac or systemic cause. Such a diagnosis of exclusion often presents problems. Does the patient with moderate systemic hypertension and 1.5-cm left ventricular hypertrophy have one or two diseases? Is 1.5-cm hypertrophy a physiological response in a highly trained athlete? Diagnostic uncertainty in the presence of other causes of left ventricular hypertrophy highlights a major limitation of the current definition of hypertrophic cardiomyopathy.

Genetics

Hypertrophic cardiomyopathy is usually familial with autosomal dominant transmission. Clinical presentation with left ventricular hypertrophy under the age of 3 years is usually caused by metabolic or mitochondrial disorders (Table 1) and is unusual in autosomal dominant hypertrophic cardiomyopathy, where morphological and clinical features typically present during or following periods of childhood or adolescent growth. Clinical history reveals familial disease in 40 to 50 per cent, but when cardiovascular evaluation of first-degree relatives includes ECG and echocardiography, 90 per cent of patients have familial disease. Variable expression of the disease is common, even within families bearing the same gene defect.

Mutations in the DNA encoding cardiac b-myosin heavy chain, essential and regulatory myosin light chain, a-tropomyosin, cardiac troponin T and I, cardiac myosin binding protein C, and cardiac actin have been identified in families with hypertrophic cardiomyopathy. Mutations in these genes are found in 60 to 70 per cent of pedigrees evaluated, with those in the b-myosin heavy chain accounting for 20 to 30 per cent, defining hypertrophic cardiomyopathy as a disease of sarcomeric contractile proteins. Most mutations involve a single base-pair change, resulting in amino acid substitutions in exons encoding highly conserved regions. *De novo* mutations occur, but appear to account for 10 per cent of cases or less.

There is allelic heterogeneity with respect to penetrance, morphology, and prognosis. b-Myosin heavy chain mutations that are fully penetrant are associated with worse prognosis (such as Arg403Glu, Arg453Cys), while disease complications are uncommon in patients with mutations that cause mild or no clinical expression (such as Leu908Val). This contrasts with troponin T disease, which may cause premature sudden death in asymptomatic patients who have only minor ECG and/or echocardiographic abnormalities. Troponin T mutations cause 5 to 15 per cent of disease and are associated with incomplete penetrance, disease expression in adolescence, severe myocyte disarray despite mild hypertrophy, and sudden death in adolescents and young adults. Diagnostic difficulties in relatives of sudden death victims who had myocyte disarray with normal or near normal heart weights underscores the importance of implementing a DNA diagnostic test for troponin T. Mutations in myosin binding protein C cause 20 to 30 per cent of disease; most are major deletions rather than single base-pair changes. Myosin binding protein C disease differs in that disease expression occurs later in life, often associated with the recent onset of mild hypertension. However, once disease expression occurs (abnormal ECG and/or echocardiogram) patients may develop symptoms and are at risk from arrhythmia, emboli, and sudden death. Disease caused by the other five recognized gene abnormalities appears to account for less than 10 per cent of all cases of hypertrophic cardiomyopathy. Recently mutations have been identified in the g subunit of AMP dependent protein kinase in families with hypertrophic cardiomyopathy, premature conduction disease, and pre-excitation cosegregating to a locus on chromosome 7.

Pathology

Hypertrophic cardiomyopathy may involve the left or both ventricles. Hypertrophy in the left ventricle is usually asymmetric, involving the anterior and posterior septum and the free wall to a greater extent than the posterior wall. Right ventricular hypertrophy, which is usually symmetric, is seen in over 30 per cent of patients; isolated right ventricular hypertrophy has not been reported. Over 60 per cent of patients have structural abnormalities of the mitral valve, including increased leaflet area,

elongation of the leaflets, and malposition or anomalous insertion of the papillary muscles. Another common macroscopic finding is a patch of endocardial thickening just below the aortic valve, which results from contact of the septum with the anterior mitral leaflet in patients with mitral leaflet abnormalities and/or left ventricular outflow tract obstruction.

The histological findings in hypertrophic cardiomyopathy are distinctive and provide the basis for the pathological diagnosis (Fig. 1). Affected myocardium shows interstitial fibrosis with gross disorganization of the muscle bundles resulting in a characteristic whorled pattern. The cell-to-cell orientation of muscle cells is lost (disarray) and there is disorganization of the myofibrillar architecture within cells. Myocardial cells are wide, short, and often bizarre in shape. Foci of disorganized cells are often interspersed among areas of hypertrophied muscle cells that are otherwise normal in appearance. Such changes are not completely specific: small amounts of fibre disarray may be seen in congenitally abnormal hearts and in secondary left ventricular hypertrophy, and something similar is found at the junction of the septum with the anterior and posterior walls of the left ventricle in normal subjects. However, the extent of myocyte disarray in normal subjects rarely exceeds 5 per cent, whilst in hypertrophic cardiomyopathy up to 40 per cent of the myocardium may be involved. Extensive myocyte disarray is occasionally found in the macroscopically normal heart of a patient who experienced typical clinical features: this highlights the broader phenotype and suggests that hypertrophy may be a secondary rather than a primary abnormality.

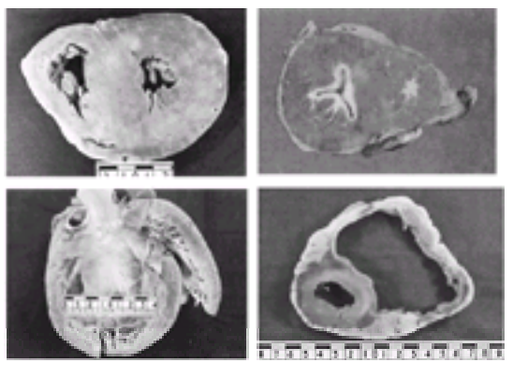

Fig. 1 Transverse short axis section through the ventricles from patients with cardiomyopathy. Upper left shows symmetrical left ventricular hypertrophy in hypertrophic cardiomyopathy. Upper right shows dense white fibrous tissue obliterating the apex of both ventricles in endomyocardial fibrosis. Lower left shows a globular, dilated left ventricle in a child with dilated cardiomyopathy. Lower right shows a grossly dilated right ventricle with adipose infiltration of the right ventricular free wall in arrhythmogenic right ventricular dysplasia. Pathophysiology

Disarray

Myocardial disarray and hypertrophy, hyperdynamic systolic function, and impaired diastolic function account for many of the clinical features of hypertrophic cardiomyopathy. The extent and distribution of myocardial disarray can only be determined at autopsy. It is probable that the disorganized architecture with abnormal myofibre and myofibrillar alignment provides a substrate for electrical instability and contributes to diastolic abnormalities, but the precise relationship between myocardial disarray and spontaneous arrhythmia, in particular the threshold for ventricular fibrillation, has not been established.

Diastole

Diastolic abnormalities are common but variable. Typically, left ventricular end-diastolic pressure and atrial pressures are elevated as consequences of abnormal left ventricular diastolic filling and reduced compliance. The isovolumic relaxation time is prolonged, filling is slow, and the proportion of filling volume that results from atrial systolic contraction (while still preserved) may be increased. Occasionally, there is rapid early filling with restrictive physiology that resembles the situation in patients with constrictive pericarditis or endocardial fibrosis (see Chapter 15.9). Altered diastolic function may be caused by myocardial hypertrophy, ischaemia, and architectural abnormalities including myocyte disarray and fibrosis. In an individual patient it is often difficult to identify the major determinant of diastolic disease.

Systole

Most young and some old patients have evidence of hyperdynamic systolic function with rapid, early, and near complete ventricular emptying. Approximately 30 per cent of patients with hyperdynamic systolic function have recordable gradients between the body and outflow tract of the left ventricle at rest; an additional 20 to 25 per cent develop such a gradient following manoeuvres that increase myocardial contractility or result in a decrease in ventricular volume with reduced afterload or venous return. The presence and magnitude of a gradient is determined not only by systolic contractile performance, but also by left ventricular outflow tract size and geometry, which are determined by the extent of upper septal hypertrophy, mitral leaflet morphology, and papillary muscle size and position. The conventionally accepted mechanism of the gradient is that Venturi forces from increased ejection velocity in the narrowed outflow tract draw the anterior and posterior mitral leaflets (which are often large and redundant) toward the septum. However, the significance of such gradients has been controversial. Many workers have claimed that the development of a left ventricular gradient in close temporal association with the development of systolic anterior motion (**SAM**) of the mitral valve and a fall in peak aortic velocity represents impediment or obstruction to left ventricular emptying, but another interpretation of these findings is that they are generated by a dynamic left ventricle that has almost completely emptied. Assessment of the significance of a left ventricular gradient in an individual patient is aided by knowledge of the relative volume ejected by the onset of the gradient. In most patients with resting left ventricular gradients (i.e. 30 to 70 mmHg), at least 70 per cent of stroke volume has already been ejected by the onset of the gradient. By contrast, patients with larger gradients usually have a significant residual volume in the left ventricle at the onset of SAM-septal contact and can be considered to have obstruction.

Ischaemia

Myocardial ischaemia despite normal epicardial coronary arteries is common and caused by several features that relate to myocardial hypertrophy (Table 2). Evidence of ischaemia, however, is not limited to those with severe hypertrophy, and abnormalities of the intramural arteries and of coronary vasomotor behaviour may also be important.

Diagnosis

Hypertrophic cardiomyopathy has been described in Western, African, and Asian populations. The prevalence in adults is estimated to be 1:500 of the population. The diagnosis of hypertrophic cardiomyopathy is based upon the demonstration of unexplained myocardial hypertrophy, which is best done using two-dimensional echocardiography. The diagnosis requires that measurements of wall thickness exceed two standard deviations for gender-, age-, and size-matched populations. In practice, in an adult of normal size, the presence of a left ventricular myocardial segment of 1.5 cm or greater in thickness, in the absence of a recognized cause, is usually considered to be diagnostic. Less stringent criteria should be applied to first-degree relatives of an affected individual, where the probability of carrying the disease gene drops from 1:500 to 1:2. Unexplained symptoms or minor ECG or echocardiographic abnormalities have a high probability of representing disease expression when there is a 50 per cent chance of carrying the gene defect. Modified diagnostic criteria are applied in the context of proven familial disease (Table 3).

In children and adolescents the diagnostic features, particularly the ECG and echocardiographic manifestations of myocardial hypertrophy, often develop during or following growth spurts. The finding of a normal ECG and echo in a child or adolescent reduces the probability of their developing hypertrophic cardiomyopathy, but re-evaluation—ideally annually during adolescence—is warranted because disease expression may not occur until adolescent growth has been completed. In adults, however, the *de novo* development of unexplained left ventricular hypertrophy has so far only been seen with myosin binding protein C disease. Hence an asymptomatic adult with familial disease of onset before age 30 years who has a completely normal ECG and two-dimensional echocardiogram is at very low risk of developing hypertrophic cardiomyopathy and in practical terms does not need re-evaluation in this regard. By contrast, when there is a family history of disease presentation in later life, the possibility of late-onset disease caused by a myosin binding protein C mutation warrants re-evaluation every 3 to 5 years, or sooner if

symptoms or ECG changes develop. This represents a clinical situation where a diagnostic DNA test could be cost-effective and aid clinical management.

Problems in diagnosis often arise in highly trained athletes and in patients with mild hypertension in whom the hypertrophic response appears greater than expected from the apparent stimulus. Competitive athletes normally have an increase in myocardial mass, with maximum increase of 2 to 3 mm in left ventricular wall thickness. The determinants of the hypertrophic response in a patient with hypertension are unknown, but at least in part racially determined; the Afro-Caribbean response appears to be greater than the Caucasian one. In athletes and hypertensive subjects, the diagnosis or exclusion of hypertrophic cardiomyopathy is dependent on the whole clinical picture. An athlete who has 1.5-cm left ventricular hypertrophy with either a small left ventricular cavity or a family history of hypertrophic cardiomyopathy probably does have the condition, whereas an athlete who has negative family history and normal or increased left ventricular cavity dimensions probably does not.

There is the potential for molecular genetic evaluation to provide a 'gold standard' when the clinical diagnosis is equivocal, or when preclinical diagnosis would be of value, for instance in families where there have been multiple sudden deaths in children and adolescents (namely troponin T disease). The finding of a mutation in one of the identified contractile protein genes would confirm disease, but absence of mutation would not exclude the possibility. Identification of the remaining gene(s) for hypertrophic cardiomyopathy would increase the potential value of DNA diagnostic testing.

Though less common than in young children (under 3 years), hypertrophic cardiomyopathy in adults may also be caused by metabolic and mitochondrial diseases. Fabry's disease may account for up to 2 per cent of adult hypertrophic cardiomyopathy: the distinguishing cardiovascular features of this autosomal recessive disorder remain to be fully elucidated, but reduced a-galactacidase enzyme activity is diagnostic. Enzyme replacement therapy is feasible and potentially may improve symptoms and decrease cardiac hypertrophy. Occasionally fatigue or extreme limitation of exercise that is out of proportion to the morphological and haemodynamic severity of the cardiomyopathy are the predominant symptoms. These are characteristics of mitochondrial myopathies and in the absence of severe cardiac failure, sleep apnoea, chronotrophic incompetence, and/or excessive b-blockade should lead to appropriate investigations. In Friedreich's ataxia the cardiac manifestations may precede neurological features by years, necessitating mutation analysis of the frataxin gene for diagnosis. Reduced peak oxygen consumption and early acidification during maximal exercise testing with metabolic gas exchange measurements suggest a coexistent skeletal myopathy. The coexistence with the hypertrophic cardiomyopathy of other somatic features including conduction disease, accessory pathways, eye abnormalities, and diabetes are also suggestive of mitochondrial disease. However, routine neurological examination often fails to elicit abnormalities and muscle biopsy with enzyme analysis is often required for diagnosis.

Clinical features

History

Symptomatic presentation may be at any age with breathlessness on exertion, chest pain, sustained palpitation, syncope, or sudden death. Hypertrophic cardiomyopathy is occasionally found at autopsy in a stillborn baby or presents during infancy with cardiac failure, which is usually fatal. In children and adolescents the diagnosis is most often made during screening of siblings and offspring of affected family members. Paroxysmal symptoms or mild impairment of exercise tolerance are often present, but in the absence of a murmur may not elicit a diagnostic cardiac evaluation. Approximately 50 per cent of adults present with symptoms; in the remainder the diagnosis is made during family screening or following the detection of an unsuspected abnormality on physical, electrocardiographic, or echocardiographic examination.

In adults dyspnoea is common (over 50 per cent) and thought to be a consequence of elevated left atrial and pulmonary capillary wedge pressures resulting from impaired left ventricular relaxation and filling. Approximately 50 per cent of patients complain of chest pain, which is exertional, atypical, or both in similar proportions of patients. Atypical pain may have no obvious precipitant; more commonly it follows exercise or anxiety-related tachycardia, when it persists for up to several hours after the stress has been removed without enzymatic evidence of myocardial damage. Approximately 15 to 25 per cent of patients have experienced syncopal episodes, but in only a minority are there findings suggestive of an arrhythmia or evidence of overt conduction disease: in most patients the mechanism cannot be determined. Patients rarely present with symptoms attributable to left or right heart failure, for example recurrent paroxysmal nocturnal dyspnoea, ascites, or peripheral oedema. Thus, there is a wide spectrum of clinical presentation in hypertrophic cardiomyopathy, from severe cardiac failure in infancy to an incidental finding at any age.

Physical examination

In most patients with hypertrophic cardiomyopathy the physical examination is unremarkable and the detection of abnormalities is dependent on the elucidation of subtle physical signs. There is usually a rapid upstroke arterial pulse, best felt in the carotid area, which reflects dynamic left ventricular emptying. Most patients also have a forceful left ventricular cardiac impulse, best appreciated on full-held expiration in the left lateral position. In about one-third of patients the jugular venous pulse may demonstrate a prominent 'a' wave, reflecting diminished right ventricular compliance secondary to right ventricular hypertrophy. The first and second heart sounds are usually normal, and—unless patients are in atrial fibrillation—there is either a loud fourth heart sound, reflecting increased atrial systolic flow into a non-compliant ventricle, or a palpable atrial beat reflecting forceful atrial systolic contraction that may or may not be associated with significant forward flow of blood.

The most obvious physical sign in hypertrophic cardiomyopathy is an ejection systolic murmur present in those patients (20 to 30 per cent) who have a resting left ventricular outflow tract gradient. This murmur starts well after the first heart sound and ends well before the second. It is best heard at the left sternal border, radiating towards the aortic and mitral areas but not into the neck or the axilla. The intensity varies with changes in ventricular volume; it can be increased by physiological and pharmacological manoeuvres that decrease afterload or venous return (amyl nitrate, standing, Valsalva), and decreased by manoeuvres that increase afterload and venous return (squatting, phenylephrine). Occasionally, ejection systolic murmurs are associated at their onset with an ejection sound.

Most patients with a left ventricular gradient also have mitral regurgitation, which may be difficult to distinguish by auscultation. Doppler examination reveals that mitral regurgitation usually begins just before (30 to 40 ms) the onset of the gradient and continues for the duration of systole. Radiation of the systolic murmur to the axilla is often the best auscultatory clue to the presence of coexistent mitral regurgitation, which may be moderate to severe, either alone or in association with a left ventricular outflow tract gradient. A mid-diastolic rumble may sometimes result from increased transmitral flow in patients with severe mitral regurgitation; more commonly it occurs in isolation, presumably reflecting inflow tract turbulence.

Early diastolic murmurs of aortic incompetence may develop following surgical myotomy/myectomy or infective endocarditis involving the aortic valve. Although such murmurs are rare in the absence of such complications, they appear to occur more commonly than would be expected by chance and may reflect traction on the non-coronary cusp of the aortic valve by the septum. An ejection systolic murmur in the pulmonary area, reflecting right ventricular outflow tract obstruction, is also rare; when present it is usually associated with severe biventricular hypertrophy in the young or in those with coexistent Noonan's syndrome and a dysplastic pulmonary valve (see Chapter 15.12).

Prognosis

Patients with hypertrophic cardiomyopathy experience slow progression of symptoms, gradual deterioration of left ventricular function, and a significant incidence of sudden death, which occurs at all ages. Referral centre data from the 1970s and 1980s reveal an annual mortality from sudden death of 2 to 3 per cent in adults and 4 to 6 per cent in children and adolescents. It is even greater in young patients with recurrent syncope or a family history of 'malignant' hypertrophic cardiomyopathy. Although the mortality figures from non-referral hospitals are lower, the risk of sudden death is still present. More recent data in managed patients reveal annual mortality rates related to sudden death and disease of 1 and 2 per cent, respectively.

Symptomatic deterioration is usually slow. However, severe symptoms may develop in association with progressive myocardial wall thinning, presumably reflecting myocyte necrosis or fibrosis and severe reduction in left ventricular systolic performance and/or diastolic filling. Patients who experience such deterioration occasionally present with a clinical picture resembling restrictive cardiomyopathy with grossly enlarged atria, signs of right heart failure, and relative preservation of left ventricular systolic performance.

Atrial dilatation and the development of atrial fibrillation/flutter are important features in the clinical course, representing a risk of embolic stroke as well as of acute and/or chronic deterioration. Earlier onset of atrial fibrillation was considered to be an ominous development but is part of the evolution of patients with diastolic dysfunction and with appropriate management need not represent a major cause of morbidity or mortality. The largest study of patients with atrial fibrillation revealed that their 5-year survival was similar to that of age- and sex-matched patients who remained in sinus rhythm and, if the ventricular response was controlled,

symptomatic status remained stable.

Left ventricular hypertrophy develops during childhood and adolescence but is not progressive in adults. The trigger and other determinants of disease expression in late-onset myosin binding protein C disease are uncertain, but (as with the other disease-causing genes) left ventricular hypertrophy does not appear to be progressive beyond the limited phase of disease expression.

Investigations

Cardiological evaluation of patients with hypertrophic cardiomyopathy is performed to confirm or make the diagnosis, to characterize the functional and morphological features to guide symptomatic therapy, and to assess the risk of complications, particularly that of sudden death.

Electrocardiography

The 12-lead electrocardiogram is the most sensitive diagnostic test, although occasionally normal (around 5 per cent), particularly in the young. Five to ten per cent are in atrial fibrillation at the time of diagnosis. Many patients have an intraventricular conduction delay, 20 per cent have left axis deviation, while complete right bundle or left bundle branch block are uncommon (less than 5 per cent). The latter may develop following surgery and is occasionally seen in the elderly. ST-segment depression and T-wave changes are the most common abnormalities and are usually associated with voltage changes of left ventricular hypertrophy and/or deep S waves in the anterior chest leads V1–V3. Isolated repolarization changes or giant negative T waves are occasionally seen. Voltage criteria for left ventricular hypertrophy are rare in the absence of repolarization changes. Approximately 20 per cent of patients have abnormal Q waves, either inferiorly (II, III, and aVF), or less commonly in leads V1–V3. P-wave abnormalities of left and/or right atrial overload are common. The distribution of the P–R interval is similar to that in the normal population, but occasionally a short P–R interval may be associated with a slurred upstroke to the QRS complex, similar to that seen in the Wolff–Parkinson–White syndrome. At electrophysiological study such changes are not usually associated with evidence of pre-excitation, although patients with hypertrophic cardiomyopathy and accessory pathways have been described. Despite the many electrocardiographic abnormalities, there is no electrocardiogram that is typical of hypertrophic cardiomyopathy; a useful rule is to consider the diagnosis whenever the electrocardiogram is bizarre, particularly in younger patients.

The incidence of arrhythmias during 48-hour ambulatory electrocardiographic monitoring increases with age (Fig. 2). Non-sustained ventricular tachycardia is detected in 20 to 25 per cent of adults and, although usually asymptomatic, is associated with an increased risk of sudden death. Supraventricular arrhythmias are also common in adults: these are poorly tolerated if sustained (more than 30 s)—unless the ventricular response is controlled—and they carry an increased risk of embolism. By contrast, most children and adolescents are in sinus rhythm and arrhythmias during ambulatory electrocardiographic monitoring are uncommon (Fig. 2). The increased incidence of supraventricular arrhythmias with age is not surprising: their development is related to increased echocardiographic left atrial dimensions and increased left ventricular diastolic pressure, both of which increase with age. The aetiology of ventricular arrhythmias is not known, but may relate to myocyte loss and myocardial fibrosis, which appear to be related to age. Documented sustained ventricular tachycardia is uncommon, but a recognized complication in patients with an apical outpouching or aneurysm, which may develop as a consequence of mid-ventricular obstruction.

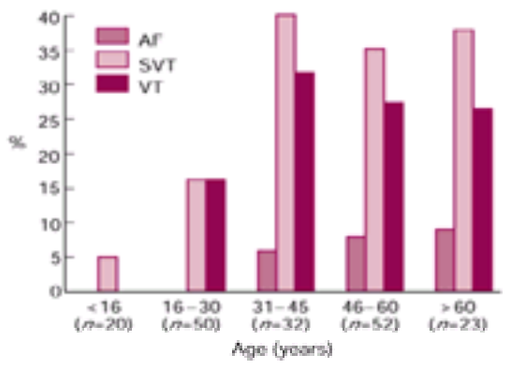

Fig. 2 The relation of arrhythmias and age in hypertrophic cardiomyopathy. SVT, supraventricular tachycardia; VT, ventricular tachycardia; AF, atrial fibrillation.

Imaging

Chest radiography

The chest radiograph may be normal or show evidence of left and/or right atrial or left ventricular enlargement; if left atrial pressure has been chronically elevated, there may be evidence of redistribution of blood flow to upper lung zones. Mitral valve annular calcification is seen, particularly in the elderly.

Echocardiography

The extent and severity of myocardial hypertrophy is best evaluated with two-dimensional echocardiography/Doppler (Fig. 3). Left ventricular hypertrophy may be symmetric or asymmetric and localized to the septum or the free wall, but most commonly to both the septum and free wall with relative sparing of the posterior wall. 'Apical' hypertrophic cardiomyopathy appears to be common in Japan, but is rare in the West, although approximately 10 per cent of patients have left ventricular hypertrophy that is maximal in the distal ventricle from the level of the papillary muscles down to the apex. Approximately one-third of patients also have hypertrophy of the right ventricular free wall, the presence and severity of which is strongly related to the severity of left ventricular hypertrophy. Typically, left ventricular end-systolic and end-diastolic dimensions are reduced, and the left atrial dimension is increased. Indices of systolic function such as ejection fraction may be increased, but systolic function is often impaired, which may be best appreciated by measurement of long axis rather than short axis function.

Fig. 3 An echocardiogram (parasternal long axis view) of a patient with hypertrophic obstructive cardiomyopathy demonstrating hypertrophy of the interventricular septum (IVS), enlargement of the left atrium (LA), and systolic anterior motion of the mitral valve, bringing it into contact with the septum (arrow).

Colour Doppler provides a sensitive method of detecting left ventricular outflow tract turbulence (Fig. 4 and Plate 1), and when combined with continuous wave Doppler the peak velocity (*V*max) of left ventricular blood flow can be measured and left ventricular outflow tract gradients calculated. Doppler-calculated gradients (pressure gradient (mmHg) = $4V\text{max}^2$) are seen in 20 to 30 per cent of patients and correlate well with those measured invasively. Systolic anterior motion of the mitral valve is usually present when the calculated outflow tract gradient is more than 30 mmHg. Early closure or fluttering of the aortic valve leaflets and Doppler evidence of mitral regurgitation are often seen in association with systolic anterior motion of the mitral valve. A posteriorly directed mitral regurgitant jet is seen in association

with and related to the magnitude of the outflow tract gradient (Fig. 4). An anterior regurgitant jet or mitral regurgitation in the absence of obstruction suggest the coexistence of structural mitral valve abnormalities.

Fig. 4 Colour flow Doppler image (parasternal long axis view) of the same patient as shown in Fig. 3, demonstrating left ventricular outflow tract (LVOT) turbulence and mitral regurgitation (MR) with a posteriorly directed jet. (See also Plate 1.)

Other imaging techniques

There is no role for routine magnetic resonance or computed tomographic imaging, but these modalities may be helpful when echocardiography fails to visualize cardiac structures adequately, particularly the left ventricular apex.

Cardiac catheterization

Two-dimensional echo/Doppler evaluation has replaced invasive haemodynamic measurements and angiography as the method of assessing left ventricular structure and function in hypertrophic cardiomyopathy. Cardiac catheterization is not necessary for diagnosis and is rarely indicated unless symptoms are refractory and direct measurement of cardiac pressures is potentially informative, particularly in assessing the severity of mitral regurgitation. Coronary arteriography may be necessary to exclude coexistent coronary artery disease in older patients who have significant angina or ST-segment changes during exercise. The left coronary arteries are usually large in calibre. The left anterior descending and septal perforator arteries may demonstrate phasic narrowing during systole in the absence of fixed obstructive lesions, but such changes do not appear to relate to symptoms.

Left ventricular angiography is rarely indicated, but recognition of the abnormally shaped ventricle, which typically ejects at least 75 per cent of its contents in association with mild mitral regurgitation, may provide a valuable diagnostic clue when hypertrophic cardiomyopathy was not suspected before catheterization.

Exercise testing

Maximal exercise testing in association with respiratory gas analysis provides useful functional and prognostic information, which can be monitored serially. Peak oxygen ventilatory capacity (peak $\dot{V}O_2$) is often moderately and occasionally severely reduced, even in patients who claim their exercise tolerance is not limited. Continuous measurement of the blood pressure during upright treadmill or bicycle exercise reveals that approximately one-third of younger patients (less than 40 years) have an abnormal blood-pressure response, with either drops of more than 20 mmHg from peak recordings or a failure to rise by 20 mmHg or more despite an appropriate increase in cardiac output. Such changes are usually asymptomatic but are associated with an increased risk of sudden death. The mechanism of the hypotensive response during exercise in hypertrophic cardiomyopathy is uncertain, but may relate to myocardial mechanoreceptor activation and altered baroreflex control causing inappropriate drops in systemic vasculature resistance despite maintenance of an appropriate cardiac output. ST-segment depression of 2 mm from baseline is documented in 25 per cent of patients. The relation of such changes to metabolic markers of ischaemia requires further evaluation and their prognostic significance has yet to be determined.

Electrophysiological studies

Electrophysiological studies may occasionally be necessary in patients with sustained, rapid palpitation to identify associated accessory pathways or aid management of sustained monomorphic ventricular tachycardia. Conventional programmed ventricular stimulation does not aid the identification of high-risk patients (see below).

Management

Pharmacological

The goal of therapy is to improve symptoms and prevent complications, in particular sudden death. b-Adrenoceptor blockers, particularly propranolol, and calcium antagonists, especially verapamil, are the mainstay of symptomatic pharmacological therapy. Both drugs have several potentially beneficial actions, including a decrease in the determinants of myocardial oxygen consumption and blunting of the heart-rate response during exercise, providing increased time for filling at equivalent workloads in those with poor relaxation and slow filling. Both agents exert a negative inotropic effect, thereby reducing hyperdynamic systolic function and left ventricular gradients; it is also claimed they improve diastolic filling, verapamil by improving relaxation and propranolol by increasing compliance. The side-effects of propranolol are rarely serious, but the suppressant effect of verapamil on atrioventricular nodal conduction may cause problems in patients with unsuspected pre-existing conduction disease, and its vasodilatory and negative inotropic effects have resulted in acute pulmonary oedema and death. In practice, both drugs are effective but it is safer to use propranolol. If this is ineffective, verapamil can then be tried, but it should be started in hospital in patients with conduction abnormalities, resting or provocable gradients, or impaired systolic function.

Surgical

Surgery is a therapeutic option in patients with obstruction and/or mitral valve abnormalities. The conventional indication for surgery has been a resting left ventricular outflow tract gradient of more than 50 mmHg in patients refractory to medical therapy, and the commonest operation has been to remove a segment of the upper anterior septum (myotomy/myectomy) via a transaortic approach. Transventricular approaches have been used, but these are associated with a higher incidence of late complications, particularly of cardiac failure. Mitral valve 'repair' and papillary muscle repositioning or remodelling may be required, and mitral valve replacement has also been advocated; excellent results have been achieved, particularly in elderly patients with severe mitral regurgitation. Specialist hypertrophic cardiomyopathy centres report perioperative mortality of 2 per cent or less, with 80 per cent success in abolishing gradients and improving symptoms. It is unlikely, however, that such excellent results are obtained in centres with more limited experience of the medical and surgical aspects of the condition. Obstruction is a function of several features including septal hypertrophy, outflow tract dimensions, ventricular geometry and flow patterns, mitral valve/papillary muscle anatomy and position, and left ventricular contractile performance. The approach to gradient reduction needs to be individualized to a greater extent than has been recognized, perhaps contributing to mortality rates of 5 to 10 per cent in early operative series.

Pacing

The pacing option was promoted following recognition that alteration of the ventricular activation sequence, with optimization of filling characteristics by DDD pacing, may result in reduction of gradients and filling pressures and improved symptoms in selected patients. The role of DDD pacing in symptomatic management of obstruction was evaluated in three randomized multicentre trials, demonstrating symptomatic improvement and gradient reduction (50 per cent), but no change in exercise capacity. However, the placebo effect of the procedure was considerable: 40 per cent reported significant symptomatic improvement with the pacemaker programmed to a standby mode. Overall, the initial enthusiasm for DDD pacing has not been substantiated by greater experience and trials. Nevertheless, pacing offers a therapeutic option in patients with obstruction that is refractory to drug treatment, and in whom surgery is either not acceptable or inappropriate. It appears

that elderly patients with localized septal hypertrophy and without significant free wall involvement or mitral regurgitation may do particularly well.

Other techniques

Injection of alcohol into the septal artery that supplies the 'obstructing' septal muscle has been developed as a percutaneous, non-pharmacological approach to gradient reduction. Most experienced centres have reported excellent results. As for surgery and DDD pacing, patient selection—in particular regarding the mechanism of the gradient—and technical considerations are important determinants of outcome. The major complication has been the need for a pacemaker in 5 to 10 per cent, and concerns remain about long-term left ventricular function and arrhythmia risk from the 'controlled myocardial infarction'. At present alcohol septal ablation offers a therapeutic option in older patients with suitable anatomy who are refractory to drugs.

Particular symptoms

Dyspnoea

Dyspnoea most often occurs in patients who also experience chest pain or discomfort. Treatment depends on the predominant mechanism. In patients with dyspnoea who have slow filling that continues throughout diastole, b-blockers and verapamil are appropriate. Conversely, those with rapid early filling may benefit from a relative tachycardia and do better without negative chronotrophic agents. When dyspnoea is associated with significant obstruction, that is, at least 50 per cent of stroke volume in the left ventricle at the onset of the gradient, b-blockers, disopyramide, and—failing this—myotomy/myectomy or the other non-pharmacological options may be beneficial. Disopyramide should be used in the maximum tolerated dose (anticholinergic side-effects may limit higher doses) in conjunction with a conventional b-blocker. Occasionally, dyspnoea is associated with severe mitral regurgitation and responds well to mitral valve replacement. Endocarditis is a rare complication of hypertrophic cardiomyopathy; it occurs in patients with left ventricular outflow tract turbulence and/or mitral regurgitation, may involve the mitral and/or aortic valve, and is usually associated with increased dyspnoea. Antibiotic prophylaxis is important in appropriate patients, such as those with intracardiac transvalvular turbulence.

Chest pain

When chest pain is severe, associated with significant ST-segment changes during exercise, or refractory to therapy, the performance of coronary arteriography is warranted to exclude coexistent coronary artery disease. The results of coronary artery bypass grafting in hypertrophic cardiomyopathy are good, even when additional procedures such as myectomy/mitral valve replacement are performed. Exertional chest pain usually responds to therapy with propranolol or verapamil, and when refractory has responded to very high doses of these agents (propranolol at 480 mg daily, verapamil at 720 mg daily). Short-acting nitrates, diuretics, and high-dose verapamil may be useful in selected patients, perhaps by reducing filling pressures and improving coronary flow to subendocardial layers. Atypical chest pain may persist long after the initial stimulus has been removed.

Arrhythmia

Arrhythmias are a common complication of hypertrophic cardiomyopathy. Treatment with anticoagulants and digoxin, with or without verapamil or b-blockers, is appropriate once atrial fibrillation is established. The aim of therapy is to control the ventricular response and prevent emboli. Most patients who develop atrial fibrillation during electrocardiographic monitoring are unaware of changes from sinus rhythm to atrial fibrillation as long as the ventricular response is well controlled. However, in a few cases the loss of atrial systolic contribution to filling volume is important, when electrical cardioversion can be facilitated by prior therapy (4 to 6 weeks) with amiodarone (300 mg daily) if pharmacological cardioversion does not occur first.

Sustained (more than 30 s) episodes of paroxysmal atrial fibrillation or supraventricular tachycardia occur, representing a risk of haemodynamic collapse and emboli. Low-dose amiodarone (1000 to 1400 mg weekly) is effective in suppressing such episodes and also provides control of the ventricular response should breakthrough occur. If episodes persist, the threshold for anticoagulation should be low as embolic complications are common, even when atrial dimensions are only moderately increased.

Non-sustained episodes of supraventricular arrhythmia are common. Though often asymptomatic they are a marker (albeit of low positive predictive accuracy) for the subsequent development of established atrial fibrillation. If they occur in the presence of atrial enlargement, the threshold to introduce amiodarone with or without anticoagulation should be low. Episodes of non-sustained ventricular tachycardia are common but are rarely symptomatic: therapy is warranted only if it can be shown to improve prognosis (see below).

Prevention of sudden death

Sudden death is probably a consequence of multiple interacting mechanisms. The histological abnormalities, particularly myocyte disarray, small vessel disease, and replacement scarring, contribute to the underlying substrate. Events may be triggered by haemodynamic alterations, myocardial ischaemia, and arrhythmias, including ventricular tachycardia, atrial fibrillation, atrioventricular block, and rapid conduction of a supraventricular arrhythmia via an accessory pathway. Intense physical exertion may also contribute to the above triggers. The interaction of triggers and substrate may be modified by inappropriate peripheral vascular responses and the development of ischaemia.

Risk factor stratification

Prevention of sudden death relies on risk factor stratification to identify the high-risk cohort. Several adverse features, which can be elicited from the clinical history and non-invasive evaluation, have been identified (Table 4). Their relative importance varies with age; for example, the finding of non-sustained ventricular tachycardia on 24-h electrocardiographic monitoring in children and adolescents is uncommon (less than 5 per cent), but is associated with an eightfold increased risk of sudden death, whereas in adults this arrhythmia is common (20 to 25 per cent), but in isolation confers only a twofold increased risk.

In the young (less than 25 years) the finding of non-sustained ventricular tachycardia, severe and diffuse left ventricular hypertrophy, unexplained syncope (particularly if recurrent or exertional), or a family history where a high proportion of affected individuals experienced premature (less than 40 years) sudden death warrants prophylactic treatment. Such patients usually also exhibit abnormal exercise blood-pressure responses, indeed the finding of a normal exercise blood-pressure response appears to identify the low-risk younger (less than 40 years) patient (negative predictive accuracy 97 per cent), allowing appropriate reassurance that is also clinically important. In adults aged 25 to 60 years the positive predictive accuracy for each of the risk factors is lower (15 to 20 per cent): in general prophylactic treatment is reserved for those with two or more risk factors who will have a predicted risk of sudden death of at least 2 per cent per year.

It is important to consider risk in all patients, even those who are asymptomatic or who have mild echocardiographic features of hypertrophic cardiomyopathy. Though children and adolescents with severe congestive symptoms may be at greater risk, the data reveals that the severity of chest pain, dyspnoea, and exercise limitation are not reliable predictors of the risk of sudden death in adults. In addition it is recognized that most patients who die suddenly have mild (1.5 to 2.0 cm) or moderate (2.0 to 2.5 cm) left ventricular hypertrophy, while some genetic defects (for instance cardiac troponin T) may cause sudden death in the absence of symptoms or hypertrophy. The presence of a left ventricular outflow tract gradient is not associated with sudden death, although data on patients with large gradients (more than 100 mmHg) are limited. Diastolic impairment with abnormal Doppler filling patterns and atrial enlargement is associated with symptomatic limitation and poor prognosis, but not with premature sudden death.

Some investigators have suggested that the induction of sustained ventricular arrhythmias during programmed electrophysiological stimulation is associated with a higher risk of sudden death. However, the predictive accuracy is low, and as most high-risk patients can be identified using non-invasive clinical markers, the inherent risks and inconvenience associated with programmed stimulation dictate that it should not be used routinely to assess risk in hypertrophic cardiomyopathy.

Dilated cardiomyopathy

Definition

Dilated cardiomyopathy is characterized by unexplained dilatation and impaired contractile performance of the left ventricle. Potential causes of ventricular

dysfunction, particularly coronary artery disease and systemic hypertension, must be excluded for the diagnosis to be made. Typical angina pectoris, fluctuating ST and T-wave changes, and regional abnormalities on two-dimensional echocardiography or thallium scintigraphy, which reflect damage to a specific vascular territory, suggest ischaemic heart disease. Renal and ocular hypertensive changes may provide a useful marker of previous systemic hypertension, but are often unremarkable in the decompensated phase in the normotensive patient. Calcific aortic stenosis may be overlooked as a cause of heart failure, particularly when the murmur is soft or absent.

Specific heart muscle disorders should also be considered in differential diagnosis (see Chapter 15.8.3). A primary cardiac presentation of diabetes mellitus, connective tissue disorders, and neuromuscular disease is rare, but arrhythmias or progressive conduction disturbance with mild left ventricular dysfunction may provide the earliest evidence of cardiac sarcoidosis.

Since the definition of dilated cardiomyopathy is a diagnosis of exclusion, it is likely that structural and functional abnormalities result from heterogeneous pathogenic processes. In North America and Europe symptomatic dilated cardiomyopathy has an incidence and prevalence of 20 and 38 per 100 000, respectively, and is the commonest indication for cardiac transplantation.

Genetics

Pedigree analysis reveals familial disease in at least 25 per cent of cases and an additional cohort (10 to 20 per cent) with mild abnormalities of left ventricular performance who possibly have early presymptomatic dilated cardiomyopathy. Inheritance is usually autosomal dominant with incomplete penetrance, although families with X-linked transmission have been reported. Different patterns of disease expression are recognized. Disease progression appears to be slow (over decades) in most cases, and conduction disturbance is a late complication related to disease severity. However, in some families (less than 20 per cent) the early stages are characterized by progressive conduction disease, and left ventricular dilatation and impairment are later manifestations, which typically occur in the 4th to 6th decade. Families are also recognized in whom dilated cardiomyopathy develops in later decades in individuals who have had sensorineural hearing loss since childhood, or in association with skeletal myopathy.

Penetrance is age dependent and has been estimated to be 10 per cent in those aged less than 20 years, 34 per cent in young adults aged 20 to 30 years, 60 per cent in adults aged 30 to 40 years, and 90 per cent in those over 40 years. Familial evaluation is recommended: guidelines have been proposed, based on the identification of major and minor criteria for the diagnosis (Table 5). It has been proposed that the diagnosis of familial dilated cardiomyopathy is fulfilled in a first-degree relative of a proband in the presence of one major criterion, or left ventricular dilatation plus one minor criterion, or three minor criteria.

Disease-causing genes have been reported in dystrophin (X-linked), taffazin (X-linked Barth syndrome), metavinculin (X-linked), cardiac actin (two small autosomal dominant families), lamin A/C (families with premature conduction disease), and desmin (1 of 44 probands with gene-positive affected family members). Lamin A/C mutations may also cause Emery–Dreifuss and limb girdle muscular dystrophy and familial partial lipodystrophy, desmin may cause conduction disease, and dystrophin mutations cause childhood (Duchenne) and adult (Becker) forms of muscular dystrophy. Mutations in these genes appear to account for less than 5 per cent of cases of dilated cardiomyopathy, but they provide potentially valuable clues in relation to aetiology and pathogenesis. The function of taffazin is unknown, but the other genes all encode cytoskeletal proteins that are involved in force transmissions between cells.The recent identification of mutations in genes which encode for sarcomere proteins (TropT, bMHC) involved in force generation may change this paradigm.

Pathogenesis

Based on the molecular genetic findings described above, dilated cardiomyopathy is hypothesized to be a disease of the cardiac cytoskeleton, but pathogenesis is poorly defined. Macroscopic examination of hearts with dilated cardiomyopathy taken at autopsy or explanted reveals dilated cardiac chambers (Fig. 1), mural thrombi, and platelet aggregates with normal extra- and intramural coronary arteries. Histology shows features consistent with healed myocarditis—patchy perimyocyte and interstitial fibrosis, various stages of myocyte death, as well as myocyte hypertrophy and rare isolated inflammatory cells (see Chapter 15.8.1). These postinflammatory findings are non-specific and do not suggest a particular pathogenesis.

The myocardial depressant effects of alcohol in normal and diseased myocardium are established. Alcohol, like pregnancy, may precipitate cardiac failure in predisposed individuals, but an additional specific aetiological or pathogenetic role remains uncertain. Viral involvement is supported by viral myocarditis progressing to dilated cardiomyopathy in specific genetic strains of a murine model, as well as in isolated rare patients, also by an association with abnormal coxsackievirus serology and hybridization studies that show non-replicating enteroviral genome in a variable proportion (0 to 30 per cent) of dilated cardiomyopathy hearts. The potential for immune pathogenesis is supported by development of autoimmune murine myocarditis and by the findings of a cardiac- and disease-specific autoantibody in over 30 per cent of patients with dilated cardiomyopathy and their first-degree relatives, inappropriate MHC class II expression on endothelial cells from cardiac tissue, and a weak HLA DR4 association.

In summary, pathogenesis of dilated cardiomyopathy remains controversial, with resolution hampered by clinical presentation at 'endstage' when pathogenesis may be largely completed. A reasonable working hypothesis proposes an immune pathogenesis, with or without a viral trigger, in genetically predisposed individuals who carry a cytoskeletal or sarcomere gene mutation.

Clinical features

Dilated cardiomyopathy has been described in Western, African, and Asian populations, affecting both genders and all ages. Initial presentation is usually with symptoms of cardiac failure (fatigue, breathlessness, decreased exercise tolerance), but an arrhythmia (atrial fibrillation, ventricular tachycardia, atrioventricular block), a systemic embolus, or the finding of an electrocardiographic or radiographic abnormality during routine screening may prompt earlier diagnosis. Symptoms, physical signs, and chest radiographic changes are those of cardiac failure (see Chapter 15.2.2) and depend on the stage of the disease.

Physical examination may be entirely normal or may reveal evidence of myocardial dysfunction with cardiac enlargement and signs of congestive heart failure. Systolic blood pressure is usually low with a narrow pulse pressure and a low volume arterial pulse. In patients with severe left ventricular failure, pulsus alternans may be present and the jugular veins may be distended, with a prominent V wave reflecting tricuspid regurgitation. In such patients the liver is often engorged and pulsatile, and there is usually peripheral oedema and ascites. The precordium often reveals a diffuse and dyskinetic left and occasionally a right ventricular impulse. The apical impulse is usually displaced laterally, reflecting ventricular dilatation. The second heart sound is usually normally split, but paradoxical splitting may be present when there is left bundle branch block, which occurs is approximately 15 per cent of patients. With severe disease and the development of pulmonary hypertension, the pulmonary component of the second heart sound may be accentuated. Characteristically, a presystolic gallop or fourth heart sound is present before the development of overt cardiac failure. However, once cardiac decompensation has occurred, ventricular gallop or third heart sound is often present. When there is significant ventricular dilatation, systolic murmurs are common, reflecting mitral and (less commonly) tricuspid regurgitation.

The development of unexplained cardiac failure during pregnancy or within the 3 months following parturition is often labelled as peripartum cardiomyopathy. Unrecognized pre-eclamptic heart disease may also present with cardiac failure and should be excluded by careful examination of the antenatal records; this has a different prognosis and recurs with increasing severity during subsequent pregnancies unless treated. Antecedent cardiac evaluation is often absent in those with peripartum cardiomyopathy, and there is usually uncertainty whether the cardiac failure is acute (for instance potentially myocarditic) or chronic and exacerbated by the haemodynamic stress of pregnancy and labour (for instance dilated cardiomyopathy). When the heart failure is acute and there is persistence of left ventricular chamber dilatation or impaired systolic performance, the diagnosis of peripartum cardiomyopathy can legitimately be made. The mechanism and true natural history is uncertain, though it is probable that the adverse prognostic effect of subsequent pregnancies is less important than the literature would suggest, particularly in those with only mild residual abnormalities of left ventricular structure and function. For further discussion of cardiac disease in pregnancy, see Chapter 13.6.

Arrhythmia

Atrial arrhythmias and particularly atrial fibrillation are common and are associated with the severity of symptoms, left ventricular dysfunction, and poor prognosis. Atrial fibrillation is a marker of disease severity, but not an independent predictor of disease progression or sudden death. Occasionally, however, focal atrial tachycardia or atrial fibrillation may cause a tachycardia that results in gradual deterioration in left ventricular function, resembling dilated cardiomyopathy. Systolic function usually returns to normal with control of the arrhythmia.

Ventricular arrhythmias are also common and like supraventricular arrhythmias are markers of disease severity. Non-sustained ventricular tachycardia during ECG

monitoring is seen in approximately 20 per cent of asymptomatic or mildly symptomatic patients and in up to 70 per cent of those who are severely symptomatic. The prognostic significance of this arrhythmia is controversial: its presence early in the course of disease, when left ventricular function is relatively preserved, is probably an independent marker of sudden death risk, whereas in general, markers of haemodynamic severity (such as ejection fraction, left ventricular end-diastolic dimension, filling pressures) are more predictive of disease-related mortality and sudden death. Sudden death risk in patients with severe disease (NYHA Class III, IV) increases approximately threefold when syncope is present.

Prognosis

The prognosis of dilated cardiomyopathy is uncertain because the diagnosis is usually not made until clinical features, which are late manifestations of the disease, become obvious. However, recent follow-up of a large cohort of asymptomatic first-degree relatives suggests that disease progression is insidious over decades. An upper respiratory tract infection or a salt or fluid load (pregnancy) often precipitates clinical presentation. Symptoms develop when filling pressures rise or stroke volume diminishes sufficiently to cause salt and water retention and oedema. Once clinical symptoms of impaired ventricular performance are apparent, prognosis is poor and related to the degree of left ventricular dilatation and impaired contractile performance. Data from adult and paediatric referral centres in the 1970s and 1980s indicate 50 per cent mortality from progressive heart failure or its complications in the 2 years following referral diagnosis. Survival will undoubtedly be improved by recognition of asymptomatic family members as well as of others with early/mild disease, and by modern management including the early introduction of ACE inhibitors, b-blockade, aggressive treatment of arrhythmias, and the availability of cardiac transplantation. Treatment will usually stabilize or improve the patient's condition once symptoms develop, with a reduction in cardiac dimensions and improvement in myocardial performance. However, conventional evaluation of cardiovascular structure and function does not permit accurate prediction of outcome and there is an annual mortality of up to 4 per cent, predominantly from sudden death, even in those who improve or stabilize.

The recent recognition of the familial nature of dilated cardiomyopathy indicates that a correct diagnosis is of practical importance for family members as there is now the potential to identify individuals with dilated cardiomyopathy at an early or preclinical stage.

Investigation

Cardiological evaluation of patients with dilated cardiomyopathy is performed to confirm the diagnosis, to determine objective measurements of functional capacity as a guide to symptomatic treatment, and to assess risk of complications, particularly progressive deterioration, arrhythmias, and sudden death.

By the time of diagnosis in a referral centre, a normal ECG is rare (less than 5 per cent) and most patients show features consistent with diffuse myocardial abnormalities. Twenty per cent are in established atrial fibrillation and paroxysmal supraventricular and ventricular arrhythmias during 24-h ECG monitoring are common.

Patient perception of functional limitation relates to many factors, including the time course of the illness, and is very variable. Maximal exercise testing, ideally with respiratory gas analysis, provides a simple reproducible measure of functional capacity and is also useful to exclude ischaemia and assess risk of arrhythmia. Similarly two-dimensional echocardiography is important in providing an easily repeated measure of cardiac cavity dimensions and systolic performance, assessment of regional wall motion as well as mural and intracavitary thrombi (Fig. 5 and Fig. 6 and Plate 2). In the young patient the origins of the right and left main coronary arteries can often be visualized to exclude mainstem coronary anomalies as the cause of myocardial dysfunction. Symptoms, exercise testing, and two-dimensional echocardiography provide the basis for assessment of treatment and monitoring of disease progression.

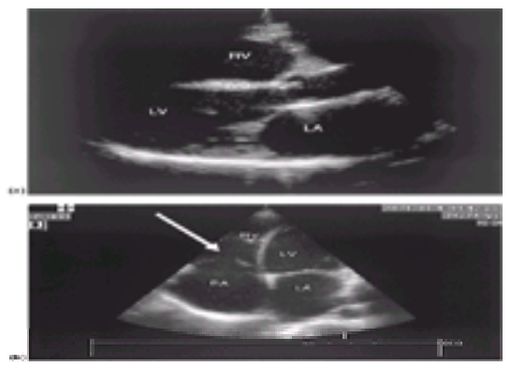

Fig. 5 Echocardiographic appearances of a young patient with familial dilated cardiomyopathy. Panel A: parasternal long-axis view showing significant left atrial (LA) and biventricular dilatation with a thin intraventricular septum (IVS). Panel B: apical four-chamber view demonstrating dilatation of all four chambers. There is failure of the tricuspid leaflets to coapt in systole (arrow). LV, left ventricle; RA, right atrium; RV, right ventricle.

Fig. 6 Colour flow Doppler image of the same patient as shown in Fig. 5 showing a regurgitant tricuspid jet (TR). (See also Plate 2.)

Many of the systemic diseases that are associated with heart muscle disorders have typical clinical, immunological, and biochemical features (see Chapter 15.8.3), and in the absence of evidence to suggest a systemic disease an exhaustive 'routine screen' is probably not cost-effective. There are, however, several potential reversible secondary causes of heart muscle disorder that may simulate dilated cardiomyopathy, and basic screening tests should include serum phosphorus (hypophosphataemia), serum calcium (hypocalcaemia), serum creatinine and urea (uraemia), thyroid function tests (hypothyroidism), and serum iron/ferritin (haemochromatosis).

Electrophysiological testing

Programmed electrical stimulation is of limited clinical value in the identification of high-risk patients. Polymorphic ventricular tachycardia is inducible in up to 30 per cent of cases, but this is a non-specific endpoint. Approximately 10 per cent of patients have inducible sustained monomorphic ventricular tachycardia; about one-third of these die suddenly, but most (75 per cent) who die in this way do not have inducible ventricular tachycardia during programmed stimulation.

Inducible ventricular tachycardia usually arises from diseased myocardium. However, bundle branch re-entry ventricular tachycardia may occur, and in one selected series was seen in up to 40 per cent of patients. This tachycardia is typically rapid (mean cycle length 280 ms) and uses a macrore-entrant circuit that involves the His Purkinje system, usually with right bundle branch anterograde conduction and left bundle branch retrograde conduction. Differentiation from myocardial ventricular tachycardia is confirmed by the presence of a His or right bundle branch potential preceding each QRS: diagnosis is important since catheter ablation of either the left

or right bundle branch usually is curative.

Cardiac catheterization/biopsy

Coronary arteriography should be performed if doubt remains regarding potential ischaemic aetiology of left ventricular dysfunction. Cardiac catheterization is also warranted for measurement of pulmonary vascular resistance in those with very severe or rapidly progressive disease in whom cardiac transplantation may be required. However, if coronary artery disease can be confidently excluded and transplantation is not an imminent consideration, then cardiac catheterization is not required for a diagnosis or symptomatic management. Useful prognostic information regarding cardiac enlargement and systolic performance can be more readily provided from echocardiographic or radionuclide studies.

The role of endomyocardial biopsy is controversial. It is warranted to exclude myocarditis and specific heart muscle disorders and to characterize patients for the presence of viral genome and markers of immune activation, but these evaluations require specialist expertise in cardiac pathology that may not be readily available and the therapeutic implications of findings are uncertain.

Management

Management in dilated cardiomyopathy is aimed at improving symptoms, attenuating disease progression, and preventing arrhythmia, stroke, and sudden death. Such non-specific therapy is unsatisfactory and will remain so until the aetiology and pathogenesis of dilated cardiomyopathy are better delineated.

Pharmacological

Symptomatic therapy is the treatment of heart failure with reliance on ACE inhibitors, b-blockers, and diuretics (see Chapter 15.2.2 and Chapter 15.5.1). Evidence-based therapy of cardiac failure has, with few exceptions, not specifically been evaluated in dilated cardiomyopathy in a randomized fashion, but is likely to be as effective as in others with this condition. Vigorous exercise and significant alcohol intake are proscribed. Moderate- to high-dose ACE inhibition is probably the goal, although in advanced disease this may be limited by hypotension and take time to achieve. The use of low-dose b-blockade with gradual dosage augmentation as tolerated over months is increasingly supported by trial evidence, with metoprolol (6.25 to 50 mg twice daily), bisoprolol (1.25 to 10 mg once daily), and carvedilol (3.125 to 50 mg twice daily) proven to be beneficial. Note, however, that rapid increase in dosage of b-blockers or their sudden withdrawal after chronic administration may precipitate deterioration and dosage changes should be made gradually. Diuretics should be reserved for patients with congestive symptoms as their inappropriate use will limit the ability to achieve optimal dose of ACE inhibitor and b-blocker.

If sustained or symptomatic arrhythmias are documented during 24-h ECG monitoring or exercise testing, conventional treatment is warranted (see Chapter 15.6). Amiodarone (100 to 400 mg daily) has no negative inotropic effect and is effective in suppressing both supraventricular and ventricular arrhythmias. Most class I antiarrhythmics will depress left ventricular function and are likely to be poorly tolerated. The use of low-dose amiodarone (200 mg od) with low to moderate dose of a b-blocker is often effective, but the combination of sotalol and amiodarone represents a proarrhythmic risk because of their additive effects on repolarization. If drug treatment is unsuccessful, the threshold for implantation a cardioverter defibrillator should be low, although concomitant antiarrhythmic therapy may still be required.

Non-pharmacological

Non-pharmalogical alternatives for the treatment of heart failure are increasingly available. Permanent pacing can correct two important intracardiac conduction abnormalities. First, a small subset of patients who have marked P–R interval prolongation (more than 220 ms), usually secondary to atrioventricular nodal disease, experience deleterious effects on left ventricular haemodynamics with reduction in diastolic ventricular filling time and the development of end-diastolic tricuspid and mitral regurgitation. Correction of P–R interval prolongation with short atrioventricular delay dual-chamber pacing may increase stroke volume and blood pressure, and decrease mitral regurgitation with dramatic clinical improvement. Second, patients with marked intraventricular conduction delay (for example left bundle branch block greater than 150 ms) experience asynchronous contraction of the left ventricular free wall and interventricular septum (which may decrease ejection fraction) and late activation of the anterolateral papillary muscle (which may increase functional mitral regurgitation). Biventricular or left ventricular pacing with specialized leads via the coronary sinus can correct both problems and early anecdotal reports of dramatic amelioration of symptoms have been confirmed in randomized trials with subjective and objective evidence of clinical improvement. In addition, the resultant increase in blood pressure and pacemaker maintenance of the desired minimum heart rate permits use of higher doses of b-blockade and ACE inhibition with potential secondary benefit.

Surgical removal of non-viable (Dor procedure) and/or viable myocardium (Batista procedure) to improve haemodynamics by reducing left ventricular volume has been advocated. Though mitral valve repair may occasionally be helpful, these and other surgical volume reduction procedures (partial left ventriculotomy) probably have no role in dilated cardiomyopathy.

Cardiac transplantation has provided a lifeline in those with progressive deterioration. However, the improvements in the pharmacological and non-pharmacological treatments of heart failure in dilated cardiomyopathy appear to be attenuating the progression to endstage disease requiring transplantation. In addition, improvements in left ventricular assist devices and artificial heart technology provide alternatives that are now reasonably seen as viable future treatment options. These issues are discussed in Chapter 15.5.4.

Prevention of disease progression, thromboembolism, and sudden death

With awareness of the importance of familial disease, patients with asymptomatic mild left ventricular dysfunction are increasingly being recognized. Though there is no proof that early treatment will attenuate or prevent disease progression, the recognition that dilated cardiomyopathy is characterized by insidious progression during the asymptomatic phase, and that analogous patients who were in the treatment limb of the Studies of Left Ventricular Dysfunction (SOLVD) prevention trial had improved survival, suggests a role for the introduction of ACE inhibitors at a presymptomatic stage.

Systemic and pulmonary emboli are common. In the retrospective series from the Mayo Clinic, 25 per cent of patients experienced a documented embolic event during 5 years of follow-up. Precise guidelines for anticoagulation are not established. However, patients with mural or intracavitary thrombi and those with established or paroxysmal atrial fibrillation should be fully anticoagulated. Those with severe left ventricular dysfunction (ejection fraction less than 20 per cent) or atrial dilatation (more than 40 mm) should also be anticoagulated, with the INR (international normalized ratio) maintained at the lower end of the therapeutic range (1.5 to 2.5).

The other major complication is sudden death, which may occur in those who are stable or improving as well as in those who are deteriorating. The mechanism is probably ventricular arrhythmia, although bradyarrhythmias may be more likely in those who are severely ill, such as those awaiting cardiac transplantation. Myocyte loss and replacement by fibrous tissue is common in dilated cardiomyopathy, creating a milieu for anisotropic conduction and re-entrant arrhythmias. At autopsy, extensive subendocardial scarring in the left ventricle is seen in approximately one-third of patients, with multiple patchy areas of replacement fibrosis in the majority. Catecholamine excess in such patients may result in several maladaptive responses, including down-regulation of b-adrenergic receptors, inappropriate sinus tachycardia, increased transmural dispersion of refractoriness, and enhanced automaticity of both atrial and ventricular ectopic foci, all of which may increase the risk of both atrial and ventricular arrhythmias.

Recent large, prospective, randomized trials have redefined the role of b-blockade in the treatment of patients with dilated cardiomyopathy and congestive heart failure, demonstrating a substantial reduction not just in sudden death rates but in total mortality, heart failure mortality, and rates of admission to hospital for heart failure. These studies underscore the importance of b-blockers as first-line therapy for symptoms and prognosis in patients with dilated cardiomyopathy.

Though ACE inhibition and angiotensin II (AT_1) receptor antagonism also improve prognosis, the effects in reducing sudden death are less consistent. ACE inhibition usually results in only a transient decrease in aldosterone concentrations. The recent Randomised Aldactone Evaluation (RALES) study, which enrolled approximately 800 patients with severe dilated cardiomyopathy (ejection fraction less than 35 per cent and NYHA class IV symptoms), showed that the addition of low-dose spironolactone (25 mg) to conventional heart failure treatment reduced sudden death as well as progressive heart failure deaths.

Primary prevention of sudden death has been limited by the absence of an accurate risk factor stratification algorithm to identify the appropriate high-risk patients and by the complications of antiarrhythmia therapy. Earlier trials of class I antiarrhythmics were associated with increased mortality from sudden death, presumably due to ventricular proarrhythmia and possibly also related to drug-related worsening of ventricular performance. Recent survival trials (involving only small numbers of

patients with dilated cardiomyopathy) provide reassurance that amiodarone is safe and possibly effective and, though unproven, it is reasonable to treat those with frequent episodes of asymptomatic, non-sustained ventricular tachycardia during ECG monitoring, as well as those with symptomatic or documented ventricular arrhythmia, with low-dose amiodarone (200 to 300 mg/day). Ongoing prospective trials are examining the role of implantable cardioverter defibrillators in the primary prevention of sudden death. They will probably be shown to be effective: the hallenge, however, is to identify those patients whose disease-related life expectancy is adequate and whose arrhythmia risk is sufficient to warrant an implantable cardioverter defibrillator.

Restrictive cardiomyopathy

Definition

Restrictive cardiomyopathy, the least common of the cardiomyopathies, is characterized by restrictive filling of one or both ventricles. This is usually caused by endomyocardial fibrosis. Two variants with similar pathology are recognized. Tropical endomyocardial fibrosis is more common and accounts for 10 to 20 per cent of deaths from heart disease is Africa. Endomyocardial fibrosis in temperate countries is rare and typically associated with hypereosinophilia. The pathology is similar in advanced cases with or without hypereosinophilia, and both variants are considered to be different manifestations of the same disease process. Idiopathic myocardial restrictive cardiomyopathy occurs with and without myocardial fibrosis, but is rare. Myocardial infiltrative diseases (amyloid, sarcoid, Gaucher's), storage diseases (haemochromatosis, glycogen, and Fabry's), and endomyocardial disease associated with malignancies (metastases, carcinoid, radiation, anthracycline toxicity) may also have restrictive physiology and mimic restrictive cardiomyopathy.

Pathology

In endomyocardial fibrosis the cardiac pathology is distinctive, with endocardial fibrosis and overlying thrombosis involving the inflow tracts and the apices, but sparing the outflow tracts of one or both ventricles. Necrotic, thrombotic, and fibrotic stages have been defined in patients with endomyocardial fibrosis and hypereosinophilia. In the necrotic stage there is an acute inflammatory reaction characterized by eosinophilic abscesses in the myocardium, with associated necrosis and arteritis. The endocardium is often thickened and mural thrombi may develop. The thrombotic stage is characterized by endocardial thrombus formation that may be severe, with massive intracavitary thrombosis causing restriction to ventricular filling and a low-output state with high filling pressures. There is a risk of systemic emboli. During the necrotic and thrombotic stages the disease may mimic a hyperacute rheumatic carditis (see Chapter 15.10.1). If the patient survives, healing by fibrosis with hyaline fibrous tissue occurs. There is no further evidence of inflammation and the impact of the disease is caused by the effect of the dense fibrous tissue on ventricular filling volume and atrioventricular valve function.

Clinical features and investigation

Disease onset is usually insidious. Clinical presentation relates to endomyocardial fibrosis: left-sided disease may present with symptoms of pulmonary congestion and/or mitral regurgitation, right-sided disease with raised jugular venous pressure, hepatomegaly, ascites, and tricuspid regurgitation. Radiographic and electrocardiographic appearances are non-specific, showing evidence of raised left and/or right atrial pressure and cardiomegaly with left ventricular hypertrophy. Pulmonary infiltrates, non-specific repolarization changes, and fascicular blocks may occasionally develop.

Two-dimensional echocardiography provides the best non-invasive means of confirming the diagnosis, allowing visualization of the structural abnormalities involving the endocardium and atrioventricular valves as well as demonstration of the abnormal physiology with restriction to filling. There may be intracavitary thrombus with apical cavity obliteration, or bright echoes from the endocardium of the right or left ventricle with tethering of the chordae and reduced excursion of the posterior mitral valve leaflet. Typically, ventricular dimensions and wall thickness are normal, whereas the atria are grossly enlarged. Left ventricular filling terminates early and is followed by a plateau phase coincident with the third heart sound.

The principal haemodynamic consequence of endomyocardial scarring is a restriction to normal filling. Early diastolic pressures are normal, but there is a rapid mid-diastolic rise (square root sign), which plateaus and is not associated with impairment of systolic performance. A similar functional haemodynamic abnormality is seen in pericardial constriction (see Chapter 15.9), but in the latter condition end-diastolic pressures are usually closely similar within the two ventricles, whereas in endomyocardial fibrosis there is usually inequality of the end-diastolic pressures. Mitral and tricuspid regurgitation may be severe and both ventricles appear abnormal in shape on angiography due to obliteration of the apices. This may be particularly marked in the right ventricle in which the infundibulum is hypertrophied and hypocontractile. In addition, the fibrotic process results in smoothing of the internal architecture of the ventricle with loss of the normal trabeculas. The presence of intracavitary thrombi in the left ventricle may give rise to the erroneous diagnosis of a cardiac tumour.

The structural and physiological abnormalities that can be demonstrated with two-dimensional echocardiography or during cardiac catheterization result from the thrombotic and fibrotic stages of the disease. During the early acute phase the appearances of the left and right ventricle are far less abnormal and the diagnosis can best be confirmed at this stage by endomyocardial biopsy. In later stages, diagnosis should be apparent and the risk of biopsy is excessive.

Management

Medical treatment of advanced disease is not particularly effective and the prognosis is poor, with 35 to 50 per cent 2-year mortality. Congestive symptoms from raised right atrial pressure can be improved with diuretics, though too great a reduction in ventricular filling pressure will lead to a reduction in cardiac output. Arrhythmias are common, but their prognostic significance is uncertain and they should therefore not be treated unless they are sustained or associated with symptoms. Antiarrhythmic drugs that significantly slow the heart rate may be deleterious because of the small stroke volume. Digoxin may be helpful to control the ventricular response in atrial fibrillation, but cannot be expected to improve congestive symptoms as systolic function is usually well preserved. Anticoagulants may help to prevent venous thrombosis and systemic emboli; both warfarin and antiplatelet drugs are advised.

Surgery with either mitral and/or tricuspid valve replacement, with or without decortication of the endocardium, has been carried out in some patients. Good long-term symptomatic results have been obtained, but there is significant perioperative mortality (15 to 20 per cent).

Arrhythmogenic right ventricular cardiomyopathy

Definition

Arrhythmogenic right ventricular dysplasia or cardiomyopathy has only recently been recognized. It is characterized pathologically by fibrofatty replacement of the right ventricular myocardium and by clinical presentation with arrhythmia and sudden death. The prevalence is unknown, but estimated to be between 1:1000 and 1:5000. It occurs worldwide, but the high incidence of disease recognized in the Veneto region of Northern Italy raises the possibility of a founder effect. In young athletes (under 25 years) who die suddenly a cardiovascular cause is identified in over 80 per cent, most commonly hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy.

Genetics

The disease is often familial (at least 30 per cent) with autosomal dominant inheritance and incomplete penetrance. Six loci have been reported in autosomal dominant families. The identification of gene abnormalities has been slow, perhaps because of problems in diagnostic ascertainment caused by age-related penetrance, which is seen even in the later decades. Mutations in the ryanidine receptor gene have been found in families with adrenergically mediated ventricular tachycardia which may overlap with the disease phenotype. In an autosomal recessive family from the Greek island of Naxos, in whom palmoplantar keratoderma and woolly hair cosegregated with arrhythmogenic right ventricular cardiomyopathy, a disease-causing mutation has been identified in the plakoglobin gene. Plakoglobin has signalling and intracellular adhesion properties and is an important constituent of the cell-to-cell junction.

Aetiology/pathogenesis

The identification of the plakoglobin gene abnormality in an autosomal recessive form of arrhythmogenic right ventricular cardiomyopathy provides a candidate gene pathway for evaluation. Whether the paradigm that arrhythmogenic right ventricular cardiomyopathy is a disease of the cell-to-cell junction is correct, analogous to hypertrophic cardiomyopathy as a disease of the sarcomere, remains to be determined. Segmental disease is usual in arrhythmogenic right ventricular

cardiomyopathy, with involvement of the diaphragmatic, apical, and infundibular regions of the right ventricular free wall. Evolution to more diffuse right ventricular involvement and left ventricular abnormalities with heart failure are more common than the earlier literature suggested. The fibrofatty replacement of the myocardium may be focal or widespread, usually involves the subepicardial layer of the right ventricular free wall, and when severe may appear transmural. Two morphological patterns are recognized: lipomatous replacement of the myocardium without fibrosis is usually seen with preservation of normal right ventricular free wall thickness in the absence of an inflammatory infiltrate, whilst the fibrolipomatous pattern is characterized by replacement myocardial fibrosis with thinning and discrete bulges of the right ventricular free wall, often in association with lymphocytic infiltrates surrounding degenerating or necrotic myocytes. Animal and *in vitro* studies support the hypothesis that mutations in plakoglobin or analogous genes involved in cell adhesion may cause myocytes under mechanical stress to detach and die, with subsequent fibrofatty replacement.

Clinical presentation and management

Clinical manifestations of the disease include structural and functional abnormalities of the right ventricle, electrocardiographic depolarization/repolarization changes, and presentation with sudden death or arrhythmias of right ventricular origin. Structural and functional evaluation of the right ventricle is problematic. There is no ideal method: reliance on invasive angiography, two-dimensional echocardiography, radionuclide angiography, computed tomography, and/or magnetic resonance imaging will depend on local expertise and facilities. Quality imaging usually reveals segmental dilatation or localized aneurysm(s) of the right ventricular free wall with minimal but occasionally severe left ventricular impairment. The typical ECG presents inverted T waves in right ventricular precordial leads (V1–V3(4)) (Fig. 7) and ventricular postexcitation 'epsilon waves'. These waves are the surface ECG manifestation of late potentials that are found on the time domain signal-averaged electrocardiogram in 40 to 50 per cent of patients who present with arrhythmia. They occur as a consequence of the inhomogenous and delayed right ventricular depolarization.

Fig. 7 A 12-lead ECG from a young woman showing the most common electrocardiographic abnormality found in arrhythmogenic right ventricular cardiomyopathy, T-wave inversion in the precordial leads V1–V4.

Symptomatic presentation is usually with palpitation and/or syncope from sustained ventricular arrhythmia. Ventricular tachycardia is of left bundle branch block morphology suggesting a right ventricular origin. Sudden death related to exercise may be the initial manifestation, especially in the young.

The diagnosis of right ventricular dysplasia is based on histological demonstration of fibrofatty replacement of right ventricular myocardium at either autopsy or surgery. Diagnosis based on biopsy specimens from the right ventricular endomyocardium is inherently difficult because the segmental nature of the disease causes false negatives (Fig. 8), and because the amount of tissue usually obtained is insufficient to differentiate fibrofatty replacement from islands of adipose tissue that are not infrequently seen between myocytes in the right ventricle of normal subjects. Nevertheless, the positive finding of fibrofatty replacement of myocytes on biopsy can be a valuable diagnostic clue.

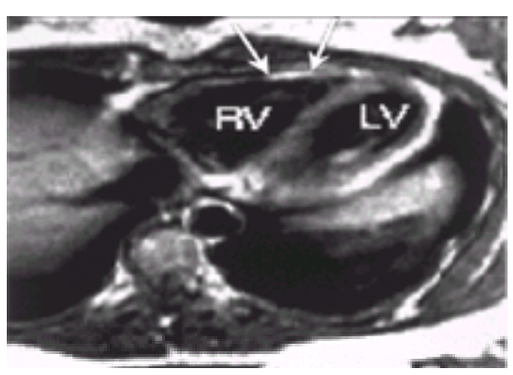

Fig. 8 A transverse plane spin-echo MRI in a young woman with arrhythmogenic right ventricular cardiomyopathy demonstrating a circumscribed area of enhanced MR signal intensity in the right ventricular (RV) free wall (arrows) due to fatty infiltration. (By courtesy of Dr Dudley Pennell, Cardiovascular Magnetic Resonance Unit, Royal Brompton Hospital, London.)

Diagnostic criteria are based on evidence of familial disease and on the clinical demonstration of structural, functional, and electrophysiological abnormalities that are caused by or reflect the underlying histological changes (Table 6). The presence of two major or one major and two minor or four minor features provides specific though possibly insensitive diagnostic criteria.

The natural history of arrhythmogenic right ventricular dysplasia is uncertain because patients at autopsy and/or those presenting with sustained ventricular arrhythmias bias published series. In the absence of sustained ventricular arrhythmia most patients will be asymptomatic. Progression from localized (with no or minor symptoms) to more diffuse right ventricular involvement with features of right ventricular failure has been reported. The left ventricle may be involved in long-standing disease, making differentiation from dilated cardiomyopathy with biventricular involvement difficult.

Management aims to identify those at risk of sustained ventricular arrhythmia and to prevent sudden death. Assessment of asymptomatic patients should include exercise testing and Holter monitoring for detection of occult arrhythmia. Antiarrhythmic treatment guided by electrophysiological studies is warranted in patients with palpitation, syncope, or documented sustained ventricular arrhythmia, and should also be considered in those with a markedly abnormal signal-averaged electrocardiogram who are at increased risk. The morphology of ventricular arrhythmia may vary, suggesting multiple sites of origin. Arrhythmias are usually progressive and therapy—whether pharmacological, ablation, or surgical—is not usually definitive. Implantable cardioverter defibrillators are the treatment of choice in patients resuscitated from haemodynamically compromising ventricular tachycardia or ventricular fibrillation.

15.8.3 Specific heart muscle disorders

William J. McKenna

Cardiac manifestations of musculoskeletal and connective tissue diseases

The cardiac manifestations of musculoskeletal and connective tissue diseases often go undetected. Every anatomical structure in the heart may be involved, there usually being no correlation between the extent of systemic disease and cardiac involvement. For details of the cardiac manifestations of musculoskeletal and connective tissue diseases, see Table 1 and Table 2.

Systemic lupus erythematosus

Systemic lupus erythematosus is a multisystem immune disorder characterized by the formation of autoantibodies to numerous organ systems. The prevalence of cardiovascular involvement is reported to be greater than 50 per cent. The pericardium is most commonly affected, with as many as 30 per cent of patients with lupus having clinical pericarditis at some stage, and up to 66 per cent affected at autopsy. Progression to constrictive pericarditis or tamponade remains extremely rare.

Myocardial involvement occurs less frequently, although reported in up to 30 per cent of patients at autopsy: signs and symptoms are uncommon, but patients may occasionally present with heart failure or arrhythmias.

As many as one-third of patients have systolic murmurs, but these usually represent hyperdynamic flow states due to other causes. The classic verrucous vegetations adherent to the endocardium described by Libman and Sachs in 1924 can be identified in up to 30 per cent of patients at autopsy. These lesions most commonly affect the mitral valve but rarely become clinically significant, although thromboembolism, valvular incompetence, and infective endocarditis are all described.

Conduction abnormalities are common: various degrees of heart block and bundle branch block can be seen, but complete heart block is rare. Arrhythmias such as atrial fibrillation and flutter may also occur, particularly in association with pericarditis. Myocardial infarction is very rarely reported in patients with systemic lupus erythematosus, atherosclerosis usually being implicated in the pathogenesis, although arteritis and steroid use may also play a role.

Death from the cardiac complications of lupus is rare. Mild pericardial disease may respond to non-steroidal anti-inflammatory drugs, heart failure is treated conventionally, and conduction defects may require pacing. Corticosteroids are thought to be useful in patients with coronary vasculitis and myocarditis, but there is no evidence for the use of other immunosuppressants.

Antiphospholipid syndrome

The antiphospholipid syndrome is recognized both in patients without (primary) and with systemic lupus erythematosus. It is a thrombophilic disorder characterized by arterial and venous occlusions, recurrent fetal loss, thrombocytopenia, and increased maternal complications of pregnancy. It is associated with persistently raised titres of anticardiolipin antibodies or the Lupus anticoagulant. Involvement of the mitral and aortic valves is particularly common and dramatic response to prednisolone has been described (see Chapter 13.14 for further information).

Systemic sclerosis

Heine in 1926 and Weiss *et al*. in 1943 first described cases of myocardial involvement: it has now been shown that up to 60 per cent of patients have cardiac involvement at autopsy. Gradual obliteration of the microvasculature leads to a 'Raynaud's' type of phenomenon in the heart, which is thought to be responsible for ischaemia that may then progress to patchy myocardial fibrosis. This pathological process most commonly affects the left ventricle. Right ventricular dysfunction is usually secondary to pulmonary vascular disease or pulmonary hypertension, but an associated right ventricular cardiomyopathy may coexist.

Dyspnoea is the most common symptom and usually attributable to pulmonary involvement, though it may be secondary to left ventricular systolic and/or diastolic dysfunction. Atypical chest pain may be secondary to pulmonary hypertension or fibrosis, pericarditis, or oesophageal reflux.

Diffuse narrowing of intramural coronary arteries may be associated with myocardial infarction or angina. Clinical pericarditis is reported in 15 per cent of patients and up to 70 per cent demonstrate pericardial involvement at autopsy.

ECG abnormalities are reported in 75 per cent of patients with scleroderma. Conduction abnormalities are seen in as many as 50 per cent of those with cardiac disease and may present with palpitations, syncope, or sudden death. The presence of left bundle branch block or bifascicular block suggests significant myocardial involvement: a septal infarct pattern or interventricular conduction abnormalities may also be seen. Ambulatory electrocardiograms frequently reveal a high prevalence of atrial and ventricular premature beats: supraventricular tachycardias are seen in 30 per cent of patients and ventricular tachycardia (which may predict future sudden death) in up to 15 per cent. The echocardiogram typically shows features of dilated or restrictive cardiomyopathy. Resting thallium perfusion abnormalities are seen in the majority of affected individuals, whilst arteriography usually reveals normal coronary arteries. Endomyocardial biopsy is rarely performed.

Treatment for pulmonary involvement may involves prostacyclin, long-term oxygen therapy, and anticoagulation. Treatment for heart failure is along conventional lines; calcium channel antagonists, nitrates, and vasodilators may improve resting myocardial perfusion.

The major cause of death in scleroderma is pulmonary hypertension, with a 5-year mortality rate of 60 per cent. Although nothing has been shown to alter the cardiac manifestations, D-penicillamine and isoretinoin have been used with some success. Symptomatic cardiac involvement predicts a poor prognosis, with a 2-year mortality of approximately 60 per cent.

Rheumatoid arthritis

Cardiac involvement is found in up to 60 per cent of patients on echocardiography, but only in 10 to 15 per cent clinically. The presence of cardiac disease tends to correlate with the severity of joint disease and the presence of rheumatoid nodules. Histological changes consist of a non-specific inflammatory infiltrate, myocyte necrosis, and fibrosis affecting any part of the heart. Rheumatoid nodules may accompany this, and the heart may also be affected by secondary amyloidosis. Myocarditis is reported in up to 20 per cent at autopsy, but symptoms are uncommon. Pericarditis occurs more frequently, and up to 40 per cent of patients have an

effusion on echocardiography, but progression to constrictive pericarditis or tamponade is rare. Acute vasculitis involving the larger epicardial arteries has been reported but is uncommon. Non-specific valvitis may affect the mitral and particularly the aortic valve: this may eventually lead to scarred, hyalinized, and even incompetent valves. Rheumatoid nodules may occasionally deform the mitral valve and lead to valvular incompetence. Conduction disturbances may be secondary to infiltration by rheumatoid nodules: the commonest ECG abnormality is first-degree heart block, but left bundle branch block and complete heart block are also described. Although pericarditis is usually responsive to steroids, it is unclear whether steroids or disease-modifying drugs alter the other cardiac manifestations.

Polymyositis and dermatomyositis

Cardiac involvement in polymyositis or dermatomyositis is present in up to 15 per cent of patients clinically and as many as 55 per cent on echocardiography. Histological changes consist of non-specific inflammatory cell infiltrate, myocyte necrosis, and fibrosis, involving particularly the cardiac conducting tissue and leading to various degrees of conduction block and arrhythmias.

There is echocardiographic evidence of pericardial disease in up to 25 per cent of patients, but this usually remains asymptomatic. Myocarditis may be present in 25 per cent of patients at autopsy, although the development of clinically apparent heart failure is uncommon. The ECG is often abnormal, particularly in children. Abnormalities consist mostly of non-specific 'ST' and 'T' wave changes and conduction delays. Treatment is based on symptomatology.

Seronegative arthropathies

This group of disorders is characterized by the absence of rheumatoid factor and includes ankylosing spondylitis, Reiter's syndrome, and psoriatic and gastrointestinal arthropathies. These may all be associated with cardiac involvement, in particular pancarditis, proximal aortitis, aortic incompetence, and varying degrees of conduction abnormalities. They may also result in amyloid deposition. On occasion cardiac disease may present before joint disease. Treatment is empirical and based on symptomatology.

Neuromuscular diseases

The muscular dystrophies are a group of disorders characterized by progressive skeletal and cardiac muscle involvement (Table 3). Dystrophic effects on skeletal muscle result in fibre necrosis, followed by fibrosis and fatty replacement. The heart is commonly affected and cardiac disease tends to be progressive. The structural and functional changes, which occur in the ventricles, can lead to the development of cardiomyopathy, in particular dilated cardiomyopathy and heart failure. The effect on the specialized conducting tissue may lead to bradyarrhythmias, conduction defects, malignant arrhythmias, and sudden death.

Duchenne and Becker muscular dystrophy are progressive disorders arising from abnormalities (deletion, duplication, or point mutation) in the genes involved in the manufacture of the extra-sarcomeric cytoskeletal protein dystrophin. In addition to defects in dystrophin, other defects that might be responsible for muscular dystrophy and dilated cardiomyopathy include those affecting the genes for the intracellular proteins, emerin and laminin. Emerin is a transmembrane protein that is embedded in the inner nuclear cell membrane. Laminin A–C are filament-like proteins that form a proteinaceous mesh underlying and attached to the inner nuclear membrane. The exact mechanism by which alterations in these proteins may lead to cardiomyopathy remains unclear.

In general, treatment of the cardiomyopathy of neuromuscular disorders is empirical and based on symptomatology and evidence of arrhythmia or conduction block. Should advances in the treatment of neuromuscular disorders by gene therapy or other means result in prolonged survival, then cardiac failure may become the limiting factor.

Amyloid

Amyloidosis describes a group of diverse protein-deposition diseases. The biochemical nature of the proteinaceous deposits and the aetiology of the underlying associated diseases differ (Table 4).

As many as 50 per cent of patients with systemic AL (primary) amyloidosis have cardiac involvement and this will manifest clinically in up to half of these. Systemic AA (secondary) amyloidosis is almost never associated with clinical cardiac amyloidosis. The heart is frequently involved in familial amyloid polyneuropathy, which is the most common type of hereditary amyloidosis and caused by more than 70 mutations in the transthyretin gene. Senile amyloidosis is extremely common, indeed almost all individuals over the age of 80 years will have scattered deposits of amyloid, particularly affecting the aorta. Clinical involvement is variable, depending on the extent of deposition, but tends to be unimportant in senile amyloidosis.

The extracellular deposition of amyloid results in a firm, thickened, non-compliant myocardium. Deposition occurs throughout the atrial and ventricular muscle. Conducting as well as nodal tissue may be affected: fibrosis of these structures may occur. Valvular function is rarely affected, although deposition in and thickening of cardiac valves is common. Intramural coronary arteries and veins frequently contain deposits, which can occasionally compromise the lumina of these vessels.

Amyloid heart disease most frequently mimics hypertrophic cardiomyopathy with restrictive physiology. The reduced compliance of the myocardium produces the characteristic diastolic dip and plateau (square root sign) in the ventricular pressure waveform that may simulate constrictive pericarditis. An impaired rate of early diastolic filling is characteristic and systolic dysfunction may also occur, leading to congestive heart failure.

Progressive infiltration of the autonomic nervous system results in orthostatic hypotension in 10 per cent of cases. Arrhythmias are common, in particular ventricular premature beats and atrial fibrillation. Complex ventricular arrhythmias may be harbingers of sudden death.

The chest radiograph may show cardiomegaly in patients with systolic dysfunction but is often normal in those with restrictive cardiomyopathy, although pulmonary congestion may be prominent. The ECG shows diminished voltages in approximately 50 per cent of patients, and loss of 'R' waves in precordial leads; the presence of 'Q' waves in the inferior leads may simulate myocardial infarction. Echocardiography reveals an increased thickness of the ventricular walls with small ventricular chambers, dilated atria, intra-atrial septal thickening, left ventricular dysfunction, and a characteristic 'sparkling' appearance to the myocardium. Asymmetrical septal hypertrophy has also been recognized. Scintigraphy with technetium-99-pyrophosphate may be strongly positive. CT and MRI may also be helpful, as may endomyocardial biopsy.

Symptomatic heart disease typically presents late in the course of amyloidosis and the presence of clinical signs is an ominous feature with mortality approaching 100 per cent at 2 years. Treatment is supportive in combination with measures to suppress the underlying amyloidogenic condition. This ranges from myeloma-type chemotherapy in AL amyloidosis to liver transplantation in familial amyloid polyneuropathy. Digoxin and calcium channel antagonists should be used with caution as they selectively bind to amyloidal fibrils, enhancing their effect. Patients with symptomatic conduction system disease require a pacemaker. Diuretics and vasodilators should be used cautiously as they may aggravate hypotension. Transplantation is feasible in selected cases but is a palliative procedure without treatment of the underlying process.

Inherited infiltrative disorders causing cardiomyopathy

Various disorders may lead to infiltration of the myocardium by an abnormal metabolic product, resulting in abnormal systolic and/or diastolic function of the heart. The disorders include glycogenoses, the mucopolysaccharidoses, Fabry's disease, and Gaucher's disease.

Fabry's disease (angiokeratoma corporis diffusum universale)

An X-linked disorder present in 1 in 40 000 live-born babies in which an inherited deficiency of the enzyme a-galactosidase results in the intracellular accumulation of a glycolipid substrate in numerous organs, including the myocardium. Most patients eventually develop symptomatic cardiovascular manifestations including hypertension, mitral valve prolapse, and congestive heart failure. The electrocardiogram often shows left ventricular hypertrophy, 'P' wave abnormalities, conduction defects, and arrhythmias. Echocardiography usually demonstrates increased thickness of the left ventricle, which may simulate hypertrophic cardiomyopathy. Differentiation from other hypertrophic or restrictive processes may require MRI or endomyocardial biopsy. A low leucocyte a-galactosidase activity is diagnostic.

Gaucher's disease

A deficiency of the enzyme b-glucosidase results in the accumulation of cerebrosides in the spleen, liver, bone marrow, lymph nodes, brain, and myocardium. Diffuse interstitial infiltration of the left ventricle leads to a reduction in left ventricular compliance and cardiac output. Clinical evidence of cardiac involvement is uncommon, but when present is characterized by left ventricular dysfunction, haemorrhagic pericardial effusion, thickened left ventricle, and calcification of left-sided valves.

Sarcoid

Sarcoid is a multisysytem granulomatous disorder of unknown aetiology. Myocardial involvement is seen in 20 to 30 per cent of patients at autopsy but is clinically apparent in less than 10 per cent of cases. Primary cardiac involvement is extremely rare.

Non-caseating granulomas may involve any region of the heart, although the left ventricular free wall and interventricular septum are the most commonly affected sites. The granulomas can be localized or widespread, and healing may result in the formation of scars. The ventricular muscle eventually becomes increasingly non-compliant; this can lead to defects in contractile function as well as wall motion. Replacement of large portions of the ventricle by sarcoid tissue may lead to aneurysm formation. Granulomas and fibrosis may also extend to involve nodal or conducting tissue. Isolated pericardial involvement is rare, although pericardial effusions are commonly seen on echo. Valvular dysfunction occurs in fewer than 5 per cent of patients and may be the result of infiltration of papillary muscles or direct valvular involvement, which is less common.

Clinical manifestations of myocardial sarcoidosis are shown in Table 5. Chest pain has been described in up to 28 per cent of patients, and since about half of these will have abnormal thallium perfusion scans despite arteriographically normal coronary arteries, this is thought to be secondary to microvascular spasm.

Sudden death is one of the most common and feared manifestations of myocardial sarcoidosis, occurring in about 65 per cent of affected patients. It is thought to be predominantly secondary to arrhythmias, including ventricular tachycardia and fibrillation. The presence of a ventricular aneurysm may be associated with resistant ventricular arrhythmias and necessitate its resection. Conduction disturbances such as complete heart block are a frequent occurrence and may also predict sudden death. The electrocardiogram is frequently abnormal with 'T' wave abnormalities and varying degrees of interventricular or atrioventricular block. Pathological 'Q' waves may simulate myocardial infarction when myocardial involvement becomes extensive. Echocardiography most commonly shows features of restrictive or occasionally dilated cardiomyopathy. Systolic and/or diastolic dysfunction as well as regional wall motion abnormalities may also be seen. Gallium or technetium pyrophosphate scanning and MRI have all been used to detect affected areas of myocardium. Endomyocardial biopsy can be diagnostic but is rarely done due to the patchy nature of the disease.

Steroids have been shown to lead to improvements in symptoms as well as electrocardiographic and echocardiographic features and myocardial perfusion defects, although there is a theoretical risk of increased aneurysm formation. Amiodarone may be of benefit in resistant arrhythmia and the insertion of an implantable defibrillator may protect against sudden death in susceptible patients. Transplantation may improve prognosis and quality of life in patients who remain symptomatic despite these measures, although recurrence has been documented. The average survival from the onset of symptomatic cardiac involvement has been reported as 1 to 2 years.

Haemochromatosis

Hereditary haemochromatosis is the most common single-gene disorder in people of northern European origin, where approximately 3 to 5 persons per 1000 are homozygous for the disease. It results in excessive and inappropriate mucosal absorption of iron, which is then deposited predominantly in the heart, liver, gonads, and pancreas. Deposition in the heart results in thickening of the ventricular walls together with dilatation of the ventricular chambers and heart failure. Histopathologically, myocardial degeneration and fibrosis occur over time and may extend to involve the conducting system of the heart.

The ECG most commonly reveals 'ST' and 'T' wave changes. Supraventricular arrhythmias are also characteristic, with atrioventricular conduction defects and ventricular arrhythmias being less common. Echocardiography typically shows a mixed dilated and restrictive cardiomyopathy with thickened ventricular walls, ventricular chamber enlargement, systolic and/or diastolic dysfunction. Endomyocardial biopsy may be useful to confirm the diagnosis but cannot rule it out. Treatment involves repeated phlebotomy and/or desferrioxamine.

There is evidence that the type of the inherited mutation may determine the development of cardiomyopathy. Two new mutations have recently been described which may predispose to the development of hereditary haemochromatosis and dilated cardiomyopathy. These affect the haemochromatosis gene on chromosome 6p (termed the HPE gene) and probably act as disease-modifying genes in dilated cardiomyopathy, although having little effect on iron status. The pathogenesis of cardiomyopathy here may be unrelated to excessive iron.

Diabetes

A man with diabetes has a relative risk of developing heart failure that is 2.4 times higher than that of a man without diabetes, and the equivalent relative risk for a woman is 5:1. The risk has been shown to be independent of age, systolic blood pressure, serum cholesterol, and weight. People with diabetes have been shown to have elevated end-diastolic pressures, reduced ejection fractions, left ventricular dilatation, and hypertrophy, even in the absence of coronary artery disease. Diastolic dysfunction as well as a diffuse hypokinesis of the myocardium has also been demonstrated. Implicated mechanisms include small vessel disease and autonomic neuropathy.

The most prominent histopathological finding is that of myocardial fibrosis. Occasionally a picture resembling restrictive heart disease is seen, with a small left ventricular chamber and reduced compliance of the left ventricle.

The treatment of heart failure is the same as in patients without diabetes, although b-blockers with intrinsic sympathomimetic activity are preferred. Preload and after-load reducing agents should be used cautiously because of autonomic dysfunction. It is unclear whether tight glucose control affects the progression of diabetic 'cardiomyopathy', but it is clearly prudent for other reasons to optimize control as well as to reduce obesity and control hypertension.

Hyperthyroidism

In general, excess thyroid hormone results in a high output state with tachycardia, increased cardiac contractility, and peripheral vasodilatation. In the long term this can result in ventricular hypertrophy and an increase in ejection fraction. However, some patients may develop a low output state with symptoms of heart failure and echocardiographic demonstration of dilated cardiomyopathy and systolic dysfunction. These changes may be a result of long-standing tachycardia and increased cardiac work, but thyroxine itself may directly alter the expression of certain cardiac proteins involved in cardiac function, and there is also some evidence that direct autoimmune attack on the myocardium may occur in Graves' disease.

Typical symptoms of hyperthyroidism include angina-like chest pain, fatigue, palpitations, and exertional dyspnoea. Cardiac findings include sinus tachycardia and atrial flutter or fibrillation in 17 to 20 per cent. These may be complicated by thromboembolism in up to 40 per cent; also by congestive heart failure. Mitral valve prolapse has been reported in patients with Graves' disease.

Control of the ventricular rate in atrial fibrillation may be obtained with digoxin, b-adrenergic antagonists, or calcium channel antagonists. The increased metabolic clearance of digoxin may necessitate a higher maintenance dose. Cardioversion should generally be deferred until euthyroid. b-Adrenergic antagonists offer prompt control of sympathomimetic manifestations. The presence of an already dilated vascular bed means that diuretics should be used with caution and vasodilators are generally contraindicated. Treatment of hyperthyroidism *per se* is discussed elsewhere.

Hypothyroidism

Patients suffering from hypothyroidism, whether in its mild form or full-blown myxoedema, present a wide variety of symptoms. Complaints of fatigue, lethargy, mental slowness, and cold intolerance usually dominate. Less frequently, symptoms suggestive of cardiac dysfunction such as dyspnoea on exertion, syncope, or angina-like

chest pain may be prominent. The most common cardiac abnormality is pericardial effusion, which is usually asymptomatic but reported in at least 30 per cent of untreated patients. Heart failure generally represents exacerbation of pre-existing cardiac disease by the superimposed haemodynamic consequences of thyroid deficiency—bradycardia, diminished myocardial contractility, and increased peripheral vascular resistance.Rarely, hypothyroidism alone can closely resemble cardiomyopathy severe enough to cause heart failure. Echocardiographic evidence of asymmetric thickening of the interventricular septum as well as reduced left ventricular outflow tract dimensions has been reported. The characteristic ECG findings are sinus bradycardia, prolongation of the QT interval, and a reduction in voltages if there is an associated pericardial effusion.

The management of heart failure involves the identification of any primary cardiac disease that may coexist; both ischaemic heart disease and aortic stenosis may be exacerbated by thyroid replacement. L-Thyroxine (T_4) significantly enhances myocardial performance within 1 week. It is generally used as first-line treatment of hypothyroidism, but in those with known or suspected coronary artery disease it should be initiated at a lower dose than usual, typically 25 µg/day, and increased slowly at 4- to 6-week intervals until the thyroid-stimulating hormone is within the normal range. Tri-iodothyronine (T_3) may be preferable in severe cases as clinical improvement occurs sooner. b-Blockade can be used prophylactically or added if treatment with L-thyroxine exacerbates ischaemic heart disease.

15.9 Pericardial disease

D. G. Gibson

Anatomy of the pericardium

The normal pericardium consists of serous and fibrous components. The fibrous pericardium is thick and unyielding, separating the heart from surrounding organs. It fuses with the central tendon of the diaphragm below and with the great vessels above, 1 to 2 cm beyond their origins. Inside the fibrous pericardium is the serous pericardium, in which the heart is invaginated. It has two layers, a parietal layer which lines the inner aspect of the fibrous pericardium and a visceral layer, sometimes called the epicardium, which covers the surfaces of the heart and the origins of the great vessels. The pericardial cavity is the potential space between the visceral and parietal layers of the serous pericardium. It normally contains only a few millilitres of fluid, but it has a considerable capacity where fluid may accumulate.

Physiology of the pericardium

The normal pericardium is not essential to life: the pericardial space is often obliterated after open heart surgery, and both layers may be removed in patients with constrictive pericarditis without apparent ill effect. Whether restraint by the normal pericardium is of any pathophysiological importance as a mechanism limiting stroke volume in disease remains uncertain.

Congenital abnormalities of the pericardium

Congenital abnormalities of the pericardium are uncommon with an incidence of 1 to 2 per 10 000 autopsies. Congenital absence of the pericardium may be partial or complete. A partial defect, involving the left side of the pericardium is about four times as common as the complete form. Either type may be associated with additional congenital anomalies in about one-third of cases, including Fallot tetralogy, atrial septal defect, or sequestered pulmonary segments. Clinical features include non-specific chest pain and sinus bradycardia, with an ECG showing right axis deviation. A chest radiograph is characteristic, with a shift of the heart to the left and prominence of the main pulmonary artery. Heart size is increased and the lower border of the cardiac shadow ill-defined. Echocardiography shows increased right ventricular size and reversed septal motion, as occurs in atrial septal defect. If the defect is partial, the left atrial appendix may herniate through it, and even strangulate leading to a clinical picture suggesting acute pericarditis. If the defect is larger, the left ventricle may herniate and undergo torsion. Alternatively, lung may become trapped in the pericardial space. These complications are treated surgically by enlarging the defect.

Pericardial cysts

These are rare, have a variety of embryological origins, and may be continuous with the pericardium or separate from it. They do not usually cause symptoms, but can be discovered on chest radiographs taken for any reason. Their nature becomes obvious with CT scanning or MRI, but the exact diagnosis is often established only when they are removed surgically.

Mulibrey nanism

Mulibrey (**mu**scle, **li**ver, **br**ain, **ey**e) nanism is an autosomal recessive condition characterized by growth failure, a triangular face, often with a hydrocephaloid skull, hypotonia, a peculiar voice, large liver, and yellowish dots and pigment dispersion in the optic fundi. The majority of cases have pericardial constriction due to congenital thickening of the pericardium, and this may be responsible for some of the clinical features. Histologically, the pericardium shows simple fibrosis. Considerable improvement follows pericardiectomy.

Acquired pericardial disease

Diseases of the pericardium may be considered from two points of view. The first is aetiological, the second is in terms of the physiological and clinical disturbances that result. There is no fixed relation between the two, so that an account will be given of the different diseases affecting the pericardium and then of the three main syndromes: acute pericarditis, pericardial tamponade, and pericardial constriction.

Aetiology

Diseases affecting the pericardium are given in Table 1.

Acute idiopathic pericarditis

Acute idiopathic pericarditis is a disease occurring in young adults, usually sporadically. Prospective studies have suggested a viral basis for around half. Coxsackie B is most commonly involved, but others including ECHO type 8, rubella, hepatitis B, mumps, and influenza have also been identified. Epidemics can occur, with

approximately equal numbers of patients developing pericarditis and myocarditis.

The commonest clinical feature is chest pain, but 'flu-like' symptoms, palpitations, orchitis, encephalitis, and radiographic appearances of pneumonitis or pleural effusion have all been reported. The condition is usually self-limiting, but a minority of cases follow a relapsing course over the succeeding 6 to 12 months. A virus may be identified from paired blood samples taken 2 weeks apart, or recovered from throat or rectal swabs, but in many cases no clear cause is identified and positive virology is not necessary for the diagnosis.

HIV infection

Pericardial effusion can occur in AIDS, usually as a late manifestation with poor prognosis. For further information see Chapter 15.10.4.

Pyogenic infection

Pyogenic infection of the pericardium is uncommon. It is usually due to bloodborne infection of a previously sterile pericardial effusion, or the result of direct spread from the lungs or pleural space. The organisms most commonly involved are staphylococci, pneumococci, or streptococci. Bacterial infection of the pericardium is not usually an isolated event and occurs more frequently in an immunologically compromised patient.

Tuberculous infection

Tuberculous infection is an important cause of pericardial disease, particularly in the Third World. It may take the form of acute pericarditis, pericardial effusion, or constriction. Acute pericarditis appears to be a 'primary' response, and can be regarded as an exudative lesion whose main basis is allergic. Chronic pericardial effusion and constriction both reflect granulomatous disease, often with fibrosis and calcification in the late stages. Both parietal and visceral layers of the pericardium may be involved, and spread of the disease to the myocardium follows. In the first instance, treatment is with antituberculous drugs. In both effusion and constriction in HIV-negative patients, adding steroids for the first 11 weeks reduces the need for pericardiectomy, increases the speed with which heart rate and venous pressure fall to normal, and expedites return to work. In the absence of specific contraindication, therefore, steroids should be added to standard antituberculous chemotherapy.

In Sub-Saharan Africa, patients with tuberculous pericarditis now have a more than 80 per cent chance of being HIV positive. Pericardial constriction severe enough to require surgery is rare, possibly reflecting depressed ability to form dense fibrosis in HIV infection. Treatment is with standard antituberculous drugs which, apart from thiacetazone, are well tolerated and effective. It is uncertain whether there is an adjuvant role for additional steroid in such patients. Long-term survival is shorter than in HIV-negative patients, due to other opportunistic infections rather than recurrence of tuberculosis.

Fungal infection

Fungal pericarditis is uncommon, but infection with actinomycosis, coccidioidomycosis, and histoplasmosis have all been recorded, the last leading to constriction and calcification. Pericardial calcification by hydatid disease is increasingly recognized in areas where the disease is endemic and may require surgical treatment if cardiac compression occurs.

Myocardial infarction

Evidence of acute pericarditis can be found in up to 15 per cent of patients in the first 24 to 72 h after acute myocardial infarction. This may take the form of a friction rub when infarction was transmural. It seldom gives rise to symptoms other than dull retrosternal pain, which differs from that due to the infarction itself by varying with posture and respiration. Patients with pericarditis have more extensive ST segment changes and a slightly higher risk of supraventricular arrhythmia. There is no evidence to suggest increased risk of complication with thrombolysis. Echocardiography may demonstrate a small pericardial effusion, but this is unlikely to require treatment.

Post-cardiotomy syndrome

Pericardial involvement is an important component of the post-cardiotomy syndrome. This is an acute febrile illness occurring up to 1 year after cardiac surgery. The onset is usually sudden, with pleural or precordial pain and pyrexia of up to 40°C. Chest radiography may show an enlarged heart or a pleural effusion. ECG is unaffected. The condition is usually self-limiting, but can recur. Diagnosis is by excluding, in particular, infective endocarditis or cytomegalovirus infection from blood transfusion. Treatment is with aspirin or indomethacin. Rarely a large pericardial effusion may develop, requiring surgical drainage.

Dressler's syndrome

Dressler's syndrome is similar to post-cardiotomy syndrome. It follows 2 to 4 weeks after acute myocardial infarction, in 3 to 4 per cent of cases. It is a self-limiting febrile illness, accompanied by pericardial or pleural pain, and by pneumonitis in more severe cases. Like the post-cardiotomy syndrome, it responds to aspirin, indomethacin, and (if necessary) steroids.

Rheumatic fever

A small pericardial effusion accompanies virtually all cases of acute rheumatic fever, where it is associated with epicardial inflammation and sometimes acute pericarditis. Less commonly, the effusion may be large enough to cause cardiac enlargement on chest radiography and so suggest myocardial disease. Healing is virtually complete, although rheumatic pericarditis may be responsible for adhesions found at the time of subsequent valve replacement, and it has also been invoked as a cause of subsequent constriction. The diagnosis is made echocardiographically, and the condition must be distinguished from myocarditis or severe valve disease.

Autoimmune rheumatic disorders

Pericardial involvement can be a serious manifestation of rheumatoid disease, particularly in male patients with positive serology. Transient pericardial pain, symptomatic pericardial effusion, and particularly pericardial constriction may all occur. Pericardial involvement is also common in systemic lupus erythematosus, whether spontaneous or precipitated by procainamide or hydralazine. Pericardial pain, asymptomatic effusion, and chronic constriction have all been reported. Pericardial effusion can also be seen in association with scleroderma, polyarteritis nodosa, and the Churg–Strauss syndrome, when it may accompany myocardial involvement and functional mitral regurgitation.

Renal failure

Pericarditis, commonly fibrinous and associated with a bloody effusion, is often seen in untreated or inadequately treated chronic renal failure. The usual presentation is with pericardial pain and a rub, both of which subside if an effusion develops. Tamponade is common in untreated cases. Collagenous thickening of the epicardium is less common, but may give rise to myocardial constriction. Either of these complications may need surgical relief.

Hypothyroidism

Clinically silent pericardial effusion is common in untreated hypothyroidism. The effusion itself has a high cholesterol content which may produce an unusual secondary pericarditis with cholesterol deposits of 'gold paint' appearance. The pericardial effusion very rarely needs to be treated in its own right, and subsides when thyroid replacement therapy is given.

Malignancy

Malignant involvement of the pericardium may be due to a primary tumour, or much more commonly to secondary involvement. The least rare primary tumours are mesothelioma or myosarcoma. Clinical manifestations of malignant involvement include supraventricular arrhythmias or atrial fibrillation as well as pericardial

tamponade or constriction. Malignant effusion is a very common cause of tamponade, and likely to need drainage. Positive diagnosis is best made by a limited surgical approach, allowing open biopsy and the fashioning of a window into the pleural cavity to prevent recurrence.

Irradiation

Pericarditis can be caused by irradiation. This is usually asymptomatic and a rub is unusual, but transient cardiac enlargement and minor ECG changes occur. It may occur at the time of the irradiation or at any time thereafter, and can be large enough to require drainage. The clinical picture needs to be distinguished from recurrence of malignancy. At operation, the pericardium is found to be thickened with fibrosis and dense adhesions. In a small minority of patients, pericardial constriction can develop up to 40 years after irradiation.

Haemorrhage

Haemorrhage into the pericardium is an important cause of tamponade. It may occur with aortic dissection involving the ascending aorta. If the leak is large it causes pericardial tamponade and death, but a small volume of blood is not uncommon with dissection. It can be detected by echocardiography, and may be responsible for ST segment changes on the ECG.

Pericardial haemorrhage may be the result of stab wounds or blunt injury, or may occur after cardiac surgery. It may also be induced by excessive anticoagulant therapy, or follow invasive procedures such as myocardial biopsy or pacemaker insertion.

Symptoms can occur at the time of bleeding, or may be delayed by 2 to 3 weeks, possibly because autolysis of clotted blood increases the volume of fluid within the pericardial space. Delayed tamponade causes a characteristic syndrome of elevated venous pressure, fluid retention, and low cardiac output that resembles myocardial disease. Haemorrhage into the pericardial space may also be the basis of delayed pericardial constriction occurring up to 10 years after open heart surgery.

Clinical syndromes associated with pericardial disease

Acute pericarditis

Clinical findings

There are three main components to the clinical syndrome of acute pericarditis: chest pain, pericardial rub, and ECG changes. The pain is usually retrosternal, continuous, and sharp or 'raw' in character. It is frequently aggravated by sudden movements or deep inspiration, and is relieved by sitting up. Less commonly it may resemble angina pectoris, or may be mild and 'atypical'. Painful breathing causes dyspnoea. The onset of the pain is usually sudden, but in idiopathic pericarditis, it may have been preceded by several days' malaise or other non-specific symptoms.

On examination, the main abnormality is a pericardial rub, audible in any position over the precordium. In patients in sinus rhythm it has two components, corresponding to atrial and ventricular systole. Rubs are frequently evanescent, and may vary with posture. They are often louder in inspiration. An irregular pulse due to supraventricular ectopic beats is common, particularly in patients with renal failure or after cardiac surgery. Atrial fibrillation or flutter are also seen.

The third clinical feature of the syndrome of acute pericarditis is an abnormal ECG. Symmetrical elevation of the ST segments by 1 mm or more in all leads other than aVr is seen in over 90 per cent of patients in whom the diagnosis is confirmed. Early in the illness, the T waves are upright, but over the next 2 to 3 weeks, they become flattened and inverted as the ST-segment changes regress. These T-wave changes are variable in incidence, direction, and extent. They usually resolve completely, but a minority of patients may be left with minor T-wave inversion, only to be detected many years later at a routine ECG.

Chest radiography is usually uninformative. It may show cardiac enlargement, but it is not possible to tell whether this is due to pericardial fluid, an increase in wall thickness, or enlargement of one or more cardiac chambers.

Echocardiography is the method of choice for detecting pericardial effusion (see section xxx). Cross-sectional echo may also detect pericardial adhesions that are responsible for the rub. However, acute pericarditis can occur without demonstrable pericardial effusion.

Diagnosis

The is usually straightforward, although it is possible that either the late systolic murmur of mitral prolapse or the systolic 'scratch' of Ebstein's anomaly may be mistaken for a pericardial rub. An underlying cause for acute pericarditis should always be sought, though it may not be found, and a final diagnosis of idiopathic pericarditis is probably the commonest outcome. The possibility of additional myocarditis should always be considered.

Treatment

Idiopathic acute pericarditis is usually self-limiting, requiring simple analgesics only. Since additional myocarditis is possible, the patient should rest until pain has subsided. Pericarditis due to Dressler's or the post-cardiotomy syndrome responds well to aspirin, or if more severe, to a non-steroidal anti-inflammatory drug. When symptoms are severe, repeated, or prolonged, steroids may be given empirically. Associated pericardial effusion is treated on its own merits: only rarely does it need to be drained. Supraventricular arrhythmias are treated in the standard way. When pericarditis is part of a generalized disease, this should obviously be treated appropriately.

Pericardial tamponade

Pathophysiology and clinical features

Pericardial tamponade occurs when the pressure of fluid within the pericardial cavity becomes high enough to interfere with ventricular filling. The volume of fluid needed to cause tamponade varies considerably between patients. If the fluid has collected slowly, 1 to 2 litres may be present, but if it has collected rapidly, or the pericardium is rigid, a much smaller volume will cause tamponade.

When pericardial pressure increases, right and left atrial pressures must necessarily rise to allow cardiac filling. The presence of fluid in the pericardium also reduces the volume of blood that can be accommodated in the cardiac chambers, such that stroke volume becomes small and fixed. Patients with cardiac tamponade therefore present with a high jugular venous pulse and clinical evidence of low cardiac output: the skin is cold, the pulse rate rapid but the volume small, and urine flow reduced, though systolic arterial pressure may be above 100 mmHg.

An important and characteristic physical sign in cardiac tamponade is arterial 'pulsus paradoxus'. Arterial pressure normally falls on inspiration by up to 10 mmHg. This fall is more obvious in patients with obstructive lung disease. Arterial paradox is unfortunately named: it is an accentuation of the normal response and not paradoxical. What is abnormal is the extent to which the arterial pressure falls. In severe tamponade the reduction in pulse pressure can readily be palpated at the radial artery, and with critical circulatory embarrassment the pulse may disappear altogether on inspiration. In milder cases, arterial paradox is sought using the sphygmomanometer.

The mechanism of pulsus paradoxus is still uncertain. Direct measurement of the pericardial pressure shows it to rise during inspiration, probably because the cavity is distorted by downward motion of the diaphragm. This increase is accompanied by a corresponding rise in right atrial and central venous pressure so that filling of the right side of the heart is maintained. By contrast, on the left side of the heart there is no corresponding increase in pulmonary venous pressure, which can fall to a low level compared with that in the pericardium and compromise left ventricular filling. During inspiration the interventricular septum then shifts from right to left, right ventricular stroke volume is maintained only by almost complete obliteration of the left ventricular cavity, left ventricular stroke volume drops dramatically, and profound inspiratory hypotension results. Finally, as pericardial pressure rises higher, there is diastolic collapse of right atrium and right ventricle.

Abnormal right ventricular filling is reflected in the venous pulse. The pressure is always raised: if it is not, the diagnosis of tamponade must be questioned. Usually it is very high, and it may be difficult to see the top. If a central venous line is in place, a further increase occurs with inspiration (Kussmaul's sign). This is a much less specific finding that arterial paradox and merely reflects the inability of the right heart to deal with an increase in stroke volume. It is seen in a variety of conditions including right ventricular disease and pulmonary hypertension. Although X and Y descents are visible, their amplitude is small, since the main disturbance is an increase in mean venous pressure. Unlike pericardial constriction, therefore, abnormalities in the form of the venous pulse are not particularly helpful in making the diagnosis.

Investigations

Chest radiography shows a large globular heart (Fig. 1), similar to that seen in dilated cardiomyopathy. More useful in making the diagnosis, therefore, is the absence of any evidence of pulmmonary congestion, which would be expected if myocardial disease were the main abnormality. Pulmonary oedema is most unusual in pure tamponade: if it is present, it suggests additional myocardial disease.

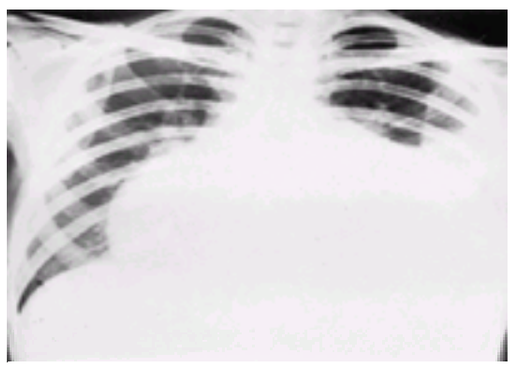

Fig. 1 Posteroanterior chest radiograph of a patient with a large pericardial effusion. The heart shadow is greatly enlarged and globular in configuration. The lung fields are normal.

ECG shows tachycardia, often with low-voltage QRS complexes, but without Q waves or conduction disturbances. If the effusion is large, electrical alternans is present, when alternate QRS complexes show differing morphology (Fig. 2), because the heart swings to and fro in a large (therefore usually malignant) effusion.

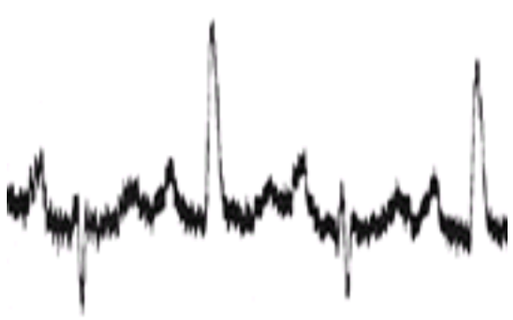

Fig. 2 Electrocardiogram from a patient with massive malignant pericardial effusion showing electrical alternans. Note that all are sinus beats with the same PR interval, but that the QRS axis alternates.

Echocardiography is a most important investigation since it allows rapid and unequivocal diagnosis of pericardial effusion, which is usually large with tamponade (Fig. 3). Evidence for circulatory embarrassment is diastolic collapse of the right ventricle or right atrium (Fig. 4), and a striking increase in the amplitude of septal motion with respiration. If electrical alternans is present, motion of the heart within the pericardium can be confirmed.

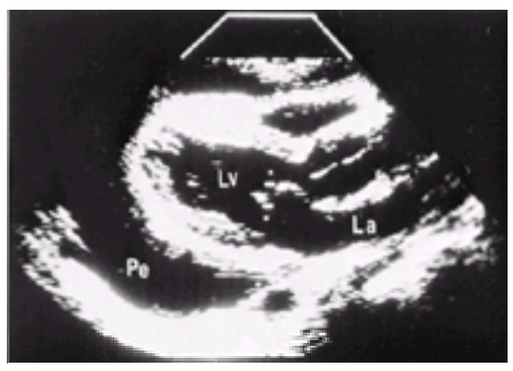

Fig. 3 Two-dimensional echocardiogram, parasternal long-axis view, showing a large pericardial effusion (Pe) posterior to the left ventricle (Lv). La, left atrium.

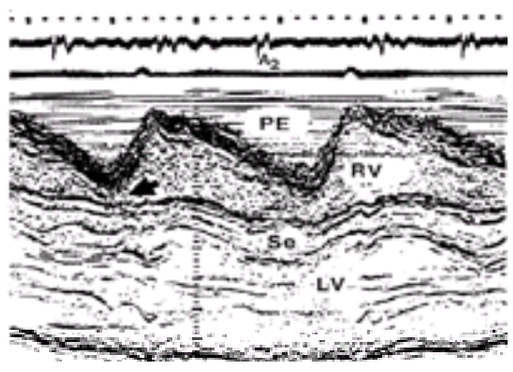

Fig. 4 M-mode echocardiogram showing diastolic collapse of the right ventricle (marked by arrow) in a patient with a large pericardial effusion. Note the minimum dimension of the right ventricle occurs at the end of the diastole. PE, pericardial effusion; RV, right ventricle; Se, interventricular septum; A2, aortic valve closure on phonocardiogram; LV, left ventricle (time marker = 200 ms)

Arterial pulsus paradox can be confirmed or excluded from a simultaneous trace of respiration and peripheral arterial Doppler (Fig. 5).

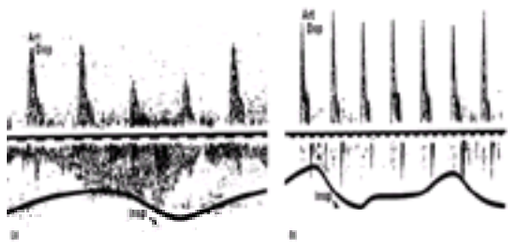

Fig. 5 (a) Arterial Doppler variation with respiration recorded from a patient with a large pericardial effusion. Note that peak arterial velocities drop to approximately half their peak values with inspiration. Art Dop, arterial Doppler; insp, inspiration. (b) The same patient after aspiration of the pericardial effusion. Note that the arterial pulse no longer varies with respiration (time marker = 100 ms).

The circulatory embarrassment occurring with pericardial effusion varies in its exact nature between cases. 'Tamponade' does not therefore represent a uniform diagnosis. In the small minority of patients in whom an echocardiographic diagnosis of pericardial effusion cannot be made for technical reasons, some other imaging method such as CT or MRI may have to be used. Cardiac catheterization is no longer necessary.

Differential diagnosis

The main step in making the diagnosis of pericardial tamponade is to think of it in a patient presenting with clinical evidence of a low cardiac output. The condition must be distinguished from severe ventricular disease, massive pulmonary embolism, hypovolaemia, or overwhelming sepsis. Hypovolaemia is ruled out by the high venous pressure, whilst the absence of added heart sounds and pulmonary congestion makes severe ventricular disease unlikely. Massive pulmonary embolism is accompanied by a right ventricular third sound and characteristic ECG abnormalities.

An echocardiogram should be obtained early in all patients with low cardiac output for which the cause is not apparent, and if there is a large pericardial effusion the diagnosis of tamponade becomes very likely. It is essential for the occasional echocardiographer to distinguish pericardial effusion from pleural effusion. This is done by locating the high-intensity echo from the fibrous pericardium posterior to the left ventricle on the left parasternal view. A pericardial effusion is inside this structure, and a pleural effusion outside. Rarely, a large pleural effusion may compress the heart and cause a clinical picture very similar to tamponade in the absence of any pericardial fluid. This seems to occur when the pleural effusion is under pressure, and haemodynamics rapidly return to normal with pleural drainage.

Treatment

Pericardial tamponade is a medical emergency. It needs urgent treatment, particularly if there is obvious arterial paradox, or if the effusion is of recent onset and fluid is collecting rapidly. Pericardial aspiration should be performed in an area where resuscitation facilities are available. Echocardiography is used to determine where to insert the needle, and to get some idea of the direction and depth. Subcostal or apical routes are possible, but the former is preferable if the heart is accessible in this way, since damage to the anterior descending coronary artery is possible from the apex. The depth of the pericardial fluid can usually be confirmed when the local anaesthetic is inserted. A larger needle or polythene cannula is then introduced into the effusion and a pig-tail catheter inserted over a guide wire. A maximum of 500 ml of fluid is removed initially and relieves any haemodynamic problem: rapid withdrawal of larger volumes can provoke cardiovascular collapse. Continuous drainage is then instituted and the remainder of the effusion drained over 12 to 24 h.

Many pericardial effusions, particularly malignant ones, are heavily bloodstained. They can be distinguished from blood associated with puncture of a chamber by their colour, since they are very desaturated, and by their failure to clot, since they are defibrinated. If necessary, the haematocrit of the fluid can be compared with that of blood taken simultaneously.

Aspiration of a pericardial effusion is necessary when there is any suspicion of tamponade. It should also be considered when the volume is large, even in the absence of specific evidence of resting circulatory embarrassment, since exercise tolerance is commonly limited before overt tamponade develops. In addition, such patients are unstable and tamponade can develop quickly with the accumulation of a relatively small additional volume of fluid.

Aspiration is not necessarily the best way of definitively managing pericardial effusion. It does not prevent recurrence, and it is not usually possible to make a diagnosis from the pericardial fluid alone. The most satisfactory line of treatment, therefore, is to undertake limited thoracotomy, either through the fifth interspace, or subcostally, the latter operation being possible with local anaesthetic. This allows an adequate specimen of pericardium to be removed under direct vision for histology, and drainage of the pericardial space can be assured by making a window to the pleura. It is also possible to deal with a loculated effusion and to remove blood clots whose presence can give rise to delayed tamponade.

Pericardial constriction

Pericardial constriction is the haemodynamic disturbance caused when ventricular filling is limited by the pericardium. The pericardium itself is usually, but not always, thickened. The myocardium may also be involved, particularly in its subepicardial layers, by atrophy and fibrosis. Constriction usually affects both ventricles symmetrically, but in rare cases it may be localized. The majority of cases, particularly in the developed world, show no evidence of inflammation, acute or chronic, so 'pericardial constriction' is a better name than 'constrictive pericarditis'.

Pathophysiology and clinical features

Pericardial constriction prevents cardiac filling in late diastole. Since the two sides of the heart are usually affected symmetrically, right and left atrial filling are equally compromised. Early diastolic ventricular pressure is normal, but since the pericardium is effectively indistensible, a normal or reduced stroke volume causes a striking increase in filling pressure. End-diastolic pressures are equal to within 1 to 2 mmHg in all four cardiac chambers. This persists with respiration or even with fluid loading, and is the main criterion on which the invasive diagnosis of constriction is based. The ventricular pressure trace during filling is also characteristic. It rises rapidly in early diastole, and then stops rising abruptly, often with a slight rebound, and remains constant for the remainder of diastole. This pattern is often referred to as the 'square root sign' from a fancied resemblance to the mirror image of the mathematical symbol for a square root. Abnormal early diastolic filling is also reflected in the transmitral Doppler trace, which shows a rapid early diastolic deceleration, and reduced or absent flow across the valve during atrial systole.

The jugular venous pulse is also characteristic. Overall pressure is raised, with the dominant descent during systole, the X descent (Fig. 6). This descent is independent of right atrial systole, occurring later in the cardiac cycle than the A wave and persisting with atrial fibrillation. Flow towards the heart in the superior cava is also systolic, meaning that right atrial volume must also be increasing at this time. The unexpected combination of an increase in right atrial volume with a simultaneous fall in right atrial pressure is caused as follows. In pericardial constriction, an increase in the transverse dimension of the ventricle is limited by the pericardium, but increase in the longitudinal axis is not. Long-axis changes are brought about mainly by motion of the atrioventricular ring, and during ventricular ejection both atrioventricular rings move towards the cardiac apex. This enlarges the capacity of the atria, draws blood in from the vena cavae, and manifests as a dramatic X descent in the jugular venous pulse.

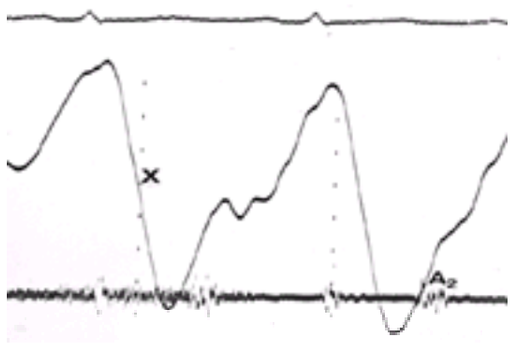

Fig. 6 Jugular venous pulse recording showing a dominant X descent in a patient with pericardial constriction. A2, aortic valve closure; (time marker = 500 ms).

The clinical picture of pericardial constriction is dominated by obstruction to right ventricular filling. The jugular venous pressure is always raised, in well developed cases by 15 cm or more, showing abrupt systolic, and to a lesser extent, early diastolic descents whether or not the patient is in atrial fibrillation. Tachycardia and atrial fibrillation are common. The precordial impulse is not usually palpable, and on auscultation the heart sounds are soft. There may be an early diastolic sound, whose timing corresponds to the end of rapid filling, and which should therefore be classified as a third sound, though it is sometimes referred to as a ventricular 'knock'. It is often earlier than the classic third heart sound, but only because rapid filling ends earlier in constriction than in uncomplicated ventricular disease. The liver is enlarged, and in patients with long-standing disease, there may be wasting and jaundice. Ascites is often more prominent than peripheral oedema, particularly when the patient is stabilized on large doses of diuretic.

Investigations

The chest radiograph is usually normal, but the heart may be enlarged and it is important to look for pericardial calcification. This appears as multiple plaques or, more frequently, as a rim covering the diaphragmatic and anterior surfaces of the heart.

The ECG often shows atrial fibrillation, low-voltage QRS complexes and non-specific T-wave abnormalities. There are no diagnostic features.

CT scanning or MRI can demonstrate the extent and distribution of pericardial thickening. While this does not make the diagnosis of constriction, it is often very useful to know that the pericardium is actually abnormal in a patient in whom this diagnosis is suspected on clinical grounds. M-mode and cross-sectional echocardiography are unhelpful in making the diagnosis of constriction. Doppler may be useful in demonstrating abnormalities of ventricular filling.

Unless the diagnosis is very obvious, cardiac catheterization is still usually performed. To establish the diagnosis, three features should be present:

1. a difference of less than 5 mmHg between the equal end-diastolic pressures in the two ventricles, persisting with respiration;
2. a peak right ventricular pressure of less than 50 mmHg; and
3. a ratio of end-diastolic to peak right ventricular pressure of more than 0.33.

It is still uncertain whether the normal pericardium can ever cause constriction in humans. The pericardium can stretch and accommodate a gradual increase in heart size. If constriction were to occur, it would probably be in the setting of rapid increase in ventricular size, for example in myocarditis or valvular regurgitation of acute onset. In these circumstances it would be difficult to dissociate from the primary manifestations of ventricular disease.

Alternative clinical presentations

A number of less common clinical presentations have been described.

1. Localized constriction may compress the outfow tract of the right ventricle or may mimic mitral or tricuspid stenosis.
2. A greatly raised venous pressure may lead to the clinical features of a protein-losing enteropathy or classic nephrotic syndrome.
3. The possibility that occult pericardial constriction might exist has been raised. In these patients, the resting venous pressure is normal and the symptoms are non-specific, including mild limitation of exercise tolerance or fatigue. There may be a history of previous acute pericarditis. The diagnostic haemodynamics of constriction can be unmasked by rapid volume infusion.

Differential diagnosis

The main differential diagnosis of pericardial constriction is restrictive myocardial disease, where the passive properties of the myocardium itself are abnormal, usually as the result of fibrosis or infiltration. The haemodynamics are very similar in the two conditions: ventricular early diastolic pressure is normal, but that at end-diastole is greatly increased. The differential diagnosis is important: both are debilitating and life-threatening conditions, but whereas constriction can frequently be treated effectively by surgery, restrictive myocardial disease cannot (other than by transplantation). Approaches used to distinguish between the two conditions include the following.

Anatomical

If the pericardium is thickened or calcified, a diagnosis of constriction is very likely. Similarly, if echocardiography shows the characteristic appearances of amyloid then it is very likely that restrictive myocardial disease is present. The same applies when only one ventricle is greatly dilated with a reduced ejection fraction. In typical restrictive disease, however, left ventricular end-systolic cavity size is normal, although stroke volume may be reduced. Tricuspid regurgitation severe enough to lead to a clinical picture resembling either condition can readily be diagnosed by echocardiography.

Haemodynamics

Raised ventricular filling pressures, with a square root sign on the pressure pulse, increased early diastolic filling velocities, and shortened early filling periods do not distinguish between the two. All three catheter criteria mentioned above should be present before a definitive diagnosis of constriction is made. A dominant systolic X rather than Y descent on the jugular venous pulse is also very characteristic of constriction, probably because longitudinal as well as circumferential filling is impaired in restrictive myocardial disease.

Clinical progress

With diuretic treatment, the venous pressure usually drops in patients with restrictive myocardial disease, albeit at the cost of causing fatigue and hypovolaemia. It is very rare to be able to bring the venous pressure down to normal in a patient with well developed constriction.

This discussion is based on the assumption that constriction and restriction are independent conditions, and that a patient has either one or the other. However, this is not always the case. When the visceral pericardium (epicardium) is involved, fibrosis can spread to involve the myocardium and such cases may show features of both constriction and restriction. This state of affairs is analogous to that seen with subendocardial thickening as occurs in eosinophilic heart disease, which is usually classified as a form of restrictive cardiomyopathy. For this reason, in particular, the differential diagnosis between constriction and restriction may not be clear even after extensive investigation, and in a minority of cases it is not possible to avoid an exploratory thoracotomy. This enables the diagnosis of constriction to be made and treated accordingly, or to be definitively excluded, so that the patient can be reconciled to medical treatment, unsatisfactory as it may be.

Pericardial constriction must also be distinguished from other causes of raised venous pressure. Superior caval obstruction is excluded by the presence of venous

pulsation. Right ventricular inflow may be obstructed by tricuspid stenosis or, very rarely, by a right ventricular tumour. Elevation of the venous pressure is also a feature of selective right atrial compression by blood clot occurring in the postoperative period (see later). Severe tricuspid regurgitation may occur on its own, or because of right ventricular disease. It seems to be becoming increasingly common as a long-term complication following mitral valve replacement. These possibilities can all be excluded by echocardiography.

Treatment

Mild pericardial constriction can usually be managed by diuretics. Although the venous pressure does not fall to normal, fluid retention can often be controlled. However, if fluid retention persists, or if an excessive dose of diuretic is needed, as shown by an increase in blood urea or impaired exercise tolerance due to fatigue, then surgery should be considered. The thickened pericardium must be removed from the anterior and inferior surfaces of the heart, and from the atrioventricular sulci. Cardiopulmonary bypass is usually needed to expose and decompress the heart satisfactorily. The operation is often a long and difficult one, particularly when the pericardium is calcified or when there is fibrosis of the myocardium. In many patients, the venous pressure is as high after the operation as it was before, though the X descent is lost and the Y descent becomes dominant. However, with digitalis and diuretic treatment, the pressure gradually falls over the succeeding weeks, as the condition of the patient improves.

Other manifestations of pericardial disease

Postoperative pericardial disease

A modified type of pericardial tamponade occurs after open heart surgery due to blood clots within the pericardium, particularly behind the left atrioventricular sulcus. Clinically this presents as a fall in urine flow and cardiac output, a reduction in skin temperature and finally hypotension. The atrial pressures may be normal or raised, and the classic arterial and venous pulse abnormalities are absent. Chest radiography and ECG show no specific abnormality. The transthoracic echocardiographic window is often poor immediately after surgery, but transoesophageal echo may show clot alongside the heart, compressing one or more chambers. The condition should be suspected in a patient who may have bled rather heavily after operation, particularly when the blood flow from the chest drains suddenly falls, and is most satisfactorily diagnosed by reopening the chest and removing the blood clots.

Clot may also compress the right atrium. This characteristically occurs towards the end of the first postoperative week, after the chest drains have been removed and when the patient is being mobilized. The main clinical features are fluid retention and elevation of the venous pressure. The diagnosis can usually be made by transthoraic echocardiography, which demonstrates distortion of the right atrial cavity by blood clot and sometimes increased right atrial filling velocities. If the precordial window is poor, transoesophageal echocardiography is required. Treatment is by drainage.

Pericardial constriction is increasingly being recognized as a long-term complication of cardiac surgery. It has a major effect on the clinical course of 1 to 2 per cent of patients; minor degrees are probably rather more common. It presents as chronic elevation of the venous pressure, and is often diagnosed as postoperative 'heart failure'. The diagnosis is suspected from the absence of any intracardiac cause of the syndrome of heart failure, such as ventricular disease, valvular regurgitation, or pulmonary hypertension, and from pericardial thickening demonstrated by CT or MRI. It can usually be controlled by a small dose of diuretic, but in a minority of cases, pericardial surgery may be needed.

Recurrent acute pericarditis

Recurrent acute pericarditis is an uncommon but clinically demanding form of pericardial disease to manage. It occurs at any time up to 10 years after an apparently uncomplicated episode of acute pericarditis of any aetiology. The commonest manifestation is chest pain, although rarely it may present as recurrent pericardial effusion. ECG changes and echocardiographic evidence of effusion occur in about half of cases. As with the original attack, immunological studies are likely to be indecisive. The clinical problem is that repeated episodes can become debilitating to the patient, particularly as they occur after what was represented as a self-limiting disease. Constriction and myocardial disease are significant complications. Management consists of maintaining a positive outlook and controlling the manifestations of acute pericarditis. Simple analgesia with aspirin is the most satisfactory means, but this may not always be adequate. Non-steroidal anti-inflammatory agents or corticosteroids may be required, the latter sometimes in large enough doses to lead to Cushingoid manifestations. There is no evidence to suggest that immunosuppressive agents have a therapeutic role. Pericardiectomy may be necessary, but is not necessarily effective, presumably because all pericardium cannot be removed. The overall prognosis of the condition is good.

Tuberculous pericardial constriction in the Third World

This runs a very different course from that seen in developed countries. In the absence of HIV infection, it occurs early in the disease and may be the presenting feature. Alternatively, it may supervene after an effusion has been drained. Patients present with sinus tachycardia rather than atrial fibrillation, a very high venous pressure, ascites, and weight loss. The venous pressure often does not show the characteristic pattern of systolic dip, and a third heart sound is present in about 50 per cent of cases. Chest radiography shows a normal-sized heart, but characteristically a 'shaggy' left heart border. There is no pericardial calcification. ECG shows sinus tachycardia and non-specific T-wave abnormalities. Cross-sectional echocardio-graphy is very helpful, showing the two layers of pericardium separated by amorphous echoes often enclosing small loculated pockets of fluid (Fig. 7). This pattern is sometimes referred to as 'effusive-constrictive' pericarditis. The amplitude of ventricular wall motion is reduced, and the pericardial surface shows a very characteristic 'frozen' appearance. Treatment is with antituberculous chemotherapy. Added steroids help, with heart rate and venous pressure returning more rapidly to normal. They also reduce the risk of death and the requirement for operation. When possible, fluid retention should be controlled by diuretics. During the early subacute phase, surgery is demanding and unsatisfactory. It may be needed, however, in a minority of seriously ill patients who cannot be held on medical treatment. In the absence of AIDS, ultimate prognosis is excellent, being indistinguishable from that of the population at large whether treatment is medical or surgical.

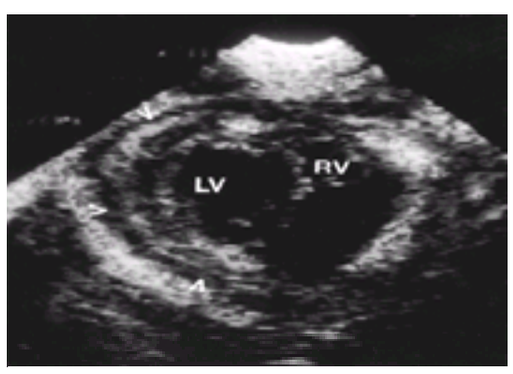

Fig. 7 Cross-sectional echocardiogram showing effusive-constrictive pattern of pericardial involvement (marked with arrow) in a patient with tuberculous pericarditis.

15.10.1 Acute rheumatic fever

Jonathan R. Carapetis

Introduction

Acute rheumatic fever is an immunologically mediated, multisystem disease induced by recent infection with group A streptococcus. Most medical practitioners in industrialized countries will rarely, if ever, see a case. However, the dramatic decline in incidence of acute rheumatic fever in industrialized countries during the second half of the twentieth century is not replicated in many developing countries, or among some indigenous and other populations living in poverty in industrialized countries. Moreover, acute rheumatic fever has recently returned as an important public health problem in some middle-class regions of the United States. Rheumatic heart disease remains the most common acquired heart disease of childhood in the world.

Epidemiology

The highest reported annual incidence of acute rheumatic fever, more than 500/100 000, occurs in the Aboriginal population of the Northern Territory of Australia. Populations in developing countries commonly have incidence rates between 50 and 200/100 000 per year. There have been dramatic declines in recent decades in many Latin American and Asian countries with improving economic and living conditions. In most populations with high incidence rates, the predisposing conditions are those that promote endemicity and high levels of transmission of group A streptococci: these include overcrowded housing, poor personal and community hygiene, poor access to medical services and, in some circumstances, widespread skin infection and scabies infestation.

Outbreaks of acute rheumatic fever occurred in middle-class areas of the United States during the 1980s and 1990s. These outbreaks arose because of the emergence of virulent strains of group A streptococci, particularly belonging to M serotypes 1, 3, and 18. By contrast, outbreaks of acute rheumatic fever have rarely, if ever, been described from developing countries; most cases appear to arise from the ongoing circulation of pathogenic group A streptococcal strains in the population.

Recurrent episodes are almost as common as primary episodes in many populations with high incidence rates of acute rheumatic fever, and account for approximately 40 per cent of all episodes among the Aboriginal population of northern Australia. Recurrences may lead to accumulated cardiac valvular damage and are therefore responsible for many cases of rheumatic heart disease, yet they are almost entirely preventable using secondary prophylaxis (see later).

In many developing countries females are affected more than males, usually in the ratio between 1.3 and 2 to 1. In affluent countries males and females appear to be affected equally. The gender association is stronger for rheumatic heart disease (especially mitral stenosis) than acute rheumatic fever; this may reflect a greater tendency to recurrences among females. Any female preponderance may relate to inherited characteristics, to greater exposure to group A streptococci because of the increased involvement of girls and young women in child-rearing in most cultures, or to reduced access by females to primary and secondary prophylaxis.

The maximum incidence of acute rheumatic fever is between the ages of 5 and 15 years in all populations. Approximately 5 per cent of cases occur in children younger than 5 years, but very rarely are children younger than 3 years affected. This age distribution parallels that of group A streptococcal pharyngitis, and supports the hypothesis that all cases of acute rheumatic fever follow this condition. However, it may be that cases do not occur in infants or very young children because of the need for maturity of the immune system (particularly of cellular immunity), or sensitization of the immune response by prior streptococcal infections. New cases occur occasionally up to age 30, but rarely beyond. Hypotheses to explain the reduced incidence in adulthood include development of non-type-specific immunity to primary group A streptococcal infections, further maturation of immune responses, or reduced sensitization by recurrent streptococcal infections.

Pathogenesis

Despite a century of research, the pathogenesis of acute rheumatic fever remains incompletely understood. The presumed pathogenetic pathway is summarized in Fig. 1.

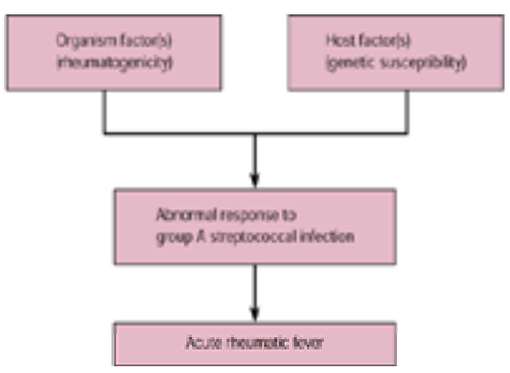

Fig. 1 Simplified approach to understanding the pathogenesis of acute rheumatic fever. (Adapted with permission from Carapetis JR, Currie BJ, Good M (1996). Editorial review: Towards understanding the pathogenesis of rheumatic fever. *Scandinavian Journal of Rheumatology* **25**, 127–31.)

Host factors

Epidemiological evidence suggests that less than 5 or 6 per cent of people have the potential to develop acute rheumatic fever after relevant streptococcal exposure, and that this proportion does not vary substantially between populations. Attack rates of acute rheumatic fever after untreated group A streptococcal pharyngitis vary from less than 1 to 3 per cent. Genetic susceptibility to acute rheumatic fever was first suggested by its familial aggregation and by a greater concordance in monozygotic than in dizygotic twins. The mode of inheritance is uncertain; autosomal recessive or autosomal dominant with partial penetrance have been suggested.

The basis for genetic susceptibility is not known. Recent work suggests an association of rheumatic heart disease with certain HLA class II alleles. A B-cell alloantigen (D8/17) is expressed in a high percentage of B cells from patients with acute rheumatic fever and their family members in many populations. However, D8/17 may not predict susceptibility in all populations; recent studies in India suggest that different B-cell alloantigens may identify patients with acute rheumatic fever there.It is not yet clear whether these putative markers are genetic or induced by streptococcal infection as part of the pathogenesis of acute rheumatic fever.

Organism factors

The observation that outbreaks of pharyngitis due to certain serotypes of group A streptococcus resulted in high attack rates of acute rheumatic fever, whereas no cases occurred after infection with other serotypes, led to the concept of 'rheumatogenicity'—that only some strains of group A streptococcus have the potential to cause acute rheumatic fever. M serotypes 1, 3, 5, 6, 14, 18, 19, 24, 27, and 29 have been most frequently implicated. However, there may be substantial genetic diversity among strains belonging to a particular M serotype, and not all strains of 'rheumatogenic serotypes' appear to cause acute rheumatic fever. Therefore, rheumatogenicity may be strain specific rather than serotype specific; that is, any group A streptococcus may acquire the potential to cause acute rheumatic fever.

The pathogenic factor(s) are not known. Parts of the organism have immunological cross-reactivity with human tissue; there is close homology between regions of the M protein and human myosin, tropomyosin, and keratin. Other components of group A streptococci, including the hyaluronic acid capsule, the cell-wall associated group-specific carbohydrate, and the cell membrane, cross-react with a variety of human tissues damaged in acute rheumatic fever, including components of heart muscle and valves, joints, and brain. Acute rheumatic fever-associated strains of group A streptococcus also tend to be heavily encapsulated with hyaluronic acid, and not to express opacity factor. Group A streptococci possess components which act as superantigens, selectively stimulating subsets of T cells without the need for antigen presentation. Their role in acute rheumatic fever pathogenesis is not yet clear.

Site of infection

Although it is widely accepted that acute rheumatic fever may result from group A streptococcal infection of the upper respiratory tract, but not of the skin, there is some evidence that this may not always be the case. Upper respiratory tract infection certainly accounts for most, if not all, episodes of acute rheumatic fever in countries with a temperate climate. However, in tropical countries where streptococcal impetigo is highly endemic but group A streptococcal pharyngitis less common, it may be that skin infection accounts for many cases of acute rheumatic fever, either *de novo* or after subsequent throat infection. Determining whether group A streptococcal skin infection may have a role in pathogenesis of acute rheumatic fever would have enormous public health implications, as it may redirect present approaches to primary prevention (see later).

The immune response

The finding of immunological cross-reactivity led to initial enthusiasm for the role of humoral immunity in the pathogenesis of acute rheumatic fever. This was supported by the finding of anti-group A streptococcal antibodies cross-reactive with heart, joint, and brain in the sera of patients with acute rheumatic fever. Immunoglobulin and complement deposits have also been demonstrated in damaged heart tissue.

More recently, patients with acute rheumatic fever were found to have elevated levels of most markers of cellular immune activation, including circulating CD4 lymphocytes, interleukins (**IL**)-1 and -2, IL-2 receptor-positive T cells, neopterin, tumour necrosis factor-a receptors, natural killer cell cytotoxicity, T-cell responsiveness to group A streptococcal antigens, and others. T-cell and histiocytic-cell infiltrates are also present in valvular and myocardial tissue during acute rheumatic fever. This has led to theories that the primary damage in acute rheumatic fever may be due to cell-mediated immune responses and that the humoral response may be secondary to antigens released from already damaged tissues. Cross-reacting antigens of group A streptococci may be presented to the immune system abnormally, or they may be abnormally recognized by helper T cells, resulting in uncontrolled activation of cellular immunity. The resulting damage targets those tissues for which the inducing strain has sequence mimicry.

Clinical manifestations

There is always a latent period between group A streptococcal infection and the development of acute rheumatic fever. This varies from 1 to 5 weeks in most cases (usually about 3 weeks), but may be shorter in recurrences. Chorea may occur up to 6 months after the precipitating streptococcal infection. The preceding infection is asymptomatic in about two-thirds of cases.

The tissues most commonly affected are the heart, joints, and brain. Although the symptoms due to each can be disabling in the short term, only cardiac damage may be permanent and progressive. Therefore, the focus in controlling or treating acute rheumatic fever is always to prevent the development of rheumatic heart disease.

The frequency with which the various clinical manifestations have occurred in recent descriptions of acute rheumatic fever is listed in Table 1.

Carditis

Although inflammation in acute rheumatic fever may affect the pericardium (causing pericardial rubs and occasionally pleuritic chest pain) or the myocardium (sometimes causing cardiac failure, and evident on biopsy with pathognomonic Aschoff bodies), endocardial inflammation is the most important cause of cardiac damage. If acute cardiac failure or chronic cardiac disease occur, they are almost always due to damage to the cardiac valves.

A murmur is the most common evidence of acute valvular disease, usually the apical pan-systolic murmur of mitral regurgitation, with or without a low-pitched mid-diastolic (Carey–Coombs) murmur. Occasionally an aortic regurgitant murmur may be heard, mainly in older adolescents or young adults. Murmurs of tricuspid or pulmonary regurgitation are rare and are usually secondary to increased pulmonary venous pressures resulting from mitral regurgitation or stenosis. Sinus tachycardia or gallop rhythms may also be present in acute carditis.

Valves affected by rheumatic carditis may have a characteristic appearance or pattern of regurgitation on Doppler echocardiography (when interpreted by experienced technicians), which may be found even in the absence of a cardiac murmur. This may be useful for diagnosis when other clinical manifestations are not definitive. However, echocardiographic criteria have not yet been standardized, and it is difficult to distinguish acute carditis from previous rheumatic valve damage.

Mitral or aortic stenosis may develop as later complications of severe and/or recurrent acute carditis due to scarring and contraction following the acute inflammatory process. Rarely, mitral stenosis may occur in young children with acute rheumatic fever—so-called 'juvenile mitral stenosis'—the reasons for the development of this condition are not clear.

Damage to the electrical conduction pathways may result in prolongation of the P–R interval on electrocardiography. Although a subset of healthy people may have this finding, the presence of a prolonged P–R interval that resolves over the ensuing few days to weeks may be a useful diagnostic feature in cases where the clinical

manifestations are not clear. Occasionally, in the acute phase, second- or third-degree heart block or a nodal rhythm may be present (Fig. 2).

Fig. 2 Electrocardiographic changes in a young adult with acute rheumatic fever, showing evolution over 18 days from complete heart block, to second-degree (Wenckebach) block, to first-degree block, and then to normal sinus rhythm. (Reproduced with permission from Bishop W *et al*. (1996). A subtle presentation of acute rheumatic fever in remote northern Australia. *Australian and New Zealand Journal of Medicine* **26**, 241–2.)

Arthritis

The characteristic joint manifestation of acute rheumatic fever is severe, large-joint, migratory polyarthritis. The knees, ankles, wrists, and elbows are most commonly involved; only rarely, and usually only when the patient is untreated for several days, are the hips or small joints of the hands or feet inflamed. One joint characteristically becomes exquisitely painful and inflamed as another is waning. Most patients have only one or two joints affected at any one time, and each joint may be involved for just a few hours or up to 1 or 2 days. The arthritis is so responsive to non-steroidal anti-inflammatory medication that its persistence more than 1 or 2 days after commencing high-dose aspirin should lead one to consider alternative diagnoses.

Arthritis of a single large joint may occur in acute rheumatic fever, although other causes (including septic arthritis) should first be excluded. Arthralgia (joint pain without objective evidence of inflammation) is usually migratory and affects large joints, and like the arthritis of acute rheumatic fever is very responsive to anti-inflammatory medication.

Sydenham's chorea

In 1686 the English physician Thomas Sydenham described rheumatic chorea, initially naming it 'St Vitus' dance'. It is the most intriguing manifestation of acute rheumatic fever, particularly as it commonly occurs in the absence of other manifestations, usually follows a prolonged latent period (up to 6 months) after the precipitating group A streptococcal infection, and occurs most commonly in females (and almost never in post-pubertal males). The rapid, jerky, involuntary movements affect predominantly the upper limbs and face, may be asymmetrical, and may be sufficiently severe to render the patient unable to eat, drink, walk, or perform other activities of daily living. Mild chorea can sometimes be detected by having the patient join palms above the head to reveal occasional twitches of the arms or the head. Typical signs include the 'milk-maid's grip' (rhythmic squeezing when the patient grasps the examiner's fingers), spooning of extended hands (caused by flexion of the wrists and extension of the fingers), darting of the protruded tongue, and the 'pronator sign' (the arms and palms turn outwards when held above the head). As with other forms of chorea, the disorder usually becomes more evident with anxiety or purposeful movements (such as drinking or writing). Movements may appear semi-purposeful, and symptoms subside during sleep. Sydenham's chorea often is associated with excessive emotional lability or personality changes: these may precede the abnormal movements.

Most patients can be reassured that Sydenham's chorea will resolve completely and leave no long-lasting effects, usually within 6 weeks and almost always within 6 months, but rarely lasting up to 3 years.

Subcutaneous nodules and erythema marginatum

Both of these manifestations are found in less than 2 per cent of patients with acute rheumatic fever, although they were described in up to 10 to 20 per cent of patients in earlier studies from the United States and the United Kingdom. Subcutaneous nodules are firm, painless lumps, usually between 0.5 and 2 cm in diameter, commonly found in crops of three or more, and usually appear 2 to 3 weeks after the onset of acute rheumatic fever. They occur mainly over extensor surfaces or bony protuberances, particularly the hands, feet, occiput, and back. The nodules are similar, though often smaller, to those found in rheumatoid arthritis, and are most likely to be associated with severe carditis. Nodules usually last from a few days to 2 or 3 weeks.

The characteristic rash, erythema marginatum, appears as a light pink macule that spreads outwards with a serpiginous, well-demarcated edge, while the central portion clears. It appears, disappears, or moves before the observer's eyes. Multiple areas are often involved, usually over the trunk, occasionally over the proximal portions of the limbs, but rarely, if ever, the face. It usually appears together with the other initial symptoms of acute rheumatic fever, but may recur intermittently for weeks or even months. This does not indicate ongoing rheumatic inflammation, and patients can be reassured that the rash will eventually disappear without complications.

Fever

With the exception of those with pure chorea, 90 per cent of patients will have a temperature at presentation higher than 37.5°C. Although it has been reported that the temperature usually exceeds 39°C, others have found only 25 per cent of confirmed cases with fever to that level. Any temperature above 37.5°C should be considered a minor manifestation. As with arthritis, fever is very sensitive to anti-inflammatory medication, usually resolving completely within 1 or 2 days of commencing high-dose salicylates.

Elevated acute-phase reactants

Almost all patients, except those with pure chorea, have a dramatically elevated erythrocyte sedimentation rate or serum C-reactive protein. There appears little difference between these measurements in their diagnostic usefulness. The C-reactive protein may return to normal more rapidly than the sedimentation rate when rheumatic activity subsides. Mild to moderate peripheral leucocytosis is common, although this is a less sensitive marker of rheumatic inflammation.

Other features

Severe, central abdominal pain is found at presentation in a small proportion of patients. It may be associated with other features of acute rheumatic fever; if not, these features usually appear within 1 or 2 days. The pain responds quickly to anti-inflammatory medication. Epistaxis was reported frequently in historical accounts of acute rheumatic fever, but does not feature prominently in recent descriptions. Pulmonary infiltrates may be found in patients with acute carditis; this has been labelled 'rheumatic pneumonia' although it is not clear whether the infiltrates represent rheumatic inflammation or another process. There may be microscopic haematuria, pyuria, or proteinuria; also mild elevations of liver transaminases: these are non-specific and not usually severe.

Associated post-streptococcal syndromes

Post-streptococcal reactive arthritis has been differentiated from rheumatic fever by some authors because it has a shorter incubation period after streptococcal infection, sometimes follows non-group A b-haemolytic streptococcal infection, may have a different pattern of arthritis (including small joint involvement), and is less responsive to anti-inflammatory medication. Because of the lack of cardiac involvement, these patients are said not to require secondary prophylaxis. However, a few patients who have subsequently developed carditis have led other authors to question the distinction between post-streptococcal reactive arthritis and rheumatic fever. If post-streptococcal reactive arthritis is diagnosed, secondary prophylaxis should be prescribed for at least 1 year and discontinued if there is no evidence of

carditis. In populations with high incidence rates of acute rheumatic fever, it may be prudent to treat all cases of possible post-streptococcal reactive arthritis as acute rheumatic fever.

The frequent finding of emotional lability, motor hyperactivity, and occasional obsessive–compulsive symptoms in patients with Sydenham's chorea led to the observation that group A streptococcal infections may precipitate or exacerbate other disorders of the basal ganglia. These include tic disorders, Tourette syndrome, and obsessive–compulsive disorder, and the term **PANDAS** (paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) has been coined. Patients with PANDAS appear not to be at risk of developing carditis. There is evidence that these patients, and some children with autism, have high proportions of circulating B cells expressing D8/17 antigen, which is a proposed marker of rheumatic fever susceptibility. It is not yet clear whether these syndromes are linked with acute rheumatic fever.

Diagnosis

Because of the diversity of symptoms and signs, and the non-specific nature of most of them, Dr T. Duckett Jones developed a set of criteria to aid in the diagnosis of acute rheumatic fever in 1944. The Jones criteria have subsequently been revised and updated a number of times to improve their positive and negative predictive values. The most recent version, the 1992 update, is shown in Table 2. The manifestations are divided into: major, those which are most predictive of acute rheumatic fever, and minor, those which are commonly found in acute rheumatic fever but are less specific.

The diagnosis requires the presence of either two major, or one major and two minor criteria, plus the demonstration of a current or recent group A streptococcal infection. Evidence of group A streptococcal infection is not required for chorea, where the onset may be delayed up to 6 months after streptococcal infection, and late-onset carditis, when low-grade inflammation may persist for prolonged periods after the precipitating infection.

The 1992 updated Jones criteria are to be used only for the diagnosis of the initial episode of acute rheumatic fever. Patients with a previous history of acute rheumatic fever or rheumatic heart disease need have only one major or two minor manifestations, have evidence of recent group A streptococcal infection, and have no other plausible explanation for their symptoms. The Jones criteria are a guideline, but cases not fulfilling the criteria should only be diagnosed as acute rheumatic fever once all other possible diagnoses have been excluded.

Proof of a recent group A streptococcal infection can include demonstrating the organism in the upper respiratory tract, either by culture or rapid antigen techniques. However, most children with acute rheumatic fever no longer have a group A streptococcus detectable by these methods, and up to 15 to 25 per cent of normal children in temperate climate countries may carry the organism in their throats . Therefore, serological techniques are most commonly used, particularly the anti-streptolysin O, anti-DNase B, or anti-hyaluronidase titres. One of any two of these tests will be positive in well over 90 per cent of recent streptococcal infections. Their usefulness is increased by performing more than one serological test, or by demonstrating rising titres in paired sera. Serology is of limited value in regions with high prevalence rates of streptococcal impetigo, where children may have positive anti-streptococcal titres most of the time. The diagnosis of acute rheumatic fever in these circumstances can be very difficult. There is therefore a need for a better diagnostic test of recent streptococcal infection, or an objective diagnostic test for acute rheumatic fever itself.

The most common clinical presentation, that of a child with fever and polyarthritis, raises multiple differential diagnoses that will vary by region. Table 3 lists some alternative diagnostic possibilities for the three most common major manifestations.

Treatment

If untreated, acute rheumatic fever lasts on average for 3 months. Except in the case of life-threatening acute carditis, there is no evidence that presently available treatments alter the outcome. Most treatments are designed to provide symptomatic relief or are based on theoretical (but unproven) approaches to attenuating the long-term damage.

All patients with acute rheumatic fever should be admitted to hospital (if practical) to confirm the diagnosis, to perform baseline investigations to ascertain the status of the heart, to provide adequate treatment for the acute phase, to commence secondary prophylaxis, to allow communication of details to personnel responsible for long-term follow-up of the patient, and to begin education of the patient and family. The mainstays of treatment are bed rest, penicillin, and salicylates.

Bed rest

Previous recommendations that children with acute rheumatic fever be rested in bed until all signs of active inflammation abated were probably more extreme than is necessary. Once symptoms of arthritis have subsided and any cardiac failure is controlled, the child may begin gentle mobilization, which may be increased as tolerated. There is no evidence that bed rest beyond the period where mobilization leads to exacerbation of pain or cardiac failure has any long-term benefit.

Penicillin

All patients with acute rheumatic fever should be given penicillin to eradicate the group A streptococcus that precipitated the attack. This is based on an early finding that, in some cases, prolonged group A streptococcal infection led to more severe acute rheumatic fever. Although in most cases the precipitating organism cannot be cultured, a treatment course of penicillin is prudent in case the strain remains present in low numbers, and to prevent its transmission to other contacts. As the aim is eradication of group A streptococcal infection, penicillin may be administered either as a single intramuscular injection of benzathine penicillin G at a dose of 1.2 million units (600 000 U for patients less than 30 kg) into the gluteal or quadriceps muscles, or as a 10-day course of oral phenoxymethyl penicillin (V) at a dose of 500 mg (adolescents and adults) or 250 mg (children) given either two or three times daily. In the case of penicillin allergy, the present recommendation is to use oral erythromycin at 20 to 40 mg/kg per day given two to four times daily for 10 days, although in some regions levels of erythromycin-resistance among group A streptococci are increasing.

Salicylates

Children with arthritis or severe arthralgia should be treated with non-steroidal anti-inflammatory medication; salicylates have been most widely used. Aspirin at a dose of 80 to 100 mg/kg per day (4 to 8 g/day in adults) usually results in defervescence and resolution of arthritis and arthralgia within 1 to 2 days. Sometimes these doses lead to nausea or vomiting; this can be minimized by increasing from lower starting doses. When the diagnosis is uncertain, salicylates should be withheld for a day or two to observe for the development of characteristic migratory polyarthritis. In such cases, codeine can be used to control pain until the diagnosis is confirmed.

There is no evidence that salicylates reduce the severity of acute carditis or the risk of chronic cardiac valve damage. Nevertheless, many clinicians administer salicylates until acute-phase reactants have returned towards normal in the belief that this may reduce the risk of long-term cardiac damage. After 2 weeks, the dose is often reduced to 60 to 70 mg/kg per day for the remaining 2 to 4 weeks. Arthritis or arthralgia may return up to 2 to 3 weeks after discontinuation of therapy; this is usually a brief and mild recrudescence, often associated with increased erythrocyte sedimentation rate or C-reactive protein, and can be managed either with rest and reassurance or a short course of lower-dose anti-inflammatory medication.

Corticosteroids

For many years, corticosteroids have been used in acute rheumatic fever, particularly for patients with severe carditis. As with salicylates, the evidence that they reduce either the severity of acute carditis or the risk of long-term valve damage is conflicting. Many clinicians continue to use them, commonly oral prednisone or prednisolone at a dose of 40 to 60 mg/day, tapering after 2 or 3 weeks.

Treatment of cardiac failure

Although the use of corticosteroids is controversial, there is no doubting the need to treat cardiac failure. Diuretics, angiotensin-converting enzyme inhibitors (especially in aortic regurgitation), and fluid restriction are most commonly employed. Digoxin is usually restricted to cases where atrial fibrillation coexists with cardiac failure, often found in older patients with established mitral stenosis.

If medical therapy fails, cardiac surgery should be considered, even during the acute phase. In populations where fulminant acute carditis is relatively common (e.g. South Africa), mitral valve repair or replacement can be life saving and surgeons have developed techniques for undertaking these procedures despite friable, acutely inflamed valvular and perivalvular tissues. In recent years, there has been a greater tendency to undertake valve repair rather than replacement, or to use homografts or xenografts rather than mechanical prostheses. This is to avoid high rates of thromboembolic complications associated with mechanical prostheses, particularly in populations where compliance with anticoagulation chemotherapy is suboptimal and there are difficulties in monitoring coagulation indices.

Treatment of chorea

Sydenham's chorea always resolves, and if mild there may be no need for specific treatment. However, medications may reduce abnormal movements in moderate or severe chorea. Haloperidol is commonly used as a first-line treatment. Other medications employed include sodium valproate, pimozide, chlorpromazine, or benzodiazepines. Occasionally, low doses of minor tranquillizers are necessary for associated anxiety and emotional lability. All of these medications should be used sparingly and only for defined periods. Salicylates and steroids have no role in treatment of chorea. Psychotherapeutic interventions have little role in the short to medium term, and may increase the stigma of this self-limited organic disease. However, if longer-term behavioural abnormalities persist (e.g. emotional lability, obsessive–compulsive traits), behavioural therapy should be considered.

Newer therapies

Because of the autoimmune nature of acute rheumatic fever, immunomodulatory therapies have been tried. Intravenous immune globulin (IVIG) has been given in some small trials. One study showed no apparent benefit on rate of improvement of clinical, laboratory, or echocardiographic parameters of acute carditis, but another suggested that it may accelerate recovery from chorea. Other therapies have yet to be formally assessed.

Prognosis and follow-up

The most important prognostic factors are the severity of the acute carditis and the number of recurrences. Overall, approximately 30 to 50 per cent of patients with a first episode of acute rheumatic fever will develop chronic rheumatic heart disease. This increases to more than 70 per cent in patients with severe carditis at the first episode, or in those who have had at least one recurrence.

Any patient with acute rheumatic fever requires long-term follow-up. Follow-up assessments should focus on cardiac status, adherence to secondary prophylaxis, early treatment of group A streptococcal pharyngitis, and prevention of streptococcal pyoderma (including hygiene and treatment or prevention of scabies infestation). Patients with evidence of cardiac valve damage should be assessed regularly by specialist physicians and considered for cardiac surgery before substantial left ventricular dysfunction occurs. Vasoactive drugs, particularly angiotensin-converting enzyme inhibitors, may delay the need for operation in asymptomatic patients with chronic aortic regurgitation. Regular echocardiography may be useful to follow the progress of rheumatic heart disease, especially in populations where follow-up may be irregular or in whom communication or cultural differences make clinical assessment difficult.

Recurrences

Approximately 75 per cent of all recurrences occur within 2 years of an episode of acute rheumatic fever. The reasons for this are not known, but are thought to relate to a time-dependent sensitization of the immune response. The clinical features of recurrences tend to mimic those present at the initial episode, particularly in the case of chorea. However, this rule is not absolute, and the risk of developing other manifestations increases with each recurrence. For example, in the Australian Aboriginal population 40 per cent of patients without carditis at the initial episode of acute rheumatic fever developed it at the first recurrence, and 70 per cent developed carditis at either of the first two recurrences. The practical implication of this is that the absence of carditis at the first episode does not help to identify patients who may not need secondary prophylaxis.

Prevention of acute rheumatic fever

Secondary prophylaxis

Every patient with acute rheumatic fever should immediately commence secondary prophylaxis: long-term, regular antibiotics to prevent primary group A streptococcal infections. This strategy is proven to reduce the incidence of recurrences and the risk of developing chronic rheumatic heart disease.

The optimal regimen is 1.2 million units of intramuscular benzathine penicillin G every 3 weeks, and this is commonly given in populations with high incidences of acute rheumatic fever and programmes in place to support the regimen. Higher doses (1.8 or 2.4 million units) given every 4 weeks may have similar effect, but further evidence is needed before such regimens can be recommended routinely. An alternative strategy is to use oral penicillin V at a dose of 250 mg twice daily; this is almost as effective as using benzathine penicillin G, but adherence is usually less reliable.

The most effective strategy for patients proven to be allergic to penicillin is to attempt desensitization using an approved protocol. If this is unsuccessful, the present recommendation is to use oral erythromycin at a dose of 250 mg twice daily. Recent trials have shown newer oral cephalosporins to be effective at eliminating upper respiratory tract carriage of group A streptococci. However, none of these antibiotics have been evaluated for their ability to prevent acute rheumatic fever.

The duration of secondary prophylaxis is dictated by the reducing risk of recurrence with increasing age, with time since the last episode, and the possible consequences of recurrences. Secondary prophylaxis should continue for at least 5 years following the most recent episode or until age 21 years, whichever comes last. However, in patients with substantial valvular disease (e.g. moderate or severe mitral or aortic regurgitation, or any mitral or aortic stenosis), secondary prophylaxis should be continued longer—to age 30 or 35 years in most populations. If the damage is severe, or in patients who have had valve surgery, the possibility that recurrence might be catastrophic mandates that secondary prophylaxis be continued for life.

Primary prophylaxis

A full course of penicillin treatment commencing within 9 days of the onset of symptomatic group A streptococcal pharyngitis will prevent the subsequent development of acute rheumatic fever in most cases. After the diagnosis has been confirmed by a throat culture or rapid antigen diagnostic test, the treatment of choice is penicillin, administered either as a single intramuscular injection of benzathine penicillin G (600 000 U for children who weigh less than 30 kg, or 1.2 million U for larger children and adults) or as a full 10 days of oral (phenoxymethyl) penicillin V (250 mg for children or 500 mg for adults given two to three times daily). The importance of completion of the 10-day course, even if symptoms abate quickly, should be stressed to patients and parents. Shorter courses of oral penicillin treatment are associated with higher risks of acute rheumatic fever. There has never been a clinical isolate of group A streptococcus that is resistant to penicillin; therefore, the use of other antibiotics for primary prophylaxis should be restricted to patients who are allergic to penicillin.

In the case of penicillin allergy, a 10-day course of an oral macrolide such as erythromycin is recommended. First-generation oral cephalosporins also may be considered. However, these agents have not been evaluated in populations with high incidences of acute rheumatic fever. Shorter courses (e.g. 5 days) of some later-generation oral cephalosporins appear to be effective in eradicating carriage, but because of their expense and broader spectrum of antimicrobial activity they should be considered as second-line agents.

It is not possible to predict which episodes of group A streptococcal pharyngitis will precipitate acute rheumatic fever, so this treatment must be offered in all cases to be effective. Unlike prevention of recurrent episodes, which is virtually complete using secondary prophylaxis, penicillin treatment of streptococcal pharyngitis will prevent only the one-third or so of cases of acute rheumatic fever that follow a sore throat. However, this important intervention may arrest the spread of pathogenic group A streptococci in the community. Penicillin treatment of group A streptococcal pharyngitis should begin as early as possible in patients with a history of acute rheumatic fever, should they not be taking secondary prophylaxis, but even then may not prevent a recurrence, hence the need for secondary prophylaxis.

In recent years the use of primary prophylaxis has been questioned in some industrialized countries where acute rheumatic fever is now rare. It is argued that the strategy prevents few cases of acute rheumatic fever but contributes to overuse of antibiotics. Similar arguments were raised in the United States during the 1970s, but faded somewhat with the resurgence of acute rheumatic fever in that country during the 1980s. Any country considering abandoning primary prophylaxis should

first have in place effective surveillance to detect changes in the epidemiology of primary group A streptococcal infections and the appearance of cases of acute rheumatic fever.

Primary prophylaxis is unsuccessful in many developing countries. It requires trained health workers, microbiology laboratories, transportation and communication infrastructure, the availability of penicillin, and a population likely to seek and adhere to treatment for sore throats. In some high-risk populations, all patients with sore throats receive intramuscular benzathine penicillin G without further attempts at diagnosis; the cost-effectiveness of this strategy has not been fully determined. Clinical algorithms to identify patients with group A streptococcal pharyngitis without resorting to laboratory tests have not been validated sufficiently for them to be recommended universally. Even if primary prophylaxis were to be instituted effectively in developing countries, acute rheumatic fever would not disappear, as most cases do not follow a sore throat.

Other methods of primary prevention are clearly needed in developing countries. Improved living standards and access to primary health care appear years or decades away in many places. Although streptococcal skin infections may be linked to acute rheumatic fever pathogenesis, there are no trials of impetigo control programmes to prevent acute rheumatic fever. There is a current focus on attempts to develop a group A streptococcal vaccine. Clinical trials of prospective vaccines are imminent, but the process will take many years, and recent experience suggests that new vaccines are often beyond the financial reach of most developing countries. For the foreseeable future at least, acute rheumatic fever prevention in many developing countries will depend on improving adherence to secondary prophylaxis and developing new strategies for primary prophylaxis.

15.10.2 Infective endocarditis

W. Littler and S. J. Eykyn

Historical background

Lazerous Riverius recorded the first case of what is now known as infective endocarditis in 1723. He described a French magistrate with an irregular pulse, oedema, and congestion, who at autopsy had fleshy masses 'the size of hazelnuts' obstructing the aortic ostia. Fifty years later Morgani (1769) made the link between infection (fulminating gonorrhoea) and 'whitish polypus concretions on the upper part of the aortic valve near its borders'.

The clinical picture of endocarditis was first described by Jean Baptiste Bouillard in 1835: 'fever, an irregular pulse, cardiomegaly (by percussion) and a bellows murmur in the heart'. He gave the disease the name 'endocarditis' or an inflammation of the inner membrane of the heart and fibrous tissues of the valve and was the first to use the term 'vegetations' for the valvular lesions.

Winge used the term 'mycoses endocardi' for the groups of micro-organisms that he saw when he examined vegetations under the microscope in 1870. In 1886 Wyssecokowitch cultured *Staphylococcus aureus* from an endocardial vegetation. Lenthartz in 1901 was the first to use blood cultures in the diagnosis of endocarditis. 'Infective endocarditis' was the term used by Thomas Horder in 1901 to describe the syndrome consisting of (i) the presence of valvular disease, (ii) the occurrence of systemic embolism, and (iii) the discovery of micro-organisms in the bloodstream.

Epidemiology

Infective endocarditis was universally fatal before the advent of antibiotic therapy. Since 1944 deaths from endocarditis have fallen by 80 per cent: about 200 deaths are recorded each year in the United Kingdom, which is probably an underestimate. The true incidence of the condition is unknown, but it is at least 25 cases per 1 000 000 of population. The incidence is greater in men, in those over 65 years of age, and in those with prosthetic heart valves. About 20 per cent of patients with infective endocarditis die and they account for about 0.1 per cent of the total deaths from diseases of the circulatory system (ICD codes 390–429).

Endocarditis does occur in children but is rare, especially in the first decade of life. In the older literature tetralogy of Fallot was the commonest cardiac problem associated with infective endocarditis, but nowadays cardiac surgery is the most likely predisposing cause.

Pathogenesis

Normal vascular endothelium is resistant to microbial infection and very few patients potentially at risk actually develop infective endocarditis. Since low-grade bacteraemia occurs frequently in everyone, a defence mechanism must exist that can eradicate microbes adherent to vegetations. Platelets play a pivotal role in the antimicrobial host defence mechanism and human platelets have been found to contain at least 10 different bactericidal proteins or 'thrombocidins'.

Damage to the endothelial surface of the heart or blood vessels induces platelet and fibrin deposition, producing a sterile thrombotic vegetation; infective endocarditis is initiated by the binding of microbes, discharged into the general circulation from a peripheral site, to these vegetations. These microbes become encased in further depositions of platelets and fibrin and multiply.

The pathogenesis of infective endocarditis involves complex interactions between microbes and the host defence mechanisms, both circulating and at the site of endothelial damage. An essential step is the activation of the clotting system and the formation of a fibrin clot on the endothelial surface. Experimental evidence suggests that the main pathogens in infective endocarditis (streptococci and staphylococci) can bind to endothelial cells and induce functional changes within these cells, causing monocyte adhesion. The combination of damaged endothelial cells, bacteria, and endothelial-bound monocytes results in the induction of tissue factor-dependent procoagulant activity which initiates clot formation. Polymorphonuclear leucocytes that are recruited to the infected endothelial site subsequently may be involved in the disease progression: probably the contents of lysosomes released by the activated leucocytes cause softening and separation of valve tissue leading to its destruction.

In endocarditis the vegetations are found predominately on the left side of the heart (95 per cent). In a large autopsy series of more than 1000 cases reported over 50 years ago the mitral valve was involved in 86 per cent, the aortic in 55 per cent, the tricuspid in 20 per cent, and the pulmonary valve in only 1 per cent. The predominance of left-sided lesions led to the belief that the higher pressures and velocities encountered in the left side of the heart and the proximal aorta must impose a greater mechanical stress on the valves and endocardium, which in turn leads to local damage.

Endocarditis is classically associated with 'jet lesions', where blood flowing from a high pressure area through an orifice to an area of lower pressure produces a high velocity jet. Vegetations are usually found in the lower pressure area, for example on the atrial surface of the mitral valve in mitral regurgitation, or the ventricular surface of the aortic valve in aortic regurgitation. This particular deposition of vegetations has been explained on the basis of the Venturi effect.

Once a vegetation is established it determines the subsequent clinical picture by four basic processes: bacteraemia, local tissue destruction, embolization, and the formation of circulating immune complexes.

Clinical features

Early reports of infective endocarditis described a low-grade febrile illness caused by viridans streptococci from the patient's mouth in those with chronic rheumatic heart disease. Night sweats, anorexia, and weight loss were followed by the development of splinter haemorrhages and Osler nodes, finger clubbing, and splenomegaly. The infection progressed relentlessly with increasing cachexia and the patient died from cardiac failure or a major embolic episode. The term 'subacute bacterial endocarditis' was used to describe this illness. 'Acute or malignant endocarditis' described an aggressive form of the disease usually caused by *S. aureus*, or other virulent bacteria.

During the past 50 years there has been a striking change in the pattern of endocarditis. The dramatic decrease in rheumatic fever in developed countries, the use of antibiotics, and the emergence of antibiotic-resistant organisms, together with surgical advances have all contributed to many clinical variants and modes of presentation.

The proportion of patients in developed countries with endocarditis with no known pre-existing cardiac lesion has risen to over 50 per cent. This change is related to both the decline in rheumatic heart disease and to the increase in extracardiac predisposing factors including intravenous narcotic abuse, haemodialysis, and the use of intravascular devices. Prosthetic heart valves are an important predisposing factor and cardiac surgery for complex congenital lesions has increased the lifespan of patients who would previously have died prematurely. The longevity of the populations in developed countries has resulted in an increasing age of patients with infective endocarditis. The mean age has risen from under 40 years before 1940 to between 60 and 70 years today.

Features of a bacteraemic illness

Discharge of the infecting agent into the circulation produces constant bacteraemia, which may present as pyrexia, rigors, malaise, anorexia, headache, confusion, arthralgia, and anaemia. However, some cases of endocarditis may present without fever, particularly in the elderly.

Features of tissue destruction

Endocarditis initially affects valve cusps, leaflets, or chordae tendineae. Tissue destruction results in valvular incompetence, cusp perforation, or rupture of the chordae producing an appropriate cardiac murmur that may change in character during the course of the illness. Large vegetations rarely obstruct a native valve, but mechanical obstruction of prosthetic valves is more common and clinically more difficult to detect. As the infective process progresses it may extend beyond the valve into the paravalvular structures. This is more common in native aortic valve endocarditis than in mitral valve infection. Aortic root abscess is a serious complication and a destructive lesion. When the abscess extends through the aortic wall into other tissues or cavities a fistula may be formed or pseudo-aneurysms produced. Involvement of the conducting tissue leads to heart block. Infection of a mechanical valve involves the sewing ring and may lead to valve dehiscence. Endocarditis involving an aortic mechanical valve is often localized to the junction between the sewing ring of the aortic valve and the aortic annulus: a large false aneurysm may develop in this area.

Features of systemic or pulmonary emboli

Fragments of an infected vegetation may be dislodged into the general or pulmonary circulation, depending on the site of the vegetation, producing the emboli that are reported in 20 to 40 per cent of cases; a higher incidence (50 per cent) has been reported in autopsy series. Emboli may lodge in any part of the circulation and present as a cerebrovascular accident, arterial occlusion of a limb, myocardial infarction, sudden unilateral blindness, or infarction of the spleen or a kidney. In right-heart endocarditis, recurrent septic pulmonary emboli may be misinterpreted as 'pneumonia'. Mycotic aneurysms arise from embolism of the vasa vasorum weakening the arterial wall: they have been reported in almost 3 per cent of clinical cases, but are found in up to 15 per cent of cases at autopsy. In the cerebral circulation such aneurysms may produce subarachnoid haemorrhage. The popliteal artery is a common site for mycotic aneurysms.

Emboli are characteristic of *S. aureus* infections and large emboli are a feature in HACEK (see below) and fungal endocarditis. Emboli usually occur before or within the first few days after starting antimicrobial therapy. The risk of emboli decreases with time during appropriate antimicrobial treatment. There is no significant difference between mitral valve and aortic valve vegetations with respect to embolization. Vegetation size does not predict systemic embolization, but large vegetations (greater than 10 mm) are associated with a poor outcome overall.

Features of circulating immune complexes

The infected vegetation contains antigens that trigger an immune response. The length of the illness seems to determine the extent of this response; chronic antigenaemia stimulates generalized hypergammaglobulinaemia, so that after several weeks of infection a variety of autoantibodies can be detected. Immune complex deposition may cause many of the extracardiac manifestations of infective endocarditis, but these classic signs are relatively uncommon and are often absent in individual patients.

Splinter haemorrhages

These are found in the nail bed of the fingers, less commonly the toes, and are linear in form (Fig. 1 and Plate 1).

Fig. 1 Splinter haemorrhages in a case of infective endocarditis. (See also Plate 1.)

Osler nodes

These transient painful erythematous nodules are found at the ends of fingers and toes and the thenar and hypothenar eminences. An alternative explanation is that Osler nodes are due to minute infected emboli.

Janeway lesions

These irregular painless erythematous macules are found in roughly the same distribution as Osler nodes. They tend to blanche with pressure.

Vasculitic rash

Immunoglobulin and complement deposits are found in the walls of skin capillaries (Fig. 2 and Plate 2). Vasculitis may account for some of the neurological findings in

infective endocarditis.

Fig. 2 Vasculitic rash on lower limb of a patient with infective endocarditis. (See also Plate 2.)

Roth spots

Boat-shaped haemorrhages in the retina are often called Roth spots, but true Roth spots are white retinal exudates that may be surrounded by haemorrhage. They consist of perivascular collections of lymphocytes.

Splenomegaly

Clinical splenomegaly is now less common than reported in the earlier literature. CT scanning of the abdomen shows the spleen to be enlarged in at least 50 per cent of cases and often demonstrates splenic infarcts.

Nephritis

Immune complexes can cause glomerulonephritis, with immunofluoresence demonstrating deposition of immunoglobulins and complement in irregular granular deposits in the glomerular basement membrane and mesangium. Proteinuria, haematuria, and cellular urinary casts may be present.

Arthralgia

The joint manifestations of infective endocarditis may result from immune complex deposition in the synovial membrane.

Other features

Up to 30 per cent of patients with endocarditis present with neurological symptoms; these are most common in staphylococcal infection, in which one-third present with the clinical features of meningitis. Headaches, confusion, and toxic psychosis can be present as well as encephalomyelitis. Cerebral embolism, which may produce a stroke as a result of cerebral infarction, is more characteristic of viridans streptococcal and enterococcal endocarditis. Mycotic aneurysms may rupture causing subarachnoid or intracerebral bleeding. Septic embolism may result in the formation of a cerebral abscess. It is not certain whether some of these neurological manifestations arise from repeated small emboli or from a vasculitic process within the cerebral circulation resulting from immune complex deposition. The cerebrospinal fluid can show an increase in white cells, but is usually sterile on culture, although very occasionally positive in staphylococcal infection.

Immune-mediated glomerulonephritis has been regarded as the typical lesion of infective endocarditis, but this assumption was based on small series pre-dating modern treatment regimens. More recent work indicates that the commonest renal histological finding is infarction, usually septic. Glomerulonephritis is usually vasculitic. Acute postinfective glomerulonephritis and membranoproliferative glomerulonephritis are less common. Circulatory compromise can cause severe renal impairment as a result of acute tubular necrosis or (very rarely) renal cortical necrosis.

Finger clubbing is one of the classic features of infective endocarditis, usually seen after 1 or 2 months of the illness. It is seldom seen now, but remains a useful sign since it rarely occurs in conditions with which infective endocarditis is confused.

Specific types of endocarditis

Prosthetic valve endocarditis

Patients with prosthetic heart valves have a small but constant risk of infective endocarditis, estimated at 0.2 to 1.4 events per 100 patient years. The incidence of prosthetic valve endocarditis is about 3 per cent in the first postoperative year, with the highest risk during the first 3 months. Prosthetic valve endocarditis is five times more common with aortic than mitral prostheses, and may involve mechanical, xenograft, and homograft valves.

Prosthetic valve endocarditis has been classified as early or late according to its temporal relationship to the time of surgery. Early prosthetic valve endocarditis accounts for 30 per cent of cases and usually occurs within 60 days of open heart surgery. It is caused either by contamination of the prosthetic valve at implantation or by perioperative bacteraemia. The commonest organisms are usually coagulase-negative staphylococci.

Late prosthetic valve endocarditis accounts for 70 per cent of cases and usually occurs 60 days or more after surgery. The pathogens are usually those seen in native valve endocarditis with a preponderance of viridans streptococci and staphylococci, but with a higher incidence of other organisms. Some patients with late prosthetic valve endocarditis will have acquired the infection at the time of surgery, but a bacteraemia is usually the principal cause.

Bacteraemia in a patient with a prosthetic valve must always be taken seriously, but it may not always be the result of endocarditis. The clinical picture of prosthetic valve endocarditis is usually fever, malaise, and weakness, but the more classic signs are usually absent. The condition is often insidious and difficult to diagnose clinically. A new murmur may appear and heart failure and embolic phenomena result in a high mortality (20 to 50 per cent). Infection in a mechanical valve is located in the sewing ring; the infection can spread into the host tissues producing annular abscesses, paravalvular leak, and prosthetic dehiscence. Myocardial abscesses can develop as a consequence of an annular abscess with xenograft or homograft valves. Infection usually involves the valve leaflets, resulting in destruction or perforation and consequent valvular incompetence. The infection involves the valve annulus less commonly than with a mechanical prosthesis. Vegetations may cause obstruction with all forms of prosthetic valve.

The diagnosis of prosthetic valve endocarditis requires a high index of clinical suspicion, blood cultures, and transoesophageal echocardiography. This technique is far superior to the transthoracic approach for finding vegetations and identifying periprosthetic spread of the infection. Vegetations are more difficult to identify in patients with mechanical valves than those with bioprostheses.

Right-sided endocarditis

Right-sided infective endocarditis accounts for only 5 per cent of cases overall, but centres that treat large numbers of intravenous drug users will have a higher incidence. The clinical picture differs significantly from left-sided disease. It is usually associated with intravenous drug addiction or indwelling intravascular devices, and in the former is found particularly in a younger population. *S. aureus* is the commonest pathogen and the tricuspid valve is more commonly affected that the pulmonary. Fever is almost always present and a cardiac murmur is found in 80 per cent of cases. Right-sided endocarditis is associated with septic pulmonary emboli, and the resultant pulmonary infarcts may cavitate. Symptoms include cough, haemoptysis, and pleuritic chest pain, while a chest radiograph shows pulmonary

infiltrates often misdiagnosed as 'patches of pneumonia' (Fig. 3). Renal involvement has been described in over half the cases; most commonly abscess formation or diffuse pyelonephritis. Myocarditis is more common in right-sided involvement than left. Peripheral stigmas of infective endocarditis, splenomegaly, and central nervous system involvement are rare, being described in 5 per cent or less of cases. Death is most commonly due to sepsis, rarely to heart failure.

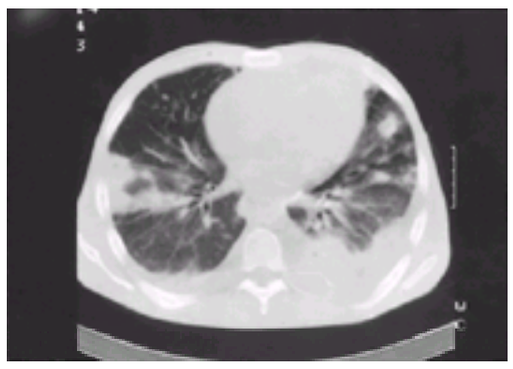

Fig. 3 CT scan of the chest showing multiple pulmonary infarcts in a case of right-sided endocarditis of the tricuspid valve in an intravenous drug user.

Endocarditis in intravenous drug users

Endocarditis is a serious complication of intravenous drug abuse. The right side of the heart is affected most commonly, but the left may also be involved in a substantial number of patients (37 per cent), and both right and left side in a minority (7 per cent). On the right side the tricuspid valve is affected in 80 per cent of cases, while the mitral and aortic valves are equally infected in left-sided disease. A history of previous heart disease is only found in some 25 per cent of cases. *S. aureus* is responsible for 40 per cent of all cases. Gram-negative bacilli are the next most frequent, with *Pseudomonas aeruginosa* and *Serratia marcescens* accounting for the majority of these. Candida can cause endocarditis in intravenous drug users and polymicrobial endocarditis accounts for 5 per cent of cases.

The skin is the commonest site from which pathogens enter the bloodstream via needles. Gram-negative bacilli are rarely recovered from needles or the drug itself and it has been suggested that these organisms come from tap water, sinks, or lavatory pans.

The clinical picture of drug-associated endocarditis depends on which side of the heart is affected. Right-sided disease is associated with fever, a murmur of tricuspid incompetence, and pulmonary infiltrates on the chest radiography. Left-sided disease behaves like that seen in cases not associated with intravenous drugs, with a high incidence of heart failure, arterial embolism, central nervous system involvement, and peripheral stigmas.

The overall mortality depends on when the patient presents: it is high if they present late and reflects, among other things, the difficulty in dealing with addicts because of their poor compliance and reluctance to discontinue their drug habit. The principles of management are similar to those for patients who do not abuse drugs. The duration of intravenous antibiotics should be at least 4 weeks, but it is usually impossible to do this in practice; while in right-sided endocarditis simple removal of the valve without replacement appears to be the best strategy.

The diagnosis of infective endocarditis

Laboratory diagnosis

Blood culture

This is the most important laboratory investigation in the diagnosis of endocarditis. Isolation of the pathogen enables an effective antibiotic treatment regimen to be devised. Blood cultures should be taken before antibiotics are given; if they have already been given, cultures should still be done, and if possible the giving of further antibiotics delayed for a few days. However, previous antibiotics may render the blood sterile for some time and the chances of recovering the pathogen, particularly when it is a viridans streptococcus, are very low. Much mystique has been attached to the number and timing of blood cultures in cases of suspected endocarditis. What is known is that the bacteraemia is usually constant and that whenever the blood is obtained for culture, and however many sets are taken, in most cases all bottles will grow the pathogen. There are of course rare exceptions when only a small proportion of bottles cultured are positive, and this is one reason why it is conventional to take two or three sets. Another reason for several cultures is to assess the relevance of the common skin contaminants, particularly the coagulase-negative staphylococci but also *Corynebacterium* spp., which can cause endocarditis.

In most laboratories blood culture systems are automated, with continuous monitoring which flags up growth for further investigation. Most cultures become positive within 48 h and after this the chances of isolating the pathogen recede, with the exception of fastidious organisms of the HACEK group (see below) that may take much longer to recover from the blood. In most laboratories blood cultures are incubated for 5 to 7 days, but this may not be long enough for the rare fastidious slow grower. The onus is on the clinical microbiologist or clinician to request prolonged incubation of blood cultures from patients in whom endocarditis is strongly suspected on clinical grounds and echocardiography who have not had previous antibiotics and whose blood cultures are sterile after a week's incubation.

Blood tests

In infective endocarditis an elevated erythrocyte sedimentation rate and C-reactive protein are almost invariable and these inflammatory markers are used most commonly to monitor the activity of the disease. A normochromic normocytic anaemia is often present and a polymorphonuclear leucocytosis is found in the majority of cases. Hypergammaglobulinaemia and a low serum complement may be present, together with a false-positive rheumatoid factor. Circulating immune complexes may be detected.

Dipstick testing of the urine may reveal the presence of proteinuria or haematuria, indicating renal involvement. When haematuria is present the pellet of a centrifuged specimen of urine should be resuspended and examined microscopically for the presence of red cell casts, which clinch the diagnosis of glomerulonephritis in this context.

Serology

Serum antibodies are used to diagnose *Coxiella burnetii* (Q fever), bartonella, and chlamydia endocarditis and should be done in any patient with convincing evidence of endocarditis and negative blood cultures. Candida antibodies are of no diagnostic value.

Echocardiography

In suspected cases of endocarditis echocardiography should be performed as soon as possible and interpreted by an experienced cardiologist. Its principal role is to detect vegetations. Echocardiography is not sufficiently sensitive to allow the clinician to exclude the diagnosis confidently on the basis of a negative result. The sensitivity depends on the size of the vegetations and the time course of the disease. Echocardiography can resolve vegetations as small as 1 to 2 mm, but it is more difficult with prosthetic than native valves, and more difficult with mechanical than biological prostheses.

Vegetations appear as thick, ragged, non-uniform echoes oscillating on or around a cardiac valve or in the path of a regurgitant jet. They do not usually restrict leaflet mobility and exhibit valve-dependent motion. On native valves vegetations are usually attached to the ventricular side of the aortic valve and the atrial side of the mitral and tricuspid valves.

Two-dimensional echocardiography should be employed initially in all cases of suspected endocarditis (Fig. 4). Transoesophageal echocardiography has improved

the rate of diagnosis of infective endocarditis over that of transthoracic echocardiography, particularly in the presence of a prosthetic valve. Transoesophageal echocardiography has made it easier to recognize many complications of prosthetic valve endocarditis, such as abscesses, fistulas, and paravalvular leak (Fig. 5). In addition to vegetations, echocardiography may demonstrate indirect signs of valvular integrity, such as excessive systolic expansion of the left atrium in mitral incompetence or fluttering of the anterior leaflet of the mitral valve in aortic incompetence. Ventricular size and contractility are both easily assessed. The diagnosis of right-sided endocarditis has been greatly facilitated by echocardiography, particularly transoesophageal echocardiography. Vegetations, which in general tend to be larger on the right side, can be demonstrated in 80 to 100 per cent of cases.

Fig. 4 Two-dimensional echocardiogram showing a large vegetation involving the posterior leaflet of the mitral valve and prolapsing into the left ventricle. LA, left atrium; LV, left ventricle.

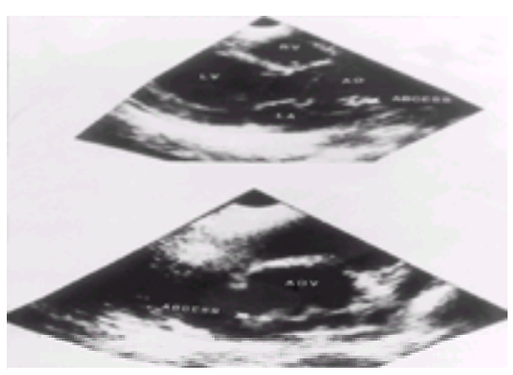

Fig. 5 Transoesophageal echocardiogram showing a large abscess communicating with aortic root. RV, right ventricle; LV, left ventricle; LA, left atrium; AO, aorta; AOV, aortic valve.

Vegetations need to be differentiated from other conditions that produce echo density on cardiac valves, including calcification, myxomatous degeneration, and atrial myxoma. Echocardiography does not provide direct information on blood flow, but Doppler echocardiography complements the technique and adds significantly to the diagnosis of valvular function. It is able to diagnose valvular regurgitation with great accuracy.

Criteria for the diagnosis of infective endocarditis

In 1994 Durack and his colleagues introduced criteria for the diagnosis of infective endocarditis that have been accepted as 'the Duke Criteria' (Table 1). These include two major criteria (typical blood culture and positive echocardiogram) and six minor criteria (predisposition, fever, vascular phenomena, immunological phenomena, suggestive echocardiogram, and suggestive microbiological findings). Application of these criteria is used to define three diagnostic categories: definite, possible, or rejected cases of infective endocarditis.

Modifications of the Duke Criteria to increase their sensitivity have been suggested by others. These include the following additional minor criteria: the presence of newly diagnosed clubbing, splenomegaly, splinter haemorrhages and petechias, a high erythrocyte sedimentation rate or a high C- reactive protein, and the presence of central non-feeding lines, peripheral lines, and microscopic haematuria.

Microbiology

While almost any micro-organism can cause infective endocarditis, particularly when this involves a prosthetic valve, certain species do so much more commonly than others and the predominant species involved in the infection have not changed significantly in their incidence in the past three decades. Overall, viridans streptococci and staphylococci account for about two-thirds of all cases. However, endocarditis cannot be considered as a microbiologically homogeneous entity as the incidence of any specific organism depends: (i) on the patient—whether an intravenous drug user or not; (ii) on the valve—whether native or prosthetic; if native whether previously abnormal or not, and if prosthetic whether mechanical or a bioprosthesis, and whether the infection was acquired early or late; and (iii) where (and how) the infection was acquired—whether in the community or (and increasingly these days) in hospital, usually via an infected intravascular device. The more common species encountered will be considered individually.

Streptococci

The genus *Streptococcus* includes species of differing virulence and pathogenicity as well as differing normal habitat in man. It has undergone numerous taxonomic revisions over the past decade or more and the previous dependence on haemolytic activity on blood agar and serological reactions has been superseded in many cases by molecular and chemotaxonomic approaches. Examples of such taxonomic change include the assignment of the faecal streptococci to the genus *Enterococcus*, of *Streptococcus morbillorum* to *Gemella morbillorum*, and of the nutritionally dependent streptococci previously known as *Streptococcus adjacens* and *Streptococcus defectivus* to the genus *Abiotrophia.* There are many other examples, but taxonomic change is of limited interest to clinicians and has no bearing on the management of infection.

Viridans streptococci

For many years it has been conventional to refer to a group of streptococci that produce greening (a-haemolysis) on blood agar as viridans streptococci, indeed many still refer (inaccurately) to a microbe 'Streptococcus viridans'. While most of these streptococci are virtually specific to the normal oropharyngeal flora and are rarely encountered at other sites, some are not found in the oropharynx at all, for example *S. bovis*, and others are found at many sites including the oropharynx, for example the milleri group of streptococci. The viridans streptococci are the commonest cause of community-acquired native valve endocarditis and community-acquired late-onset prosthetic endocarditis. The commonest species of the viridans streptococci that are specific to the oropharynx are *S. sanguis*, *S. oralis*, and *S. mutans*, but there are others. Dextran formation may be a virulence factor in these streptococci. Contrary to popular belief they do not require a dental extraction to enter the bloodstream and cause frequent bacteraemias after chewing, tooth brushing, and so on. They are organisms of low virulence and thus usually only infect previously abnormal heart valves. Whereas *S. oralis* and *S. sanguis* are occasionally isolated from blood cultures of patients who do not have endocarditis, the isolation of *S. mutans* from the blood is virtually synonymous with endocarditis.

Streptococcus bovis

This streptococcus, which may appear 'viridans' on blood agar, is part of the normal intestinal flora but may initially be mistaken for an oral streptococcus. In common

with the enterococci it bears the Lancefield group D antigen and thus can also be mistaken for *Enterococcus faecalis*, though it is sensitive to penicillin whereas the latter is resistant. There is a significant association between *S. bovis* bacteraemia (and hence endocarditis) and colonic pathology, and any patient with *S. bovis* endocarditis thus warrants ppropriate investigation for this. *S. bovis* endocarditis is much less common than that caused by oral streptococci.

Pyogenic streptococci

These organisms, often referred to as b-haemolytic streptococci, cause endocarditis less frequently than the viridans streptococci, but are more aggressive microbes and are likely to affect (and often rapidly destroy) a previously normal valve. The commonest pyogenic streptococcus to cause endocarditis is the Lancefield group B b-haemolytic streptococcus (**GBS**) sometimes referred to as *S. agalactiae*. This organism is found as normal flora in the genital and gastrointestinal tracts. As with *S. aureus*, any patient with community-acquired GBS bacteraemia should be assumed to have infection in bone, joint, or on a heart valve until proved otherwise. Groups C and G b-haemolytic streptococci occasionally cause endocarditis and group A even more rarely. The milleri group of streptococci are best regarded as pyogenic streptococci. These streptococci form part of the normal flora of all mucous membranes and occasionally cause endocarditis, though much more often abscesses at many different sites. The milleri group consists of three species, *S. constellatus*, *S. intermedius*, and *S. anginosus*. Interestingly these streptococci can bear the Lancefield antigens A, C, G, or F (or none); all group F streptococci are milleri but not all milleri are group F.

Streptococcus pneumoniae (pneumococcus)

Pneumococcal endocarditis accounted for about 10 per cent of cases of endocarditis in the preantibiotic era, but is now rarely seen, although it is sometimes diagnosed at autopsy of patients with fatal pneumococcal infection. The pneumococcus is a virulent pathogen and attacks normal heart valves. Patients with endocarditis generally have pneumonia and sometimes meningitis, the organism originating in the upper respiratory tract.

Enterococci

Enterococci form part of the normal gastrointestinal flora. They are more virulent than viridans streptococci and more resistant to antibiotics. The past decade has seen an increase in enterococcal endocarditis, particularly in the elderly, but this infection is still much less common than that caused by viridans streptococci. While there are many species of enterococci, those causing endocarditis are usually *E. faecalis* and occasionally *E. faecium*. Most cases are community acquired but the infection can be acquired in hospital, sometimes as a result of urological instrumentation. Any patient admitted from the community with *E. faecalis* in the blood should be investigated for endocarditis.

Staphylococci

Staphylococci now account for about a third of cases of community-acquired endocarditis and are the commonest cause of hospital-acquired endocarditis. Most of these staphylococci are *S. aureus*, but an increasing proportion is now due to coagulase-negative staphylococci. All staphylococci are skin organisms and patients become infected from their own skin flora, or in the case of methicillin-resistant *S. aureus* (**MRSA**) from that of others by cross-infection.

Staphylococcus aureus

S. aureus is an important and aggressive pathogen in community-acquired native valve endocarditis. Sometimes a trivial skin lesion can be identified as the source of the organism, but there is often no obvious lesion. *S. aureus*, and increasingly now MRSA, is the commonest cause of hospital-acquired endocarditis. Prosthetic valves can become infected with *S. aureus* both early as result of sternal wound sepsis and late as with native valves. *S. aureus* is the commonest pathogen causing endocarditis in intravenous drug users.

Coagulase-negative staphylococci

Although still regarded by many as pathogens of prosthetic rather than native valves, coagulase-negative staphylococci also cause native valve infection and this has become more common, or certainly more commonly recognized, in the last two decades. The infecting species is most often *S. epidermidis* (*sensu stricto*) but in many reports the designation *S. epidermidis* tends to be used for any unspeciated coagulase-negative staphylococcus. Many other species have been reported in native valve endocarditis including *S. lugdunensis*, *S. simulans*, *S. warneri*, *S. capitis*, *S. caprae*, and *S. sciuri*. Coagulase-negative staphylococci are normal skin flora and different species vary in their distribution throughout the body. As in community-acquired *S. aureus* endocarditis, there is sometimes a presumptive predisposing skin lesion. Most patients have a pre-existing cardiac abnormality. Many of these staphylococci can be as virulent as *S. aureus* and actually share some of the same virulence factors.

Other organisms

A wide variety of organisms account for the small percentage of cases of endocarditis that are not caused by streptococci, staphylococci, or enterococci. Only a few warrant a specific mention here.

HACEK group

These are fastidious slow-growing species that are oropharyngeal commensals and have a predilection for heart valves, such that their presence in blood cultures is virtually synonymous with this infection. The group consists of *Haemophilus aphrophilus/paraphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*. *A. actinomycetmecomitans* in particular seems more likely to infect prosthetic than native valves. The large vegetations thought to be characteristic of HACEK organisms in native valve infection may be the result of diagnostic delay and prolonged illness rather than any inherent property of the microbes *per se*.

Organisms that cannot be cultured by routine techniques

Endocarditis is a rare (and late) sequel of acute *Coxiella burnetii* (Q fever) infection. Most infections occur in middle-aged men with pre-existing valve disease. The reservoir of the organism is usually sheep or cattle, but the source and mode of transmission in many human cases is unknown. The diagnosis is usually made serologically, although *C. burnetii* can be recovered from the blood and excised valves by special techniques. The disease is almost certainly underdiagnosed and some cases are labelled 'culture negative' endocarditis.

Bartonella quintana endocarditis was first recognized in 1995 in homeless alcoholic patients; *Bartonella henselae* infection may be associated with cat or cat flea contact and other species of bartonella have also been described causing endocarditis. Bartonella infection is usually diagnosed by serology, although these bacteria can also be recovered from the blood and excised valves by special culture techniques and their presence detected by polymerase chain reaction (PCR). False-positive serology for *Chlamydia* spp. has been reported with bartonella infections, but *Chlamydia* spp.—and particularly *C. psittaci*—can also cause endocarditis (very rarely); it is possible that some cases attributed to chlamydia in the past on the basis of serology may have been caused by bartonella.

Fungi

Fungal endocarditis is very rare and more likely to occur on prosthetic than native valves, except in intravenous drug users. Most infections are acquired in hospital, when infection at intravascular access sites and broad-spectrum antibiotics predispose to candida infections. *Candida* spp., usually *C. albicans*, are the commonest fungi, but *Aspergillus* spp. and more exotic genera have also been reported. Blood cultures are only likely to be positive with *Candida* spp., and then often only intermittently; for other fungi the diagnosis must be made by serology and culture of the fungus from the excised valve or detection on valve histology.

Blood culture negative endocarditis

The possibility that the illness is not endocarditis should always be entertained when blood cultures are repeatedly negative. However, in 5 to 10 per cent of definite cases of endocarditis the blood cultures will be negative. The commonest explanation for this is previous antibiotics. In a few cases the pathogen will be recovered from another site, including the excised valve, excised emboli, or specifically in right-sided endocarditis, respiratory specimens. Other causes of negative blood

cultures are infection with organisms that cannot be grown by conventional blood culture methods and infections that are diagnosed by serology such as *C. burnetii*, *Bartonella* spp., and *Chlamydia* spp.

Treatment

Initial therapy

In those patients who have been chronically unwell for many weeks, antibiotic treatment can be deferred until the blood cultures are positive and the pathogen known. In patients who are acutely ill, antibiotic treatment should be started after taking blood cultures, using a broad-spectrum combination that can be adjusted when the pathogen is known. However, in many who are acutely ill with native valve infection, endocarditis is often not suspected initially—there may be no obvious signs of this—and the antibiotics are started for 'septicaemia'. There are many possible combinations for acutely ill patients, but intravenous vancomycin and gentamicin will encompass most possible pathogens. When methicillin-resistant staphylococci (whether *S. aureus* or coagulase-negative staphylococci) are likely pathogens, vancomycin or teicoplanin are an essential component of any combination.

Definitive therapy

There are various national guidelines for the treatment of specific organisms. It is important to realize that very few are based on clinical trials that show efficacy of any particular regimen. It is possible to conduct such trials in endocarditis caused by viridans streptococci, but well nigh impossible in cases caused by virulent organisms such as staphylococci as the patients are seldom comparable, with many needing surgery after varying periods of antibiotic treatment. It is conventional to estimate the minimum inhibitory concentration (**MIC**) of the antibiotic for the pathogen, though in practice routine disc sensitivity tests are quite satisfactory in many cases. Although it is widely believed that prosthetic endocarditis requires a longer duration of antibiotic treatment than native valve infection, there are few data to support this. Recommendations for the commonest causative organisms will be given.

Penicillin-sensitive streptococci (MIC < 0.1 mg/l)

It was shown 30 years ago that native valve endocarditis caused by sensitive streptococci could be treated effectively with 2 weeks of intravenous penicillin and an aminoglycoside (originally streptomycin but now gentamicin). The purpose of the aminoglycoside is to achieve synergy, so a full therapeutic dose is not given. This regimen is seldom used in practice in the United Kingdom. Patients allergic to penicillins should be given vancomycin or teicoplanin and gentamicin.

Streptococci with reduced sensitivity to penicillin (MIC > 0.1 mg/l)

The regimens given above should be continued for 4 weeks

Enterococci

Enterococci are rather more sensitive to amoxicillin and ampicillin than penicillin and thus these agents are recommended rather than penicillin. Many enterococci are still relatively sensitive to gentamicin and this drug is given with amoxicillin (for synergy, not a full therapeutic dose) for 4 weeks. Patients allergic to penicillin should be given vancomycin and gentamicin. Some enterococci are now resistant to high levels of gentamicin and for such strains gentamicin should not be given. Some gentamicin-resistant strains are sensitive to streptomycin and, if so, this can be used instead of gentamicin. If not, high-dose amoxicillin should be given for 4 to 6 weeks. Unfortunately some enterococci (usually *E. faecium*) are resistant to amoxicillin, gentamicin, and vancomycin and for them expert help should be obtained.

Staphylococci

The same antibiotic regimens should be used whether the staphylococcus is *S. aureus* or a coagulase-negative strain—it is the antibiotic sensitivity that matters not the infecting species. Strains that are sensitive to penicillin should be treated with this, those that are penicillin resistant but methicillin sensitive should be treated with flucloxacillin, and methicillin-resistant strains with vancomycin. There is no evidence that the addition of gentamicin (for gentamicin-sensitive strains) to the b-lactam antibiotic improves cure rates, but it may result in more rapid defervescence and clearance of bacteraemia.

Practical treatment recommendations are shown in Table 2 and Table 3.

Monitoring of treatment

Serum bactericidal titres against the infecting organism are no longer recommended. There was always great variation in the monitoring methods used for these tests and in the interpretation of their results. At best they could only predict bacteriological not clinical cure and bacteriological failure is very rare. The most useful laboratory test for monitoring the response to treatment (which is usually obvious clinically) is serial C-reactive protein estimation. This is of much more use than the erythrocyte sedimentation rate, which is much slower to fall.

Prevention and prophylaxis

While antibiotic prophylaxis in 'at-risk patients' is accepted as reasonable, there are many uncertainties about its value and data confirming its effectiveness are lacking. The rationale for antibiotic prophylaxis depends on indirect data from *in vitro* studies, experimental animal models, and clinical bacteraemia studies. Despite this uncertainty, all authorities continue to recommend antibiotic prophylaxis to cover certain procedures associated with a predictable and significant bacteraemia in patients known to be at risk, but accept that prophylaxis may fail, even with the recommended regimens, and that adverse reactions to the antibiotics are important even if relatively uncommon.

An international consensus group has recently undertaken a comparative analysis of the published national guidelines, which in the main are quite similar, though the antibiotic regimen for a given procedure may vary according to the perceived cardiac risk. Controversial areas include fibreoptic bronchoscopy, colonoscopy, vaginal hysterectomy, and vaginal delivery. Based on their analysis the consensus group have proposed universal guidelines for cardiac (Table 4 and Table 5) and procedural (Table 6) risks. Prophylactic regimen are shown in Table 7.

Surgical treatment of infective endocarditis

Surgery will be required in about 30 per cent of cases during the acute phase (first 4 months) of endocarditis and 20 to 40 per cent of cases thereafter (Fig. 6 and Plate 3). Since surgery may be required at any time during an episode of endocarditis, it is essential to involve a cardiac surgeon in the overall management from the outset: in practical terms this means transferring the patient to a centre with cardiac surgery wherever possible. Even so, surgery for endocarditis carries a risk of 10 to 25 per cent mortality, and up to 25 per cent of patients develop a paravalvular leak requiring a further operation. The main predictive factors for mortality associated with surgery are prosthetic valve endocarditis, infections due to staphylococci or candida, perioperative shock, or late referral. The timing of surgery is all important and demands experience and clinical judgement, which is best achieved by a team approach with cardiologists, cardiac surgeons, and microbiologists.

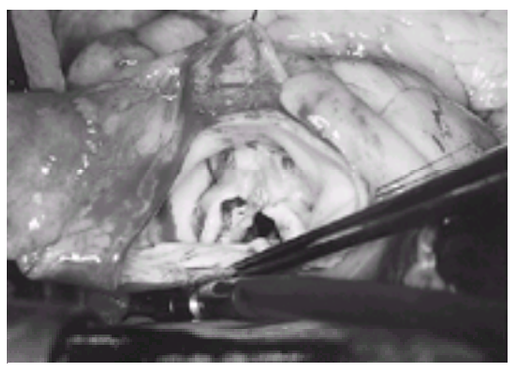

Fig. 6 A large vegetation on the aortic valve of a patient with infective endocarditis as seen at the time of surgery. (See also Plate 3.)

The main indications for surgery are haemodynamic instability and persistent infection. In such cases surgery should never be delayed, even if only hours or days of antibiotic treatment have been given. The primary goals of the surgeon are to remove all infected material and to reconstruct the heart and/or restore valvular function at the lowest operative risk. An understanding of the surgical anatomy of infective endocarditis is a precondition for surgical success, which means the involvement of an experienced surgical team. Wherever possible surgeons now strive to preserve the native valve, either by removal of the vegetation(s) or valve repair. In prosthetic valve endocarditis removal of all foreign material is mandatory.

There are two unresolved issues with regard to the surgical treatment of endocarditis. The first concerns the timing of surgery in patients who have had a cerebrovascular accident either as a result of an embolic stroke or from haemorrhage due to a ruptured mycotic aneurysm. As a general rule, if haemorrhage is detected by CT scanning, delay of at least 1 week is suggested; if there is no haemorrhage, surgery can be undertaken within 72 h.

The second issue concerns the duration of antibiotic treatment postoperatively. If the excised valve is sterile it is doubtful whether further antibiotics are of any benefit. If the pathogen is isolated from the excised valve, antibiotics should be given for a further 2 weeks. If debridement is incomplete, whatever antibiotics are given may fail.

15.10.3 Cardiovascular syphilis

B. Gribbin and I. Byren

Introduction

Cardiovascular syphilis is a feature of tertiary syphilis and no longer a prominent cause of heart disease: even in specialized cardiac units it is now a rarity. Left untreated, about 12 per cent of patients with syphilis will eventually develop cardiovascular complications. Although gummas can occur in the pericardium, myocardium, and endocardium, and have been the cause of Stokes–Adams attacks when present in the atrioventricular node or the bundle of His, the characteristic lesion is an aortitis. This follows spirochaetal infection of the aortic wall, leading to an endarteritis and periarteritis of the aortic vasa vasorum, initially in the adventitia and subsequently in the media. Lymphocytes and plasma cells surround these small feeding vessels and obliterative changes result in the loss of medial smooth muscle and elastic fibres, occasionally with frank necrosis and eventually with fibrous tissue replacement. This causes scarring of the aortic wall and weakening of its structure. Macroscopically the intima becomes thickened in a gelatinous patchy fashion and fibrosis produces an irregular linear thickening that has been termed the tree-bark appearance. Intimal scarring may involve the ostia of the coronary arteries, which are susceptible to further narrowing by accelerated and superimposed atheroma.

The ascending aorta is involved in about half of all cases, the arch is next in frequency, and the descending aorta in only 10 per cent, with changes virtually limited to that part of the vessel lying above the renal arteries. As the aortic wall structure weakens, so dilatation occurs, resulting in aneurysm formation, which in turn leads to further dilatation and the risk of rupture. The major branches of the aorta may also be affected, especially the innominate artery.

Enlargement of the aortic root and separation of the cusp commissures causes aortic reflux, and although thickening and retraction of the leading edges of the cusps also occurs, this is thought to be a secondary change due to abnormal turbulence rather than a consequence of direct syphilitic involvement of cusp tissues.

Clinical features

Because cardiovascular syphilis can take up to 40 years after primary infection to become apparent, most patients are middle aged or elderly, although tertiary syphilis has been known to occur within a year or two of primary infection. Men are more often affected. Patients with aortitis can present in four main ways: asymptomatic aortitis (most common), aneurysm formation (10 per cent), aortic reflux (25 per cent), and lastly as the result of coronary artery ostial stenosis (25 per cent). The last three are not mutually exclusive and aortic reflux plus ostial stenosis may coexist with aneurysm formation. Gummatous disease of the myocardium is extremely rare.

Aortitis in asymptomatic patients is usually diagnosed as the result of radiographic findings of a dilated ascending aorta with calcification in the wall (Fig. 1). Although aortic calcification is common, particularly in the elderly and hypertensive population, it is then virtually limited to the aortic knuckle and descending aorta. More generalized thoracic aortic calcification is sometimes seen in patients with widespread atheromatous disease, but when visible in the ascending aorta, particularly in a linear fashion, syphilitic aortitis should come to mind and supporting evidence, such as mild aortic reflux, be sought. Serology is likely to be positive.

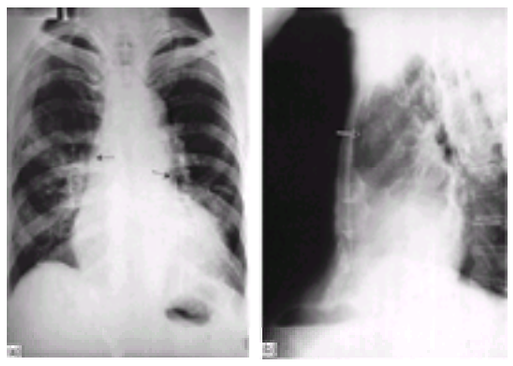

Fig. 1 Posteroanterior and lateral radiographs showing evidence of syphilitic aortitis. A line of calcification (arrowed) is visible in the wall of the dilated ascending aorta.

Syphilitic aortic aneurysms tend to be saccular rather than fusiform and occur most commonly in the ascending aorta, also in the arch, and with increasing rarity down the descending aorta. This is in contrast to atherosclerotic aneurysms, which tend to involve the distal aorta below the renal arteries. The clinical features vary depending on the site of the aneurysm, its size, and whether or not compression and even erosion of adjacent structures occurs. A large aneurysm may cause no symptoms, but pain can be a prominent feature, often sustained and boring in nature, influenced by position, and exacerbated by impending rupture. Pain due to ascending aortic aneurysms is felt in the upper chest wall to the right of the sternum, and with large aneurysms a bulge may appear at this site and erosion of ribs and even sternum may be apparent on radiographs. Aneurysms of the arch produce pain over the upper sternum and occasionally in the throat and there may be visible arterial pulsation in the root of the neck with tracheal deviation. Pressure on upper mediastinal structures can produce superior vena caval obstruction, dysphagia, stridor, and a tracheal tug in time with the pulse. Involvement of the upper descending aorta causes pain between the scapulae or to the left of the spine, and there is a risk of hoarseness from pressure on the left recurrent laryngeal nerve and complications arising from compression of the left main bronchus. Rupture can occur into the bronchus, into the left pulmonary artery, or the left pleural space, and erosion of vertebrae may result in chronic and debilitating pain.

Syphilitic aortic reflux may have a number of features to help distinguish it from the more usual varieties (see Chapter 15.7). Radiographic or clinical evidence of aneurysmal dilatation of the ascending aorta is one, and explains the fact that the early diastolic murmur may be heard better at the right, rather than the more usual left, sternal edge position. Furthermore, an ejection click may be audible, probably as a result of sudden distention of the dilated aortic root by the large stroke volume. However, these auscultatory signs are not entirely specific and may be found in patients with annuloaortic ectasia, now a more common condition, and characterized by a flask-like dilatation of the proximal ascending aorta. Even severe aortic reflux may be tolerated well for years, but eventually the volume overload of the left ventricle leads to cardiac failure: this carries a poor prognosis without, and sometimes despite, surgical intervention.

Coronary ostial stenosis is not restricted to cases of syphilitic aortitis and may occur as a variant of the more usual atheromatous coronary artery disease. It presents as angina, the true cause of which may be missed unless a thin line of calcification is noted in the ascending aorta, or there is other evidence of syphilitic disease in the cardiovascular system or elsewhere. Myocardial infarction may occur as a complication.

Diagnosis

The diagnosis of cardiovascular syphilis is usually made by detecting a positive serum antibody test in a patient who may give a history of past syphilitic infection, and who has evidence of aortitis or one of its complications. It is important to note that 10 to 25 per cent of patients with cardiovascular syphilis also have central nervous system involvement.

Non-specific antibody tests such as the Venereal Diseases Research Laboratory (**VDRL**) or rapid plasma reagin (**RPR**) may be negative in cardiovascular syphilis. If positive in high titre, they may indicate active untreated disease and can be used to gauge response to treatment. However, they have drawbacks: false positive results are not uncommon, and they are invariably positive in patients with endemic non-venereal treponematosis. Specific tests such as the fluorescent treponemal antibody absorption test (FTA-ABS) and *Treponema pallidum* haemagglutination test (TPHA) are almost always positive. They remain positive despite treatment and therefore cannot be used to assess response to treatment. Sexual and vertical transmission does not occur with cardiovascular syphilis, but nevertheless it is prudent to consider testing of known sexual partners and the children of women with cardiovascular syphilis. For more detailed information see Chapter 7.11.33.

Treatment

It is generally accepted that antibiotic treatment is indicated for patients with cardiovascular syphilis who have not received effective antibiotic treatment in the past. There is, however, no evidence that this reduces the severity of aortitis or improves prognosis. All patients with active cardiovascular syphilis should be examined for neurosyphilis and treated accordingly (see Chapter 24.14.4). If absent, treatment consists of 2.4 million IU of benzathine penicillin intramuscularly at weekly intervals for a total of three doses, alternatively 600 000 IU of procaine penicillin daily by intramuscular injection for 21 days. For patients known to be allergic to penicillin some practitioners desensitize and then use penicillin and others use doxycycline (200 mg orally, twice a day, for 28 days). There are insufficient data to unequivocally recommend the use of other drugs such as ceftriaxone and azithromycin.

Following treatment patients should be reviewed and those with positive non-treponemal tests (VDRL/RPR) should be checked serologically at 6-monthly intervals, with a declining titre used to confirm the adequacy of treatment.

There has been a concern that provocation of a Jarisch–Herxheimer reaction might lead to inflammatory swelling of the aortic wall with the risk of rupture or further critical narrowing of ostial stenoses. However, large numbers of patients with cardiovascular syphilis have been given penicillin without untoward effects, and whereas the Jarisch–Herxheimer reaction can occur rarely, it has never been shown to cause life-threatening changes in the aortic wall.

Surgery may be required to deal with the complications of aortitis. Symptoms of ischaemic heart disease caused by severe ostial stenosis have been relieved successfully by endarterectomy of the coronary orifices, although coronary bypass grafting is the usual treatment of choice. Theoretically, coronary stenting may offer another therapeutic option, although the degenerative changes apparent in the surrounding aortic wall make this seem even less attractive than when atheromatous disease is the cause. Aortic valve replacement has been carried out successfully for severe aortic reflux. Saccular and the less common fusiform aneurysms have been excised and scarred aortic tissue replaced by grafts. Indications for the latter form of surgery are based on: the need to relieve pain; to prevent rupture, the risk of which is considerable when the aneurysm reaches 6 to 7 cm in diameter; and the need to decompress adjacent organs such as the left main bronchus, pulmonary artery, or oesophagus.

15.10.4 Cardiac disease in hiv infection

N. Boon

Some form of heart disease is demonstrable at autopsy in approximately 40 per cent of patients with AIDS, and by echocardiography in approximately 25 per cent. However, many of these lesions are mild and heart disease probably causes symptoms in less than 10 per cent and death in only 1 to 2 per cent of all patients infected with HIV.

The common cardiac manifestations of HIV infection are listed in Table 1. Although, tuberculous pericarditis is a major problem in Africa (see section 15.09), heart muscle disease is the most important cardiac complication of AIDS in the Western world.

Pericardial effusion

HIV-related pericardial effusions are usually exudates and tend to occur in patients with advanced disease. The annual incidence of pericardial effusion in AIDS is approximately 10 per cent and the prevalence in all forms of HIV infection is approximately 20 per cent. The development of an HIV-related pericardial effusion is an independent risk factor for early death and when this complication occurs in AIDS the median survival is less than 6 months.

Less than 5 per cent of HIV-related pericardial effusions are associated with pericardial pain or friction rubs. Breathlessness, however, is common and approximately 10 per cent of effusions are associated with the symptoms and signs of tamponade.

Small subclinical effusions do not usually have an identifiable cause and often resolve spontaneously; they can therefore be managed conservatively. By contrast, moderate and large effusions are often symptomatic and are frequently due to specific opportunist infections or malignancy: aspiration is usually advisable. A wide variety of viral, bacterial, and fungal pericardial infections have been reported and conventional antimicrobial therapy combined with drainage procedures can produce good results in those with early disease.

Pericardial tuberculosis is a frequent complication of HIV infection and has become the commonest cause of pericardial effusion in many parts of the world, particularly sub-Saharan Africa. The clinical features vary widely but most patients present with prolonged fever, breathlessness, and pleuropericardial pain. Antituberculous chemotherapy is usually effective but it is not clear whether the benefits of corticosteroids seen in HIV-negative tuberculous pericarditis extend to patients who are HIV positive (see Chapter 15.9).

Malignant effusions are usually due to non-Hodgkin's lymphoma.

Malignant cardiac tumours

Kaposi's sarcoma, which is associated with human herpesvirus-8, is the most common cardiac tumour in HIV disease. The heart is involved in approximately 25 per cent of patients with disseminated Kaposi's sarcoma and there have been a few reports of primary cardiac disease. The tumour shows a predilection for subepicardial adipose tissue and seldom infiltrates the myocardium. Pericardial effusion is a surprisingly rare complication and the diagnosis is usually made at autopsy.

Non-Hodgkin's lymphoma can also involve the heart and is more likely to cause cardiac symptoms and signs. These tumours are usually derived from B cells and may be associated with Epstein–Barr virus or human herpesvirus-8. They are usually metastatic, although primary cardiac tumours do occur, and tend to invade the epicardium. In contrast to Kaposi's sarcoma, this tumour often causes symptomatic pericardial effusion and can also infiltrate the myocardium, provoking fatal arrhythmias including venticular fibrillation and all forms of heart block.

Heart muscle disease

HIV-related heart muscle disease tends to occur in the late stages of HIV infection and usually presents with heart failure or otherwise unexplained cardiomegaly. Left ventricular systolic dysfunction (dilated cardiomyopathy) is present in approximately 15 per cent of patients with AIDS and overt heart failure will develop in approximately 25 per cent of these patients.

The symptoms and signs of heart muscle disease include breathlessness, fatigue, tachycardia, a high jugular venous pressure, a gallop rhythm, and crepitations at the lung bases; they can be subtle and are sometimes mistakenly attributed to anaemia or chest infection. The ECG is usually abnormal, but changes are non-specific and seldom aid diagnosis; increased ventricular ectopic activity, a variety of repolarization changes, and features of left atrial hypertrophy, left ventricular hypertrophy, and left bundle branch block have all been documented. Although chest radiographs may reveal cardiomegaly and pulmonary venous congestion, the diagnosis usually depends on echocardiography, which typically shows global left ventricular dysfunction with enlargement of all the cardiac chambers.

HIV-related dilated cardiomyopathy carries an exceptionally poor prognosis with a median survival of approximately 100 days compared with 500 days for patients with similar disease and normal hearts (Fig. 1); death is often due to progressive heart failure or arrhythmia. Conventional therapy for heart failure is given, but many patients tolerate vasodilators poorly, possibly because peripheral vascular resistance tends to be low due to recurrent sepsis.

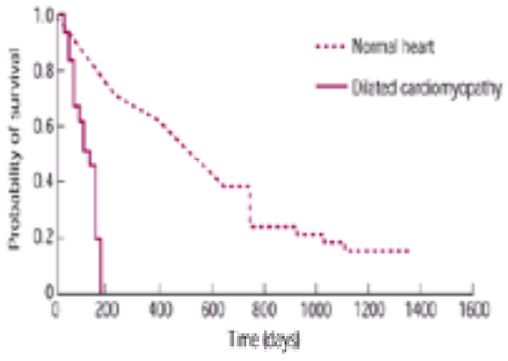

Fig. 1 Kaplan Meir survival curves for patients with HIV-related dilated cardiomyopathy and patients with structurally normal hearts and otherwise similar HIV disease (CD4 count < 20 × 10^6 cells per litre). (Modified from Currie *et al*. (1994). *British Medical Journal* **309**, 1605–7, with permission.)

The aetiology of HIV-related heart muscle disease has not been established beyond doubt and is almost certainly complex and multifactorial. However, it seems likely that an autoimmune lymphocytic myocarditis is the usual substrate for HIV-related dilated cardiomyopathy. There are intriguing parallels between HIV-related heart muscle disease and idiopathic dilated cardiomyopathy (see Chapter 15.8.1 and Chapter 15.8.2), and the pathogenesis of the two conditions may be very similar.

Autopsy and endomyocardial biopsy studies have shown that some form of myocarditis is present in approximately 40 per cent of patients with AIDS and up to 80 per cent of patients with HIV-related heart muscle disease. The Dallas criteria for the diagnosis of myocarditis are seldom satisfied but it can be argued that these are not appropriate in the presence of marked immunodeficiency. Specific forms of myocarditis (e.g. *Toxoplasma gondii* and penicillin hypersensitivity) have been described but these are rare and a non-specific focal lymphocytic myocarditis appears to be the underlying problem in the majority of patients with HIV-related heart muscle disease. The inflammatory infiltrates are composed mainly of CD8+ lymphocytes with increased MHC (major histocompatibility complex) class I antigen expression. In some cases there are excess circulating cardiac autoantibodies.

A variety of molecular techniques have demonstrated that a few transcripts of HIV-1 are present in the myocardium of many patients with heart muscle disease. Myocardial damage is unlikely to be due to direct HIV toxicity because the viral load is low and there is no CD4 receptor on the myocyte; nevertheless, it is possible that the presence of the virus could trigger an autoimmune reaction. Other factors that might contribute to or amplify cardiac damage include increased oxidative stress due to micronutrient (particularly selenium) deficiency, coinfection with cardiotropic viruses (e.g. cytomegalovirus), and direct cytokine-mediated injury.

The antiretroviral drug zidovudine can cause a specific dose-related reversible skeletal myopathy by inhibiting mitochondrial g-DNA polymerase; it can also damage cardiac muscle in rats and may be implicated in some cases of HIV-related heart muscle disease.

Infective endocarditis

Non-bacterial thrombotic (marantic) endocarditis is a disease of unknown aetiology, in which friable clumps of platelets and red blood cells adhere to the cardiac valves. The condition is sometimes complicated by systemic embolism and is associated with a variety of debilitating illnesses. It is a recognized complication of AIDS, but is infrequent and seldom causes clinical problems.

HIV infection is not associated with an increased incidence of infective endocarditis. However, intravenous drug use is an important risk factor for infective endocarditis in this patient group. *Staphylococcus aureus* is the most common pathogen in this setting and the clinical features of the condition appear to be identical in HIV-positive and HIV-negative drug users; the tricuspid valve is usually involved and infected pulmonary emboli may occur. Survival rates are around 80 per cent.

There have been surprisingly few reports of infective endocarditis in HIV-positive individuals who do not use intravenous drugs. Nevertheless, infections with a wide variety of unusual organisms (e.g. *Aspergillus fumigatus* and *Pseudoalleschira boydii*) have been described and it has been suggested that severe immunodeficiency may modify the presentation and course of disease. Salmonella endocarditis, which is usually associated with devastating cardiac complications in HIV-negative patients, appears to carry a surprisingly good prognosis in HIV-positive patients and it is conceivable that, in some situations, even minor changes in the inflammatory reaction may impair vegetation formation and limit valvular damage. On the other hand, there is evidence that other forms of infective endocarditis run a more fulminant course when they occur in the late stages of HIV infection.

Pulmonary hypertension

Significant pulmonary hypertension occurs in approximately 5 per cent of patients with advanced HIV infection. This usually presents with increasing breathlessness and right heart failure. The ECG typically shows right ventricular hypertrophy and the diagnosis is often established by echocardiography which shows characteristic dilatation of the right ventricle with flattening of the interventricular septum (Fig. 2).

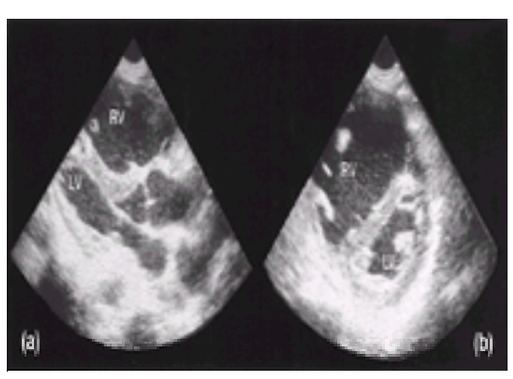

Fig. 2 (a) Long-axis and (b) short-axis parasternal view of a two-dimensional echocardiogram from an HIV-positive intravenous drug user with idiopathic pulmonary hypertension illustrating dilatation of the right ventricle and flattening of the interventricular septum.

The common causes of HIV-related pulmonary hypertension are recurrent chest infections, thromboembolism, and idiopathic or primary pulmonary vascular disease. Patients with left heart failure do not usually live long enough to develop pulmonary hypertension.

The symptoms and signs of right heart failure in patients with cor pulmonale due to recurrent chest infections often improve with appropriate antibiotic therapy and oxygen supplementation. Pulmonary thromboembolism is particularly common in active intravenous drug users, who can sometimes obliterate their pulmonary vascular bed by inadvertently injecting themselves with particulate material.

Approximately 2 per cent of patients with advanced HIV infection develop idiopathic pulmonary vascular disease. The clinical and histological features of this condition are indistinguishable from those of primary pulmonary hypertension (see Chapter 15.15.2.1) and it has been suggested that both conditions may have an autoimmune basis. Treatment is usually ineffective and the outlook is extremely poor.

Sudden death

Sudden death due to ventricular arrhythmias or heart block is a rare but recognized complication of HIV infection. It is usually attributed to a combination of factors including autonomic dysfunction, heart muscle disease, and drug effects. Autonomic dysfunction is a common and disabling complication of AIDS and may cause syncope, presyncope, symptomatic hypotension, and a broad range of arrhythmias, including ventricular tachycardia and ventricular fibrillation. Many potentially proarrhythmic drugs are used in the treatment of HIV infection; these include pentamidine and ganciclovir, which prolong the QT interval and can cause the form of ventricular tachycardia known as Torsades des Pointes (see Chapter 15.6).

15.11.1 Cardiac myxoma

Thomas A. Traill

Introduction

Cardiac myxomas are benign, typically golfball-sized tumours that grow in the lumen of the atria, usually the left, attached by a stalk to the atrial septum. They are not common, but are important because they can present in a number of ways to general physicians, and because most can easily and permanently be removed by heart surgery. They are easily demonstrated by conventional transthoracic echocardiography, and it is usually the echocardiographer who makes the diagnosis; seldom has the patient been referred with this possibility in mind. Estimates of the prevalence of such a rare condition are necessarily approximate and range from 1 to 5 per 10 000 in autopsy series, or 2 per 100 000 in the general population, with a sex ratio of 2:1 in favour of women. As a cause of left atrial obstruction, myxomas are 200 to 400 times less common than mitral stenosis. The majority of patients are between 30 and 60 years, but there are reports of tumours occurring in infants and in the elderly.

Most myxomas are sporadic, unassociated with other diseases, but there is at least one mendelian syndrome involving myxoma, best named the Carney complex. This is characterized by lentiginosis, multiple myxomas (most of them cardiac), skin fibromas, and various kinds of endocrine overactivity, which has included Cushing's syndrome caused by pigmented adrenocortical hyperplasia, acromegaly, and Sertoli cell tumour. Unlike the usual kind of atrial myxoma, myxomas in Carney's syndrome may arise anywhere in the heart, are commonly multiple, and frequently recur. Inheritance of this rare disease is autosomal dominant, with centrofacial freckling as the most obvious outward marker of the phenotype. This freckling often involves unusual areas, for instance the lips, conjunctiva, and vulva.

Pathology

Cardiac myxomas are benign. Local invasion is unknown and metastatic growth is exceptional, despite the lesions' situation in the bloodstream. They take the form of polypoid masses arising from a stalk, ranging in size from 3 cm to as much as 10 cm or more, with a smooth or lobulated surface and gelatinous consistency. They are frequently covered with more or less adherent thrombus. More than 75 per cent occur within the left atrium, with the base of the pedicle arising from the fossa ovalis or its rim. Occasionally they arise from the base of the mitral valve leaflets, from the posterior part of the left atrium, or from within the right atrium. Sometimes they grow in both atria, in the form of a dumb-bell. Ventricular myxomas are exceptional and seen almost exclusively as part of Carney's syndrome. Because they are in the systemic circulation, left atrial myxomas usually draw attention to themselves at a size smaller than those on the right side.

The histology is that of a loosely woven, sparsely cellular, connective tissue tumour with very infrequent mitotic figures. Several cell types are identifiable, including undifferentiated stellate and polygonal cells, as well as smaller numbers of fibroblasts, smooth muscle cells, and endothelial cells. Among these are found macrophages and plasma cells, and rarely other mesodermal tissues, including bone. Cytogenetic studies fit with the general presumption that these indolent masses are indeed neoplastic, but immunohistochemical studies of differentiation markers do not clearly define the cell type of origin. It is suggested that the source is a primitive multipotential mesenchymal cell and that the predilection of these tumours for the atrial septum reflects the abundance of such cells in this region.

Clinical features

Presentation

Although the wide availability of echocardiography has made the diagnosis of atrial myxoma straightforward, it remains true that the prerequisite for recognizing this rare lesion is to include it in the differential diagnosis of patients presenting with symptoms and signs of much more common conditions. Left atrial myxomas may mimic mitral stenosis and cause left atrial obstruction. They may be the source of emboli to the systemic circulation, and occasionally they may present as an obscure constitutional illness with fever. Right atrial myxomas seldom cause symptoms until they are very large, when they cause right atrial obstruction with elevated systemic venous pressure, splanchnic congestion, and oedema.

Left atrial obstruction

The most common symptoms and signs mimic those of mitral stenosis, with left ventricular inflow obstruction as the chief pathophysiological change. The presenting symptoms are progressive breathlessness, orthopnoea, paroxysmal nocturnal dyspnoea, fluid retention, and atrial arrhythmias. Examination suggests rheumatic heart disease, and before the routine use of ultrasound a few such patients were referred for mitral valve surgery and the lesion was first diagnosed at operation. Some patients may develop pulmonary hypertension before the diagnosis becomes apparent.

Systemic embolism

Systemic emboli occur in about 40 per cent of patients and are frequently the first manifestation of disease. By contrast to mitral stenosis, such emboli often occur while patients are in sinus rhythm. Emboli may be sizeable, large enough even to occlude the aortic bifurcation, and besides thrombus they frequently contain tumour material, so that histological examination may be diagnostic. Thus, when systemic emboli are removed from patients they should always be sent for histological analysis. Typically, patients with systemic embolism are referred for echocardiography, and the diagnosis is then easily made.

Constitutional effects

Constitutional effects of the neoplasm predominate in a few patients. These include fever, weight loss (which is more conspicuous than in mitral stenosis and often occurs without severe left atrial obstruction), Raynaud's phenomenon (rare), finger clubbing (rare), a raised erythrocyte sedimentation rate (present in about 60 per cent of patients), and abnormal serum proteins with elevated immunoglobulin levels. These changes are usually attributed to abnormal proteins secreted by the tumour, although the nature of these has not been determined. Other haematological abnormalities include anaemia, which may be due to mechanical haemolysis, polycythaemia, associated particularly with right atrial tumours, leucocytosis, and thrombocytopenia. Such constitutional changes may prompt an initial diagnosis of infective endocarditis in patients who have heart murmurs, or lead to the suspicion of collagen vascular disease or occult cancer.

Physical signs

In many patients specific cardiovascular signs of myxoma are inconspicuous or absent. In others they vary from a prominent first heart sound to obvious changes similar to those of mitral valve disease. These include apical systolic murmurs, somewhat more common than diastolic rumbles, and signs of pulmonary hypertension with accentuated pulmonary closure and tricuspid regurgitation in some patients. Some may have an audible 'tumour plop' in early diastole, analogous to a mitral opening snap, but this is often heard best only after echocardiographic diagnosis. On combined echocardiographic and phonocardiographic recordings the plop is

seen to coincide with the end of the tumour's downward movement into the ventricle, usually a short time after mitral valve opening. A rare but specific feature of the condition is variation of the auscultatory findings with change in posture; this may be particularly obvious in right atrial tumours.

Investigations

Chest radiography and electrocardiography do not help to distinguish myxoma from mitral valve disease. Left atrial enlargement is common but seldom marked and signs of pulmonary venous hypertension are infrequent. Calcification within the tumour is rarely demonstrable.

Echocardiography

While the first account of left atrial myxoma diagnosed during life was not until 1951, it is now exceptional for the diagnosis to be made first at autopsy. This is chiefly attributable to the wide availability of echocardiography, which has proved itself both reliable and specific for recognizing these tumours. The characteristic pattern of left atrial myoma is easily recognized, and it is no accident that the echocardiographic appearance of these lesions was among the first clinical reports by ultrasonographers, in 1959. Figure 1 illustrates a typical two-dimensional echocardiogram from a patient with left atrial myxoma. This 'four-chamber view' shows the characteristic dense mass of echoes from the tumour lying just above the mitral valve orifice. A video recording would demonstrate the mobility of the mass as it flops to and fro within the atrium, restrained only by its peduncle. Trans-oesophageal echocardiography affords the opportunity to examine the tumour and its attachment with great precision; generally this extra clarity is unnecessary, but on occasion the trans-oesophageal technique is helpful if there is difficulty in differentiating tumour from an atrial thrombus.

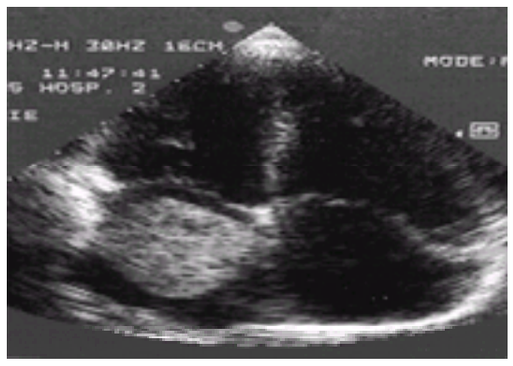

Fig. 1 Echocardiogram in the four-chamber view showing a myxoma occupying much of the left atrium.

The differential diagnosis of left atrial myxoma is seldom difficult. Large masses may occasionally be difficult to distinguish from left atrial ball thrombus, a lesion that is even rarer than myxoma. Smaller left atrial masses may be papillary fibroelastomas or infective vegetations caused by endocarditis. These can usually be distinguished by their clinical context. Masses in the right atrium may also represent thrombus, sometimes propagated from the inferior vena cava, or occasionally venous extension of abdominal cancers, particularly renal cell cancer. In a few patients abundant strands of the Chiari network of right atrial trabeculation may give rise to similar echocardiographic appearances.

Cardiac catheterization

The echocardiographic appearance is so characteristic that angiography no longer has a role in diagnosis of myxoma. The only time to undertake it is in an older patient in whom there is fear of occult coronary artery disease.

Treatment and prognosis

Atrial myxoma is treated by urgent surgical removal. The risk is low, comparable with that of surgery for mitral valve disease. It is important to ensure complete removal of the base by excising a full-thickness button of the atrial septum. The resulting defect is repaired with a small patch.

Functional results of surgery are good. Some patients are left with mitral regurgitation, but this is seldom severe. Recurrence is uncommon, provided excision has been complete, except in Carney's syndrome. In these patients regular echocardiographic follow-up is required, at intervals of 6 months. The rare occurrence after excision of the usual kind of myxoma generally occurs within the first 2 years; thereafter follow-up can safely be infrequent.

15.11.2Other tumours of the heart

Thomas A. Traill

While each individually is rare, taken together the other tumours of the heart have an incidence that roughly equals that of myxoma. They include benign lesions, seen especially in children, sarcomas, and secondary involvement by metastasis or direct tumour extension. They are generally first recognized or suspected during echocardiography. Magnetic resonance imaging, or occasionally echo-directed transvenous biopsy, usually yield the diagnosis.

Benign cardiac tumours

Papillary fibroelastoma

The most common tumour seen in adult patients is the papillary fibroelastoma, a small pedunculated mass that hangs off one of the left-sided valve leaflets, usually the mitral valve. Its echocardiographic appearance is very characteristic. The size of the mass and presence of a peduncle distinguish this small tumour from the usual kind of Lambl's excrescence, but histologically they are identical and, like Lambl's excrescences, papillary fibroelastomas probably arise through organization of fibrinous material that collects at the trailing edges of the valve leaflets. Their importance lies in the fact that they have been labelled as a potential source of systemic embolism, and that some authors have recommended that they should be removed as a matter of routine. The evidence to support this view is thin, and this author's recommendation is to remove them only if they have been discovered in the search for a source of otherwise unexplained embolism. If they are an incidental echocardiographic finding then it is safe to leave them alone; aspirin treatment may be recommended.

Fibroma, rhabdomyoma, hamartoma, haemangioma

These are tumours of childhood, rhabdomyoma being the characteristic cardiac tumour in patients with tuberous sclerosis. By contrast to myxomas and fibroelastomas they grow within the myocardium, not into the lumen of the heart. Rhabdomyomas are usually asymptomatic, and when they are they should be left alone, since most regress spontaneously. Fibromas and hamartomas are both very rare, and may present with arrhythmias (particularly ventricular hamartomas, or Purkinje cell tumours) or with haemodynamic abnormalities caused by their mass effect. They require surgical excision, and when this is feasible the long-term results of treatment are very good. Haemangiomas, also very rare, tend to grow, and to develop multiple feeding vessels, so that surgical excision is usually recommended.

Cardiac sarcoma

Primary cardiac sarcomas can have one of several cell types. They are found more often in the right heart than in the left. Haemangiosarcoma is the most common, and typically develops in the right atrium. Rhabdomyosarcoma may develop in the ventricular septum or in the right ventricular outflow tract, as may the still rarer osteosarcoma, or tumours that are undifferentiated. Since these tumours often present with mechanical effects, typically obstruction at the atrial or outflow tract level, surgical resection is often attempted. However, recurrence and metastasis are common, and long-term results are very poor.

Cardiac involvement by other malignancies

Microscopic secondary deposits within the myocardium can often be found in patients who die of metastatic cancer, but intramyocardial secondaries of a size large enough to be of clinical importance are very rare. By contrast, pericardial involvement by lymphoma, or by cancers of the lung, breast, pancreas, and other tumours is not uncommon, and may sometimes be the first presentation of the tumour (see Chapter 15.9). Treatment is analogous to that of malignant pleural effusions, with drainage, creation of a window, or intrapericardial chemotherapy depending on the rest of the clinical situation.

Intraluminal spread of cancer, by direct extension up the inferior vena cava, is a particular feature of renal cell cancers. Diagnosis by echocardiography is generally obvious as the tumour has a very characteristic appearance as it waves, like seaweed in the right atrium and even dangles through the rest of the right heart. It may prove possible to resect the cava, along with the kidney and the tumour mass, under circulatory arrest.

15.12 Cardiac involvement in genetic disease

Thomas A. Traill

Introduction

Singling out a few of the more prominent mendelian disorders seen by cardiologists may seem a somewhat arbitrary basis for a chapter, especially in an age when we are exploring the molecular genetic basis for so many more of the common heart diseases. However, this is a grouping that works in practice. Many clinicians find themselves faced from time to time with a patient who has a family history of a known disorder, such as Marfan's syndrome, or who has non-cardiac features that suggest a syndrome, perhaps Noonan's. They may wonder how to make the diagnosis, what else to look for, and how to screen family members.

Two important familial heart diseases are covered elsewhere in this book, namely familial hypertrophic cardiomyopathy (see Chapter 15.8.2), and the long QT syndromes (see Chapter 15.6). Both are genetically heterogeneous: familial hypertrophic cardiomyopathy is caused by mutations in any of a number of the sarcomere proteins responsible for contraction, and the long QT syndromes are caused by mutations of ion channels that affect the cardiac action potential.

The first part of this section deals with syndromes that include congenital cardiac structural defects and is restricted to a few relatively common disorders seen in adult patients. The second part describes the two common connective tissue disorders—Marfan's and Ehlers–Danlos syndromes. A number of other heritable diseases that affect the heart are listed in a table, without discussion in the text. Haemochromatosis (Chapter 11.3) and Friedreich's ataxia (Chapter 24.13.12) are discussed elsewhere in this book; the others, though important to other organ systems, offer little opportunity to the cardiologist for diagnosis or management.

Syndromic congenital heart disease

Aneuploidy disorders

The two commonest chromosomal disorders in adult patients are Down's and Turner's syndromes, and each includes characteristic cardiac abnormalities. A third, Klinefelter's syndrome, does not. Twenty-five to fifty per cent of patients with Down's syndrome have congenital heart disease. The characteristic lesion, present in about half of the affected hearts, is atrioventricular canal defect. This ranges from the relatively simple primum atrial septal defect to the complete type, in which the defect involves both the atrial and ventricular septa, between which there lies a single atrioventricular valve ring. In other patients, ventricular septal defect, tetralogy of Fallot, and persistent ductus arteriosus are seen in roughly equal numbers. Some suspect that patients with Down's syndrome are especially prone to develop pulmonary vascular disease, and hence Eisenmenger reaction, but growing experience with surgical repair for affected children seems to show that this suspicion is ill-founded. Patients with Down's syndrome undergo surgery most easily when they are infants, and the tendency has shifted away from a nihilistic approach to operating on patients with serious cardiac malformations early in life.

Turner's syndrome causes abnormalities of the aorta. The two principal lesions are coarctation and congenital abnormalities of the aortic valve, usually a bicuspid valve. Most patients with coarctation have a bicuspid aortic valve as well, and patients with a bicuspid valve frequently have some degree of anuloaortic ectasia. In some patients with Turner's syndrome the whole aorta is abnormal, either hypoplastic or weakened by the presence of cystic medial necrosis. Aortic dissection may occur, and aortic surgery, to repair coarctation for example, can sometimes be very difficult. Other congenital heart abnormalities are not common in Turner's syndrome, except for anomalies of pulmonary venous return.

Mendelian 'single-gene' disorders causing congenital heart disease

Noonan's syndrome

Noonan's syndrome is the most common heritable syndrome that characteristically causes congenital heart disease. The syndrome shares a number of features with the Turner phenotype, and the two were confused between 1930 and Noonan's studies in the 1960s, which coincided with the advent of karyotyping. In 1963 Noonan described a small series of patients with pulmonary stenosis who shared a characteristic facial appearance. Since then the phenotype has been well described, associated with a normal karyotype and autosomal dominant inheritance. Cardiac involvement has been recognized to include not only pulmonary stenosis, but a wide variety of other lesions, much wider than in Turner's syndrome. A locus has been mapped to chromosome 12.

Patients with Noonan's syndrome are of short stature, with a facies that is variously described as elfin or triangular. There is ocular hypertelorism, and the palpebral fissure may slope downwards (the antimongoloid slant), which may be emphasized by ptosis or an epicanthal fold. The ears are set low and rotated forwards so that the lobes are prominent, and there is characteristic webbing of the neck, the most obvious of the features that may lead to confusion with Turner's syndrome. Pectus deformities are common, as are other miscellaneous skeletal abnormalities, including cubitus valgus. Patients with Noonan's syndrome are prone to develop keloid scars. Cryptorchidism is common, as is delayed sexual maturation, but not infantilism as in Turner's syndrome. Unlike Turner's syndrome, a proportion of patients with Noonan's syndrome have a degree of mental retardation, but this is quite variable. Among this author's patients with Noonan's syndrome are a physician, an architect, a certified accountant, and a high-school mathematics teacher.

The frequency of cardiac involvement in Noonan's syndrome is unknown, since the diagnosis is so easily missed in the absence of congenital heart disease. The most characteristic lesion is pulmonary stenosis, but in contrast to the almost stereotypical cardiovascular findings in Turner's syndrome, the range of congenital heart abnormalities in Noonan's syndrome is broad. In many patients the stenotic pulmonary valve leaflets are not simply fused, as in non-syndromic pulmonary stenosis, but may be dysplastic, thickened, and immobile, unsuitable for simple balloon or surgical valvotomy. Other congenital lesions found in Noonan's syndrome are ventricular and atrial septal defects, tricuspid atresia, single ventricle, and abnormalities of the left ventricle including congenital mitral stenosis, subaortic stenosis, and a combination of these two lesions. The electrocardiogram often shows a superior axis (left axis deviation), even when there is pulmonary stenosis and right ventricular hypertrophy.

The most ominous complication of Noonan's syndrome is cardiomyopathy, taking the form of myocardial hypertrophy complicated by progressive fibrosis. This leads over the course of 5 to 15 years to low cardiac output with very high ventricular diastolic pressures—the pathophysiology of restrictive cardiomyopathy. Since the valvular abnormalities are for the most part correctable, this hypertrophic restrictive cardiomyopathy is the main factor limiting life-expectancy.

Williams' syndrome and familial supravalve aortic stenosis

Williams' syndrome is a contiguous gene phenomenon, caused by a macrodeletion that includes the elastin gene on chromosome 7. A loss-of-function mutation or hemizygosity of the elastin gene alone causes familial supravalve aortic stenosis, inherited as a dominant trait, in which a tight constriction develops in the aorta just above the sinuses of Valsalva. The aortic lesion is generally accompanied by a similar abnormality of the left and right pulmonary arteries, leading to peripheral pulmonary artery stenosis. In Williams' syndrome more far-reaching effects caused by deletion of contiguous genes accompany these cardiac abnormalities. The full syndrome comprises a characteristic facial appearance, with round blue eyes, a distinctive stellate pattern of the irises, depression of the nasal bridge, outwards tilting of the nostrils, abnormal dentition, and big lips, together with small stature, mental retardation, and a history of infantile hypercalcaemia. Mental retardation in Williams' syndrome takes on very individual forms, the patients often being articulate and socially adept: several purported idiots savants have had

Williams'syndrome. Supravalve aortic stenosis in either of these syndromes can lead to severe left ventricular outflow obstruction, with left ventricular failure or even sudden death: surgical treatment may be required.

DiGeorge and velocardiofacial syndromes (chromosome 22 deletion syndrome)

DiGeorge syndrome, described in 1965, comprises abnormalities of the parathyroid glands, absence or hypoplasia of the thymus, and conotruncal abnormalities of the heart such as pulmonary atresia and severe forms of tetralogy of Fallot. A number of affected patients have learning disabilities or schizophrenia. It was recognized soon after the original description that the syndrome is generally caused by deletions in a region of chromosome 22.

Velocardiofacial syndrome, or Shprintzen's syndrome, described in 1981, comprises similar cardiac abnormalities along with cleft palate, a characteristic facies, and learning difficulty. It has since proved to be caused by deletions in the same region of chromosome 22, now often referred to as the DGCR (DiGeorge critical region). A third syndrome, known as 'conotruncal anomalies face', also linked to this site has been described.

With a broad spectrum of phenotypic variation, and deletions that are often quite large, it was suspected for some time that these syndromes are related manifestations of a contiguous gene phenomenon, just as in Williams' syndrome. However, it has emerged that the size of the deletion does not predict the extent of the phenotype, and that within a family the same (presumably stable) deletion can be the cause of a wide range of phenotypes. Mutations that may well account for the entire range of phenotypes have been recently been discovered in a single gene (*Ufd1*) within the region, in which case renaming as a single gene syndrome will become appropriate.

Heart–hand syndromes

The two commonly recognized heart–hand syndromes are Holt–Oram syndrome and Ellis–van Creveld syndrome.

Holt–Oram syndrome

Holt–Oram syndrome, inherited as an autosomal dominant trait, was described in 1960, comprising a secundum atrial septal defect and skeletal abnormalities, principally affecting the upper limbs and shoulder girdle, never the legs, and more pronounced in the left arm. Within a family, affected individuals may have skeletal abnormalities, congenital heart disease, or both. The limb abnormalities cover a wide spectrum from just a triphalangeal thumb to phocomelia. Abnormalities of the hand and forearm always involve the radial side and thumb (in contrast with Ellis–van Creveld syndrome). The characteristic cardiac abnormality is fossa ovalis (secundum) atrial septal defect, but affected patients may have other relatively simple lesions, for example ventricular septal defect or pulmonary stenosis.

Holt–Oram syndrome has been mapped and cloned. The mutation is in a transcription factor known now as TBX5, a close homologue of a transcription factor seen as phylogenetically far back as the fruit fly. Mutations of the homologous gene in the fruit fly produce abnormalities of the wing.

Ellis–van Creveld syndrome

Ellis–van Creveld syndrome is inherited as a recessive trait, hence the more complete clinical descriptions have come from studies in genetically circumscribed communities, notably the Old Order Amish of Pennsylvania where thanks to a founder effect the gene is common and homozygotes abound. The syndrome, described in 1940, includes dwarfism, caused mainly by shortening of the forearms and lower legs, and symmetrical polydactyly affecting the ulnar side with accessory sixth and even seventh digits attached to or beyond the little finger. Cardiac involvement is very common, present probably in three-quarters of homozygotes. The characteristic lesion is common atrium—a lesion that has the appearance on echocardiography and to the surgeon of a very large primum atrial septal defect. A few patients have more complete forms of atrioventricular canal defect, and, at least among the Amish, there is a high perinatal mortality rate among affected infants, suggesting the possibility of still more extensive cardiac involvement. The gene has been mapped to chromosome 4 and sequenced, but the protein's function is unknown.

Connective tissue disorders

Marfan's syndrome

Thanks principally to the work of McKusick and his collaborators, beginning in 1955, Marfan's syndrome has become the paradigm for the clinical and genetic investigation of the heritable disorders of connective tissue. The importance of the syndrome is heightened by the fact that its recognition and treatment have had a dramatic impact on survival among those affected. In 1896 Marfan described a patient with what he termed arachnodactyly. In the century since, it has been appreciated that the syndrome is mendelian and pleiotropic, involving several apparently unrelated organs whose common feature proves to be the importance of elastic tissue to their structural integrity. Ocular involvement, with the lens subluxed because of failure of its suspensory ligament, was recognized early in the twentieth century. Cardiovascular involvement was noted incidentally in the 1940s, and studied systematically from the 1950s onwards. Skeletal involvement includes—besides long limbs and arachnodactyly—scoliosis and other abnormalities of the thoracic cage. The sternum may be pushed outwards or inwards by the abnormally long ribs, hence pectus carinatum and/or excavatum, often asymmetrical. Skin involvement is identified by light-coloured striae, which should be looked for over the deltopectoral groove and the flanks. Less common findings are dural ectasia, which can sometimes be so marked as to cause radicular symptoms, and spontaneous pneumothorax or apical blebs.

The characteristic cardiovascular findings in Marfan's syndrome are aneurysmal dilatation of the aorta, and occasionally other large arteries, and floppy mitral valve. The former was recognized in the 1920s but not really addressed until McKusick showed that it was the principal cause of early death in the disease. Shortly afterwards, echocardiography became available to identify and follow these abnormalities, and surgical techniques were developed by Bentall and Gott to repair the aneurysms. Until then, median life expectancy for men with Marfan's syndrome had been 45 years, for women a year or two longer.

Fibrillin gene mutations

The syndrome is caused in almost all patients by mutations of the fibrillin gene on chromosome 15. Fibrillin is a pleated protein laid down in sheets, and a mutation functions as a dominant negative by coding for a misshapen protein that interferes with this polymerization. This is a common mechanism among the connective tissue disorders, seen in Ehlers–Danlos syndrome and in osteogenesis imperfecta. It appears from animal models that in Marfan's syndrome the stage is set for abnormal arterial wall development early in fetal life.

The fibrillin molecule is large and most of the disease-causing mutations have yet to be described, hence genetic diagnosis by screening for known mutations is seldom possible and diagnosis usually depends on applying clinical criteria. There are a number of polymorphisms within the gene, so in some kindreds it is possible by tracking particular alleles to determine which is associated with the disease, and therefore contains the pathogenetic mutation. This has allowed diagnosis of the syndrome in individual family members in whom the clinical findings were uncertain, and has been used for prenatal diagnosis. Furthermore, the technique makes it possible to infer the existence of a fibrillin mutation in kindreds where the phenotype has not met clinical criteria for Marfan's syndrome; if aortic ectasia segregates with a particular copy of the fibrillin gene, then the chances are high that a fibrillin mutation somewhere in that copy is the pathogenetic mechanism.

Diagnostic criteria

The clinical diagnosis of Marfan's syndrome rests on major and minor criteria. In an index case, involvement of three organ systems is required, with major criteria in two. Major criteria can be aortic aneurysm, lens subluxation, characteristic skeletal abnormalities, or dural ectasia. Minor criteria can be striae, mitral valve prolapse, joint laxity, the facies, or moderate pectus excavatum. Characteristic skeletal abnormalities can be: arachnodactyly (encircling the wrist with the thumb and little finger, the 'wrist sign', and making a fist with a protruding thumb, the 'thumb sign'), marked pectus deformity, increased wing-span to 5 per cent more than the height, and scoliosis. In the relative of an index case, the positive family history becomes another major criterion.

In clinical practice, determining whether a patient satisfies these criteria may be fairly subjective and requires experience with the syndrome. Often it is enough to know whether or not there is cardiovascular involvement, and there are numerous families with aortic aneurysms or ectasia whose full phenotype does not satisfy clinical criteria for Marfan's syndrome, yet whose long-term management is identical. Equally, a lanky patient who has a normal aorta needs only infrequent follow-up,

even though there may be a suspicion that he has a mild case of the syndrome.

Clinical management

Patients with Marfan's syndrome should be followed up with annual or 6-monthly echocardiograms to examine the aortic root. If there is reason to suspect that the aorta may be dilated above the echo plane then CT scanning or MRI is required at least once to validate the echo measurement. When the maximum measurement across the aorta reaches 5 cm, we generally recommend surgical replacement of the aortic root, to prevent aortic dissection (see Chapter 15.14.1), which becomes a real risk once the dimension reaches 6 cm. The traditional and very successful approach is with the composite graft: a mechanical aortic valve prosthesis to which is indissolubly attached a tubular vascular prosthesis is used to replace the entire aortic root and annulus. The coronary artery ostia are excised from the native aorta and reattached to the prosthetic root. Recently, to avoid anticoagulation in certain patients, there has been interest in a valve-sparing technique of root replacement in which a vascular prosthesis is fitted snugly over the aortic valve commissures, with the native leaflets suspended in their normal anatomical arrangement. Long-term success with this approach will depend on the degree to which the valve leaflets themselves degenerate because of the connective tissue abnormality. The Ross (pulmonary autograft) procedure is not appropriate in Marfan's syndrome. After surgery, and especially in patients whose surgery was done as an emergency for dissection, follow-up is with periodic imaging by CT or MRI to keep the remaining aorta under surveillance. Management of mitral prolapse and regurgitation in Marfan's syndrome is the same as in other patients. Surgery is required for severe or symptomatic regurgitation; mitral valve repair has proved surprisingly successful.

It is usual to treat patients who have aortic involvement with b-blockers, to slow the progression to aneurysm. We generally advise against excessively demanding sports, particularly competitive basketball, but in all affected children it is important to balance the risks of aortic disease against the importance of normal psychological development. Pregnancy is not contraindicated in all women with Marfan's syndrome, but genetic counselling should be offered, and it is advised that people not become pregnant if the aorta is enlarged to over 4 cm.

Ehlers–Danlos syndromes

In the early part of the twentieth century Ehlers and Danlos described an association between hyperextensibility of the skin, atrophic scarring, and hypermobility of the large joints. Several different mendelian Ehlers–Danlos syndromes are now defined, caused by mutations of different collagen molecules (and some others besides collagen). Since phenotypes may be highly variable, even within a single family, the details of classifying these diseases according to their pathogenesis are still not completely worked out.

Three principal cardiovascular manifestations of the Ehlers–Danlos syndromes are recognized, namely vascular fragility and rupture, mitral valve prolapse, and aortic root ectasia. The first of these is the potentially fatal feature of the vascular type of Ehlers–Danlos (formerly type IV), inherited as a dominant trait and caused by mutations in the type III procollagen molecule. Patients with this form are prone to spontaneous rupture of large and medium-sized arteries. The aorta does not dilate as in Marfan's syndrome and dissection is less common than simple through and through tearing. Less common, but also potentially fatal complications of the vascular type, are spontaneous perforations of the bowel: with severe vascular fragility, treatment of this or other surgical emergencies can be difficult or impossible.

The classic form of Ehlers–Danlos syndrome (formerly types I and II), inherited as a dominant trait, is characterized by marked skin extensibility, joint laxity, and characteristic wide, atrophic ('cigarette paper') scars at the sites of previous injury or surgery. Patients frequently have mitral valve prolapse, as do many people with joint laxity who do not have diagnosable Ehlers–Danlos syndrome, but only a few progress to develop severe mitral reflux or to the point of requiring surgery. Enlargement of the aortic sinuses of Valsalva may occur, but this is seldom severe or progressive. Surgical replacement of the aortic root, as is performed in Marfan's syndrome, is exceptional in Ehler–Danlos syndrome.

Other heart-related connective tissue and metabolic disorders

Osteogenesis imperfecta causes aortic and mitral regurgitation, as do several of the mucopolysaccharidoses (Table 1). It is striking, particularly in the case of osteogenesis imperfecta, how healing is almost non-existent where there is foreign material. If the opportunity arises, even years later, to inspect the operative result in a patient who has undergone valve replacement, the sutures look as though they had only just been placed, with minimal endothelial reaction and scar tissue formation.

Inherited disorders of heart muscle

All three principal groupings of cardiomyopathy—dilated, hypertrophic, and restrictive—include mendelian forms, but familial hypertrophic cardiomyopathy is by far the best studied (see Chapter 15.8.2). Mutations in the actin molecule have been implicated in some families with dilated cardiomyopathy, as have inborn errors of metabolism affecting high-energy phosphate production, for example carnitine deficiency. Other types of familial dilated cardiomyopathy are seen in several striated myopathies, notably Becker's muscular dystrophy, and in mitochondrial dystrophies. The severity of cardiac involvement in muscular dystrophy is quite variable, and the converse, so that some cases involving both kinds of myopathy may be missed. For example, muscle wasting caused by limb-girdle dystrophy may be ascribed to cardiac cachexia in a case of severe cardiomyopathy, and cardiomegaly in a patient with endstage muscular dystrophy may be wrongly attributed to cor pulmonale.

Arrhythmogenic right ventricular dysplasia is a familial disease, inheri-ted as a dominant trait, that affects almost exclusively the right ventricle. The pathology consists of replacement of islands of right ventricular myocardium with fatty and fibrous connective tissue. Generally these islands are small and the disease seldom leads to any detectable mechanical deficit. However, the areas of fibrous replacement create the substrate for ventricular arrhythmias and the clinical presentation is with palpitations, syncope, and even sudden death. Exercising may unmask the tendency to arrhythmias, so the disease is particularly recognized among athletes. Echocardiography or MRI usually establishes the diagnosis. Treatment is by management of the arrhythmia; severely affected patients may require implantation of an automatic defibrillator.

15.13 Congenital heart disease in adolescents and adults

*S. A. Thorne and P. J. Oldershaw**

Introduction

Doctors in all areas of medicine and surgery will encounter the growing number of patients with congenital heart disease who survive beyond childhood. It is therefore important that all doctors have an understanding of the principles of congenital heart disease and enough knowledge to know when to refer such patients to a specialist centre.

The future size of the population of long-term survivors will be influenced by a number of factors. In the era before paediatric and neonatal cardiac surgery, 70 per cent of the approximately 4 per 1000 live-born babies diagnosed as having congenital heart disease died before their 10th birthday. However, with advances in medical and surgical care during childhood the majority can now expect to survive into adulthood, increasing the numbers of patients with operatively modified disease. The advent of echocardiography has allowed less severe lesions that previously presented later in life to be diagnosed in infancy, so that the true incidence of congenital heart disease is around 10 per 1000 live-born babies. In societies where termination of pregnancy is available, prenatal diagnosis by fetal echocardiography may result in a reduced incidence of live-born infants with severe congenital heart disease, but its full impact on the population of long-term survivors remains to be determined.

Many of those who survive to adulthood do so with surgically modified lesions, and the continuing evolution of new surgical techniques creates a population with different residual lesions, long-term complications, and survival than earlier generations with the same initial diagnosis. Careful follow-up is therefore crucial, not only to provide high standards of clinical care, but also to provide feedback about late results in order to inform initial management in infancy. For example, as a result of such long-term follow-up information, the operation of choice for transposition of the great arteries is now the arterial switch, because of the late problems encountered in patients who had undergone interatrial repair with the Senning or Mustard operations.

The concepts of congenital and acquired heart disease are arbitrary, lesions may change and develop during a patient's lifetime either as part of the natural history, or in response to surgical intervention. For example, aortic regurgitation may be acquired in the presence of a subaortic ventricular septal defect because the aortic valve which forms the roof of the defect is unsupported and becomes incompetent as a result of the Venturi effect 'sucking' one of the valve leaflets into the defect. In double-inlet left ventricle with ventriculoarterial discordance, the aorta arises from the rudimentary right ventricle via a ventricular septal defect that is usually non-restrictive and hence does not limit aortic flow. However, age-related or surgically induced ventricular hypertrophy and interventions that reduce the volume load on the ventricle may reduce the size of the ventricular septal defect, causing subaortic stenosis. Changing lesions can also be observed *in utero*, further challenging the division between congenital and acquired disease. In some cases of pulmonary atresia with intact interventricular septum, serial fetal examinations may show pulmonary stenosis evolving into pulmonary atresia, with concomitant failure of development of an initially normal-looking right ventricle.

Molecular genetics in congenital heart disease

Advances in molecular genetics are changing our understanding of congenital heart disease, not only in terms of recurrence risks, but also in embryogenesis and in genetic–environmental interactions. Recently, single gene abnormalities have been identified in Holt–Oram syndrome (skeletal and cardiac anomalies, especially atrial septal defect) and in non-Down's atrioventricular septal defect. New technologies have begun to explain the overlapping phenotypes of di George syndrome and velocardiofacial syndrome which comprise a variety of defects of neural crest-derived tissues, and are also known by the acronym, CATCH 22. In both syndromes there is deletion or microdeletion of a region of chromosome 22q11, the phenotypic spectrum being dependent on the degree and position of the deletion. This discovery has implications for genetic counselling: if a patient has tetralogy of Fallot with 22q11 microdeletion, the chances of their offspring inheriting the microdeletion and a phenotypic abnormality are higher than if there is no microdeletion.

Some cardiac defects have a clear environmental cause, such as patent arterial duct and peripheral pulmonary arterial stenosis in maternal rubella and ventricular and atrial septal defects in maternal alcohol abuse. However, in up to 80 per cent of congenital heart defects, no clear single genetic or environmental factor is implicated, that is, the cause is multifactorial and due to interactions between gene(s) and the environment. Candidate genes for specific stages in embryogenesis are beginning to be identified. For example, septation of the ventricular outflow tract appears to be dependent on the HIRA gene regulating migration of neural crest cells; attenuated expression of this gene may play a role in di George and velocardiofacial syndromes.

Cyanotic congenital heart disease

Cyanosis and pulmonary vascular disease are common problems in congenital heart disease and are discussed in general terms below.

Eisenmenger syndrome: defects with secondary pulmonary vascular disease

The Eisenmenger reaction describes the pathophysiology of patients who have pulmonary hypertension at systemic level as a result of high pulmonary vascular resistance with a reversed or bidirectional shunt. The shunt is usually a non-restrictive communication between the systemic and pulmonary circulations and may occur at atrial, ventricular, or arterial levels. Pulmonary vascular disease is established early in life when the shunt is at ventricular or arterial level. A continuing large left to right shunt at systemic pressure causes the pulmonary vascular resistance to rise progressively until it exceeds systemic vascular resistance and the shunt reverses, establishing Eisenmenger physiology. By comparison, the pulmonary hypertension associated with non-restrictive shunts at atrial level usually occurs later in life.

Clinical findings

Whatever the underlying defect, some examination findings are shared. Patients have cyanosis and clubbing and may be plethoric. There is a right ventricular heave and the pulmonary component of the second heart sound is palpable and loud. A pulmonary ejection click may be audible, also a soft early diastolic murmur of pulmonary regurgitation (Graham–Steell murmur). A soft systolic flow murmur may be heard from the dilated pulmonary artery. No systolic murmur can be heard from the lesion responsible for the pulmonary vascular disease since the chambers on both sides of it are at equal pressures. Thus the presence of a loud systolic murmur brings in to doubt a diagnosis of Eisenmenger syndrome, although the murmur of associated tricuspid regurgitation may occasionally be loud.

It is frequently possible to distinguish between the common lesions associated with the Eisenmenger syndrome on clinical grounds (Table 1). The patient with an Eisenmenger duct has differential cyanosis and clubbing since fully saturated blood from the left ventricle supplies the aortic arch and its branches before mixing occurs with desaturated pulmonary arterial blood via the patent duct. The right hand may therefore be pink with no clubbing, the left may be slightly more cyanosed because of the origin of the left subclavian artery opposite the duct, and the toes are more deeply cyanosed and clubbed (see Taussig–Bing anomaly for reversed differential cyanosis). The second heart sound may be closely or normally split. By contrast, cyanosis and clubbing is uniform when the right to left shunt occurs at atrial, ventricular, or ascending aortic (as in truncus arteriosus) levels. The second sound is single in ventricular septal defect, atrioventricular septal defect, and truncus but may be split in an atrial septal defect.

Natural history and complications

Survival into adulthood with the Eisenmenger syndrome is common. Symptoms of breathlessness relate to the degree of hypoxia; many patients feel worse in hot weather or after a hot bath because the resulting systemic vasodilation is not accompanied by a reduction in pulmonary vascular resistance, so the right to left shunt is enhanced and the patient becomes more hypoxic.

The patient with Eisenmenger syndrome is prone to all the complications of cyanotic heart disease discussed below. In addition, exercise-induced syncope may occur and is exacerbated by hot weather and dehydration. Haemoptysis is common and may be fatal. It is usually due to rupture of small hypertensive intrapulmonary vessels, or more rarely to thrombosis *in situ* and pulmonary infarction. All patients with haemoptysis should be admitted and the systemic pressure kept low by bed rest and b-blockade; the pulmonary artery pressure is the same as that measured in the brachial artery. Any non-steroidal anti-inflammatory agents should be stopped and vasodilators should not be used. If the haemoptysis is massive, diamorphine should be administered and consideration given to selectively intubating the non-bleeding lung. Fresh frozen plasma or cryoprecipitate may be given. Bronchoscopy has no role and may worsen the haemorrhage. Spiral CT differentiates pulmonary artery thrombosis from intrapulmonary haemorrhage. Few data exist to direct management of patients with pulmonary arterial thrombus. Warfarin may increase the risk of bleeding whilst failing to reduce the thrombus, and aspirin should be avoided as it may exacerbate haemorrhage associated with thrombocytopenia.

Right ventricular failure may be precipitated by atrial arrhythmia and usually occurs after the age of 30 years. Decline may be heralded by the onset of right ventricular failure, supraventricular arrhythmia, and haemoptysis. Death is sudden in about 30 per cent of patients and results from arrhythmia or massive haemoptysis. In some patients death appears to follow progressive hypoxia, terminating in bradycardia and asystole from which resuscitation is impossible.

Pregnancy (see below) and non-cardiac surgery pose major risks. The latter is particularly dangerous when carried out without the benefit of expert cardiological anaesthetic and perioperative care. A sound understanding of the pathophysiology and the importance of avoiding vasodilators, dehydration, hypotension, and air emboli are vital.

Investigations

The chest radiograph shows a dilated pulmonary trunk because of high pulmonary blood flow in earlier life, but the lung fields are oligaemic (Fig. 1 and Fig. 2). Unless cardiac failure intervenes, the cardiac silhouette is usually normal, the effects of volume overload having regressed as pulmonary vascular resistance increased and the left to right shunt diminished and disappeared. The electrocardiogram shows p pulmonale and biventricular hypertrophy. The echocardiogram should establish the site of the shunt and allow an estimation of pulmonary arterial pressure and ventricular function.

Fig. 1 Chest radiograph of a 35-year-old woman with Eisenmenger secundum atrial septal defect. The aortic knuckle is small and the central pulmonary arteries enlarged, indicating pulmonary arterial hypertension; the lung fields are clear. The cardiac silhouette is not enlarged.

Fig. 2 Chest radiograph of a 45-year-old woman with Eisenmenger arterial duct which is calcified and fills the indentation between the aortic knuckle and main pulmonary artery (arrow). There has been an exploratory left thoracotomy.

Cardiac catheterization is unnecessary and potentially dangerous for patients with established pulmonary vascular disease. The only indication is for those patients

whose pulmonary vascular disease is suspected to be reversible and who would be considered for surgical repair if reversibility can be confirmed. This situation is rarely encountered in the adult population. Histologically, pulmonary vascular disease progresses from medial hypertrophy through intimal proliferation with migration of smooth muscle cells, to progressive fibrosis and obliteration, dilatation, the development of angiomas, and finally fibrinoid necrosis. Those who have developed fibrotic and obliterative changes are likely to have irreversible pulmonary vascular disease. Routine lung biopsy is not recommended; it carries a high risk in the adult with pulmonary hypertension and is unlikely to show reversible pathology. In addition, thoracotomy scars are a relative contraindication to heart–lung transplantation.

Treatment options in the Eisenmenger syndrome

Avoiding unnecessary intervention is the mainstay of management. Heart failure and arrhythmia should be treated with care to avoid overdiuresis and vasodilation. The limited role of phlebotomy for symptomatic hyperviscosity is discussed below.

Heart–lung transplantion, or lung transplantion with repair of the cardiac defect, are often seen as the ultimate options. However, current donor shortages and the high risk of transplanting patients with long-standing cyanosis who are prone to excessive haemorrhage, renal failure, and technical surgical difficulties due to previous thoracotomy, mean that many patients never receive a transplant. Whether chronic therapy with oxygen or with pulmonary vasodilators, such as prostaglandin or nitric oxide, has a role in improving morbidity or mortality in adults remains to be seen. Given the shortage of organ donors, it may not be realistic to consider such approaches as a temporary bridge to transplantation.

Cyanotic heart disease: a multisystem disorder

Cyanotic heart disease is a multisystem disorder; its manifestations are listed in Table 2.

Secondary erythrocytosis

Chronic hypoxia is the stimulus to the increased red blood cell mass and high haematocrit found in cyanotic heart disease. This physiological response increases the oxygen carrying capacity of the blood and may improve tissue oxygenation sufficiently to reach a new equilibrium at a higher haematocrit. However, adaptive failure occurs if the increase in blood viscosity brought about by the high haematocrit impairs oxygen delivery and negates the beneficial effects of erythrocytosis.

The secondary erythrocytosis of cyanotic heart disease is a physiological response, often associated with thrombocytopenia. It is fundamentally different to the generalized increase in all haemopoietic stem cell lines found in the malignant disease, polycythaemia rubra vera. Failure to differentiate between these two phenomena has contributed to the persistent mismanagement of erythrocytosis in cyanotic heart disease. Three misconceptions lead to inappropriate venesection in cyanotic heart disease:

- Misconception 1—volume replacement is not necessary. If venesection is performed without simultaneous volume replacement, the sudden fall in systemic blood flow, oxygen delivery, and cerebral perfusion may result in cardiovascular collapse. Simultaneous infusion of an equal volume of 0.9 per cent saline or colloid should be given.
- Misconception 2—venesection is performed to reduce the risk of stroke. The risk of stroke in adults with cyanotic heart disease does not relate to the haematocrit, but rather to microcytosis and iron deficiency brought on by injudicious venesection.
- Misconception 3—venesection should be done routinely to keep the haematocrit less than 65 per cent. The only indication for venesection is for the temporary relief of symptoms of hyperviscosity in hydrated, iron-replete individuals with a haematocrit greater than 60 to 65 per cent (Table 3 and Table 4). If the patient does not gain symptomatic improvement then further venesection is unlikely to be beneficial. Any dehydration should be corrected before assessing the need for venesection. Some patients reach a stable equilibrium with a haematocrit greater than 70 per cent; venesection is not indicated if there are no symptoms of hyperviscosity. The only exception is the preoperative patient with thrombocytopenia and a high haematocrit, when venesection may cause a temporary rise in platelet count and a reduction in perioperative bleeding.

Microcytic iron-deficient erythrocytes have a reduced oxygen carrying capacity and are less deformable than biconcave iron-replete cells and so increase blood viscosity, negating any beneficial effect of venesection in reducing the haematocrit. Iron deficiency also causes muscle weakness and myalgia independent of its effect on blood viscosity. If standard doses of iron supplements are given, uncontrolled erythropoiesis occurs and the haematocrit rises rapidly, resulting in a cycle of excessive venesection and iron deficiency, leaving the patient symptoms of hyperviscosity induced by both the haematocrit level and iron deficiency. Low-dose iron replacement (ferrous sulphate, 200 mg daily) combined with close monitoring of the blood count so that iron therapy is withdrawn as soon as the haematocrit rises (often within a week) should allow the gradual recovery of iron stores and the avoidance of counterproductive venesection and further iron deficiency. Hydroxyurea is an antitumour agent that may have a role in suppressing the erythrocytotic response to iron therapy in patients with a high haematocrit. It also causes thrombocytopenia and neutropenia, so should be used with caution.

Disorders of coagulation

Why patients with cyanotic disease are at increased risk of haemorrhage and thrombosis is poorly understood. There is often a mild thrombocytopenia that may be partly due to shortened platelet survival time, and the large multimeric forms of von Willebrand factor and other clotting factors may be depleted. Bleeding may be minor and mucocutaneous, but major haemorrhage can occur during surgery, or from pulmonary haemorrhage (see above). Coagulation testing may yield spurious results in patients with a haematocrit greater than 55 per cent unless the amount of citrate anticoagulant is reduced, according to the following equation:

$$\text{Volume of anticoagulant per ml blood} = 100 - \text{haematocrit}595 - \text{haematocrit}$$

Other complications of cyanotic heart disease

Right to left shunting creates a risk of paradoxical embolism causing stroke and cerebral abscess as well as air emboli from venous lines not fitted with filters. Patients who require transvenous pacing should be formally anticoagulated with warfarin to prevent paradoxical thromboembolism from pacing leads.

Despite the high incidence of hyperuricaemia, attacks of acute gout are uncommon and asymptomatic hyperuricaemia does not require treatment. Acute attacks should be treated with colchicine, avoiding non-steroidal anti-inflammatory agents because of their detrimental effects on haemostasis and renal function. As in primary hyperuricaemia, allopurinol is useful in preventing recurrence. The renal abnormalities outlined in Table 2 are rarely associated with abnormal baseline renal function. However, renal failure may be precipitated by hypotension and dehydration, especially in combination with radiographic contrast media or non-steroidal anti-inflammatory agents. Acne is a common complaint in adolescents and adults with cyanotic disease and may be widespread and psychologically debilitating. When severe it may also increase the risk of bacteraemia and endocarditis.

Digital clubbing is almost universal in cyanotic heart disease, and some degree of hypertrophic osteoarthropathy of the long bones may occur in up to one-third of patients. Symptoms include aching and tenderness of the long bones of the forearms and legs. There is oedema and cellular infiltration, causing lifting of the periosteum that is visible radiographically, and new bone formation and resorption. Localized activation of endothelial cells by an abnormal platelet population, with the ensuing release of fibroblast growth factors, may play a central role in the pathogenesis of both phenomena.

Cyanotic patients become more hypoxic during air travel as the partial pressure of oxygen in a pressurized aircraft is lower than that at sea level. However, such travel seems to be well tolerated and supplemental oxygen should not normally be necessary. Travellers should be warned to avoid dehydration and to plan their journeys to avoid having to carry baggage long distances within large airports.

Classification of congenital heart disease

A classification according to pathophysiological groups allows discussion of the basic physiological principles of congenital heart disease (Table 5 and Table 6). A full morphological classification and discussion of segmental sequential analysis is beyond the scope of this chapter.

Specific lesions

Anomalies of pulmonary venous drainage

Total anomalous pulmonary venous drainage

Total anomalous pulmonary venous drainage occurs in 1 per 17 000 live-born babies. All four pulmonary veins drain into the right atrium either directly, or via a common vein into a systemic vein. The anomalous veins may follow:

1. a supracardiac course draining to the superior vena cava, azygos, or brachiocephalic veins;
2. a cardiac course, draining to the right atrium directly or to the coronary sinus directly or via a persistent left superior vena cava connection; or
3. an infradiaphragmatic course, draining to the portal vein or inferior vena cava.

The presence of pulmonary venous obstruction is the most important predictor of a poor outcome. Associated anomalies include an obligatory right to left shunt, nearly always at atrial level.

The condition presents in infancy and 98 per cent of patients reaching the adolescent or adult clinic will have survived corrective surgery in early life. Unless there is residual pulmonary hypertension most such adults should be asymptomatic, have a normal cardiovascular examination, and an excellent prognosis. In the long term, atrial arrhythmias may develop, probably with a similar incidence to that following repair of secundum atrial septal defect. Patients who are still growing may develop obstruction of the redirected pulmonary venous pathway and present with dyspnoea, signs of pulmonary oedema, evidence of pulmonary venous congestion on the chest radiograph, and an obstructive Doppler flow signal at the site of the stenosis.

The rare patient who reaches adulthood without an operation is likely to have survived because of a large atrial septal defect and unobstructed pulmonary venous drainage. They will be cyanosed, have developed pulmonary vascular disease, and be at risk of atrial tachyarrhythmias and right heart failure. The chest radiograph has the appearance of a large atrial septal defect with a small aortic knuckle, cardiomegaly, and a dilated main pulmonary artery. In addition the anomalous veins may cause an abnormal vascular shadow.

Partial anomalous pulmonary venous drainage

There is anomalous drainage of some of the pulmonary veins to the right atrium. In 90 per cent of cases the anomalous pulmonary venous connection is between the right upper or middle pulmonary vein to the superior vena cava or right atrium, usually in association with an atrial septal defect. Ten to fifteen per cent of all atrial septal defects and 80 to 90 per cent of superior vena cava-type sinus venosus atrial septal defects are associated with partial anomalous pulmonary venous connection.

Partial anomalous pulmonary venous drainage may present in adult life with signs of a left to right shunt at atrial level, and the pathophysiological consequences are the same as for an atrial septal defect with an equivalent shunt. When in coexistence with an atrial septal defect, the clinical findings of the two lesions are inseparable. If the atrial septum is intact, physiological splitting of the second heart sound enables anomalous venous drainage to be distinguished from atrial septal defect.

The chest radiograph may reveal the abnormally draining pulmonary vein. Transthoracic echocardiography may be indicative of a shunt at atrial level, but in adults it may not be possible to image the pulmonary veins and a transoesophageal approach is likely to be necessary. The identification of all the pulmonary veins is crucial in assessing the suitability of a secundum atrial septal defect for transcatheter device closure, this technique being contraindicated in the presence of anomalous pulmonary veins (see later).

The indications for surgical repair are the same as those for repair of an atrial septal defect. In the most common variant of right pulmonary venous connection to the superior vena cava in association with a sinus venosus defect, the patch closing the atrial septal defect is placed to direct the anomalous vein into the left atrium.

Scimitar syndrome (Fig. 3)

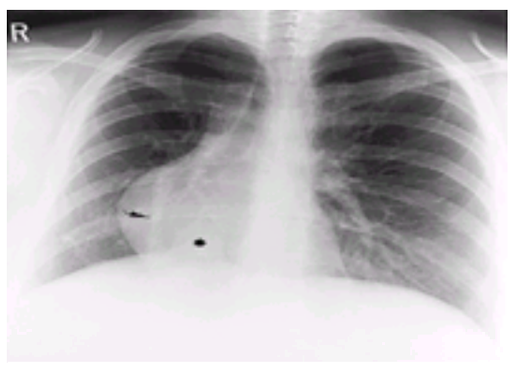

Fig. 3 Chest radiograph of a 25-year-old woman with scimitar syndrome. The heart is shifted into the right hemithorax because the right lung is small. The 'scimitar' shadow (arrow) is produced by the anomalous descending venous channel which drains into the dilated inferior vena cava(*).

Partial anomalous pulmonary venous drainage also occurs as part of the rare familial 'scimitar syndrome' in which part or all of the right pulmonary venous drainage is to the inferior vena cava below the diaphragm. The affected lung lobes are usually hypoplastic and are supplied with arterial blood from the descending aorta. Recurrent infection and bronchiectasis may develop in the hypoplastic lung. Magnetic resonance imaging demonstrates the abnormal arterial supply and venous drainage of the affected lung segment, and may obviate the need for diagnostic cardiac catheterization. Surgical repair may be complicated by difficulty in maintaining perfusion to the affected lung, and lobectomy may by required. In view of this it should be remembered that patients presenting with scimitar syndrome for the first time in adult life have a good prognosis without an operation, similar to that of a small atrial septal defect.

Anomalies of systemic venous drainage

These anomalies frequently form part of a more complex lesion, particularly atrial isomerism.

Superior caval vein anomalies (Fig. 4)

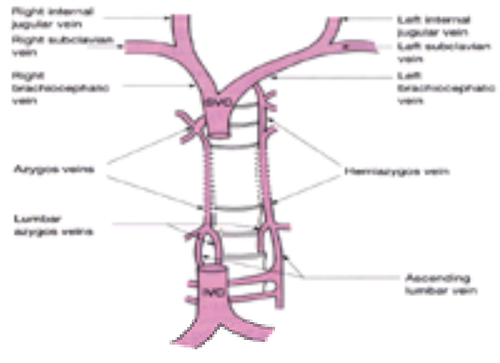

Fig. 4 Schematic diagram of normal systemic venous drainage.

A persistent left-sided superior vena cava occurs in 0.3 per cent of the general population, around 3 per cent of patients with congenital heart disease, and 15 per cent of those with tetralogy of Fallot. The left superior vena cava may be visible on the chest radiograph; it drains to the right atrium via the coronary sinus which is seen to be dilated on two-dimensional echocardiography. A right-sided superior vena cava is usually also present and the two cavae do not usually communicate via the brachiocephalic vein. This common anomaly should be sought routinely at cardiac catheterization; although it does not have any haemodynamic significance, it may cause technical difficulties during transvenous pacemaker insertion and cardiac surgery (Fig. 5).

Fig. 5 Chest radiograph of a 56-year-old man with bicuspid aortic valve, aortic regurgitation, and coarctation. A left superior vena cava draining via the coronary sinus to the right atrium is marked by the path taken by the transvenous pacing leads, inserted for complete heart block.

Other superior vena cava anomalies are the following.

1. An absent right superior vena cava is associated with arrhythmias including atrioventricular block, sinus node dysfunction, and atrial fibrillation.
2. The left, or rarely the right superior vena cava may connect directly to the left atrium, causing an obligatory right to left shunt and cyanosis. It is associated with isomerism of the atrial appendages.

Inferior caval vein anomalies

Azygos continuation of the inferior vena cava occurs in 0.6 per cent of patients with congenital heart disease. The infrahepatic portion of the inferior vena cava is absent and continues to the superior vena cava via an azygos vein; the hepatic veins drain directly into the right atrium. It is often associated with complex lesions, particularly left atrial isomerism. The chest radiograph reveals an absence of the inferior vena cava at the junction of the diaphragm with the right heart border and a dilated azygos vein (Fig. 6). Direct connection of the inferior vena cava to the left atrium is rare; the patient is cyanosed, as in the superior vena cava to left atrium connection.

Fig. 6 Chest radiograph of a 50-year-old man with abdominal situs inversus (*) and laevocardia. Left atrial isomerism is inferred from the symmetrical long bronchi. The inferior vena cava is absent at the level of the diaphragm (small arrow), and the azygos vein receiving inferior caval venous blood is prominent (large arrow).

Atrial arrangement and isomerism of the atrial appendages

Atrial situs solitus is the term used to describe normal atrial arrangement, that is, a right atrium with right-sided morphology and a left atrium with left-sided morphology. Atrial situs inversus is a mirror image arrangement: the right-sided atrium has left morphology and that on the left is a morphological right atrium. The term isomerism refers to abnormal symmetry of paired structures which are normally asymmetrical and have laterality. In right isomerism, both atrial appendages are of right morphology; both are of left morphology in left isomerism. A full description is beyond the scope of this book, but the major features of different atrial arrangements are outlined in Table 7 and illustrated in Fig. 6 and Fig. 7.

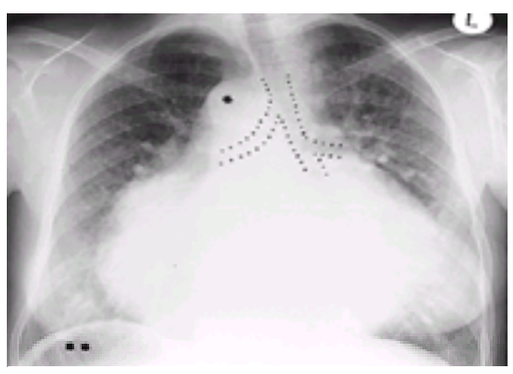

Fig. 7 Chest radiograph of a 21-year-old woman with abdominal situs inversus (**), bronchial and inferred atrial situs inversus, mesocardia, and right aortic arch (*). She has tetralogy of Fallot with pulmonary atresia, palliated with an aortopulmonary shunt via a left thoracotomy.

The key for the physician is to be alerted by the presence of isomerism to the coexistence of complex associated lesions, including a variety of abnormalities of venous connections which may cause technical difficulties at cardiac catheterization and permanent pacemaker insertion. Right isomerism is commoner in males and left in females. Survival to adulthood with right isomerism is uncommon because of associated asplenia and severe cyanotic heart disease, including obstructed

anomalous pulmonary venous drainage (the pulmonary venous confluence is a left atrial structure), complete transposition of the great arteries, atrial septal defect, atrioventricular septal defect, absent coronary sinus (a left atrial structure), severe pulmonary stenosis or atresia, and univentricular heart. The lesions associated with left isomerism tend to produce left to right shunts and little if any cyanosis. They include atrioventricular block, atrioventricular septal defect, common atrium, and left ventricular outflow tract obstruction.

Atrial septal defects

Atrial septal defects account for approximately 10 per cent of congenital heart disease. The exact figure depends on the definition of atrial septal defect, since small or probe-patent foramen ovale occurs in around 10 per cent of the population. The sites of the various types of atrial septal defect are shown in Fig. 8.

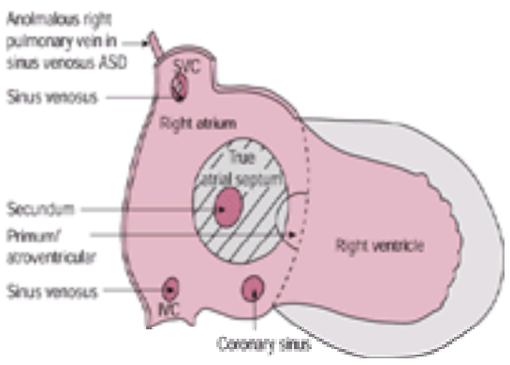

Fig. 8 Sites of atrial septal defects. The shaded area delineates the true atrial septum. Sinus venosus and coronary sinus defects are therefore not strictly atrial septal defects although they permit shunting at atrial level.

Ostium secundum atrial septal defect

Secundum atrial septal defect accounts for 40 per cent of left to rights shunts in adults over 40 years of age. It is commoner in females, with a sex ratio of 2:1, and may be familial. Atrial septal defect may be an incidental finding in a geriatric patient at autopsy and diagnosis in life may be delayed well into adulthood because of the absence of symptoms and subtlety of clinical signs. However, the natural history of this lesion is not benign, only 50 per cent of those with non-restrictive atrial septal defects surviving without operation to the age of 40 years, and 10 per cent beyond 60 years of age.

Presentation in adulthood may be with symptoms or as a result of incidental clinical or radiographic findings. Patients over the age of 30 years with unrepaired atrial septal defect commonly develop paroxysmal and eventually chronic atrial arrhythmia, but also flutter and ectopic atrial tachycardia. Most patients over the age of 60 years are symptomatic with exertional dyspnoea and palpitation. A left to right shunt at atrial level predisposes to paradoxical embolus since simple manoeuvres such as the Valsalva are sufficient to increase right atrial pressure and reverse the shunt. Patients with unoperated atrial septal defect are therefore at risk of embolic stroke, and should not dive because of the risk of paradoxical gas embolism. An age-related reduction in left ventricular compliance augments the left to right shunt and is one of the causes for the progression of symptoms with age. In addition, modest pulmonary arterial hypertension increases with age so the right ventricle is exposed to pressure as well as volume overload and may eventually fail.

Clinical signs

If the defect is non-restrictive, the a and v waves of the jugular venous pulse tend to be equal. In older patients with reduced left ventricular compliance, the left and therefore right atrial pressure is raised, reflected in an elevated jugular venous pressure. A right ventricular heave may be felt at the left sternal border and the dilated pulmonary artery may be palpable in the left second intercostal space. The first sound is loud due to increased diastolic flow across the tricuspid valve. The second heart sound is widely split and fixed, and there is loss of normal sinus arrhythmia if the left to right shunt is equal to 2:1 or greater. There may be a pulmonary flow murmur at the upper left sternal edge. Only if the atrial septal defect has a high gradient across it will it generate a murmur itself, usually a soft continuous murmur. This is the case if the defect is small and restrictive and the left atrial pressure high, for example if there is associated mitral stenosis. If the patient has pulmonary vascular disease, the signs will be the same as for pulmonary hypertension with right to left shunt (see above).

Associations

Acquired disease may coexist and interact with congenital heart disease, especially in the ageing patient. Left ventricular dysfunction due to coronary artery disease and systemic hypertension may increase the left to right interatrial shunt, resulting in a more rapid clinical deterioration than would be expected. Similarly, mitral regurgitation increases the effective interatrial shunt and mitral valve abnormalities may be acquired secondary to the effects of a secundum atrial septal defect. There may be distortion of the anterior mitral valve leaflet with fibrotic shortened chordae due to the abnormal position of the interventricular septum as a result of chronic right ventricular overload. Concomitant pulmonary stenosis may be overestimated in the presence of an atrial septal defect, since Doppler velocities are increased in the presence of a left to right shunt.

Lutembacher's syndrome is the association of mitral stenosis with secundum atrial septal defect. The presence of mitral stenosis increases the left to right shunt at atrial level, causing an overestimation of the significance of the atrial septal defect and an underestimation of the severity of mitral stenosis. Repair of the atrial septal defect alone may unmask severe mitral stenosis.

Pulmonary vascular disease and atrial septal defect

Only around 10 per cent of atrial septal defects develop a right to left shunt secondary to pulmonary vascular disease, and a causal relationship between atrial septal defect and the Eisenmenger reaction remains controversial. In atrial septal defect, unlike other lesions which may cause the Eisenmenger reaction such as large ventricular septal defect, the pulmonary vasculature is not exposed to increased flow at systemic pressure.

Atrial septal defect with a right to left shunt due to pulmonary vascular disease and pulmonary hypertension occurs most commonly in young women and in some cases may be due to primary pulmonary hypertension with an incidental atrial septal defect. In this combination, the prognosis may be better than for primary pulmonary hypertension with intact atrial septum, the septal defect protecting the right heart from pressure overload by allowing right to left shunting. Persistence of the fetal pulmonary vascular pattern may be implicated in the development of pulmonary hypertension in some young patients with atrial septal defect. Patients living or born at high altitude have a higher incidence of pulmonary vascular disease. In older patients with atrial septal defect there may be a relationship with *in situ* pulmonary arterial thrombosis and the development of pulmonary hypertension.

Investigations

The electrocardiogram may show sinus node dysfunction and, less commonly, prolongation of the P–R interval. The QRS axis is usually vertical. The QRS complex may be prolonged with rSr' in lead V1: this does not represent incomplete right bundle branch block, but occurs because the last part of the myocardium to depolarize is the right ventricular outflow tract, which is enlarged and thickened due to volume overload. The sinus node may be damaged when the superior vena cava is cannulated during surgery: occasionally perioperative sinus bradycardia and sinus pauses persist and a permanent pacemaker is required. The P–R interval may return to normal as right atrial size decreases. Macro-reentry circuits at the site of atrial surgery may result in postoperative ectopic atrial tachycardias.

The typical chest radiograph shows dilated proximal pulmonary arteries with a small aortic knuckle, plethoric lung fields, and cardiomegaly secondary to dilatation of the right atrium and ventricle.

Transthoracic echocardiography demonstrates the volume overloaded right atrium and ventricle. The size of the shunt can be estimated and colour flow Doppler

facilitates the detection of the site of the shunt. If transcatheter device closure is considered, a transoesophageal approach is necessary to define the site and size of the atrial septal defect precisely and to identify the pulmonary veins.

Cardiac catheterization is only indicated to calculate pulmonary vascular resistance if there is a suspicion of pulmonary hypertension, or to exclude coexisting congenital or acquired cardiac pathology such as coronary artery disease.

Indications for closure of atrial septal defect

Surgical repair carries low mortality and morbidity. However, vigilance is required to detect postoperative pericardial effusions, which appear to be more common than following other operations. Closure of an atrial septal defect is indicated if there is exertional dyspnoea, if the left to right shunt is greater than 1.5:1, if there is right heart volume overload, or in order to prevent recurrent paradoxical embolism. Repair of an isolated secundum atrial septal defect by the third decade results in a normal life expectancy, between the ages of 25 and 41 years it results in a good but shorter than normal life expectancy, and beyond the age of 41 years, morbidity and mortality remain significantly higher than normal. None the less, functional status and longevity are improved following repair over the age of 40 years, 5- and 10-year survival being estimated as 98 and 95 per cent, respectively, for patients who underwent repair, and 93 and 84 per cent for those treated medically. Surgical repair in older patients does not reduce the risk of late atrial arrhythmia, particularly if there is right ventricular dysfunction, elevated pulmonary artery pressure, or pre-existing atrial arrhythmia. Whether the incorporation of a modified maze procedure or cryoablation into the surgical repair of atrial septal defect will reduce the long-term incidence of existing or *de novo* atrial arrhythmia remains to be determined.

Secundum atrial septal defects up to 3 cm in stretched diameter may be closed by transcatheter devices as long as the surrounding rim of atrial septal tissue is sufficient. Criteria for device closure of secundum atrial septal defect are: size less than 3 cm; a situation away from the atrioventricular valves, pulmonary and caval veins; and normal pulmonary venous drainage. Following closure, antiplatelet or anticoagulant therapy is recommended for 3 months. Device closure is the procedure of choice for patent foramen ovale complicated by paradoxical embolism.

Sinus venosus defect

Sinus venosus defects account for 2 to 3 per cent of atrial septal defects and have an equal sex incidence.

They are not truly defects of the atrial septum, but since they allow shunting at atrial level, they are included in the classification of atrial septal defects. The inferior border of the more common superior vena cava type of sinus venosus defect is made by the superior limbus of the fossa ovalis, and the upper border comprises the junction of the superior vena cava with the atrial mass. The superior caval vein overrides the atrial septum, connecting to both atria, and the right upper pulmonary vein usually drains anomalously into the superior vena cava. There may be an ectopic atrial pacemaker because the defect is located in the area of the sinoatrial node. This may be reflected by a leftwards p-wave axis and an inverted p wave in lead III.

Coronary sinus defect

The rarest form of atrial septal defect, this defect is at the site of entry of the coronary sinus to the right atrium. The unroofed coronary sinus is a variation of coronary sinus defect in which the partition between the coronary sinus and the left atrium is absent as the coronary sinus runs posteriorly along the floor of the left atrium. In this condition, a left superior vena cava commonly connects directly to the left atrium, producing a right to left shunt and cyanosis.

Atrioventricular septal defect

The sites of ostium primum and atrioventricular septal defects are shown in Fig. 8, and the leaflet patterns in atrioventricular septal defects in Fig. 9.

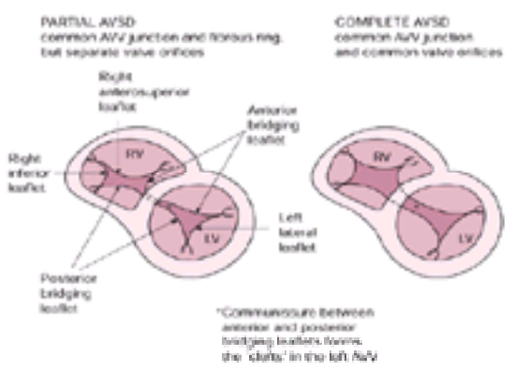

Fig. 9 Leaflet patterns in atrioventricular septal defect. Diagrams are in short axis, as imaged by two-dimensional echocardiography. (Modified from Anderson RH *et al*., 1983, *Morphology of congenital heart disease*. University Park Press, Baltimore.)

Ostium primum defect describes the atrial component of the atrioventricular septal defect, previously termed endocardial cushion defect or atrioventricular canal. The atrioventricular septum is absent and the atrioventricular valves share a common junction and fibrous ring, with a five leaflet atrioventricular valve. Since they share common leaflets, the valves are not correctly called mitral and tricuspid valves, but left and right atrioventricular valves. As a consequence the normal offsetting of the right atrioventricular valve towards the right ventricular apex is absent. In addition, the aorta is 'unwedged' from its normal position between the left and right atrioventricular valves, with loss of the normal fibrous continuity between the 'mitral' and aortic valves. The left ventricular outflow tract is therefore elongated ('gooseneck') and has the propensity to develop obstruction. 'Cleft mitral valve' refers to the commissure between the anterior and posterior bridging leaflets which renders the left atrioventricular valve potentially regurgitant. The left ventricular papillary muscles are abnormally placed anteriorly and posteriorly instead of in the normal anterolateral and posteromedial positions. A partial atrioventricular septal defect has a common atrioventricular junction, but the right and left atrioventricular valves have separate orifices and the ventricular component of the defect is usually small or absent. There are both a common atrioventricular junction and a common valve orifice in a complete atrioventricular septal defect, and the ventricular component of the defect is usually large.

Atrioventricular septal defect occurs with equal sex incidence. The complete form of the defect is most commonly associated with Down's syndrome. A single gene defect may be responsible for atrioventricular septal defect with normal chromosomes; the recurrence risk is high: around 10 per cent if the mother has an atrioventricular septal defect, less if the father is affected.

The physiological consequences of an atrioventricular septal defect are the same as for other conditions with left to right shunting at atrial or ventricular level, but may be complicated by left atrioventricular valve regurgitation or left ventricular outflow tract obstruction. If the ventricular septal defect is large and non-restrictive, pulmonary vascular disease may develop. Patients with Down's syndrome are at particular risk of this complication; coexisting upper airway obstruction and sleep apnoea, and abnormal pulmonary parenchyma may be contributory factors.

Investigations

The electrocardiogram is distinctive, with a left and superior QRS axis and notching of S waves in the inferior leads. The chest radiograph appearances depend on the degree of interatrial shunting and left atrioventricular valve regurgitation; the former producing cardiomegaly due to left heart dilatation and the latter, left atrial enlargement. There may be increased pulmonary vascularity, particularly in young patients with complete atrioventricular septal defect and high pulmonary blood flow. Transthoracic echocardiography reveals the detailed anatomy of the defect and establishes the site and degree of shunting, the presence of left ventricular outflow tract obstruction, and the function and anatomy of the atrioventricular valves, including the classic'fish mouth' deformity of the left atrioventricular valve during diastole. The indications for cardiac catheterization are the same as for secundum atrial septal defect, namely to exclude inoperable pulmonary vascular disease. In addition, useful information may be obtained regarding the severity of left atrioventricular valve regurgitation and left ventricular outflow tract obstruction.

Clinical course

First presentation may occur in adulthood if the left to right shunt is small and the left atrioventricular valve is competent. Physical signs are the same as in other atrial septal defects: there may also be an apical pansystolic murmur. Paradoxical embolism is less common than in secundum atrial septal defect, since the position of the primum defect low in the interatrial septum avoids the streaming of inferior vena cava blood which is most likely to carry emboli and is directed towards the mid-portion of the septum.

Most adult patients have undergone surgery to repair the defect and left atrioventricular valve. Others have survived without an operation and may have developed pulmonary vascular disease.

Whether or not it has previously been repaired, the abnormal left atrioventricular valve may become regurgitant in later life, particularly in response to changes in the left ventricle due to ageing, ischaemia, or systemic hypertension. The risk of endocarditis relates largely to the abnormal left atrioventricular valve. Atrial arrhythmias occur in the same way as in secundum atrial septal defect, however there is a higher incidence of postoperative atrioventricular block in atrioventricular septal defect because of the proximity of the atrioventricular node to the site of repair.

Lesions affecting ventricular inflow

Cor triatatrium

This is a very rare defect in which one of the atria (nearly always the left) is partitioned by a fibromuscular membrane into an upper chamber that receives the pulmonary veins, and a lower chamber connecting with the atrial appendage and mitral valve. The membrane usually inserts into the atrial septum at the fossa ovalis, where an atrial septal defect coexists in around 50 per cent of cases, allowing communication between the right and left atria. The membrane may be intact, or pierced by one or more holes that are usually restrictive, causing supramitral stenosis. First presentation in adulthood is unusual unless the membrane is non-restrictive or coexists with a large atrial septal defect. Patients may have signs of an atrial septal defect or mitral stenosis. The diagnosis is made by echocardiography. The chest radiograph is also characteristic, showing signs of pulmonary venous congestion, but not the left atrial appendage enlargement that accompanies valvar mitral stenosis, since the appendage lies in the low pressure atrial chamber. The lateral chest radiograph may show enlargement of the pulmonary venous compartment of the left atrium. Treatment is surgical resection and the postoperative prognosis is good.

Congenital mitral valve anomalies

These anomalies are rare and frequently coexist with other lesions. A supramitral ring often coexists with congenital mitral stenosis. It differs from cor triatatrium in that the ring is sited inferiorly to the os of the appendage and lies immediately above the mitral valve.

Shone syndrome comprises four levels of left heart obstruction: supramitral ring, parachute mitral valve, subaortic stenosis, and coarctation of the aorta. Parachute mitral valve exists when the two papillary muscles are fused or there is hypoplasia or absence of one papillary muscle; the valve and its apparatus are often additionally dysplastic. Obstruction occurs at the level of the abnormal papillary muscles. The parachute mitral valve may also be regurgitant if the chordae are elongated and not significantly fused.

Isolated cleft mitral valve differs from the 'cleft' seen in an atrioventricular septal defect in being in the anterior (aortic) leaflet, directed towards the aortic outflow tract, rather than being in the space between the bridging leaflets and pointing towards the septum. The isolated cleft can be readily repaired to resemble a competent normal mitral valve.

Ebstein's anomaly of the tricuspid valve

This rare condition occurs in 1 per 20 000 live-born babies and affects both sexes equally. The risk may be increased by maternal exposure to lithium during the first trimester. In the normal heart, the mitral and tricuspid valves are offset so that the tricuspid valve is displaced up to 1.5 cm towards the right ventricular apex. In Ebstein's anomaly, the anterior leaflet usually inserts normally at the atrioventricular junction, but the attachments of the septal and sometimes mural (posterior) leaflets are apically displaced, causing atrialization of the proximal part of the right ventricle and reducing the size of the functional right ventricle. In addition the movement of the septal and mural leaflets is usually limited either by being thickened and fibrotic, or by being tethered by short chordae to the septum. The major haemodynamic effect is usually tricuspid regurgitation, but occasionally a muscular shelf or fused anteromedial commissure causes tricuspid stenosis.

Associated abnormalities

A patent foramen ovale or atrial septal defect is present in most cases. Left heart abnormalities occur as a consequence of alterations in left ventricular geometry due to leftwards displacement of the interventricular septum: for example, mitral valve prolapse may occur as a result of relatively long chordae in a left ventricle of reduced cavity size. Twenty per cent of patients have coexistent Wolff–Parkinson–White syndrome, usually with a right-sided or multiple pathway(s).

Clinical presentation and course

There is a broad spectrum of severity, ranging from intrauterine death to presentation in late adulthood. Mortality is influenced by age at presentation, the condition of the tricuspid valve, the cardiac rhythm, and the functional capacity of the right ventricle, including the severity of right ventricular outflow tract obstruction and the size of the right atrium in relation to the other cardiac chambers.

Cyanosis may develop in adulthood if there is an associated atrial septal defect or patent foramen ovale; as the right ventricular filling pressure increases there is a parallel rise in right atrial pressure, and a right to left interatrial shunt is established. These patients are at risk of paradoxical embolism. The risk of endocarditis is low, because the tricuspid regurgitant jet is of low velocity.

Heart failure may intervene as a result of the combination of severe tricuspid regurgitation and the onset of atrial fibrillation or flutter. These atrial arrhythmias may be particularly troublesome if a coexistent accessory pathway allows a rapid ventricular response rate. The onset of atrial fibrillation is a predictor of death within 5 years, and may account for the increased death rate in the fifth decade.

Physical signs

The patient may be acyanotic or cyanosed and clubbed. Even when tricuspid regurgitation is severe the jugular venous pressure may not be particularly high, nor the v wave prominent, because of the capacity of the right atrium and thin-walled atrialized right ventricle to accommodate the low pressure regurgitant volume. Once right ventricular failure develops the jugular venous pressure rises further and the a and v waves become more prominent. In the uncommon situation of tricuspid stenosis, the a wave is increased and may be giant. The first heart sound is widely split with a delayed tricuspid component, due to the extra distance that the large anterior leaflet has to travel to reach the limit of its systolic excursion. The second heart sound may be single because low pressure in the right ventricular outflow tract renders the pulmonary component inaudible, or it may be widely split reflecting right bundle branch block. The systolic murmur of tricuspid regurgitation varies from inaudible to loud enough to generate a thrill, but is classically decrescendo and scratchy.

Investigations

The chest radiograph is characteristic (Fig. 10). The electrocardiogram typically shows a superior axis and right atrial enlargement, with or without right bundle branch block. The p wave may be peaked and the P–R interval prolonged, reflecting the prolonged conduction in the large right atrium, or there may be evidence of pre-excitation. Right bundle branch block may occur due to abnormal activation and conduction in the atrialized right ventricle.

Fig. 10 Chest radiograph of a 43-year-old woman with classic cardiac silhouette of Ebstein's anomaly due to right atrial enlargement. The aortic knuckle and pulmonary arteries are inconspicuous and the lung fields oligaemic.

Two-dimensional echocardiography with colour flow Doppler establishes the diagnosis and severity of Ebstein's anomaly. The atrialized and functional portions of the right ventricle can be identified, as can the precise attachments and degree of tethering of the anterior leaflet of the tricuspid valve. Echocardiography is the investigation of choice in planning surgical intervention, tethering and restricted motion of the anterior leaflet and a small right ventricle being strong predictors of the need for tricuspid valve replacement rather than repair. Cardiac catheterization is only necessary if specific haemodynamic questions remain after non-invasive assessment.

Treatment

Once atrial arrhythmias develop, patients should be anticoagulated, particularly if there is an atrial septal defect. If re-entry tachycardias cannot be controlled with antiarrhythmic drugs, radiofrequency ablation of accessory pathways may be performed. However, ablation may be made difficult by the size and abnormal shape of the right atrium and abnormal position of the accessory pathway or pathways.

Surgery is indicated when the patient's clinical status deteriorates and aims to reduce the size of the right atrium and repair the tricuspid valve so that valve function and right ventricular geometry are improved. The best haemodynamic results are achieved if the valve can be repaired rather than replaced. The addition of a right-sided maze procedure may reduce the long-term risk of developing atrial fibrillation. In a subset of patients with a small right ventricle, the addition of a bidirectional Glenn anastomosis to offload the ventricle may facilitate repair.

Other right ventricular anomalies

Uhl's anomaly and arrhythmogenic right ventricular dysplasia (right ventricular cardiomyopathy) are rare sporadic or familial conditions affecting the right ventricle. Table 8 lists the key distinguishing features.

Ventricular septal defect

With the exceptions of bicuspid aortic valve and mitral valve prolapse, ventricular septal defect is the commonest congenital cardiac malformation, occurring in around 3 per 1000 live-born babies. Defects may exist in isolation, in association with other lesions such as coarctation of the aorta, or as an integral part of lesions such as tetralogy of Fallot. This section deals with isolated ventricular septal defects.

Morphology and classification

The ventricular septum is mostly muscular, with a small fibrous membranous portion. Ventricular septal defects are classified according to their borders, seen from the right ventricular aspect. There are three types: muscular, perimembranous, and doubly committed subarterial (Table 9). The position of muscular and perimembranous ventricular septal defects may be inlet, trabecular, or outlet, depending on which part of the right ventricle they open into.

Perimembranous ventricular septal defect is the commonest type of defect, only 5 to 7 per cent of ventricular septal defects in Europe and North America are doubly committed subarterial defects, whereas they account for up to 30 per cent of defects in Asian patients. Outlet perimembranous ventricular septal defects usually occur due to a malalignment between the outlet and trabecular septa with overriding of either the aortic or pulmonary valve. If the malalignment of the outlet septum is towards the right ventricle, the aorta overrides the defect and tends to cause subpulmonary obstruction; this is the type of defect typical of tetralogy of Fallot. Malalignment towards the left ventricle may cause subaortic obstruction and may be associated with hypoplasia of the aortic arch.

Clinical presentation and complications of unoperated ventricular septal defect

The grades of unoperated ventricular septal defect are shown in Table 10. Adults with unoperated restrictive ventricular septal defects are usually asymptomatic. There is a high risk of endocarditis in small ventricular septal defects due to the high velocity jet from left to right ventricle, particularly if the jet is directed on to the tricuspid valve. There is a small increased incidence of sudden death and ventricular tachycardia in unoperated small ventricular septal defect, but longevity is otherwise normal. The adult with an isolated unoperated restrictive ventricular septal defect is acyanotic with normal arterial and jugular venous pulses. There may be a thrill at the left sternal border, the left ventricular apex may be thrusting if the defect is large enough to cause volume overload, and a dilated pulmonary artery may be palpable. The second heart sound is usually normally split. There is a loud harsh pansystolic murmur at the left sternal edge; the murmur being softer and shorter (early systolic) in very small defects.

Larger ventricular septal defects rarely present for repair in adulthood since the large left to right shunt is unlikely to allow unoperated survival unless pulmonary vascular disease developed. Non-restrictive defects are not associated with the classic ventricular septal defect murmur since left and right ventricular pressures are equal.

Investigations

Investigation should determine the type and number of ventricular septal defects, the size of the defect (restrictive or non-restrictive), estimate the size of the shunt (Qp:Qs), pulmonary artery pressure and resistance, and assess left and right ventricular function, and volume and pressure overload. Associated lesions that may alter management should be identified, especially aortic regurgitation, subaortic stenosis, and right ventricular outflow tract obstruction.

The chest radiograph is normal if the defect has been small from birth. If the ventricular septal defect is, or has been, larger, the left ventricle, left atrium, and pulmonary trunk may be dilated and there may be increased pulmonary vascularity. The electrocardiogram shows a normal QRS axis unless there are multiple defects, in which case there may be left axis deviation. In the presence of a large left to right shunt the p wave may be broad and there may be evidence of left ventricular hypertrophy. Two-dimensional echocardiography identifies the number and site of defects as well as describing the morphology and associated defects. Doppler is used to estimate the size and direction of the shunt, and right ventricle to left ventricle pressure difference, but this may not be accurate if there is an obliquely lying muscular ventricular septal defect. Cardiac catheterization is important to measure the size of shunt and pulmonary vascular resistance with reversibility studies if baseline resistance is high.

Indications for repair and postoperative sequelae

Repair of a ventricular septal defect is indicated in the presence of symptoms, if Qp:Qs is greater than 2:1, or if there is ventricular dysfunction with right ventricular pressure overload or left ventricular volume overload. Repair should also be undertaken if there are coexisting lesions such as significant right ventricular outflow tract obstruction, more than mild aortic regurgitation, or aortic valve prolapse in the presence of an outlet ventricular septal defect. A second episode of endocarditis may

also be considered as an indication for ventricular septal defect closure. If the pulmonary artery pressure is greater than two-thirds systemic pressure, repair should only be considered if Qp:Qs is greater than 1.5:1 or if there is evidence of reversibility in response to pulmonary vasodilators such as oxygen and nitric oxide.

The surgical approach to repair aims at avoiding damage to important structures such as the conducting tissues that are especially vulnerable in perimembranous defects. Transatrial repair reduces the risk of postoperative ventricular arrhythmias by avoiding a right ventriculotomy. Transient postoperative complete heart block is associated with an increased risk of late high-degree block. Permanent pacemaker implantation is indicated in the 1 to 2 per cent of patients in whom complete heart block persists, even if they are asymptomatic, because of the significant risk of sudden death. The prognosis after ventricular septal defect repair in the early years of life is good. However, left ventricular dilatation may persist and systolic function be impaired if repair is delayed into late childhood. Long-term postoperative survival depends on the presence of pulmonary hypertension, left ventricular dysfunction, and complications such as aortic regurgitation and endocarditis.

Transcatheter device closure of ventricular septal defects is possible providing that valvar apparatus can be avoided. The approach is most suited to muscular ventricular septal defects, especially multiple defects that are difficult to close surgically and it may be combined with a surgical approach for inaccessible muscular defects.

Double-outlet right ventricle

In double-outlet right ventricle more than half the circumference of both great vessels arises from the morphological right ventricle. A complete or partial muscular infundibulum lies beneath each arterial valve. This definition includes variants of tetralogy of Fallot in which the aorta overrides the ventricular septal defect by more than 50 per cent.

The degree of pulmonary stenosis and the relation of the ventricular septal defect to the great vessels determine the haemodynamics. Eighty per cent of subaortic defects have pulmonary stenosis and Fallot-like physiology.

The Taussig–Bing anomaly accounts for less than 10 per cent of double-outlet right ventricle and describes a subpulmonary defect without pulmonary stenosis. There is transposition-like physiology with cyanosis and high pulmonary blood flow. As the pulmonary vascular resistance rises, pulmonary blood flow falls and cyanosis increases. Unoperated survival to adulthood is uncommon but occurs occasionally if the pulmonary vascular resistance establishes adequate, but not excessive, pulmonary blood flow. If such a survivor also has a patent arterial duct, there will be reversed differential cyanosis. Deoxygenated blood selectively enters the aorta to supply the arch vessels, whereas oxygenated blood enters the pulmonary artery and supplies the descending aorta via the duct: thus the fingers are more cyanosed and clubbed than the toes.

Tetralogy of Fallot

Tetralogy of Fallot is the commonest cyanotic defect, occurring in 1 per 3600 live-born babies. The four hallmarks of tetralogy of Fallot are:

- subvalvar pulmonary stenosis
- ventricular septal defect
- aortic valve overrides the ventricular septal defect
- right ventricular hypertrophy.

The fundamental abnormality is anterocephalad deviation of the outlet septum that both creates the subpulmonary stenosis and accounts for the aortic valve overriding the muscular septum. There is great anatomical variation, ranging from minimal aortic override to double-outlet right ventricle, and from minimal pulmonary stenosis to pulmonary atresia. The ventricular septal defect is perimembranous and there is usually additional pulmonary valvar stenosis.

Defects associated with tetralogy of Fallot include a right-sided aortic arch in 16 per cent, a left superior vena cava in around 15 per cent, additional ventricular septal defects in 5 per cent, and a secundum atrial septal defect ('pentalogy' of Fallot) in 8 per cent. The most important associated coronary anomaly is the crossing of the right ventricular outflow tract by a left anterior descending coronary artery arising anomalously from the right coronary sinus and vulnerable to damage during surgical repair via a right ventricular approach.

Unoperated natural history and management

Without surgical intervention, only 2 per cent of patients survive to their 40th year. Those that do survive may represent a select group in whom subpulmonary stenosis was not severe in early life, but progressed with advancing age. Such patients may rarely live into their eighth decade; one of our patients survived 77 years. Unoperated patients are at risk of the complications of cyanosis, endocarditis, atrial and ventricular arrhythmias, progressive ascending aortic dilatation, and aortic regurgitation which causes volume overload of both ventricles and subsequent biventricular failure. Systemic hypertension adds additional pressure overload to the work of both ventricles and further contributes to the onset of biventricular failure.

There is cyanosis and clubbing, a right ventricular heave, and sometimes a thrill over the right ventricular outflow tract. A right-sided aorta may be palpable to the right of the sternum. The second heart sound is usually single, and there is a loud pulmonary ejection murmur. There may be aortic regurgitation.

The electrocardiogram shows right axis deviation, right ventricular hypertrophy, and the QRS duration may be prolonged in older patients. The classic cardiac silhouette is a 'coeur en sabot', that is, a clog-shaped heart, but it is more likely to be seen in tetralogy with pulmonary atresia (see below). The heart size is usually normal and pulmonary vascularity reduced. There may be a right-sided aortic arch indenting the right of the trachea and also a prominent dilated ascending aorta. Two-dimensional echocardiography reveals infundibular stenosis with or without pulmonary valve stenosis, right ventricular hypertrophy, the typical ventricular septal defect, and varying degrees of aortic override. There may be evidence of left ventricular volume overload, aortic root dilatation, and aortic regurgitation. Cardiac catheterization should be performed prior to radical repair in adults. The anatomy of the right ventricular outflow tract obstruction (Fig. 11) and pulmonary arteries is defined, and pulmonary vascular resistance assessed. Selective coronary angiography demonstrates any anomalous origin and course as well as acquired coronary disease. Aortography shows aortic root dilatation and any aortopulmonary collaterals.

Fig. 11 Right ventricular angiogram (lateral projection) of a 45-year-old woman with unoperated tetralogy of Fallot. The right ventricle is entered via the aorta overriding the ventricular septal defect. There is severe muscular infundibular stenosis (small arrows), the pulmonary valve is thickened and doming (large arrow), and there is right ventricular hypertrophy.

Palliated history

Helen Taussig first suggested palliative surgery in 1943, and the first Blalock–Taussig shunt was performed in 1945 (Fig. 12 and Table 11). Nowadays, palliative shunts are usually performed as a staging procedure in small infants; however, occasional patients reach the adult clinic having had palliation without subsequent

radical repair. They are cyanosed and clubbed and have a continuous murmur under the clavicle and over the scapula on the side of the shunt. In a classic Blalock–Taussig shunt, the ipsilateral radial pulse is diminished or absent and the hand often small. Late complications of systemic to pulmonary artery shunts include infective endarteritis, acquired pulmonary atresia, aortic regurgitation, biventricular failure, increasing cyanosis, bronchopulmonary collateral development if the shunt blocks or is outgrown, and pulmonary vascular disease if the shunt is too big.

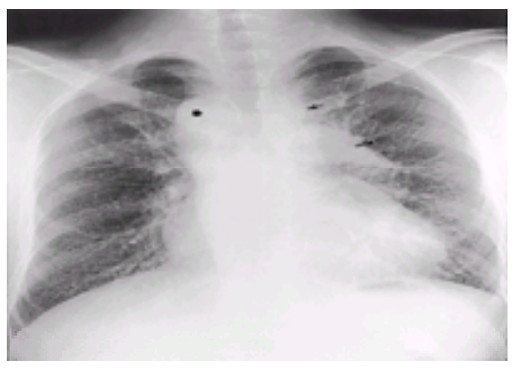

Fig. 12 Chest radiograph of a 36-year-old man with tetralogy of Fallot palliated by a classic left Blalock–Taussig shunt (small arrow). There is secondary dilatation of the left pulmonary artery (large arrow) and a right aortic arch (*).

Follow-up after radical repair

Radical repair involves patch closure of the ventricular septal defect with infundibular resection with or without pulmonary valvotomy or replacement. Eighty-six per cent of patients who undergo radical repair survive to 32 years of age, and these represent the majority of patients with tetralogy seen in the adult clinic. However, they remain at risk of late complications including pulmonary regurgitation and stenosis, arrhythmia, sudden death, endocarditis, and aortic regurgitation. Those repaired beyond late childhood have a higher morbidity and mortality than those repaired by the age of 12 years.

Free pulmonary regurgitation may be present since surgery if the valve was removed, or become progressively more severe, particularly if a monocusp valve or transannular patch was placed. Although well tolerated for many years, pulmonary regurgitation may result in progressive right ventricular dilatation and increased risk of atrial and ventricular arrhythmias. A progressive prolongation of the QRS duration may reflect these changes and a QRS greater than 180 ms is a marker for patients at particular risk of ventricular arrhythmia. The timing of replacement of a regurgitant pulmonary valve remains difficult, but is indicated if there is dyspnoea, palpitation, and progressive right ventricular enlargement or dysfunction. Pulmonary regurgitation is worsened in the presence of pulmonary arterial stenosis that can occur at the site of a previous shunt. Right ventricular outflow tract obstruction may recur, especially if a valved right ventricular to pulmonary artery conduit was placed; this may be due to excessive formation of neointima (peel) in the conduit or to calcification of the valve. Valve calcification is readily seen on the lateral radiograph and can be followed as it encroaches on to the valve cusps to cause stenosis (Fig. 13).

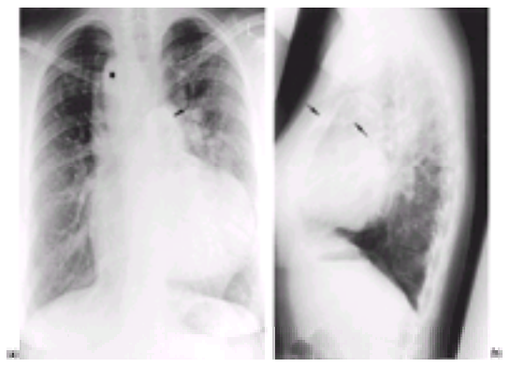

Fig. 13 Chest radiographs, (a) posteroanterior and (b) lateral, of a 30-year-old woman with tetralogy of Fallot and pulmonary atresia who underwent repair with a valved homograft conduit from right ventricle to pulmonary artery and ventricular septal defect closure 10 years previously. There is a right aortic arch (*) and a 'coeur en sabot' cardiac silhouette. The calcification in the homograft (arrows) is more clearly seen on the lateral radiograph. The abnormal pulmonary vasculature reflects persisting aortopulmonary collaterals.

The majority of patients have right bundle branch block after repair (Fig. 14). Bifasicular block and transient postoperative complete heart block carry a risk of developing late complete heart block. Atrial arrhythmias occur in 30 per cent of long-term survivors and are a major cause of morbidity. Those with left-sided volume overload and left atrial dilatation secondary to residual ventricular septal defect or previous shunts are at particular risk of atrial flutter and fibrillation. Rapidly conducted atrial flutter is particularly poorly tolerated and is likely to be responsible for a proportion of sudden deaths. Ventricular arrhythmias occur in up to 45 per cent of patients. However, the incidence of late sudden death is only 1 to 5 per cent, so not all patients with ventricular arrhythmias are at risk. Sustained monomorphic ventricular tachycardia is likely to be a significant risk factor for sudden death, as are atrial arrhythmias and heart block. Right ventricular risk factors may include right ventricular dilatation, outflow tract obstruction, hypertrophy, aneurysm, impaired myocardial blood flow, and pulmonary regurgitation. Surgical risk factors for late sudden death include transventricular as opposed to transatrial repair, large ventriculotomy scar, residual ventricular septal defect, previous complex or multiple operations, impaired left ventricular function, older age at operation, and length of follow-up.

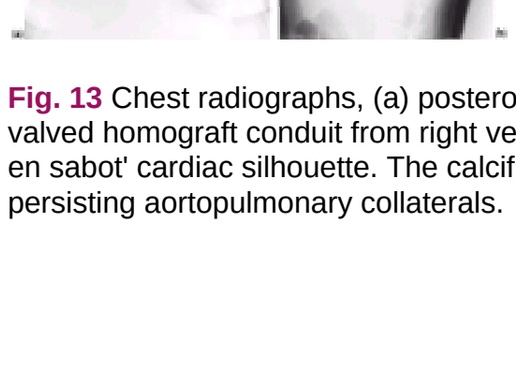

Fig. 14 Electrocardiograms of a 35-year-old woman who underwent radical repair of tetralogy of Fallot. Preoperatively (a) there is right ventricular hypertrophy, postoperatively (b) there is right bundle branch block, due to damage to the right bundle as it runs in the floor of the ventricular septal defect.

Tetralogy of Fallot with pulmonary atresia (pulmonary atresia with ventricular septal defect)

This condition represents the extreme end of the spectrum of tetralogy. There is considerable anatomical variation, including acquired pulmonary atresia with well-developed confluent pulmonary arteries, hypoplastic confluent pulmonary arteries that may not supply all segments of the lungs, non-confluent pulmonary

arteries, and complete absence of central pulmonary arteries. The right ventricular outflow tract is blind-ended and the pulmonary blood supply is derived entirely from three types of systemic vessels: a large muscular duct that resembles a collateral, a diffuse plexus of small 'bronchial' arteries arising from mediastinal and intercostal arteries, or from large tortuous systemic arterial collaterals. These large collaterals arise directly from the descending aorta, from its major branches (usually the subclavian artery), or from bronchial arteries. They may connect with central pulmonary arteries or supply whole segments or lobes of lung independently. This variation has also been termed complex pulmonary atresia.

Examination findings are similar to those of unoperated Fallot without pulmonary atresia, except that there are continuous collateral murmurs and often a collapsing pulse. Coexistent chromosome 22q11 deletion is more common than in tetralogy without pulmonary atresia. There may be dysmorphic facies, hypertelorism, narrow eye fissures, puffy eyelids, a small mouth, deformed earlobes, and sometimes a cleft palate.

The chest radiograph shows a right aortic arch in 25 per cent of cases and has a typical appearance (Fig. 15). The pulmonary collateral vessels may follow a bizarre pattern. Colour flow Doppler may identify collateral vessels, but conventional angiography is required to delineate precisely their origin, degree of ostial stenosis, and intrapulmonary course (Fig. 16). Coronary–pulmonary collaterals are a frequent finding (Fig. 17). Three-dimensional magnetic resonance angiography is likely to prove a useful tool in imaging complex pulmonary vasculature.

Fig. 15 Chest radiograph of a 21-year-old woman with tetralogy of Fallot and pulmonary atresia, no central pulmonary arteries, and multiple aortopulmonary collaterals which create an abnormal pulmonary vascular pattern. The typical 'coeur en sabot' silhouette is due to right ventricular hypertrophy and the pulmonary bay where the pulmonary artery should be (arrow).

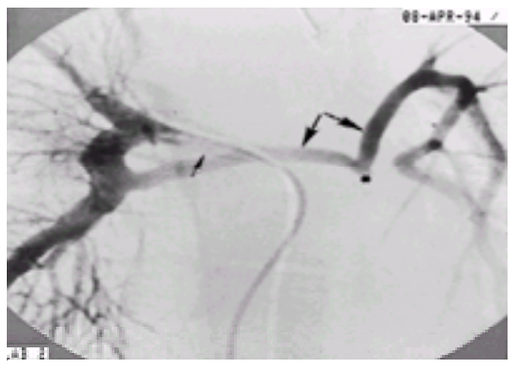

Fig. 16 Aortopulmonary collateral angiogram of a 24-year-old woman with tetralogy of Fallot and pulmonary atresia. There is a stent (small arrow) at the origin of the collateral from the descending aorta. Only after dilation and stenting of the collateral was its connection with confluent main pulmonary arteries (large arrows) apparent. The atretic main pulmonary artery is indicated (*).

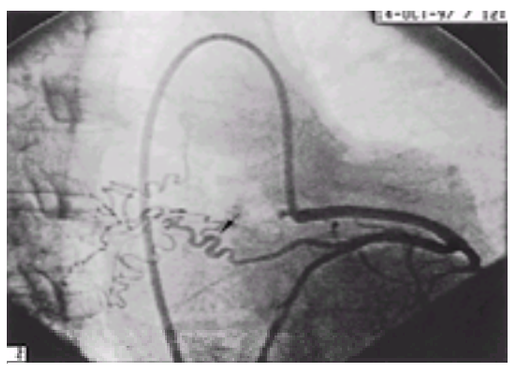

Fig. 17 Selective left coronary angiogram in same patient as Fig. 11 showing a circumflex coronary artery to pulmonary collateral (arrow).

Overall survival, including the effects of operation, is around 25 per cent at 20 years. Late complications in unoperated survivors include increasing cyanosis due either to the development of pulmonary vascular disease in lung segments perfused at systemic pressure through non-stenosed collaterals, or to the progressive stenosis of collateral vessels. In the latter, good symptomatic relief may be obtained from stenting the stenotic vessel. The aortic root may become markedly dilated and aortic regurgitation develop, resulting in biventricular volume overload and failure. Aortic valve endocarditis is a particular risk. Surgery to repair or replace the aortic valve in an unrepaired patient with pulmonary atresia is particularly hazardous because of the aortopulmonary collateral vessels. When cardiopulmonary bypass is instituted, aortic blood flows into the low resistance pulmonary collateral vessels so that it is not possible to maintain an adequate systemic perfusion pressure or to control pulmonary venous return to the left atrium.

Surgery to unifocalize collateral vessels (i.e. disconnect them from the aorta and anastomose them to the pulmonary artery, maintaining pulmonary blood supply by means of a shunt) may need to precede radical repair. Suitability for radical repair depends on the size of the pulmonary arteries and the proportion of lung they supply. The ventricular septal defect is closed and the right ventricular outflow tract connected to the pulmonary artery via a valved conduit. Right ventricular hypertension may follow surgery if the pulmonary arteries are small or distal pulmonary vessels inadequate. Both these factors and the number of aortopulmonary collaterals decrease long-term survival.

Tetralogy of Fallot with absent pulmonary valve syndrome

This variation accounts for around 3 per cent of cases of tetralogy. There is a ring-like malformation, usually stenotic, with failure of development of the pulmonary valve cusps. The central pulmonary arteries are usually hugely dilated or aneurysmal (Fig. 18).

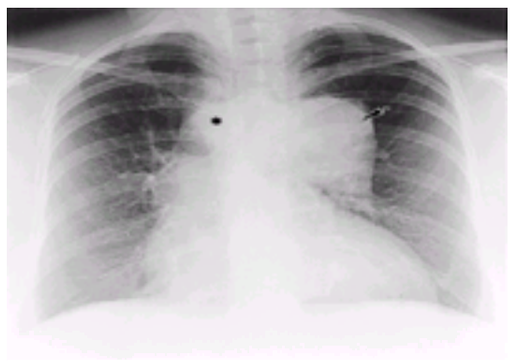

Fig. 18 Chest radiograph of a 54-year-old woman with repaired tetralogy of Fallot and absent pulmonary valve syndrome. The central pulmonary arteries are hugely dilated (arrow) and there is a right aortic arch (*).

Other right-sided obstructive lesions

Isolated pulmonary valve stenosis

Pulmonary stenosis is discussed in detail elsewhere. Cyanosis may be present if severe stenosis coexists with an atrial septal defect or patent foramen ovale. Noonan's syndrome is associated with valvar and infundibular stenosis as well as with hypertrophic cardiomyopathy.

Lone infundibular stenosis and double-chambered right ventricle

Abnormally placed muscle bands cause either infundibular obstruction, or if placed more inferiorly, subinfundibular obstruction and a double-chambered right ventricle. The degree of obstruction may be mild in childhood, but progress into adult life and cause symptoms as the right ventricle hypertrophies. A perimembranous ventricular septal defect usually coexists and may close spontaneously. Treatment is by surgical resection of the obstructing muscle bands.

Pulmonary atresia with intact septum

A full discussion of this complex lesion is beyond the scope of this chapter, since patients do not survive unoperated beyond infancy. Those currently in the adult clinics represent the mild end of the spectrum of this condition and are likely to have had a pulmonary valvotomy or valved right ventricular to pulmonary artery conduit.

Left ventricular outflow tract obstruction

Bicuspid aortic valve

The commonest congenital cardiac anomaly, occurring in 1 to 2 per cent of the population, bicuspid aortic valve is four times as common in males as females. In 20 per cent of cases it is associated with other lesions such as patent arterial duct and coarctation. There is also an association with aortic root dilatation and dissection. Aortic stenosis is discussed in detail elsewhere.

Supravalvar aortic stenosis

In this least common form of left ventricular outflow tract obstruction, there is a localized narrowing of the aorta immediately above the aortic sinuses. Fibromuscular thickening of the aortic wall at the site of obstruction may encroach into the coronary ostia or on to the aortic valve leaflets and adversely influence prognosis. Unlike other forms of left ventricular outflow obstruction, the coronary arteries lie proximal to the obstruction and so are exposed to high left ventricular pressures, resulting in premature atherosclerosis. The condition may be associated with Williams' syndrome, when the prognosis may be worse since there is diffuse arterial involvement that may involve the pulmonary and renal arteries.

Subaortic stenosis

Subaortic stenosis is due either to a discrete fibromuscular ridge or ring, or a long muscular tunnel. It may exist in isolation or as part of another lesion such as atrioventricular septal defect where the aorta is 'unwedged' and the left ventricular outflow tract elongated, or mitral valve anomalies where abnormal insertion of the mitral valve causes obstruction. Whether discrete or tunnel-like, subaortic stenosis tends to progress and may recur following surgical resection. It may result in functional disruption of the aortic valve and secondary aortic regurgitation, which may progress, even after resection of subaortic stenosis.

Coarctation of the aorta

One of the commonest congenital cardiac lesions, occurring in 1 per 12 000 live-born babies with a male to female ratio of 3:1, aortic coarctation is a narrowing of the aorta usually sited near the ligamentum arteriosum. There is considerable variation in anatomy and severity, ranging from a mild obstruction to interruption of the aorta, and from a discrete fibromuscular shelf to hypoplasia of the arch. Coarctation is most strongly associated with bicuspid aortic valve; other associations are ventricular septal defect, patent ductus arteriosus, subaortic ridge and mitral valve abnormalities. It is a frequent finding in Turner's syndrome and is also associated with congenital aneurysm of the circle of Willis.

Unoperated history

Most patients present in infancy, but some survive into adulthood before being diagnosed at routine examination or during investigation for hypertension, leg claudication (uncommon unless there is coexisting abdominal aortic coarctation), angina, heart failure, or cerebral haemorrhage. More than 75 per cent of patients with unoperated coarctation die by age 50 years, from coronary disease, stroke, or aortic dissection.

Clinical findings include upper body hypertension: the leg blood pressure is lower, as is that in the left arm if the subclavian artery is involved in the coarctation. If there is a good collateral supply, femoral arteries may be easily palpable, but they are usually reduced, with radiofemoral delay. Intercostal collaterals may be both visible and palpable over the patient's back. There is an ejection systolic murmur from the site of coarctation, and systolic collateral murmurs may be heard. Fundoscopy shows a typical corkscrew appearance of the retinal vessels and there may be evidence of hypertensive retinopathy.

There may be electrocardiographic evidence of left ventricular hypertrophy. The chest radiograph (Fig. 19) has a typical appearance. Transthoracic echocardiography may show left ventricular hypertrophy, but the coarctation site may not be visualized on two-dimensional imaging, although the severity of coarctation can be assessed using Doppler mode from the suprasternal notch. A peak gradient of gretaer than 20 mmHg is significant, especially if accompanied by a diastolic tail. Angiography allows full haemodynamic and anatomical data to be obtained from both the coarctation site and related vessels, as well as assessing secondary ischaemic myocardial disease. Magnetic resonance imaging provides excellent non-invasive haemodynamic data and two- and three-dimensional images of the coarctation site and related vessels. It may obviate the need for angiography unless coronary disease is suspected.

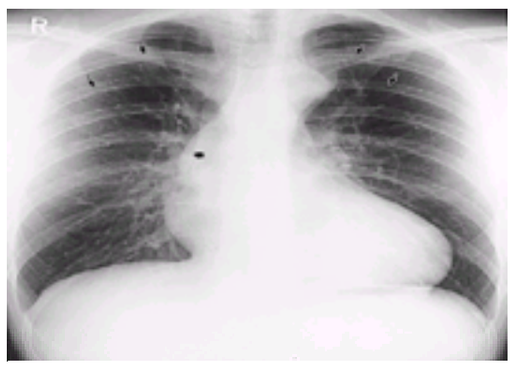

Fig. 19 Chest radiograph of an 18-year-old man with unoperated coarctation of the aorta and bicuspid aortic valve. There is bilateral rib notching (arrows), a dilated ascending aorta (*), and a prominent deformed aortic knuckle.

Repair of coarctation

Surgical repair is the conventional approach. There is a 0.4 per cent incidence of perioperative spinal cord ischaemia and paraplegia: patients without an abundant collateral circulation may be most at risk. Those with well-developed collaterals are at risk of significant intraoperative haemorrhage. Early postoperative hypertension is common and may be difficult to control, and postoperative intestinal ileus may persist for several days.

Transcatheter balloon dilatation and primary stenting of native coarctation in adults are reported, but data are limited and the procedures should still be considered experimental. Stenting has the hypothetical advantage of supporting the dilated segment of aorta which may sustain a significant intimal tear, and preventing aortic rupture or aneurysm formation.

Follow-up after coarctation repair

Follow-up after repair of coarctation should be life-long, since late complications are frequent: recoarctation, aneurysm formation, persistent hypertension despite adequate repair, premature atherosclerotic disease, and progression of associated lesions such as bicuspid aortic valve. Older age at repair is the main risk factor influencing longevity. Late survival is 92 per cent for patients repaired in infancy, 25-year survival is 75 per cent for those repaired between the ages of 20 and 40 years, but 15-year survival is only 50 per cent for those repaired at age 40 years or more.

Recoarctation may be diagnosed when the resting arm–leg systolic blood pressure gradient is 20 mmHg at rest and 50 mmHg postexercise. It occurs most commonly in neonatal repair by end-to-end anastomosis. Recoarctation should be sought when there is new or persisting hypertension. Blood pressure should be recorded in both arms of all such patients; spuriously low readings may be obtained if one of the subclavian arteries (usually the left) is involved in the repair or recoarctation. Magnetic resonance imaging is the investigation of choice for both recoarctation and aneurysm formation after coarctation repair (Fig. 20). Balloon angioplasty with or without stent insertion is used to relieve the majority of recoarctations, but reoperation is required for some patients with complex anatomy.

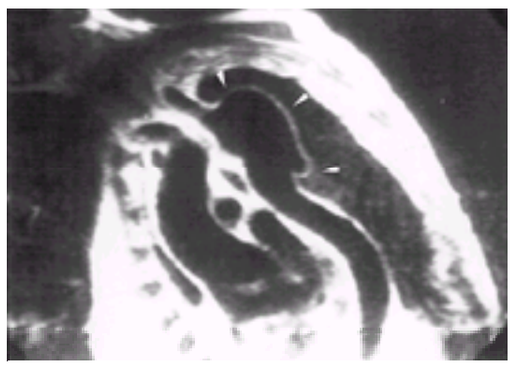

Fig. 20 Magnetic resonance spin echo image showing aneurysm of the descending aortic arch (arrows) following previous Dacron patch repair of coarctation

Hypertension is a major risk factor for atherosclerotic disease and may persist despite an apparently good result from surgical repair. Continuing hypertension is thought to relate in part to older age at time of surgery. None the less, even if repaired in adulthood, systolic hypertension becomes less marked and easier to control, b-blocking agents being the antihypertensives of choice.

The 14-year incidence of aneurysm formation at the site of repair is up to 27 per cent, it occurs most commonly in adults and in those with Dacron patch repair (Fig. 20). The aneurysm may rupture into the bronchial tree: any patient with a history of coarctation who presents with haemoptysis should undergo emergency non-invasive diagnostic imaging (preferably MRI) and surgical repair. Bronchoscopy and conventional angiography are contraindicated since they may cause further damage to the ruptured area.

Congenitally corrected transposition of the great arteries (atrioventricular and ventriculoarterial discordance)

This rare condition accounts for less than 1 per cent of all congenital heart disease. Both atrial and arterial connections to the ventricles are discordant, so pulmonary venous blood passes through the left atrium, through the right ventricle, and into an anteriorly lying aorta. Similarly, systemic venous blood reaches the pulmonary trunk via the left ventricle. The circulation is therefore physiologically 'corrected', but the morphological right ventricle and tricuspid valve support the systemic circulation.

More than 95 per cent of cases have associated anomalies, most commonly ventricular septal defect and pulmonary stenosis, but also Ebstein anomaly of the systemic (tricuspid) atrioventricular valve, aortic stenosis, atrioventricular septal defect, abnormalities of situs, and coarctation. Congenital complete heart block occurs in around 5 per cent of patients and may develop at any stage of life, particularly following surgery to the atrioventricular valve.

Presentation depends on associated lesions. Patients with isolated congenitally corrected transposition of the great arteries may remain asymptomatic and undiagnosed into old age, but failure of the systemic ventricle, systemic atrioventricular valve regurgitation, or the onset of complete heart block and atrial arrhythmias usually result in presentation with symptoms from the fourth decade onwards. Those with ventricular septal defect and pulmonary stenosis may be cyanosed, and those with ventricular septal defect alone may present with pulmonary hypertension.

A parasternal heave is usually palpable from the pressure-loaded anteriorly lying systemic right ventricle; this may be especially prominent if it is also volume-loaded by systemic (tricuspid) atrioventricular valve regurgitation. There may be a prominent aortic pulsation in the suprasternal notch and the aortic component of the second heart sound may be palpable and loud. The pulmonary component is soft or inaudible due to the posterior position of the pulmonary artery.

The electrocardiogram may show varying degrees of atrioventricular block or evidence of pre-excitation due to accessory pathways (associated with Ebstein-like anomalies of the systemic atrioventricular valve). There may be left axis deviation. The right and left bundles are inverted, so the initial septal activation is right-to-left, resulting in Q waves in V1 to 2 and an absent Q in V5 to 6; this pattern is often wrongly interpreted as a previous anterior myocardial infarction. The chest radiograph has a typical appearance (Fig. 21). Echocardiography confirms the discordant relations and assesses ventricular and systemic (tricuspid) atrioventricular valve function as well as other associated lesions. Ebstein's anomaly may be diagnosed if the tricuspid valve is apically displaced more than 8 mm. Cardiac catheterization

is indicated to assess the haemodynamic importance of associated lesions.

Fig. 21 Chest radiograph of a 23-year-old woman with congenitally corrected transposition of the great vessels. There is a narrow pedicle due to the abnormally related great arteries (small arrow) and the left heart border is straight (large arrow) due to the abnormal position of the left-lying anterior ascending aorta.

ACE inhibitors may be useful when there is systemic ventricular dysfunction or atrioventricular valve regurgitation, but there are no trial data to support their use. Transvenous atrioventricular sequential pacing is indicated for complete heart block: active fixation ventricular leads are required because of the absence of coarse apical trabeculations in the morphologically left subpulmonary ventricle. If there are associated intracardiac shunts, patients should be formally anticoagulated to reduce the risk of paradoxical embolism, or epicardial pacing should be considered.

The conventional surgical approach to systemic atrioventricular valve regurgitation is tricuspid valve replacement (repair is rarely successful), but if systemic ventricular function is poor (ejection fraction less than 40 per cent), transplantation may be the only option. Where there is coexistent ventricular septal defect and pulmonary stenosis, classic repair involves closure of the ventricular septal defect and insertion of a valved conduit between the left ventricle and pulmonary artery; the right ventricle continuing to support the systemic circulation.

Anatomical repair, so that the morphological left ventricle supports the systemic ventricle, has achieved short-term success in children with systemic atrioventricular valve regurgitation and systemic ventricular dysfunction. For patients with an associated non-restrictive ventricular septal defect the left ventricle is at systemic pressure and therefore 'pre-trained' to support the systemic circulation. If there is no pulmonary stenosis, a 'double switch' is performed, combining an intraatrial repair (usually Senning operation) with an arterial switch operation. If there is also pulmonary stenosis, the Senning operation is combined with a Rastelli-type repair, in which the ventricular septal defect is closed so that the left ventricle is tunnelled to the aorta, and a right ventricular to pulmonary artery conduit is placed. The regurgitant tricuspid valve and right ventricle are therefore placed in the pulmonary circulation. For children with corrected transposition whose left ventricle is at low pressure, a period of left ventricular 'training' is required before a double switch operation can be performed. Training is achieved by placing a pulmonary artery band to increase left ventricular pressure and induce hypertrophy. Pulmonary artery banding *per se* may improve symptoms, since the increased left ventricular pressure causes the interventricular septum to move towards the systemic ventricle, reducing systemic atrioventricular regurgitation. The long-term outcome of these anatomical approaches to corrected transposition is not yet known; complications relating to conduit replacement, neo-aortic valve regurgitation, and arrhythmia may become significant. There are reports of adults with ventricular septal defect and pulmonary stenosis having successfully undergone Mustard–Rastelli repair. However, whether it is possible to 'train' the adult left ventricle that has been at low pressure for many years remains to be seen, so this approach remains experimental in older patients.

Complete transposition of the great arteries (atrioventricular concordance, ventriculoarterial discordance)

Complete transposition of the great arteries accounts for around 5 per cent of congenital cardiac malformations and is four times more common in males than females. Associated anomalies such as ventricular septal defect and pulmonary stenosis occur in about one-third of patients. Desaturated systemic venous blood passes through the right atrium into the right ventricle and then to the aorta, and oxygenated pulmonary venous blood passes into the left atrium, through the left ventricle and back into the lungs. Once the arterial duct closes, survival depends on an intracardiac communication (non-restrictive patent foramen ovale or ventricular septal defect) allowing mixing of blood between the two separate circuits. Without intervention, 30 per cent of patients die within the first week and only 10 per cent survive their first year. A prostaglandin infusion maintains patency of the arterial duct until a balloon atrial septostomy is performed. The neonate remains cyanosed, but there is usually adequate mixing to allow him or her to thrive until definitive surgery.

Most patients in the adult clinic have survived intra-atrial repair (Senning or Mustard operation), or for those with associated ventricular septal defect and pulmonary stenosis, a Rastelli operation. Intra-atrial repair involves excision of the atrial septum and placement of a saddle-shaped patch ('baffle') to direct pulmonary venous blood into the right atrium, right ventricle and then to the aorta, and systemic venous blood into the left atrium, left ventricle and then into the pulmonary artery. The right ventricle supports the systemic circulation. In the Rastelli operation, the ventricular septal defect is closed so that the left ventricle carrying oxygenated blood empties into the aorta, and a conduit is placed between the right ventricle and pulmonary artery. The left ventricle supports the systemic circulation.

Since the late 1970s anatomical correction by the arterial switch operation began to supersede intraatrial repair as the operation of choice for most patients with transposition of the great arteries. Blood is redirected at arterial level by switching the aorta and pulmonary arteries so that the left ventricle becomes the subaortic ventricle supporting the systemic circulation. The coronary arteries are reimplanted into the neo-aortic root.

'Palliative' Mustard or Senning operations are performed for patients with transposition of the great arteries, ventricular septal defect, and pulmonary vascular disease to improve mixing of blood and oxygenation. The ventricular septal defect is left open. These patients should be treated as other patients with the Eisenmenger syndrome.

Follow-up

After intra-atrial repair of transposition of the great arteries, the systemic right ventricle causes a parasternal heave, the aortic component of the second heart sound may be palpable and loud, and the second sound single, due to the anterior-lying aorta. The presence of cyanosis suggests a baffle leak allowing right to left shunting between the systemic and pulmonary venous atria. Systemic venous pathway obstruction may be associated with elevation of the jugular venous pressure and hepatomegaly. The chest radiograph may show a dilated azygos vein indicative of systemic venous pathway obstruction, with run-off from the obstructed to the unobstructed pathway. Pulmonary interstitial fluid may reflect pulmonary venous pathway obstruction. Although late results of intraatrial repair are good, failure of the systemic right ventricle is exacerbated as the atrioventricular valve becomes regurgitant. In addition, baffle obstruction causing systemic or pulmonary venous obstruction may require transcatheter intervention or reoperation. Atrial arrhythmias, especially atrial flutter, occur in up to 10 per cent of patients 10 years postoperatively. They may be poorly tolerated and are associated with an increased risk of sudden death. Late sinus node dysfunction and complete heart block may also occur: active fixation leads are required to pace both the systemic venous atrium and left ventricle. As in congenitally corrected transposition of the great arteries, the conventional surgical approach for systemic atrioventricular valve regurgitation is tricuspid valve replacement. It is uncertain whether pulmonary artery banding to train the left ventricle and reduce regurgitation, followed by the arterial switch operation, will benefit adults in this situation.

The major late complication following the Rastelli operation is the need for conduit replacement. Late results from the arterial switch operation are awaited. It is likely to have long-term advantages over intra-atrial repair, since it restores normal connections so that the left ventricle supports the systemic circulation without the need for a conduit. Follow-up is needed to detect late pulmonary arterial stenosis, neo-aortic regurgitation, and coronary ostial stenoses.

Hearts with univentricular atrioventricular connection (double-inlet left ventricle and tricuspid atresia)

Also known as univentricular or single ventricle hearts, these hearts are defined by the connection of both atria to one ventricle, or by the absence of one of the atrioventricular connections. There is one dominant ventricle, with a second rudimentary and incomplete ventricle. When the rudimentary ventricle is of right morphology, it nearly always lies anteriorly. Less commonly, there is a posteriorly lying morphologically left rudimentary ventricle, and rarely there is solitary ventricle

of indeterminate morphology.

This section considers double-inlet left ventricle and tricuspid atresia. Less common variants such as double-inlet right ventricle, mitral atresia, and more complex univentricular hearts are beyond the scope of this chapter. Hearts with a large ventricular septal defect and two fully formed ventricles are not correctly termed univentricular and are also excluded. None the less the pathophysiological principles are similar.

In double-inlet left ventricle, ventriculoarterial discordance (transposed great arteries) usually coexists; the aorta arises from the rudimentary right ventricle via the ventricular septal defect. Double-inlet left ventricle with concordant ventriculoarterial connection (Holmes heart) is rare. Tricuspid atresia has a number of morphological variations, but the different morphologies do not affect the basic haemodynamics: the only route out of the right atrium is via an atrial septal defect into the left atrium and then to the ventricular mass. The ventriculoarterial connection is most commonly concordant.

Pathophysiology

For all univentricular hearts, key factors determining the mode of presentation and survival are the presence and degree of pulmonary stenosis, presence and degree of subaortic stenosis, and the morphology of the dominant ventricle.

In hearts with concordant ventriculoarterial connections, pulmonary stenosis may be both valvar and subpulmonary, caused by a restrictive ventricular septal defect, since the pulmonary artery arises from the rudimentary ventricle. Absence of pulmonary stenosis results in high pulmonary blood flow and eventual pulmonary vascular disease. Severe pulmonary stenosis or atresia causes marked cyanosis but protects against pulmonary vascular disease. In hearts with ventriculoarterial discordance, a restrictive ventricular septal defect causes subaortic stenosis, since the aorta arises from the rudimentary ventricle. Subaortic stenosis may be acquired (see Introduction), resulting in preferential pulmonary blood flow and reduced cardiac output. If the dominant ventricle is of left morphology it is better able to adapt to its abnormal geometry and chronic volume overload than a right ventricle.

The outcome is most favourable for patients with left ventricular morphology, moderate pulmonary stenosis, and no subaortic stenosis. Unoperated survival into adulthood is uncommon, 50 per cent of patients with double-inlet left ventricle die before 14 years, 50 per cent with double-inlet right ventricle die by 4 years of age. None the less, rare patients with balanced circulation reach their sixth decade without surgical intervention.

Clinical signs in the unoperated adult

There is cyanosis and clubbing. A giant 'a' wave may be present in the jugular venous pulse in tricuspid atresia. An absent right ventricular impulse and prominent left ventricular impulse are characteristic of double-inlet left ventricle and tricuspid atresia. There may be a precordial thrill from pulmonary stenosis, particularly if the pulmonary artery lies anteriorly. If there are discordant ventriculoarterial connections, the aortic pulsation of the anteriorly lying aorta may be prominent in the suprasternal notch. The second heart sound is usually single and there may be a pulmonary ejection systolic murmur radiating laterally, also a pansystolic murmur of mitral regurgitation.

If pulmonary vascular disease has developed there will be additional signs of pulmonary hypertension. Signs of congestive heart failure may be present in the ageing patient, particularly with the onset of atrial arrhythmia: the venous pressure may be raised, with hepatomegaly and peripheral oedema.

Investigations

The chest radiograph shows cardiomegaly due to chronic ventricular volume overload. If ventriculoarterial connections are discordant, there is a narrow pedicle and the ascending aorta forms a straight edge along the left heart border. Pulmonary vascularity reflects the pulmonary blood flow. The main pulmonary arteries are small where there is significant pulmonary stenosis. Large main pulmonary arteries indicate high pulmonary blood flow, either past or present.

In tricuspid atresia the electrocardiogram usually shows right atrial hypertrophy, normal P–R interval, small or absent right ventricular forces, and left axis deviation. There is left axis deviation and large left ventricular forces in double-inlet left ventricle. If the rudimentary chamber lies to the right, the P–R interval is usually normal, but if it lies to the left, the P–R interval may be prolonged or there may be complete heart block.

Two-dimensional echocardiography and colour flow Doppler allow detailed assessment of the anatomy and physiology, including ventricular morphology and pulmonary and subaortic stenosis. Cardiac catheterization is required to assess pulmonary artery pressure and resistance and to detail pulmonary artery anatomy.

Operations for hearts with univentricular atrioventricular connections

All surgical approaches are palliative, since a biventricular repair is not possible. The aim of definitive surgery is to separate the systemic and pulmonary circulations. Early procedures such as the Glenn anastomosis partly achieved this aim, and it remains a useful staging procedure in children prior to definitive surgery, with the advantage of offloading the ventricle and perfusing the lung at low pressure. However, the relative contribution of the superior vena cava reduces as the child grows, so progressive cyanosis develops. It is therefore inadequate as the sole source of pulmonary blood supply in adults. Pulmonary arteriovenous fistulas are a late complication of Glenn anastomoses and are thought to relate to the exclusion of hepatic venous blood from the pulmonary circulation.

The Fontan operation creates an atriopulmonary connection so that systemic venous blood passes directly to the pulmonary artery, thus bypassing the ventricle, completely separating the systemic and pulmonary circulations and abolishing cyanosis. The ventricle supports the systemic circulation and systemic venous blood flows passively into the pulmonary arteries. The evolution of the Fontan operation and its successor, the total cavopulmonary connection is outlined in Fig. 22. Many variations of the Fontan operation have been developed that are beyond the scope of this chapter.

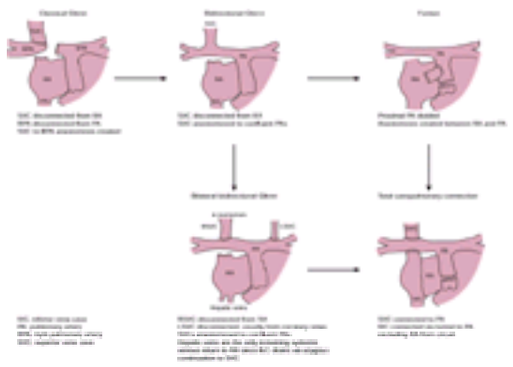

Fig. 22 Evolution of the Fontan operation and total cavopulmonary connection.

The Fontan-type circulation is one of a low cardiac output that can only be increased by increasing the heart rate. This lack of reserve and dependence on adequate systemic venous return both limits exercise tolerance and renders the patient susceptible to subsequent anaesthesia and surgery. Meticulous fluid balance and avoidance of hypovolaemia and excessive vasodilatation are required to prevent cardiovascular collapse.

Survival after Fontan-type surgery is dependent on patient selection and ranges from 81 per cent at 10 years for 'perfect candidates' to 60 to 70 per cent for all patients. Patients with preoperative adverse risk factors for Fontan-type surgery (Table 12) are also more likely to develop long-term complications (Table 13). Paroxysmal atrial flutter (intra-atrial re-entry tachycardia) is a major cause of morbidity in long-term survivors. Right atrial distension, high atrial pressures, atrial suture lines, and obstruction to the Fontan circuit contribute to the development of arrhythmias. Transoesophageal echocardiography and magnetic resonance imaging may visualize the Fontan connection, but cardiac catheterization is usually required to quantify the degree of obstruction. Since the velocities within the Fontan circuit are

low (less than 1 m/s), a pressure drop of only 2 to 3 mmHg between the pulmonary artery and right atrium may indicate haemodynamically important obstruction. Atrial flutter is poorly tolerated so cardioversion should not be delayed. The arrhythmia may become increasingly difficult to control, and if ventricular function is impaired, amiodarone may be the most effective and best tolerated antiarrhythmic. However, amiodarone-induced thyrotoxicosis occurs in up to 40 per cent of Fontan survivors and may precipitate further tachyarrhythmias and heart failure, so thyroid function should be monitored carefully. Whether by excluding the atrium from the systemic venous–pulmonary artery circuit the total cavopulmonary connection will reduce atrial arrhythmia remains to be seen. There is early evidence that conversion of the Fontan to a total cavopulmonary connection, in combination with arrhythmia circuit cryoablation, may reduce the incidence of arrhythmia and improve functional class.

There is usually echocardiographic evidence of spontaneous contrast in Fontan survivors with a dilated right atrium, indicating sluggish flow and a high risk of thrombus formation. Patients with atrial arrhythmia are at particular risk and should be formally anticoagulated. A deficiency of anticoagulation factors in patients after Fontan procedures may also contribute towards thromboembolism.

Protein-losing enteropathy is one of the most debilitating complications of Fontan-type surgery, occurring in up to 13 per cent of late survivors, with a 5-year survival after its onset of less than 50 per cent. It is thought to result from the effects of chronically elevated systemic venous pressure on the lymphatic system causing gastrointestinal protein loss, with malnutrition, oedema, effusions, and ascites due to hypoalbuminaemia, as well as infections secondary to hypogammaglobulinaemia. The diagnosis is confirmed by a low serum albumin and high faecal a_1-antitrypsin. A high protein, low fat, high medium-chain triglyceride diet has been advocated, but is unpalatable. Treatment with corticosteroids, unfractionated heparin, or transcatheter fenestration of the atrial septum may be beneficial. Surgical relief of any Fontan obstruction may be successful, but carries a high mortality and cardiac transplantation may be the only option, although protein-losing enteropathy may recur.

Most patients in the adult clinic have undergone Fontan-type surgery in childhood or adolescence. However, those patients with univentricular heart that survive to adulthood without an operation or with previous shunts are often considered for Fontan-type surgery. Such patients represent a highly selected group of survivors with a well-balanced circulation, and the long-term complications of cyanosis and ventricular volume overload should be weighed carefully against the risk of Fontan surgery in an adult and its long-term complications.

Other arterial anomalies

Persistent patent ductus arteriosus

The pathophysiological consequences of a patent arterial duct in adulthood depend on the size of the shunt. Small ducts are of no haemodynamic significance and are associated with a low risk of infective endarteritis. Moderate-sized ducts may cause left heart volume overload and late atrial fibrillation and ventricular dysfunction. A large non-restrictive duct may cause pulmonary vascular disease (see Eisenmenger syndrome).

If a duct is clinically detectable, that is there is a machinery murmur in the left subclavicular area, then closure is usually recommended to avoid long-term haemodynamic complications. Ducts up to about 8 mm in diameter are usually suitable for transcatheter device closure, but calcification and aneurysmal dilatation around the area of the duct may necessitate surgical repair. In large ducts, pulmonary vascular disease should be excluded before surgical repair is undertaken.

Truncus arteriosus

A single great artery arises from the heart and gives rise to the coronary arteries, aorta, and pulmonary arteries. There is a single semilunar 'truncal' valve that has three or more leaflets, and a subtruncal ventricular septal defect. Figure 23 shows the different patterns by which the pulmonary arteries arise, type 1 is the most common.

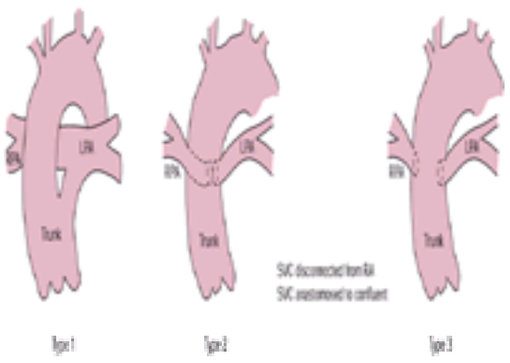

Fig. 23 Truncus arteriosus. Type 1 has a short main pulmonary artery arising from the common arterial trunk. Types 2 and 3 can be considered together, the pulmonary arteries have separate origins from the common trunk. LPA, left pulmonary artery; RPA, right pulmonary artery.

Most patients present in infancy with heart failure. If left unoperated, pulmonary vascular resistance rises, cyanosis becomes more marked, and the Eisenmenger reaction becomes established. Repair before pulmonary vascular disease develops involves closure of the ventricular septal defect, detachment of the pulmonary arteries from the common arterial trunk, and placement of a valved right ventricular to pulmonary artery conduit. The truncal valve then functions as the aortic valve. Late complications include truncal regurgitation and the need to replace stenotic conduits.

Aortopulmonary window

In this rare condition there is a direct communication between adjacent portions of the proximal ascending aorta and pulmonary artery. The communication is usually large and the physiological consequences are the same as for a patent arterial duct. Rare patients surviving without operation into adulthood are likely to have developed the Eisenmenger reaction. If pulmonary vascular resistance is low at the time of childhood repair, long-term postoperative survival is good.

Coronary artery anomalies

The importance of congenital coronary anomalies lies in their potential to impair myocardial blood flow and cause ischaemia and sudden death. Evidence of ischaemia is the main indication for repair. The major types of coronary anomaly are shown in Table 14.

Anomalous origin of the coronary arteries from an inappropriate aortic sinus

Ischaemia is particularly associated with an anomalous proximal coronary course between the aorta and pulmonary trunk, an intramural proximal segment of the coronary artery inside the aortic wall, and acute angulation between the origin of an anomalous coronary artery and the aortic wall.

Anomalous origin of the left coronary artery from the pulmonary artery

This rare condition usually presents in infancy with myocardial ischaemia and left ventricular failure when pulmonary vascular resistance decreases. However, 10 to 15 per cent survive into adulthood because an adequate intercoronary collateral circulation is established. Adults may be asymptomatic or present with myocardial ischaemia or mitral regurgitation due to papillary muscle dysfunction. Survival following surgical repair depends on the amount of ischaemic myocardial damage and degree of mitral regurgitation.

Congenital coronary arteriovenous fistulas

The coronary arteries arise normally from their aortic sinuses, but a fistulous branch communicates directly with the right ventricle in 40 per cent of cases (Fig. 24), the right atrium in 25 per cent, pulmonary artery in 15 per cent, or rarely the superior vena cava or pulmonary vein. Survival to adulthood is usual, but life expectancy is reduced and depends on the size of the fistulous connection and the presence of myocardial ischaemia resulting from any coronary steal phenomenon. Symptoms increase with age and there is a risk of endocarditis, heart failure, arrhythmia, myocardial ischaemia and infarction, and sudden death. Surgical repair is recommended unless there is a trivial isolated shunt. Some smaller fistulas are suitable for transcatheter device occlusion.

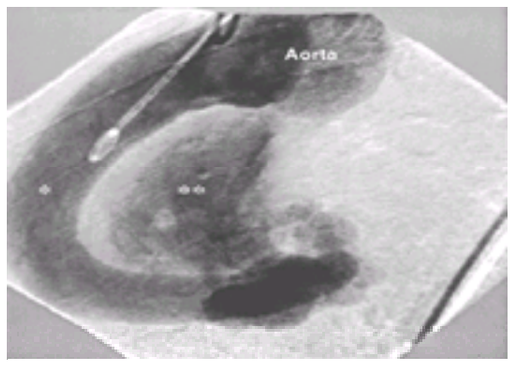

Fig. 24 Angiogram (left anterior oblique) of a 32-year-old man with a huge right coronary artery fistula (*) to the right ventricle (**).

Ruptured sinus of Valsalva aneurysm

Any of the three aortic sinuses of Valsalva may become aneurysmal and rupture. The right and non-coronary cusps are most often affected; rupture of the non-coronary sinus aneurysm is nearly always into the right atrium and of the right coronary sinus into the right ventricle or atrium. Involvement of the left coronary sinus is rare. Rupture usually occurs in early adulthood and may be precipitated by endocarditis. If sudden, it is accompanied by tearing chest pain, breathlessness, and congestive cardiac failure with a loud continuous murmur. Small perforations may remain asymptomatic for many years. The diagnosis and site of the rupture is confirmed angiographically prior to surgical repair. Transcatheter closure has also been reported.

Pregnancy in women with congenital heart disease

In general, the combined oral contraceptive pill is contraindicated in cyanosis, pulmonary hypertension, and following Fontan-type surgery. The progesterone-only pill and progesterone depot injections are safe alternatives, but the former is less reliable. Intrauterine devices are not ideal for many women because of the risk of endocarditis and menorrhagia. Women with pulmonary hypertension may wish to consider sterilization: although a delicate issue, sterilization of the male partner is not recommended as he is likely to outlive the patient and may wish to start a family later. Ventricular dysfunction and arrhythmias tend to deteriorate during pregnancy: regurgitant lesions are better tolerated than stenotic lesions. Pregnancy is contraindicated in pulmonary hypertension, severe systemic ventricular dysfunction (ejection fraction (EF) less than 20 per cent), and severe unoperated left-sided obstruction.

Unoperated atrial septal defect

Atrial septal defect is usually well tolerated in pregnancy; the major risk is of paradoxical embolism, so meticulous leg care and low-dose aspirin are important to avoid venous thrombosis. Haemorrhage may cause a significant increase in left to right shunting by reducing systemic venous return and increasing systemic vascular resistance. Women older than 30 years are at higher risk of developing atrial arrhythmias and right ventricular dysfunction as a result of the increased blood volume of pregnancy.

Tetralogy of Fallot after radical repair

Pregnancy is usually well tolerated after radical repair, provided there is little outflow tract gradient and ventricular function is good.

Ebstein anomaly

The risks relate to an inability of the functional right ventricle to accommodate the increased blood volume of pregnancy. Cyanosis and the risk of paradoxical embolism may present for the first time in pregnancy because of a rise in right ventricular pressure.

Systemic right ventricle

The ability of patients with congenitally corrected transposition of the great arteries or previous Mustard operation to tolerate pregnancy depends on the function of the systemic ventricle, systemic atrioventricular regurgitation, pulmonary venous baffle obstruction (patients with a Mustard procedure), and atrial tachyarrhythmias, all of which may worsen as pregnancy progresses. Patients with complete heart block may tolerate pregnancy better after the insertion of a permanent pacemaker.

Coarctation of the aorta

Pregnancy is a risk factor for aortic dissection and rupture, especially if there is an aneurysm at the site of repair or a coexisting bicuspid aortic valve. Histology of any dissected area shows cystic medial necrosis. Meticulous control of blood pressure is important and the second stage of labour should be kept short to reduce arterial wall stress.

After Fontan operation

Despite the limited ability to increase cardiac output, successful pregnancy is possible in patients with a good postoperative result who have not developed major late complications. There is a high incidence of early miscarriage.

Women with cyanosis but no pulmonary hypertension

Maternal mortality is considerably less in women with cyanosis but normal or low pulmonary artery pressures than in those with pulmonary hypertension. Maternal morbidity and fetal outcome are determined by ventricular function and cyanosis. The reduction in systemic vascular resistance and increase in cardiac output during pregnancy increases the right to left shunt, resulting in a fall in SaO_2. If resting SaO_2 is less than 85 per cent, the risk of miscarriage is around 80 per cent, with additional risks of low birth weight and prematurity. Heart failure may be precipitated by the increased blood volume, particularly if there is aortic regurgitation. The hypercoaguable state of pregnancy combined with a high haematocrit increases the risk of thrombosis and paradoxical embolism. Patients are also at risk of haemorrhage during delivery, particularly if a section is performed. Labour and delivery must be managed carefully, avoiding hypovolaemia and vasodilatation which may precipitate intense cyanosis, syncope, and death.

Eisenmenger syndrome

Maternal mortality remains unchanged at about 40 per cent. Women should be counselled strongly against pregnancy, given adequate contraceptive advice, and be advised to undergo therapeutic termination if contraception fails.

Management of pregnant women with the Eisenmenger syndrome is difficult and requires expertise, not least because data to support treatment decisions are sparse.

The fixed pulmonary vascular resistance and reduction in systemic vascular resistance enhance the right to left shunt, increasing maternal and fetal hypoxia. The patient should be admitted for bed rest during the second trimester and meticulous care given to avoid deep venous thrombosis, dehydration, and vasodilation. Oxygen therapy, nitric oxide, and heparin may be given, although there is no firm evidence that any are beneficial, and heparin increases the risk of haemorrhage. Abrupt changes in systemic vascular resistance or blood pressure during labour and delivery may induce intense cyanosis and death. Opinion is divided as to whether vaginal delivery with forceps assistance or caesarean section should be performed. Vaginal delivery may be safer, causing less rapid haemodynamic changes and less blood loss. The risk of sudden death continues for the first 2 weeks after delivery, either from deteriorating haemodynamics or pulmonary infarction.

Bacterial endocarditis

Endocarditis is discussed elsewhere; the risks for specific congenital lesions are outlined in Table 15.

15.14.1 Thoracic aortic dissection

B. Gribbin and A. P. Banning

Introduction

Acute dissection of the thoracic aorta is uncommon: approximately 20 to 40 cases may be seen in a specialist cardiac unit each year. Unrecognized and untreated it carries a mortality of up to 2 per cent per hour and 90 per cent within the first few weeks.The catastrophic and potentially lethal nature of the dissection process means that quick recognition and treatment are fundamental. Non-invasive diagnostic imaging must be rapid, safe, and accurate. For patients with confirmed dissection of the ascending aorta, emergency surgery may be lifesaving, but when the ascending aorta is spared, aggressive control of blood pressure is the usual initial management, with surgery being considered if there is evidence of further progression of dissection or ischaemic complications.

Despite advances in aortic imaging, surgery, and anaesthesia, survivors of acute dissection have an uncertain long-term prognosis. Careful medical follow-up is recommended and serial aortic imaging can provide important prognostic information, but optimal management of survivors remains controversial.

Pathogenesis

The aortic wall is composed of three layers: a thin intimal lining; a thicker medial layer, largely composed of elastin fibres that provide strength; and a thinner adventitial outer layer from which small blood vessels, the vasa vasorum, arise to nourish the outer layers of the media. Dissection occurs when a breach in the integrity of the intima allows blood at high pressure to penetrate the media. Through this tear, pulsatile blood flow can then propagate distally, parallel to the lumen, often spiralling and splitting the arterial wall into an inner (intima–medial) and outer layer (media–adventitial). This process of tearing within the wall results in the formation of a false lumen, parallel to the original true lumen, and commonly of similar size (Fig. 1 and Plate 1). Further communication(s) between the lumens (or re-entry tears) can occur and may reduce the pressure within the false lumen thus limiting propagation of the dissection. However, the process often extends along the entire length of the aorta to the common iliac artery, threatening the origins of branch vessels which may be avulsed or narrowed by the mass effect of the false lumen, leading to ischaemia in the dependent vascular territories. When dissection extends retrogradely towards the heart it can cause occlusion of a coronary artery and distortion of the aortic valve causing aortic regurgitation. It may also rupture into the pericardial space causing tamponade. The weakened aortic wall can rupture at any point along its length: this is usually fatal.

Fig. 1 Post-mortem specimen of aortic dissection. The intimal/medial flap is pulled back with a retractor to show the false lumen parallel to the true lumen. (See also Plate 1.)

Classification

The commonest sites for thoracic aortic dissection to begin are in the ascending aorta just above the sinuses of the aortic valve and in the upper descending aorta just beyond the origin of the left subclavian artery. Two classifications are used to describe the extent of aortic involvement. De Bakey and colleagues described a classification of dissection that is primarily anatomical and involves three groups: type 1—involving the ascending aorta and arch, with or without involvement of the descending aorta; type 2—involving the ascending aorta alone, without involvement of the arch or descending aorta; and type 3 —involving only the descending aorta. When dissection involves the ascending aorta, emergency surgery is the usual treatment, whereas medical treatment is the initial treatment for patients with uncomplicated dissection sparing the ascending aorta. Therefore, using the De Bakey classification, types 1 and 2 dissection would be considered for surgery.

The Stanford group have subsequently proposed a classification that is directly linked to patient management. Dissection involving the ascending thoracic aorta is classified as type A and demands immediate surgery, whereas dissection which spares the ascending aorta is classified as type B and initial management is usually medical. This classification is recommended as it is unambiguous (Fig. 2).

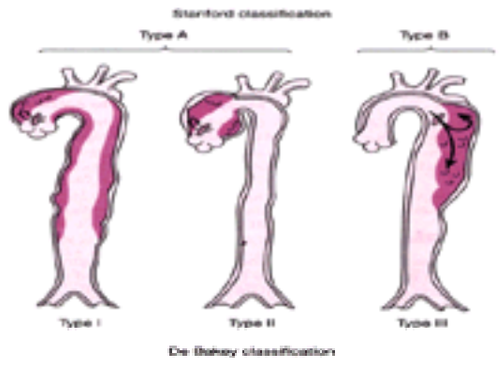

Fig. 2 Diagram of the Stanford and De Bakey classifications of aortic dissection.

Aetiology

The most common predisposing factor is hypertension, which is present in the great majority of patients with aortic dissection. Although the processes involved in the initiation of dissection remain incompletely understood, medial haemorrhage from rupture of vasa vasorum appears to be important. When this process is self-limiting and there is no expansion of the resultant haematoma by recurrent bleeding, healing may occur with reabsorption of the haemorrhage. Alternatively, and particularly when the bleeding is extensive or recurrent, a large intramural haematoma may form around the circumference of the aorta. This alters the distribution of tensile stresses within the aorta, with much of the redistributed stress affecting the intima/endothelium overlying the mass. An intimal tear may then result in splitting and separation of the media, propagation of a false lumen, and dissection.

Patients with the Marfan syndrome may present with aortic dissection or aortic root dilatation (see Chapter 15.12). It is proposed that abnormal fibrillin within the aortic media results in intimal instability, particularly when aortic dilation leads to increased wall stress. Although the absolute risk of dissection rises with increasing size of the ascending aorta, it is important to remember that all patients with Marfan syndrome are at risk, particularly when there is a family history of dissection. Patients with Ehlers–Danlos syndrome are also at risk of spontaneous dissection, not only of the aorta but of its principal branches, including the coronary arteries.

Patients with coarctation of the aorta and those with bicuspid aortic valves appear to be at increased risk of dissection: it is uncertain if this association is related to a defect in aortic wall composition. Dissection may also occur in patients with Turner syndrome, Noonan syndrome, and in the later stages of pregnancy, particularly in patients with Marfan syndrome. In high-risk patients with Marfan syndrome with dilated aortas or a family history of dissection, deferring pregnancy until after elective aortic root replacement may be advisable.

Clinical presentation

Most patients present with characteristic symptoms and clinical findings, in which case the diagnosis of dissection can be made with reasonable assurance. However, a minority present atypically and it is worth considering the possibility of aortic dissection in any patient who is haemodynamically unstable without satisfactory explanation.

The pain of acute dissection of the aorta can be described in terms of (i) its instantaneous onset, (ii) its cataclysmic severity, (iii) its pulsatile and tearing quality, (iv) its location either in the anterior thorax or back, and (v) its migration as it follows the course of the dissection through the thorax. Careful interrogation about the presence of these five features will usually allow differentiation from other causes of chest pain. The instant onset, tearing/pulsatile quality, and migratory pattern contrasts particularly with the pain of cardiac ischaemia, which is usually gradual in onset, tight or crushing, and more unchanging in its distribution in the anterior chest. Syncope shortly after the onset of typical pain is not common but is another characteristic presentation of dissection, often caused by rupture of the false lumen into the pericardial cavity. Other uncommon modes of presentation include stroke and limb ischaemia with or without pain and very occasionally congestive heart failure resulting from severe aortic regurgitation.

Although patients with dissection usually appear shocked, their blood pressure may be normal or raised and their heart rate relatively slow. The distribution of the abnormalities detected by physical examination usually reflects the region of the aorta involved in the dissection and pressure on adjacent structures. Signs of aortic regurgitation or tamponade are likely to be found in a patient with dissection involving the ascending aorta, whereas absent upper limb pulses and cerebral abnormalities suggest involvement of the aortic arch. Expansion of the arch may compress venous return and cause engorgement of one or both jugular veins. Similarly, hoarseness and Horner's syndrome can follow pressure on the left recurrent laryngeal nerve and superior cervical ganglion, respectively. Tenderness over a carotid artery may be due to dissection extending up the artery from the arch. Involvement of the descending aorta can result in visceral and lower limb ischaemia.

Although traditional teaching emphasizes the relevance of blood pressure discrepancy between the arms, this is not a particularly sensitive sign, particularly when dissection spares the ascending aorta and arch. However, evidence of new aortic regurgitation or development of pulse deficits are specific signs of dissection and should be actively sought by the examining physician.

Abnormalities of the chest radiograph and electrocardiogram are not uncommon in patients with dissection, but neither investigation is diagnostic and further imaging is always necessary. Potential abnormalities on the chest radiograph include tracheal deviation, left pleural effusion, a widened mediastinum, and the 'calcium sign' (Fig. 3).

Fig. 3 Chest radiograph showing calcium in the aortic knuckle, which is displaced medially (arrows).

Non-specific ST-segment and T-wave changes on the electrocardiogram are often found, as are changes related to previous hypertension. Actual involvement of a coronary artery is relatively uncommon although the right coronary artery is more likely to be affected. An atypical distribution of ischaemic changes (i.e. generalized acute changes, not consistent with just one coronary territory) is more usual and should always alert the physician to the possibility of a diagnosis other than acute myocardial infarction and the danger of the inadvertent administration of thrombolytic treatment.

Emergency management

Lowering systolic blood pressure and limiting shear stress reduces the likelihood of progression of dissection. Every patient with a clinical suspicion of dissection should therefore receive effective pain relief (intravenous morphine is usually required) and antihypertensive medication pending a definitive diagnosis by imaging. Patients should be cared for in a high dependency area with continuous monitoring of the electrocardiogram and regular blood pressure and urine output measurement. Ideally, systolic blood pressure should be maintained below 110 mmHg, using intravenous labetalol (initial dose 1 mg/min) or esmolol. Both of these agents produce a rapid and titratable reduction in blood pressure, with b-blockade particularly appropriate in this context as it reduces the force of cardiac contraction and the rate of rise of the arterial pressure. If blood pressure control remains suboptimal, an additional infusion of sodium nitroprusside may be used (0.5 to 8 µg/kg.min).

Optimal management of patients with dissection requires close liaison between district hospitals and cardiac surgical centres, using local guidelines for investigation that should reflect the available expertise and surgical opinion. Patients with a low clinical index of suspicion of dissection who are in a stable cardiovascular state should undergo prompt investigation in their local hospital, using a nominated non-invasive technique—usually CT scanning. Unless non-invasive imaging is available immediately, unstable patients with a high clinical index of suspicion should receive medical treatment and be transferred immediately to a surgical centre for both diagnostic imaging and management. This approach minimizes delay, a critical aspect of the management of acute aortic dissection.

Imaging

The priorities when imaging a patient with suspected dissection are to confirm the diagnosis and to decide if the ascending aorta is involved (Stanford type A) as this

will determine whether or not surgery is required. The surgeon wants to know the entry site of the dissection, if the aortic valve is competent, if there is a pericardial effusion or tamponade, and if there is involvement of the coronary arteries. Several diagnostic techniques are available.

Historically, aortography was the investigation of choice, but it has several disadvantages. These include delay during the assembly of the catheter laboratory team, the risk of aortic rupture during catheter manipulation, and the nephrotoxicity of radiological contrast media when renal function may already be compromised by hypotension or renal artery involvement. Computed tomography (**CT**), magnetic resonance imaging (**MRI**), and echocardiography all have proven advantages over aortography.

Contrast-enhanced CT is non-invasive, but requires the use of radiological contrast medium. Its sensitivity and specificity is at least equivalent to aortography, but its accuracy is inferior to both MRI and transoesophageal echocardiography, although improved diagnostic accuracy has been demonstrated by ultrafast and spiral CT.

MRI is non-invasive and provides excellent images of the whole aorta. Its sensitivity and specificity for dissection is up to 100 per cent in some series, and the addition of cardiac gated and 'cine' techniques can give information on luminal blood flow and valvular regurgitation. MRI is therefore the investigation of choice for most diseases affecting the aorta, but it has several limitations in patients with suspected acute dissection of the aorta. These include the requirement for patient transfer to the scanner, with attendant delays, restricted access to the patient during scanning, and the high degree of patient co-operation required to obtain artefact-free images.

Transthoracic echocardiography cannot exclude aortic dissection as it has limited sensitivity and specificity. However, in some patients dissection of the ascending aorta can be confidently diagnosed using parasternal and suprasternal imaging, mandating urgent transfer to a surgical centre where additional information can be obtained by transoesophageal echocardiography in the anaesthetic room.

Transoesophageal echocardiography provides detailed anatomical information about the morphology of a dissection and can also demonstrate the consequences of proximal extension, including the presence of aortic regurgitation, pericardial effusion, and involvement of the coronary artery ostia, thus making complementary investigations such as angiography unnecessary. It can be performed rapidly by a single operator with nursing assistance, in an environment where the patient can be monitored and remains accessible to medical staff. This approach minimizes delay and allows rapid transfer to the operating theatre, making transoesophageal echocardiography the ideal diagnostic tool for the emergency situation (Fig. 4and Plate 2).

Fig. 4 Transoesphageal transverse two-dimensional and colour Doppler echo images of the ascending aorta showing a dissection membrane partitioning the true (TL) and false lumen (FL). Upper left panel shows systolic flow in the true but not the false lumen. (See also Plate 2.)

Surgery for dissection of the ascending aorta

When the dissection involves the ascending aorta (Stanford type A), immediate surgery is required as there is a high risk of proximal extension causing dissection of the coronary arteries, incompetence of the aortic valve, and rupture into the pericardium. Surgery usually involves excision of the intimal tear in the ascending aorta and interposition of a dacron graft. This procedure protects the lower ascending aorta and valve from progressive dissection and prevents distal extension by reducing pressure within the false lumen. The false lumen may subsequently thrombose, or in cases with multiple intimal tears, may remain patent but decompressed.

Replacement of the aortic valve is usually performed only when resuspension of the valve is not possible. However, in patients with Marfan syndrome the ascending aorta and valve are usually replaced with a composite graft to prevent subsequent annular dilatation. In cases where dissection extends into the aortic arch, some surgeons advocate that the arch and great vessels should be included in the initial repair as arch involvement is a strong predictor of a requirement for repeat surgery. However, this extended surgery increases the duration of the operation and the risk of central nervous system damage, hence inclusion of the arch in dissection repair is generally restricted to centres with particular expertise.

Management of descending aortic dissection

Proximal extension towards the heart is less likely when the dissection begins distal to the left subclavian artery (Stanford type B). These patients tend to be older than those with ascending aortic involvement and are more likely to have comorbidity. Diligent blood pressure management is the usual initial treatment as surgery upon the descending thoracic aorta carries significant mortality and morbidity, including impaired blood supply to the spinal cord and paraplegia.

This approach is not universally accepted, however, and some centres recommend elective surgery (after several weeks) in selected patients with Marfan syndrome, in younger patients with dissection associated with large aneurysms, and if thrombosis of the false lumen fails to occur. In addition, surgery for type B dissection should always be considered if there is evidence of proximal extension of the dissection, progressive aortic enlargement threatening external rupture, or ischaemic complications from involvement of major arteries. For example, the prognosis is extremely poor when ischaemia occurs in the territory of a major abdominal artery, in which case emergency surgical fenestration of the intimal flap can be lifesaving.

Encouraging results have recently been achieved using endovascular stenting for patients with complicated dissection starting distal to the left subclavian artery. Using vascular access from a groin incision, a covered stent can be delivered to cover the intimal tear. In suitable cases this obliterates flow into the false lumen, relieving branch ischaemia and preventing further aneurysmal dilatation.

Follow-up of patients with aortic dissection

Strenuous efforts to control blood pressure are indicated for all patients who have survived aortic dissection. b-Blocking drugs are the agents of choice for most, with other agents added as required.

Despite advances in the medical and surgical management of patients with aortic dissection, their long-term prognosis remains uncertain, with several adverse risk factors identified. These include new or progressive dissection, aneurysm formation at the site of surgical anastomosis, and persistence of flow in the false lumen, the last seemingly related to the presence of multiple intimal tears that allow communication between the lumens. Management is controversial, but it has been suggested that in the chronic situation, endovascular stenting may have a role in sealing these communications, thus allowing thrombosis of the false lumen.

Imaging at least once a year is recommended, using the modality with which there is most local expertise. Increased frequency of imaging is recommended following any acute event, for example severe chest pain, and for some patients with Marfan syndrome.

Modern imaging techniques have shown that variants of acute aortic dissection occur. They present in much the same way as classic dissection and may be considered part of the acute aortic syndromes. They include spontaneous intramural haematoma and penetrating atherosclerotic ulcer.

Spontaneous intramural haematoma

Spontaneous intramural haematoma was described by pathologists in 1920. It occurs when the small arterioles (vasa vasorum) which run in the outer media of the aorta rupture and bleed. As it is a medial/adventitial event, the intima remains intact and there is no false lumen. The clinical presentation may mimic that of dissection and the diagnosis can only be made by exclusion of an intimal tear or a penetrating atherosclerotic ulcer. The intramural haematoma is not readily identifiable by aortography, but using non-invasive imaging, a circular or crescentic thickening of the aortic wall of more than 0.7 cm in depth ssociated with central displacement of any intimal calcification supports the diagnosis (Fig. 5).

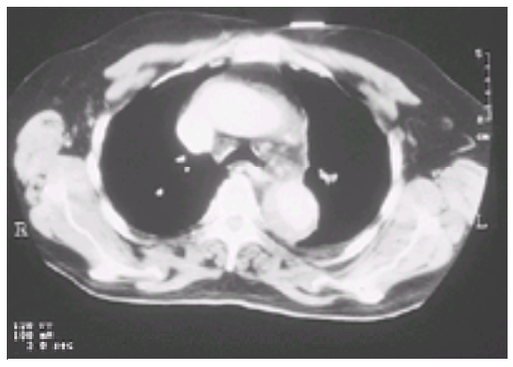

Fig. 5 CT of the thorax showing crescentric thickening of the posterior wall of the descending aorta (adjacent to the vertebra) without compromise of the aortic lumen. Transoesophageal echocardiography showed no intimal flap. The diagnosis is spontaneous haematoma of the aortic wall.

As outlined earlier, there is increasing evidence that spontaneous intramural haematoma may be a precursor of aortic dissection. Clinical studies have supported this assertion: despite aggressive blood pressure control, up to 50 per cent of patients with an intramural haematoma develop dissection or aortic rupture and many now regard this condition as an indication for surgery when the ascending aorta is involved.

Penetrating atherosclerotic ulcer

Penetrating atherosclerotic ulcer presents with similar symptoms to aortic dissection, usually in patients with disseminated atheroma. Intimal disruption caused by atheroma results in perforation and secondary haemorrhage into the media. Imaging demonstrates an out-pouching from the lumen into the aortic wall with localized haemorrhage and evidence of diffuse atheroma.(Fig. 6). Rarely, this can cause a localized dissection, but the main threat is the high incidence of rupture. Treatment is currently surgical, but in the future endovascular stenting may be useful.

Fig. 6 Transoesophageal two-dimensional echo image of a penetrating ulcer (arrow).

15.14.2 Peripheral arterial disease

Janet Powell and Alun Davies

Introduction

Peripheral arterial disease, defined for the purpose of this chapter as diseases of the abdominal aorta and its branches, has risk factors and features that overlap with, but can be distinguished from, those of coronary artery disease. The two conditions often coexist, but patients with coronary disease are almost always referred directly to physicians, whilst those with peripheral arterial disease are referred directly to vascular surgeons, particularly in regions where angiology is a poorly developed specialty, since there are few effective medical therapies. Vascular surgeons also manage patients with arterial disease in the carotid vessels and upper limbs. These aspects will receive only passing mention in this chapter: for discussion regarding the clinical features and management of carotid artery disease, see Section 15.14.

The most common presentations of peripheral arterial disease are intermittent claudication and abdominal aortic aneurysm. Most peripheral arterial disease remains asymptomatic. It is not a new disease that results from a modern Westernized lifestyle. Atherosclerotic disease, partially occluding the peripheral arteries, has been described in the mummies of ancient Egypt. Life as a cavalry officer was associated with an increased risk of popliteal aneurysm, a condition treated by ligation by John Hunter, the pioneering eighteenth-century surgeon. Albert Einstein died of a ruptured abdominal aortic aneurysm.

Techniques for repairing abdominal aortic aneurysms were not developed until the middle of the twentieth century. This was the golden era for the development of vascular surgery as a specialty, with the increasing use of bypass surgery hat has minimized the need for amputation. Today newer, less invasive approaches are being used—angioplasty and endovascular stenting—but few medical therapies are on the horizon.

Aetiology and epidemiology

Peripheral arterial disease may occur in the young but the prevalence increases sharply with age. Both young and old may suffer from occlusive (stenosing) disease of the peripheral arteries or dilating (aneurysmal) disease, while vasospastic disease is uncommon. However, the underlying causes of peripheral arterial disease in those below and above 50 years of age tend to be very different.

Peripheral arterial disease in patients less than 50 years old

In younger patients the cause of disease is most likely to be genetic, congenital, immunological, infectious, or traumatic. Patients with familial hypercholesterolaemia and related inherited disorders of lipid metabolism may present with peripheral limb ischaemia. There are also congenital causes of early-onset leg ischaemia. These include aortic hypoplasia, which occurs during the embryonic fusion of the distal aortas, and popliteal entrapment, where the popliteal artery takes an unusual course through the head of the gastrocnemius muscle, with exercise involving knee flexion causing intermittent occlusion of the artery and calf pain that resembles intermittent claudication. A fierce immunological inflammatory response to smoking causes Buerger's syndrome, which involves the artery, vein, and associated nerves in both the legs and the arms. This disease, seen principally in men, is particularly prevalent in the Indian subcontinent, and may resolve if the patient stops smoking. Sudden thrombotic occlusion of the iliac and distal arteries may occur in those below 50 years of age, suggesting the presence of an inherited thrombotic disorder. Embolic occlusion from a proximal source is also possible.

Marfan syndrome may sometimes be confirmed (mutation in the fibrillin-1 gene) only after a patient has presented with a ruptured abdominal aortic aneurysm. In some variants of Ehlers–Danlos syndrome, patients with mutations in type III collagen present with visceral artery aneurysms. In South Africa (and elsewhere) aneurysms of the abdominal, femoral, or popliteal arteries in those under 50 years have been attributed to infectious causes, from HIV to tuberculosis. Syphilitic aneurysms, which used to affect principally the thoracic aorta, are now rare.

Peripheral arterial disease in patients over 50 years old

For patients over 50 years of age, the principal risk factor for peripheral arterial disease—stenosing, aneurysmal, or vasospastic—is smoking. The pathology is atherosclerotic change with superimposed thrombosis. Of patients who present with peripheral arterial disease, less than 5 per cent have never smoked. For this reason, more men than women presented with peripheral arterial disease in the past, but recently more women have been presenting with the condition, perhaps a reflection of the increasing number of women who smoke. Nevertheless, unlike Buerger's disease, cessation of smoking is not associated with an immediate dramatic improvement in symptoms and it may take several years without smoking to improve prognosis.

Diabetes is another important risk factor for stenosing peripheral arterial disease. Other risk factors include hypertension, raised levels of plasma fibrinogen, and hyperlipidaemia, with elevated plasma triglycerides being a common finding. The risk factors for dilating arterial disease are similar, with the exception of diabetes, which is rare.

For aortic aneurysms, although strong familial clustering has been observed, no specific genetic mutations associated with aneurysmal disease have been identified and atherosclerotic change is commonplace. Caucasian and northern European populations appear to be at higher risk of aneurysmal disease than black populations. Stenosing and aneurysmal disease are associated with degenerative changes of the artery wall, the prevalence of both diseases increasing sharply with age (Table 1). Epidemi-ological studies also indicate a difference between stenosing and aneurysmal disease, with death from aneurysmal disease (aortic aneurysm) being more common amongst those of higher social classes and in affluent geographical areas.

Clinical features of leg ischaemia

The terms acute and chronic relate purely to the length of time that symptoms have been present and must not be confused with terms related to severity, such as

critical limb ischaemia.

Critical leg ischaemia

Critical leg ischaemia is defined as gangrenous change, ulceration, or rest pain lasting for 2 weeks with an absolute ankle pressure of less than 50 mmHg, although patients with diabetes are difficult to include in this classification.

Acute leg ischaemia

The incidence of acute leg ischaemia, which presents as a painful, pale, and pulseless limb, is 1 in 12 000 patients per annum. It can be due either to an embolic event or thrombosis of an atherosclerotic stenosis. The commonest cause of a peripheral embolus used to be rheumatic heart disease in a patient with atrial fibrillation, but this is becoming less common, and other sources of emboli, such as an aortic aneurysm, must be considered. The development of a thrombosis at the site of an atherosclerotic stenosis, either in the superficial femoral artery or popliteal artery, is undoubtedly now the commonest cause of acute leg ischaemia. However, it should be stressed that, whatever the cause, there is no difference on clinical examination of the acutely ischaemic limb.

Arterial trauma, due to road traffic accidents and knife or gunshot wounds is becoming commoner, as is iatrogenic trauma following the insertion of intra-arterial catheters for diagnosis or therapy. A rare but dramatic cause of acute leg ischaemia is phlegmasia cerulea dolens, in which massive thrombosis of all the major veins of the limb occurs with gross swelling that obstructs the arterial supply.

Patients with a thrombosis of a popliteal aneurysm may present with classic symptoms of pain, paralysis, loss of power, paraesthesia, pallor, lack of pulse, and perishing cold. If the blood supply is not restored, fixed blue staining of the skin is a further sign of irreversible ischaemia, as is a tense calf with plantar flexion. However, the majority of patients presenting with acute ischaemia have symptoms that are less severe.

Chronic leg ischaemia

Chronic leg ischaemia is much more common than acute ischaemia (Table 1) and its main cause is atherosclerosis. In the young patient one should also consider cystic adventitial disease, entrapment of the popliteal artery, and occasionally fibromuscular hyperplasia of the iliac arteries, particularly in women.

Symptoms are pain on walking, claudication affecting the calf and thigh, rest pain, ulceration, and gangrenous change. Less commonly patients may present with buttock claudication and impotence (Leriche's syndrome). Whilst the differential diagnoses of the acutely ischaemic limb are few, in the chronically ischaemic limb pain may be due to nerve root compression or arthritis of the hip or knee. Classically the patient with claudication will complain of cramp-like pain in the calf, appearing after walking a particular distance, relieved by a few minutes rest, and recurring again at the same distance if the patient resumes walking. Failure of the pain to disappear on resting, or its reappearance after a shorter distance after each rest, suggest a possible musculoskeletal cause, particularly if distal pulses are present on examination. However, it should also be remembered that distal pulses may be felt at rest in the limbs of patients with claudication due to peripheral vascular disease, but disappear on exercise to the point of pain.

Investigation of the patient with an ischaemic leg

The main diagnostic method used to confirm the diagnosis of peripheral arterial disease is Doppler ultrasonography (duplex scanning), an example of which is shown in Fig. 1 and Plate 1. The ratio of systolic blood pressure at the ankle and in the arm, ankle–brachial pressure index (**ABPI**), provides a physiological measure of blood flow at the level of the ankle. At rest, in a normal leg, the ABPI lies between 1.0 and 1.4. As the blood flow in the leg is compromised, the ABPI falls sharply and values below 0.9 are considered abnormal and likely to confirm the diagnosis of peripheral vascular disease. To emphasize the important overlap between this condition and coronary artery disease, a reduction in ABPI nearly always signals the presence of coronary artery disease, which is the cause of death in the majority of patients with peripheral arterial disease.

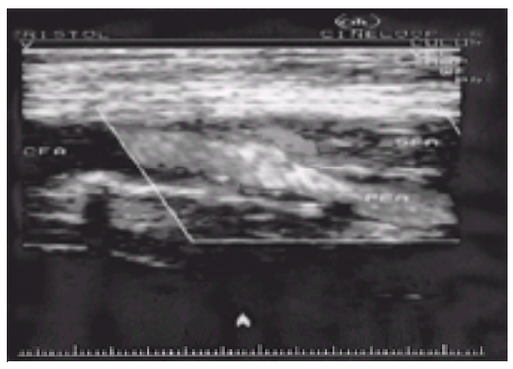

Fig. 1 Occlusion of the superficial femoral artery demonstrated by colour-coded duplex ultrasonography. On the left, the common femoral artery (CFA) lies outside the colour box. In the colour box antegrade flow through the profunda femoris artery (PFA) is shown in blue. The red flash represents rebound flow against the occluded origin of the superficial femoral artery (SFA). (See also Plate 1.)

Exercise testing provides an objective method of assessing walking distance and helps with the identification of disease processes such as angina that may be limiting. It only needs to be used in those people who have a history of claudication but have normal resting ankle–brachial pressure indices, and it can be used as a way of eliminating or suggesting other diagnoses.

In addition to establishing the diagnosis of peripheral arterial disease, duplex ultrasonography is able to determine the site of disease and to indicate the degree of stenosis or length of an occlusion and hence aid in the planning of interventional treatment. Angiography is only required as an adjuvant to endovascular treatment, for surgical planning in some circumstances, or in the management of the acutely ischaemic limb.

Attention to risk factors, in particular smoking and blood pressure, are important issues.

Management of critical and acute limb ischaemia

Critical limb ischaemia requires administration of analgesia and rapid surgical intervention. The severity of ischaemia will determine the treatment options considered. However, all patients with a severely ischaemic limb should be given adequate analgesia and 5000 units of heparin intravenously. Many will be old and frail, with significant medical comorbidities. These issues must be considered in deciding whether or not surgical intervention is appropriate for any individual case, with action taken to improve those aspects of the patient's medical condition that can be improved before surgery, or as part of continuing medical management.

For a patient with irreversible ischaemia (fixed skin staining and tense muscles), the main decision is whether a primary amputation or palliative care should be offered. If severe but potentially reversible ischaemia is present (white leg), surgery is usually the treatment of choice. Delay while thrombolytic therapy is tried is not advisable in this group. For patients with moderate limb ischaemia, where there is no paralysis and only mild sensory loss, arteriography with a view to thrombolysis should be performed. However, it should be remembered that thrombolysis is associated with numerous potential complications, most notably gastrointestinal haemorrhage and stroke. If the limb is salvageable, it may be possible to offer the patient an endovascular procedure, such as an angioplasty (with or without stenting). Surgical treatment can involve simple embolectomy, but may require a bypass procedure or endarterectomy, and in the severely ischaemic limb fasciotomies may be needed to treat or prevent a compartment syndrome. For at least 10 per cent of patients, it will not be possible to offer revascularization. Such patients may benefit from the use of a prostacyclin analogue (Iloprost), which has been shown to reduce amputation rates and alleviate pain. Limb salvage rates for

patients presenting with critical limb ischaemia are variable, probably 50 to 60 per cent at 2 years, dependent on the severity of disease.

In a patient presenting with acute leg ischaemia the outlook is poor with only about 60 per cent leaving hospital with an intact limb. The 30-day mortality for this group of patients can be as high as 30 per cent, the main cause of death being cardiac disease. The strategy for management is described in Fig. 2. The controversies that exist in the treatment of acute leg ischaemia are mainly related to the role of arteriography and which technique of thrombolysis is the safest and most cost effective.

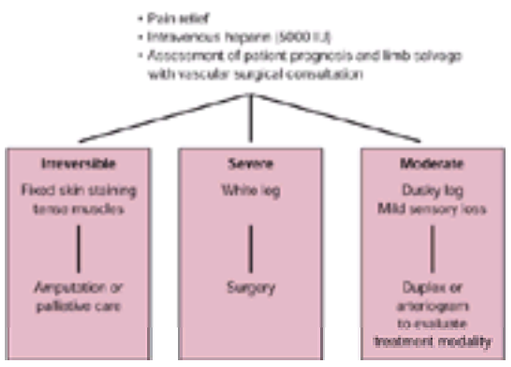

Fig. 2 Management of the acutely ischaemic leg.

In the patient who has had an embolic event, long-term anticoagulation should not be forgotten. Nor should a search for the source of embolus: if the patient is not in atrial fibrillation, has normal cardiac enzymes and 12-lead ECG, then they should have an echocardiogram to exclude any valvular lesion, a 24-h ECG to look for arrhythmia, an ultrasound to exclude abdominal aortic aneurysm, and a screen for thrombophilia.

Management of the chronically ischaemic leg

In chronic limb ischaemia management depends upon the severity of the disease. The vast majority of patients present with claudication, which is relatively benign. Only about 5 per cent of those who have claudication will go on to lose a limb, but claudication identifies patients with a threefold increased risk of death from either heart disease or cerebrovascular disease compared with age- and sex-matched controls. It is important when planning treatment that all the potential risk factors are covered. The general advice is to stop smoking and to exercise, with the use of structured exercise programmes shown to be of benefit. Surgical intervention is not usually required. Over 80 per cent of patients do not require any form of interventional procedure, and at least a third will have improvement of symptoms with simple medical treatment. The management of patients with chronic lower leg pain is shown in Fig. 3.

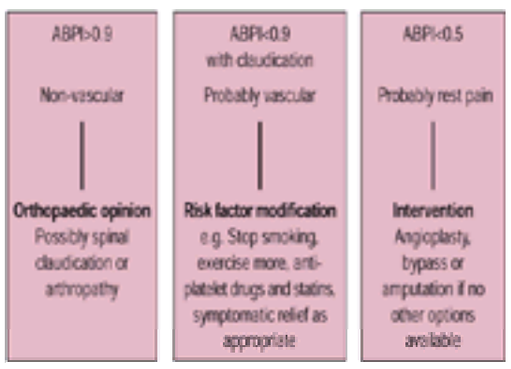

Fig. 3 Management of the patient with chronic lower leg pain.

General management

Careful attention must be paid to the cleanliness of ischaemic feet to avoid infection, and particular care should be given to the cutting of toe nails. In many patients this is best done by a careful younger relative or chiropodist, since apparently minor lacerations can lead to ulcers, infection, and gangrene. Walking to the point of claudication is not harmful, and may improve collateral circulation with beneficial results.

Smoking is by far the most significant risk factor for occlusive arterial disease and every effort should be made to encourage smokers to stop. If patients undergo surgical treatment, then the long-term patency rate following arterial reconstruction is four times greater in smokers who stop than in those who persist.

Medical treatment

Since coronary artery disease is the main cause of death in those with peripheral arterial disease, low-dose aspirin therapy (75 to 325 mg/day) should be recommended for all patients. If aspirin cannot be tolerated, ADP-receptor antagonists, such as clopidrogel, are equally effective in reducing the risk of cardiovascular events (stroke, myocardial infarction, and vascular deaths) and particularly effective for patients with peripheral arterial disease.

Secondary prevention trials have demonstrated the benefits of statin therapy following myocardial infarction. It is likely that similar benefits would be seen for patients with stenosing atherosclerotic disease of the peripheral arteries, particularly in those with elevated serum cholesterol concentrations. The new generation of fibrates, which lower both plasma fibrinogen and triglycerides, may also be effective in reducing cardiovascular events in patients with peripheral arterial disease, but randomized trials have not yet reported. Chelation therapy offers no benefits.

Few patients with peripheral arterial disease are prescribed b-blockers for control of hypertension or angina. However, when these patients require surgery, perioperative cover with a b-blocker is likely to minimize myocardial ischaemia and diminish postoperative morbidity and mortality associated with major vascular surgery.

Surgical treatment

In general, surgeons are becoming more conservative with respect to interventional treatment for patients with claudication, despite a possible early benefit for those having an endovascular procedure. However, in the patient who has severe claudication, with symptoms that significantly affect their quality of life, it is certainly possible and appropriate to offer interventional treatment.

Several issues in the management of chronic limb ischaemia are the subject of ongoing clinical trials. These include comparison of endovascular angioplasty and bypass surgery. For infrainguinal bypass, good-quality autologous vein is the conduit of choice. However, reasonable results can be obtained with synthetic grafts, particularly where the distal anastomosis is above the knee. Below the knee an adjuvant vein interposition in the form of either a Miller cuff or Taylor patch is used. The role of stenting in the leg vessels is contentious, and it may not be of value. The role of exercise therapy compared with angioplasty in the treatment of mild to moderate claudication continues to be debated.

Ischaemia of the arm

Ischaemia of the arm is usually a result of embolism from the heart. Occasionally the subclavian artery is diseased or has suffered traumatic injury or radiation damage following radiotherapy. The basic principles of investigation and management are the same as for the leg. However, it should be noted that the upper limb has multiple interconnection of collateral vessels, hence occlusion of the major arterial supply may still leave a viable limb. The other disease process that needs to be considered is the thoracic outlet syndrome, which gives rise to symptoms in the arm as a result of arterial, venous, or neurological compression caused by an additional cervical rib or by scalene bands. Management may require surgical intervention, either cervical rib excision or thoracic outlet decompression with the removal of the first rib.

Mesenteric ischaemia

Mesenteric ischaemia is uncommon. Over one-third of cases of acute mesenteric ischaemia are due to arterial embolism, with emboli lodging at the ostium of the superior mesenteric artery in many cases. Patients with acute mesenteric artery thrombosis have often had symptoms of mesenteric ischaemia prior to the acute episode. Chronic mesenteric ischaemia typically presents with weight loss and abdominal pain on ingestion of food, the classic story being that the patient is constantly hungry, but frightened to eat. Other causes of acute mesenteric ischaemia include venous thrombosis and non-occlusive ischaemia secondary to hypoperfusion.

Patients with acute mesenteric ischaemia will usually present with abdominal pain, but the abdominal physical signs may be much milder than would be anticipated from the subsequent clinical course. Suspicion of the diagnosis should be heightened in the presence of atrial fibrillation or widespread atheromatous vascular disease. Patients may deteriorate suddenly and present in shock.

The diagnosis of acute mesenteric ischaemia is difficult to make. In the acute situation clues to look for include leucocytosis, hyperamylasaemia, and unexplained acidosis. Liver function tests are usually normal. Radiological imaging is rarely able to make a positive diagnosis, although it can be very useful in excluding other possibilities. Angiography is not always accurate. CT scanning can be helpful in the diagnosis of mesenteric venous thrombosis.

Intensive resuscitation to replace fluids is essential. Surgery is usually necessary for the patient to survive, and the possibility of acute mesenteric ischaemia remains one of the dwindling number of reasons for requiring an emergency diagnostic laparotomy. Depending on the findings, resection of small bowel may suffice, but formal arterial surgery may be necessary, and in some unfortunate instances the extent of irreversible ischaemia can preclude an attempt at resection or revascularization. In cases where the surgeon is unsure of the viability of bowel remaining after resection, a second laparotomy may be planned to assess the situation a few days later. Repeat laparotomy may also be required to examine, and if necessary resect, more bowel in the patient who is not 'doing well' postoperatively. The prognosis for patients who present with acute mesenteric ischaemia is poor.

For patients who present with chronic mesenteric ischaemia, the aim of treatment is to improve blood flow and to act as a prophylactic procedure to prevent the catastrophic disaster of arterial occlusion. The potential options, having identified the site of the disease process by duplex scanning and angiography, include angioplasty, endarterectomy, reimplantation, or a surgical bypass procedure.

Abdominal aortic aneurysm

Definition

There is no fixed definition of an abdominal aortic aneurysm. It is a localized dilatation of the abdominal aorta, usually fusiform, with dilation starting distal to the renal arteries. One definition is when the maximum aortic diameter is more than 1.5 times the diameter of the undilated proximal aorta. Manual palpation to detect abdominal aortic aneurysms is unreliable, unless undertaken by a specialist on non-obese patients. The most convenient method of screening for the presence of these aneurysms is ultrasonography, measuring the anterior–posterior diameter. Since the reproducibility of ultrasound measurements of the suprarenal aorta is poor, a convenient working definition of an abdominal aortic aneurysm is when the maximum diameter exceeds 3 cm, which in most people is more than 1.5 times the diameter of the undilated proximal aorta. In practice, it is only aneurysms of 4 cm or greater in diameter that have been of clinical concern.

Epidemiology

Population screening studies in northern Europe have shown that the disease is usually without symptoms, much more common in men than in women (Table 1), and is strongly associated with smoking. The prevalence of large aneurysms (greater than 5 cm in diameter) detected by screening is only about 1 per cent in men and the large majority of these screen-detected aneurysms are 3 to 5 cm in diameter. The natural history of abdominal aortic aneurysms is progressive enlargement (with the diameter increasing by 2 to 5 mm each year) without symptoms, until the aortic wall is so weakened that it ruptures. Rupture is a catastrophic event.

The infrarenal aorta is by far the most common site of aneurysmal dilatation, and usually the abdominal aorta is the only site of dilatation. When patients present with aneurysms of the iliac, femoral, or popliteal arteries, abdominal aortic aneurysm is often present and screening for this is mandatory. This emphasizes the tendency of some patients to have a more generalized form of dilating arterial disease.

Ruptured aneurysms

The symptoms of a ruptured abdominal aortic aneurysm are collapse (shock) and severe back or abdominal pain.

Rarely a ruptured aneurysm will present with gastrointestinal bleeding from an aortoduodenal fistula or high-output cardiac failure from an aortocaval fistula.

Less than 20 per cent of patients with a ruptured abdominal aortic aneurysm reach hospital alive, and even among those that undergo emergency surgical repair almost half will die within 30 days of surgery. With this bleak prognosis and the very significant costs associated with emergency repair following rupture, it has been suggested that widespread screening to detect those with the largest aneurysms, at highest risk of rupture, would be cost-effective. A screening trial is in progress to assess the benefit of such a policy.

Management of ruptured aneurysms requires:

1. access lines, cross-matched blood, and resuscitation;
2. confirmation of diagnosis—ultrasound (to show aneurysm), CT scan or experienced vascular surgeon (to confirm diagnosis of rupture);
3. rapid assessment of whether patient would benefit from emergency repair; and
4. if yes, immediate surgical repair.

Aneurysms detected before rupture

Abdominal aortic aneurysms are commonly symptomless but rupture is catastrophic. However, elective repair of an abdominal aortic aneurysm, a major surgical procedure, is not without risk. Traditionally, larger aneurysms have been repaired by cross-clamping of the aorta and insertion of a Dacron inlay graft at open surgery. This is a durable procedure and effectively 'cures' the patient. However, although some specialized surgical centres report an operative mortality of less than 2 per cent associated with this elective procedure, on a population basis the mortality is more likely to be 5 to 8 per cent. This very significant surgical mortality is an important reason for avoiding surgery in those with small aneurysms.

Recently, the United Kingdom Small Aneurysm Trial showed that for aneurysms of 4.0 to 5.5 cm in diameter the policy of early elective surgery conferred no long-term survival benefit, and surgery should not be recommended. For such patients surveillance, with measurement of ultrasound diameter every 6 months, is a safe policy which engenders little patient anxiety, and the risk of aneurysm rupture is very low—1 per cent per year. By contrast, for patients with aneurysms greater than 6 cm in diameter the risk of rupture may be as high as 25 per cent per year, and in most such cases elective repair is recommended.

Repair is recommended also when symptoms are attributed to the aneurysm, whatever its size, the commonest being back or abdominal pain, or tenderness to palpation. It is assumed that such aneurysms are at high risk of rupture and need early repair. As the aneurysm dilates, layers of laminated thrombus deposit in the lumen, like onion skins, leaving a blood flow channel of approximately normal aortic diameter. These layers of thrombus are very stable and only in rare circumstances are the source of emboli to the legs. The aneurysms which most often provoke symptoms have very thick, inflamed, fibrotic walls, which entrap nerves and may become adherent to other tissues. These are known as inflammatory aneurysms and the thickened wall can often be detected by CT scan or magnetic resonance imaging. They are technically demanding to repair. There is no convincing evidence that a course of preoperative corticosteroids is beneficial. In the Japanese population inflammatory aneurysms have been associated with active cytomegalovirus infection.

A strategy for the management of abdominal aortic aneurysms detected before rupture is shown in Fig. 4. Patients with small aneurysms should stop smoking and have their blood pressure controlled. Since screening detects mainly small aneurysms, it would clearly be beneficial if a treatment to limit aneurysm growth were available. Although propranolol has proved effective in limiting the dilation of the proximal aorta in patients with Marfan syndrome, as yet there is no evidence that it is effective for abdominal aortic aneurysms. Furthermore, many patients with abdominal aortic aneurysm have impaired lung function, perhaps through smoking, and b-blockers often are poorly tolerated. However, effective control of blood pressure and cessation of smoking are both likely to minimize the rate of aneurysm growth and the risk of rupture. Pathophysiological studies suggest that inflammation and proteolysis are important processes driving aneurysm growth, but there is no firm evidence that either anti-inflammatory or antiproteolytic therapy is effective. Surgery remains the only available treatment for aneurysms larger than 5.5 cm in diameter.

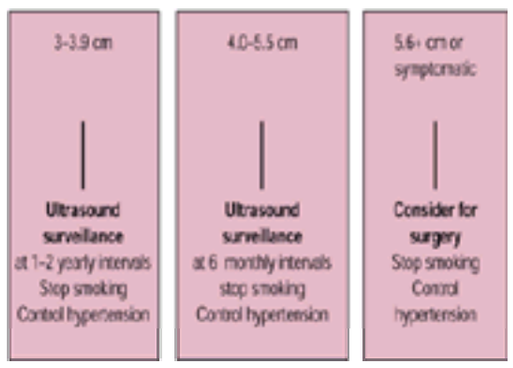

Fig. 4 Management of unruptured abdominal aortic aneurysms depending on their size as demonstrated by ultrasonography.

Recently a less invasive repair procedure has been developed, where an aortic graft is inserted via the femoral artery. This technique remains under development, its durability is being investigated, and several randomized trials are comparing this new endovascular approach with the traditional surgical one.

Conventional surgical management

Preoperative evaluation requires CT or magnetic resonance imaging to define the anatomy and extent of the aneurysm. Cardiac, pulmonary, and renal function should always be assessed, poor renal and lung function being associated with an increased risk of postoperative morbidity and mortality.

The most common surgical approach to an abdominal aortic aneurysm is through a transperitoneal incision under general anaesthesia. The retroperitoneal approach, which avoids bowel manipulation and permits a more rapid return to oral diet, has similar cross-clamp, operating, and recovery times. The transperitoneal approach offers the advantage of exploring the abdominal cavity for other pathology. In this approach, after the bowel has been removed from the operative field, the aorta is exposed anteriorly from the left renal vein to the bifurcation. The infrarenal neck of the aneurysm is exposed anteriorly and laterally so that an occluding clamp may be applied. Both common iliac arteries are exposed for the placement of the distal occluding clamps. With the clamps in place, the aneurysm is opened longitudinally on the anterior surface and the remainder of the procedure performed from inside the aneurysm cavity, usually following a small dose of intravenous heparin. Clot and debris are evacuated and any back-bleeding lumbar or mesenteric arteries ligated. A Dacron prosthesis is then sutured, end to end, to the normal-diameter aorta above the aneurysm. This anastamosis is tested for leaks before the graft is trimmed to appropriate length and sutured in place above the aortic bifurcation. The aneurysm sac is closed over the prosthesis, before replacement of abdominal contents. Such tube grafts are the most common type, but when the iliac arteries are dilated or diseased a bifurcated prosthesis is used. The cross-clamp time should be less than an hour and the whole procedure completed within 2 to 4 h. The longest procedures involve inflammatory aneurysms and cases where the proximal aneurysm neck lies above the renal arteries. The patient should be ready to leave hospital 7 to 12 days after the operation, with a durable repair.

Endovascular aneurysm repair

The technique of endovascular repair was introduced in the early 1990s and the technology is still evolving. The procedure may be performed under general or epidural anaesthesia. This flexibility allows endovascular repair in patients where pulmonary or cardiac function is too poor to consider open repair, and the avoidance of aortic cross-clamping is an additional benefit for those with limited cardiac reserve.

Preoperative investigation to evaluate the extent and size of the aneurysm (spiral CT or magnetic resonance imaging) is of critical importance. The length of the aneurysm neck below the renal arteries, angulation of the aorta, and tortuosity of the iliac arteries must be evaluated precisely so that the correct size of graft can be placed via the femoral artery. The insertion of the graft is performed under fluoroscopic control. This requires the use of significant amounts of contrast material, which may underlie the unfavourable results reported in patients with high serum creatinine. The proximal end of the graft is held in place either by hooks or balloon-expandable stents.

The length of the procedure and the transfusion requirements are similar to those for open surgical repair, but the patient recovers rapidly and is ready to leave hospital within 2 to 5 days. The long-term success of the procedure depends on the successful exclusion of the aneurysm sac and the security of the proximal attachment to prevent graft migration. Endoleaks may develop when the aneurysm is not completely excluded or there is back-bleeding from lumbar vessels or the inferior mesenteric artery into the aneurysm sac. These are associated with an important risk of continued aneurysm expansion and rupture. For these reasons continued vigilance and repeated evaluation of the aneurysm with duplex or CT scanning is necessary at 6-monthly intervals. Currently, neither the durability of endovascular grafts nor their use in patients unfit for open repair has been properly evaluated in clinical trials.

15.14.3 Cholesterol embolism

C. R. K. Dudley

The clinical features of cholesterol embolism mimic a number of conditions, particularly systemic vasculitis, and if misdiagnosed can result in the inappropriate use of powerful immunosuppressive drugs.

Introduction

When atheromatous plaques ulcerate and become denuded of their endothelial covering, the underlying cholesterol-rich extracellular matrix can become detached and embolize. If the dislodged atheroma is sufficiently large, occlusion of a major systemic artery results in infarction of the organ or ischaemia of the limb supplied. This has been termed 'atheroembolism'. By contrast, cholesterol-crystal embolism occurs when much smaller and more numerous particles, composed principally of cholesterol crystals, lodge in a number of small arteries simultaneously. The presence of a collateral circulation usually prevents infarction and the event frequently passes unrecognized by the patient or their physician. However, tissue damage in a number of organs can result from multiple showers of emboli. Because severe ulcerative atherosclerosis is most frequently present in the abdominal aorta, cholesterol embolism commonly affects the lower limbs, gastrointestinal tract, and kidneys. The condition usually presents as a complication of vascular surgery or angiographic procedures, when mechanical dislodgement of crystals from ulcerated plaques occurs. Anticoagulant and thrombolytic use has also been implicated as a predisposing factor. The clinical features are those of a systemic disorder with renal failure that can mimic vasculitis.

Epidemiology

The incidence of cholesterol-crystal embolism found at postmortem is high: 77 per cent after aortic surgery, 30 per cent after aortography, and 25.5 per cent after cardiac catheterization. By contrast, the clinical syndrome of cholesterol-crystal embolism is rare, complicating less than 2 per cent of cardiac catheterizations.

Since the condition occurs in patients with severe atheromatous disease, it is most often seen in older male patients with obvious risk factors (hypertension, diabetes mellitus, smoking) and overt vascular disease (ischaemic heart disease, abdominal aortic aneurysm, cerebrovascular disease, etc.). Although spontaneous cholesterol embolism can occur, it is much more common after vascular surgery or invasive radiology including aortography, angiography, and angioplasty. Under these circumstances direct trauma to the vessel may result in detachment of atheromatous material from a ruptured plaque, or denude the endothelial lining of the vessel exposing the underlying atheroma for subsequent embolization. Anticoagulant use has been associated with cholesterol embolism, and it has been proposed that by preventing thrombosis of ulcerating atheromatous plaques, anticoagulants favour the dissemination of atheromatous material. However, a causal relationship is unproven and many patients with widespread atherosclerosis coincidentally receive anticoagulants for a variety of reasons. Cholesterol embolism following the use of thrombolytic agents has been rarely reported.

Clinical features

Symptoms are often non-specific with fever, weight loss, and myalgia. The clinical features are otherwise determined by the pattern of organ involvement and are usually referable to the gastrointestinal tract, kidneys, and lower limbs. Bilateral skin changes over the lower extremities are the commonest physical finding and include livedo reticularis, a purpuric rash, 'trash feet', blue toes (acral cyanosis), and focal digital necrosis (Fig. 1 and Fig. 2 and Plate 1 and Plate 2). Ulceration, nodules, and petechiae have also been described. Despite these skin changes and the presence of calf claudication (or frank myositis), pedal pulses may be felt easily, emphasizing that small vessels are occluded in this disorder. Carotid and femoral bruits are frequently heard, reflecting widespread and generalized atherosclerosis.

Fig. 1 Livedo reticularis and vasculitic-like erythematous nodules on the leg of a patient in whom cholesterol-crystal embolization occurred after coronary angiography. (See also Plate 1.)

Fig. 2 Purpuric spots and acral cyanosis of the toes from cholesterol embolism after aortic aneurysm repair. (see also Plate 2.)

Abdominal pain, gastrointestinal bleeding, and pancreatitis may occur and embolism to the stomach, small bowel, colon, gallbladder, and spleen have all been reported. The most frequently involved of these sites is the colon.

Because of their large blood supply and proximity to the abdominal aorta, the kidneys are commonly affected. This usually manifests as a subacute stepwise

deterioration in renal function over 2 to 6 weeks, invariably accompanied by a worsening of pre-existing hypertension that can be labile and difficult to control. Cardiac failure with pulmonary oedema is a common accompaniment. Acute renal failure with necrotizing glomerulonephritis and crescent formation on renal biopsy has been described but is rare. Thus a typical case is an elderly man presenting after angiography with progressive renal failure accompanied by a low-grade fever, abdominal pain, livedo reticularis of the lower body, and purpura over the feet with focal digital ischaemia of the toes.

Transient ischaemic attacks, amaurosis fugax, and strokes can occur when embolism is from the carotid arteries or aortic arch. Retinal cholesterol-crystal emboli may be observed on ophthalmoscopy as bright refractile plaques within the retinal arterioles, especially at their bifurcation. Spinal cord infarction has also been reported.

Investigations

Laboratory findings are non-specific, but frequently include a raised erythrocyte sedimentation rate (**ESR**), plasma viscosity, and C-reactive protein (**CRP**). Leucocytosis and a transient eosinophilia are common and may be pronounced. Depending on the tissue involvement, an elevation in creatine phosphokinase, amylase, lactate dehydrogenase (**LDH**), serum aspartate aminotransferase (**AST**), and alkaline phosphatase may all be seen. Hypocomplementaemia is rare and usually mild. Antineutrophil cytoplasmic antibodies (**ANCA**) have been reported, and their presence may further confuse the diagnosis with a multisystem vasculitic process. Mild proteinuria is generally present and nephrotic-range proteinuria has been reported. Urine microscopy may be bland or reveal red cells, white cells (particularly eosinophils), and hyaline and granular casts. Renal failure is frequently non-oliguric.

Histology

The definitive histological diagnosis of cholesterol-crystal embolism can usually be made from biopsies of kidney, skin, or muscle (including clinically uninvolved areas), although sampling error may miss the lesion due to its patchy distribution. Antemortem histological diagnoses have also been made from other tissues, including a gastric biopsy, prostatic currettings, and a bone marrow biopsy.

The diagnostic feature is of biconvex, needle-shaped cholesterol clefts within the lumen of arteries or arterioles that remain after the crystals have dissolved during routine histological preparation (Fig. 3 and Plate 3). In fresh samples, the crystals can be identified by birefringence under polarized light or by specific histochemical staining of cholesterol. In the kidneys, the typical finding is occlusion of small arteries and arterioles of between 150 and 200 µm in diameter, such as the arcuate and interlobular arteries, resulting in patchy areas of ischaemia and small areas of infarction. Crystals can also be seen within the glomeruli. In chronic cases, ischaemia produces a wedge-shaped lesion involving all components of the renal cortex radiating towards the capsule. The glomeruli appear ischaemic and sclerosed and the tubules become atrophic and separated by interstitial fibrosis. Grossly, the kidneys may be reduced in size with a rough granular surface and wedge-shaped scars.

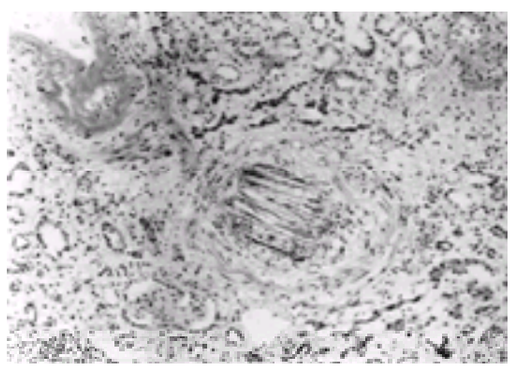

Fig. 3 Renal biopsy demonstrating the characteristic needle-shaped cholesterol clefts occluding a medium-sized renal arteriole with surrounding inflammatory cell infiltration, intimal proliferation, thickening, and concentric fibrosis. There is extensive autolysis (postmortem sample). (See also Plate 3.)

Based on animal studies involving the injection of atheromatous material, the presence of cholesterol crystals in the vascular lumen is thought to trigger a localized inflammatory and endothelial vascular reaction. Inflammatory cells (mainly macrophages and eosinophils) infiltrate, and multinucleated giant cells engulf the cholesterol crystals, but these are resistant to the scavenger effects of macrophages and may persist for many months. The inflammatory phase is followed by marked intimal thickening with concentric fibrosis and occlusion of the vessel. Depending on the extent of organ involvement, these pathological changes result in ischaemia, infarction, or, rarely, necrosis of the distal tissue.

Differential diagnosis

The diagnosis is frequently missed during life. A high index of clinical suspicion is therefore required, particularly in elderly patients with evidence of atherosclerotic disease who develop renal failure after arteriography or following aortic or cardiac surgery; cholesterol embolism should also be considered in the differential diagnosis of a multisystem disease in elderly patients. Spontaneous cholesterol-crystal embolism associated with renal failure, fever, rash, and eosinophilia may not surprisingly be misdiagnosed as a vasculitic illness such as Wegener's granulomatosis, microscopic polyangiitis, Churg–Strauss syndrome, polyarteritis nodosa, or bacterial endocarditis (see Section xxxx, Rees). A false-positive ANCA test may further compound the diagnostic difficulty. Under these circumstances, renal biopsy is mandatory to make the correct diagnosis.

Clinical course and management

Mortality is high due to the coexistence of cardiac and vascular disease with renal failure in an elderly patient. Renal impairment may remain stable, but frequently progresses such that dialysis is required, although partial recovery has been reported, even after several months of dialysis. The mechanism of this recovery is uncertain.

There is no effective therapy. Steroids, aspirin, dipyridamole, and low molecular weight dextran have all been tried, but without any clear effect. There are anecdotal reports of a response to human menopausal gonadotrophin coenzyme A (**HMG CoA**)-reductase inhibitors (theoretically inducing plaque stabilization), but recovery may have been spontaneous. Anticoagulants are of no proven benefit and should be avoided given their potential role in the pathogenesis of the disorder. Encouraging results with iloprost have recently been reported although these observations require replication.

Computed tomography (**CT**) scanning of the aorta has been used to identify the precise source (for instance, aortic aneurysm, localized aortic plaque) of cholesterol emboli, and surgical replacement of the diseased vessel with a graft has been advocated. However, major surgery in elderly vasculopaths with renal impairment carries significant risks and is generally avoided.

Supportive therapy is directed at the control of hypertension and appropriate management of renal failure. Prevention is important, particularly with the increasing number of older patients submitted to invasive angiography. Non-invasive methods of arterial imaging such as CT or magnetic resonance (**MR**) angiography are to be preferred in patients with diffuse atherosclerosis. When invasive angiography is unavoidable, careful attention must be paid to the angiographic technique, including the arterial approach (brachial instead of femoral for cardiac catheterization), use of softer, more flexible catheters and reduced catheter manipulation.

15.14.4 Takayasu arteritis

Fujio Numano

Introduction

Takayasu arteritis is a systemic chronic vasculitis that mainly involves the aorta and/or its major branches as well as the coronary and pulmonary arteries. Chronically progressive inflammation induces arterial stenosis and/or occlusion due to thrombus formation, resulting in the characteristic clinical picture of weak or absent arterial pulses (Fig. 1). By contrast, acute inflammation causes dilatation of vessel walls and/or aneurysm formation, which can lead to serious problems such as aneurysmal dissection, aortic regurgitation due to dilatation of the ascending aorta, or even aortic rupture. Clinical manifestations will clearly depend on which arteries are involved. The disease generally has a chronic progressive course, often presenting with non-specific inflammatory symptoms such as intermittent fever, fatigue, and malaise that may exist for months to years prior to the onset of full-blown vasculitis.

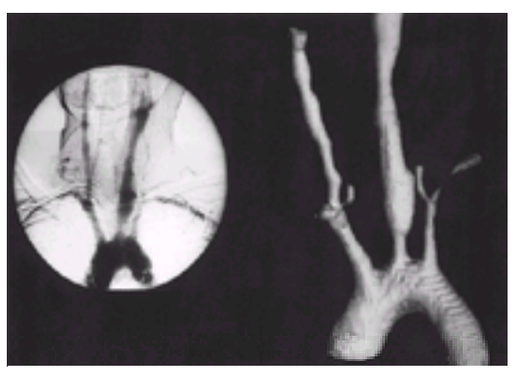

Fig. 1 Digital subtraction angiography and three-dimensional CT of the aortic arch and its branches in a patient with Takayasu arteritis.

The first case of this disease was reported in 1908 at the Japan Ophthalmology Society Meeting by Mikito Takayasu who described interesting fundal findings in a 21-year-old woman suffering from pulmonary tuberculosis, characterized by coronary anastomosis of central retinal arteries (Fig. 2 and Plate 1). Similar ocular appearances were corroborated at the same meeting by K. Ohnishi and T. Kogoshima. Furthermore, both pointed out that they were associated with absence of one or both radial pulses. Today this condition is known to be a vasculitis and the characteristic ophthalmic condition thought to be the result of ischaemia of the retinal circulation due to stenosis or obstruction by arteritis of cervical arteries.

Fig. 2 Typical coronary anastomosis of retinal vessels in Takayasu arteritis. (See also Plate 1.)

The first detailed pathological study was reported by K. Oota in 1940 of a 25-year-old woman with Takayasu arteritis who was admitted to hospital for visual loss and frequent syncopal attacks. He confirmed that this patient had systemic vasculitis involving the aorta, cervical arteries, and pulmonary arteries, and that inflammatory changes were seen not only in the media but in both intima and adventitia, thus calling this condition 'panarteritis'. In 1951, studying the clinical features of 31 cases, K. Shimizu and K. Sano applied the name 'pulseless disease' to the triad of clinical features comprising pulselessness, coronary anastomosis in the retinal vasculature, and accentuated carotid sinus reflex due to ischaemia of the cervical circulation.

Epidemiology

Takayasu arteritis is frequently encountered in Asian countries such as Japan, Korea, China, Singapore, Thailand, Vietnam, India, Israel, and Turkey; also on the American continent in countries such as Peru, Mexico, Brazil, and Colombia. The disease is rarely seen in Caucasian populations. There are geographical differences in sex-specific prevalence. In Japan more than 5000 patients have been treated, of which more than 80 per cent are women with a peak age in the twenties. A recent international comparative analysis revealed a decline of this female preponderance as one moves westwards from Japan; in Israel the sex ratio is almost equal.

Aetiology

The aetiology of Takayasu arteritis is still unknown. The suggestion that it might be due to tuberculosis is now discounted by most authorities, at least in Japan where tuberculosis has drastically decreased, whereas Takayasu arteritis is actually slightly increasing in number. Another hypothesis argues that vasa vasoritis due to virus infection may be the initiating phenomenon, and hyperoestrogenism is still discussed as one of the major causative factors because of the high prevalence of Takayasu arteritis in young women. However, clinical and laboratory findings together with a favourable response to steroid therapy strengthen the argument that autoimmune mechanisms are important.

HLA and other genetic factors

Familial occurrence of Takayasu arteritis has been reported, including three pairs of monozygotic twin sisters in Japan, India, and Brazil, strongly suggesting that some genetic factor(s) is involved in pathogenesis.

There is a close association of Takayasu arteritis with HLA B52 and DR2 in Japan, B5 in India, and B52, DR2, and DQ2 in Korea. In Japan, patients with Takayasu arteritis carrying haplotype A24-B52-DR2 show rapid progression and are resistant to steroid therapy when compared with patients of other haplotypes. Furthermore, patients carrying this haplotype sometimes have other coexisting autoimmune disorders such as Behçet's disease, systemic lupus erythematosus, or ulcerative colitis. Analysis of the MIC gene, which is located near the HLA B locus, also exhibits a close association with Takayasu arteritis. It may suggest that genes involved in pathogenesis may be located between the MIC and HLA B gene locus.

Pathology

Nasu classified Takayasu arteritis histologically into three types—granulomatous inflammation, diffuse productive inflammation, and fibrotic type—which chronologically characterize the progression of this disease. Hochi stressed elastophagia as an important characteristic feature of Takayasu arteritis, progressing segmentally and from the adventitial side towards intima. Inflammation originates around vasa vasorum in the outer side of the media and/or its neighbouring adventitia. The infiltrating cells are mainly T cells, which later are mixed with macrophages. Progression to vasculitis is characterized by destruction of medial smooth muscle cells, elastophagia, and fibrosis. Fibrocellular thickening of intima follows and atherosclerotic changes may accelerate intimal thickening, a complication that makes the diagnosis of Takayasu arteritis difficult in older patients. Skipped lesions composed of a mixture of involved and non-involved areas were once deemed to be a characteristic feature of Takayasu arteritis, but with early diagnosis and treatment this is no longer the case.

Clinical features

Some patients are totally free of symptoms and are diagnosed incidentally as having Takayasu arteritis during regular health examinations because of pulselessness, difference in blood pressure between the arms, or an elevated erythrocyte sedimentation rate. However, Takayasu arteritis can present with non-specific symptoms or, depending upon which vessels are involved, with a wide variety of symptoms, hence the diagnosis is sometimes very difficult to make.

Japanese patients usually have involvement of the ascending aorta and cervical vessels (Fig. 1 and Fig. 3), with the main complaints relating to ischaemia of cerebral, ophthalmological, and/or upper extremity circulation—for example dizziness, syncope, visual disturbance, weak pulse, or pulselessness—as well as inflammatory symptoms such as general malaise, neck pain, and palpable cervical lymph nodes. These inflammatory signs in young women are sometimes misdiagnosed as tuberculosis, viral infection, or rheumatoid arthritis. A 'bird face' due to atrophy of facial muscles (Fig. 4), intermittent claudication of jaw muscles, and perforation of the nasal septum due to long-term cervical circulatory disturbance are helpful in establishing the diagnosis. Today it is becoming rare to find patients whose fundi show a typical retinal coronary anastomosis due to early diagnosis and early treatment; indeed the American College of Rheumatology Subcommittee has excluded this rarely seen ophthalmic condition from the diagnostic criteria of Takayasu arteritis.

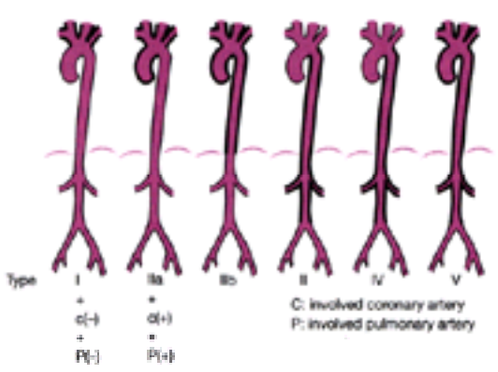

Fig. 3 New classification of the angiogram in Takayasu arteritis, according to the International Conference on Takayasu Arteritis, 1994. Type I involves branches of the aortic arch. Type IIa involves type I plus the ascending aorta and aortic arch. Type IIb involves type IIa plus the thoracic descending aorta. Type III involves the thoracic descending aorta, abdominal aorta, and/or renal arteries. Type IV involves only the abdominal aorta and/or renal arteries. Type V involves the whole aorta and its branches.

Fig. 4 'Bird face' of Takayasu arteritis: hollow cheeks and eye sockets.

Headaches and dizziness associated with hypertension are the most common symptoms of Takayasu arteritis in Asian countries except Japan. These patients mainly have involvement of the abdominal aorta, inducing renovascular hypertension, and they show hypertensive retinal changes. Although rare in Japan, intermittent claudication is another characteristic symptom in China, India, and Thailand.

The commonest finding on physical examination is a weak or absent pulse in one or both brachial, radial, and/or ulnar arteries, which is noticed in almost 80 per cent of Japanese patients. These abnormalities are found more often in the left arm than the right, perhaps because the left axillary artery comes directly from the aortic arch whereas the right one arises from the brachiocephalic artery, thus making the left side more prone to inflammation.

Cardiac manifestations have become the most important cause of death in patients with Takayasu arteritis in Japan. Careful evaluation is required, particularly of aortic regurgitation due to a dilated ascending aorta, which can sometimes present as an emergency with congestive heart failure. The manifestations of ischaemic heart disease, including chest pain, arrhythmia, and/or congestive heart failure, have increased among patients with Takayasu arteritis. This may be due to involvement of the coronary arteries and/or complicated coronary atherosclerosis, which results from the increased longevity of many patients with Takayasu arteritis.

Respiratory symptoms such as dyspnoea, haemoptysis, and pleurisy due to involvement of the pulmonary artery or arteries are not uncommon. Easy thrombus formation predisposes to pulmonary infarction, but this may be clinically silent requiring a pulmonary scintigram in all patients diagnosed with Takayasu arteritis. More than 70 per cent of patients exhibited segmental and/or non-segmental pulmonary infarction in Japanese subjects.

Renal involvement in Takayasu arteritis is usually characterized by renovascular hypertension and renal dysfunction. In India, almost half of all patients with Takayasu

arteritis exhibit renal artery involvement, including the ostia and a variable length of proximal renal artery. Severe proteinuria and hypercholesterolaemia (i.e. nephrotic syndrome) are characteristic of the renal dysfunction that arises in long-standing cases. It is believed that non-specific ischaemic glomerular lesions and mesangial deposition of immunoglobulin during the extended lifespan of patients receiving modern treatment have created this new renal complication of Takayasu arteritis and that it will become a major cause of death.

Hypertension and/or easy thrombus formation cause cerebral vascular accidents in many patients. Although these are no longer the dominant cause of death of patients with Takayasu arteritis in Japan, fatal stroke, hemiplegia, sensory disturbance, and aphasia are still frequently encountered despite well controlled blood pressure.

Laboratory findings and imaging modalities

The inflammatory process of Takayasu arteritis is expressed as an elevated erythrocyte sedimentation rate and C-reactive protein as well as hypergammaglobulinaemia and leucocytosis, as shown in Table 1. Changes of these indicators are well correlated with inflammatory activity and response to steroid therapy. Two national surveys in Japan conducted 10 years apart demonstrated almost equally high frequencies of accelerated erythrocyte sedimentation rate (greater than 20 mm/h) and positive C-reactive protein (greater than 20mg/l). Anaemia is often seen, probably due to chronic inflammation, and total T-cell count is significantly elevated. Other common findings are an increased antistreptolysin O titre and positive rheumatoid factor, which may suggest a common mechanism with rheumatic diseases.

There is a remarkable thrombogenic tendency during the acute inflammatory stage. Accelerated platelet aggregation, hyperfibrinogenaemia, expression of adhesion molecules, and accelerated coagulability give valuable information for assessing the clinical condition of these patients. HLA analysis also provides an additional clue to the diagnosis and is helpful in selecting patients for steroid treatment.

Calcification of the aorta on the chest radiograph in young women sometimes points to the diagnosis in patients free of subjective complaints. A definitive diagnosis can be established by angiography, which provides precise information about the vessels and sites involved, as well as about changes of the inner surface of blood vessels. For example, determining the affected site in the carotid artery is important, but not always straightforward, since it is possible that an easily palpable vessel is aneurysmal, whereas a poorly palpated one is normal. Digital subtraction angiography has become particularly popular because it does not require arterial puncture (Fig. 1). Imaging modalities such as CT, MRI, and /or magnetic resonance angiography (MRA) are also very useful in confirming Takayasu arteritis, even at an early stage, without seriously burdening the patient. Stenosis, dilatation, aneurysmal formation, and thrombosis can be well documented (Fig. 1). These procedures are also good for following the therapeutic effects of steroid treatment on the vasculature. In particular, as aortic regurgitation caused by dilatation of the ascending aorta is a serious complication that determines the prognosis, follow-up of the diameter of the ascending aorta by echocardiogram, MRI, or CT is critically important.

Figure 4 shows an angiographic classification of Takayasu arteritis. An international comparative study demonstrated that half of the patients in every country are type V; many Japanese patients show mainly involvement of cervical vessels and the aortic arch (type I, II); whilst many Indian and Thai patients have involvement of the abdominal aorta (type II, IV) (Table 2).

Diagnosis

Unless the physician is well aware of the disease, the diagnosis of Takayasu arteritis is frequently delayed due to its non-specific presentation. Table 3 includes the guidelines for clinical diagnosis of Takayasu arteritis summarized by the Committee of Takayasu Arteritis of the Ministry of Health and Welfare of Japan. Another set of criteria published by the American College of Rheumatology in 1990 lists six characteristics:

1. age less than 40 years old;
2. claudication of the arm;
3. decreased brachial arterial pulse;
4. greater than 10 mmHg difference in systolic blood pressure between the arms;
5. bruit over subclavian arteries or aorta; and
6. angiographic evidence of narrowing or occlusion of the aorta or its primary or proximal branches.

Presence of three out of six criteria is required for diagnosis, but by these criteria patients in several Asian countries whose abdominal aorta is predominantly involved would elude diagnosis. Although ophthalmological findings and/or symptoms are excluded, in Japan approximately 35 per cent of patients show abnormal ophthalmological findings including microaneurysm, retinal haemorrhage, cataract, or glaucoma.

Therapy

Steroid and antiplatelet therapies are essential in addition to symptomatic treatments such as antihypertensive and vasodilating drugs. The disease requires long-term observation, even after patients are completely free from symptoms, because vascular changes can progress silently and recurrence of vasculitis is not rare.

Steroids and immunosuppressants

Significant improvement can be achieved by steroid treatment, particularly when the disease is at an acute or active stage, starting with 0.5 to 1.0 mg/kg per day of prednisolone, then reducing by 5 mg/day every 2 to 3 weeks, depending upon the response of the erythrocyte sedimentation rate and C-reactive protein as well as symptoms. The target maintenance dose is 5 to 10 mg/day, gradually tapering before being discontinued, which in our experience is possible in 50 per cent of cases. If patients show a haplotype of HLA-B52-DR2 or B*3902, a larger dose (30 to 40 mg/day) of steroid and a longer tapering period may be necessary. Close observation is required because vasculitis can easily flare up during a common cold or other infection, requiring repeated steroid therapy or increased dose.

Immunosuppressive therapy is sometimes combined with steroid, allowing a lower dose and a shorter tapering period to be achieved, which is especially important for patients carrying an HLA B52-DR2 or B*3902 haplotype whose disease is relatively steroid resistant. Conventionally, 100 mg of cyclosporin is administered daily or every other day together with 10 to 20 mg/day of steroid.

Antithrombotic therapy

Antiplatelet therapy should be given to all patients for protection against subsequent thrombus formation. A small dose of acetylsalicylic acid (child bufferin) is the most popular drug used in Japan. Other antiplatelet drugs such as dipyridamole, ticlopidine, or cilostazol are sometimes employed, either alone in patients who cannot tolerate aspirin or combined with child bufferin. Thrombus formation is easily induced on the roughened surface of the arterial wall and active inflammation accelerates thrombus formation even more. Anticoagulant therapy with or without fibrinolytic therapy is necessary when thrombus formation is proceeding or already complete.

Percutaneous vascular intervention

Angioplasty and/or stenting can be effective procedures for some vascular complications of Takayasu arteritis, especially for coronary atherosclerosis. Several authors have reported successful percutaneous transluminal angioplasty (PTA) treatment of patients with renovascular hypertension, but this procedure seems most effective for atherosclerotic disorders involving mainly the intima and far less useful for Takayasu arteritis characterized by thickened adventitia and fibrous intima.

Surgery

The option of surgical treatment (usually bypass procedures) should always be considered for complications of Takayasu arteritis that are beyond medical treatment, for instance renovascular hypertension, coarctation of the aorta, severe ischaemia of the cerebral circulation, severe aortic regurgitation, progression of aneurysm, and dissecting aneurysm. Surgery should be performed, if possible, when inflammation is reasonably under control.

Prognosis

By early diagnosis and early initiation of treatment the prognosis of this disease has been improved. The clinical characteristics of 897 Japanese patients with Takayasu arteritis were studied in 1998: 71 per cent were well controlled and enjoyed an almost normal healthy lifestyle, many receiving no treatment. By contrast, 25 to 30 per cent suffered from severe complications such as aortic regurgitation, congestive heart failure, renal failure, or low visual acuity. In Japan the complications that determine prognosis are heart failure due to aortic regurgitation, thrombus formation leading to cerebrovascular accident, pulmonary infarction, and myocardial infarction. Cerebral haemorrhage due to hypertension is the main cause of death in Asian countries other than Japan.

15.15.1 The pulmonary circulation and its influence on gas exchange

Tim Higenbottam, Eric Demoncheaux, and Tom Siddons

Introduction

The main functions of the lungs are the uptake of oxygen and elimination of carbon dioxide. These are driven by the respiratory demands of active cells in the body. The lungs also have important metabolic and endocrine functions. Gas exchange is achieved by a reciprocating cycle of airflow into and out of the lungs through a complex branching system of airways, the bronchi. The gas exchange takes place in the alveoli, the peripheral airspaces that are surrounded by circulating pulmonary capillary blood. This capillary blood is delivered continuously from the right ventricle and passes on to the left atrium. The total cardiac output circulates through the lungs, at flow rates that can vary from 5 litre/min at rest, to 24 litre/min during exercise. The functional anatomy of the airways and lungs are described in detail in Chapter 17.1.2; this section will focus on the pulmonary circulation.

The pulmonary circulation in health

Functional anatomy

The lungs receive blood from the pulmonary and bronchial arteries. The pulmonary arteries deliver the major blood flow, the bronchial blood supply normally being limited to a tiny fraction of the total, 1 to 2 per cent of the cardiac output, but in disease this can expand and disturb gas exchange.

The main pulmonary trunk and the large pulmonary arteries are responsible for connecting the right ventricle to the pulmonary circulation. They accompany the bronchi into the lungs and within the bronchovascular bundles branch dichotomously alongside the bronchi down to the level of the terminal bronchioles, before breaking up into the alveolar capillary bed. The close association of the dense capillary network containing deoxygenated blood to the alveoli offers an ideal environment for gas exchange to take place. Pulmonary venules collect the capillary blood and drain laterally to the periphery of the lung lobules, returning the blood to the left atrium by four branches of the pulmonary veins.

The vessels of the pulmonary circulation have thin walls and can be classified according to their calibre: those of greater than 1000 µm are considered as elastic arteries, those between 100 and 1000 µm as muscular arteries, and smaller ones with endothelial lining and a single elastic lamina but no muscular lining as pulmonary arterioles. The pulmonary capillaries form a dense network around the alveoli and are lined only by endothelial cells. Their diameter is about 7 µm and their walls fuse directly to the alveolar wall (in most places). There are rich anastomotic channels between pulmonary and bronchial vessels.

At rest the pulmonary capillary blood flow is about 5 litre/min. The pulmonary circulation has a pressure drop (from pulmonary artery to left atrium) of only 10 mmHg across it, as against 100 mmHg for the systemic circulation. The resistance of the pulmonary circulation is thus about 10 per cent of the systemic, making it a high-flow, low-resistance circuit. The pulmonary vascular bed has a high reserve capacity to adapt to increased blood flow, adaptation occurring in both large and small pulmonary arteries. The large vessels are dilated by a nitric oxide-dependent mechanism; blocking the production of endothelial nitric oxide limits adaptation. We as yet cannot explain the mechanism by which the precapillary arteries adapt to increased blood flow: these are responsible for the recruitment of previously unperfused capillaries, resulting in a change in gas exchange.

It has been suggested that the alveolar capillary bed is similar to a thin sheet of blood, interrupted in various places by posts, much akin to a large sprawling room with pillars. The oxygenated blood is collected from the capillary network by small pulmonary veins that anatomically run between the lobules of the lung, converge as four pulmonary veins (in humans), and drain back into the left atrium to be pumped by the left ventricle around the systemic circulation.

The lung also derives a very minor part of its circulation from bronchial arteries, which usually arise from the descending aorta and distribute oxygenated blood at systemic pressure to many different sites in the lungs, including the pleura, the nerves, walls of the pulmonary vessels, the intrapulmonary lymph node, and the bronchi down to the terminal bronchiole. Most of the blood supplied by the bronchial arteries drains in the pulmonary veins, thereby contributing to a limited degree of desaturation of arterial blood, a 'physiological shunt', which is present in normal healthy individuals. Small amounts of blood drain in the bronchial veins that enter the azygos and hemiazygous veins.

In pulmonary embolic disease blood flow from the bronchial arteries can sustain the lung tissue and prevent infarction of the lung. The bronchial arteries may undergo hypertrophy in chronic pulmonary inflammation and bronchial neoplasia. Major haemoptysis such as bronchiectasis or aspergilloma arises from hypertrophied bronchial rather than pulmonary arteries and may be treated with therapeutic bronchial artery embolization.

Physiology

The pulmonary circulation offers much lower resistance to flow and operates at lower perfusion pressure than the systemic circulation. The normal mean pulmonary artery pressure is in the region of 15 mmHg with a systolic of 25 mmHg and diastolic of 8 mmHg compared with the systemic pressures of 120/80 mmHg.

At the resting systolic pressure of the right ventricle, 15 mmHg, and in the upright position, gravity causes preferential flow to the basal regions of the lungs rather than the apices. Another mechanism that affects the distribution of blood flow is vasoconstriction of the resistance pulmonary arteries, which are localized just before the alveolar capillaries. Hypoxia in the alveoli and mixed venous blood (blood from the central veins) acts directly on smooth muscle cells in these vessels to cause vasoconstriction, leading to diversion of blood flow from regions of the lung with low oxygen levels towards those regions of higher oxygen tension. This acts to autoregulate the 'matching' of distribution of blood flow to distribution of ventilation.

The relationship between ventilation and perfusion

In the upright lung, after a full expiration at residual volume, the intrapleural pressure at the base of the lung (+3.5 cmH_20) is higher than the atmospheric pressure, but the apex (–4 cmH_20) still remains below atmospheric pressure. During tidal breathing, however, the region of the lung that experiences the greatest change in volume is the dependent part, the bases, when we are in an upright position. This is a result of the sigmoidal shape of the pressure-volume curve of the lung.

The effects of gravity mean that the rate of blood flow is not uniform throughout the lungs (Fig. 1), being higher in the basal regions than the apices. The different hydrostatic pressures within the blood vessels of the lung can explain this uneven distribution. An upright lung may be divided into three zones—1, 2, and 3. The blood flowing in the lung will also act like a continuous column due to the effect of gravity. In the uppermost parts, zone 1, alveolar air pressure (P_A) is usually greater than both arterial (*P*a) and venous (*P*v) pressures. This causes the 'squashing' of capillary beds and restriction of flow.

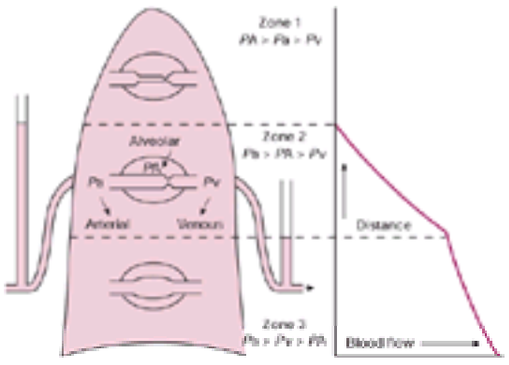

Fig. 1 Diagram of West showing the distribution of blood flow through the lung, which explains the uneven distribution of blood flow in different regions of the lung. *P*a, arterial pressure; P_A, alveolar pressure; *P*v, venous pressure. (Reproduced from West J (2000). *Respiratory physiology*, 6th edn. Lippincott Williams and Wilkins, with permission.)

In the intermediate parts of the lung, zone 2, pulmonary artery pressures are increased due to the hydrostatic effect, but venous pressures (*P*v) may still not be high enough to overcome alveolar pressures and blood flow is only slightly increased compared with the apex (zone 1) regions of the lung.

In the basal part of the lung, zone 3, the hydrostatic pressures generated in both the arterial and venous vessels due to the effect of gravity are greater than alveolar pressures. The flow here is chiefly determined by arterial–venous pressure difference and is therefore higher than in the intermediate and apical regions.

In summary, tidal ventilation is higher at the bases of the lung. Perfusion follows the same distribution to the bases. Ventilation–perfusion ratio (V/Q) values are high at the apex and diminish towards the base of the lung. In a normal healthy individual the overall V/Q ratio is closely matched to allow for efficient gas exchange to take place. Some small areas in the lung may still exist with good perfusion but poor ventilation (or vice versa). In many lung diseases it is likely that gross mismatch of V/Q ratios in many areas impair the process of gas exchange despite the individual having almost normal total ventilation and normal total pulmonary blood flow.

The three-compartment model of ventilation–perfusion and gas exchange

The lungs may be partitioned into a number of functional units in terms of ventilation–perfusion: these do not have discrete anatomical definitions but provide reference points for analysis of gas exchange.

In the absence of a diffusion barrier, the partial pressures of O_2 and CO_2 of the air in each alveolus are the same as those of the end-capillary blood draining it. For the lung as a whole this situation does not arise due to lack of uniformity of ventilation–perfusion within its various units, resulting predominantly from gravitational effects and pleural pressure gradients as described in the preceding section. To obtain the V/Q ratio of such units, the alveolar composition of O_2 and CO_2 would need to be known. Direct sampling of the alveoli is technically not feasible. Sampling at the mouth after deep maximal exhalation is flawed by the dependence of the technique on the speed of exhalation and the baseline state of lung inflation. Alveolar partial pressures of O_2 and CO_2 vary in different parts of the lungs and at different times in the respiratory cycle, hence samples obtained at the mouth are likely to be influenced by the rate and time of emptying of the various lung units.

The three-compartment model of Riley visualizes the lung perfusion as comprising (i) a physiological shunt (Qs), perfusing an area with no ventilation; (ii) alveolar capillary blood equilibrating with ideal alveolar air; and (iii) physiological deadspace (*V*d). Detailed calculations are beyond the scope of this text, but in a resting man up to 70 per cent of the pulmonary ventilation is distributed to the well perfused areas of the lung and up to 95 per cent of the pulmonary capillary blood flow supplies lung units that are well ventilated. These areas are well matched for ventilation and perfusion and constitute the functional part of the lungs in terms of respiratory gas exchange. Approximately 30 per cent of the lung units are ventilated but unperfused, and this constitutes physiological deadspace. Similarly, at rest, 5 per cent of the lung units are well perfused but not ventilated and they constitute the physiological shunts.

There are methods by which the 'matching' between ventilation and perfusion can be assessed: these are still underdeveloped and need refinement, but are none the less providing improved understanding. One such method is the multiple inert gas excretion technique (MIGET). A physiological saline solution of the six inert gases is injected into a peripheral vein. The mixed arterial concentration of each of the gases is measured and taken as the blood-flow weighted mean for the various compartments of the lung. Mixed expired levels are measured and taken as the ventilation weighted mean of the compartmental values. Cardiac output and minute ventilation are also measured and used to calculate the corresponding mixed venous and alveolar concentrations. Based on mass balance considerations a lung ventilation–perfusion distribution is mathematically derived, which is compatible with the arterial and alveolar concentrations of all the inert gases concurrently (Fig. 2).

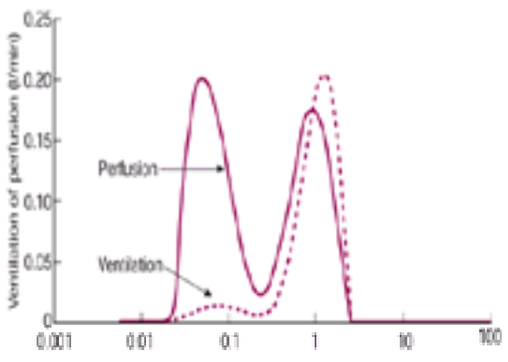

Fig. 2 A representative ventilation–perfusion distribution obtained from a patient with severe airways obstruction at rest. Large areas of perfusion are insufficiently ventilated resulting in hypoxaemia.

15.15.2.1 Primary pulmonary hypertension

Tim Higenbottam and Helen Marriott

Introduction

This chapter will consider the nature of primary pulmonary hypertension and how it relates to the other types of pulmonary hypertension. It will also consider the impact of pulmonary hypertension on survival in both primary pulmonary hypertension and that associated with other disease. The causes of the disease and effects of current treatments will be reviewed.

The publication of reports from the National Institutes of Health (**NIH**) sponsored registry of primary pulmonary hypertension provided a description of the clinical features and prognosis, also a clear diagnostic pathway for investigation. The introduction of heart–lung transplantation in 1981 by Bruce Rietz in Stanford University, California, offered the first real hope of long-term survival for those with primary pulmonary hypertension. However, the realization that transplant surgery could only be offered as a treatment for a tiny minority of patients provided the stimulus to consider alternative medical treatments. This led to the introduction of long-term intravenous infusion of prostacyclin (prostaglandin I_2) in 1984, first considered as a bridge to lung transplantation, but subsequently demonstrated in controlled studies to improve survival and enhance quality of life. Inhaled nitric oxide was later recognized to act as a selective vasodilator of the pulmonary circulation (unlike prostacyclin) and has recently gained United States Food and Drug Administration approval as a therapy, specifically for neonatal pulmonary hypertension.

Finally, the quest to understand familial primary pulmonary hypertension has identified causal mutations of the gene for the bone morphogenetic protein receptor II. This is a member of the superfamily of transforming growth factor-b receptors, and mutations appear to increase the sensitivity of cellular responses to this important growth factor. The hope for new therapies that alter the structure rather than physiology of the pulmonary circulation could now be realized.

What is pulmonary hypertension?

In all its forms, pulmonary hypertension is characterized by fibromuscular intimal hypertrophy that results in narrowing and obliteration of the lumen of blood vessels, most commonly the precapillary arteries (Fig. 1 and Plate 1). By the time of presentation with primary pulmonary hypertension up to 80 per cent of lung vessels have been 'lost' (Fig. 2).

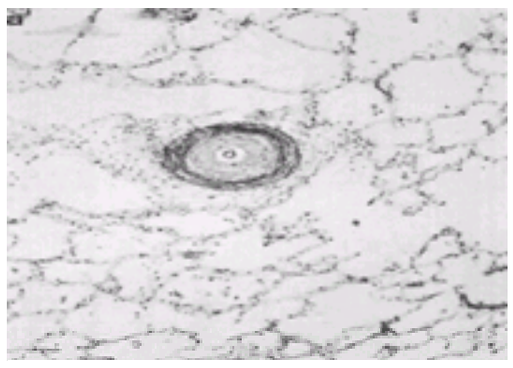

Fig. 1 Intimal thickening of a pulmonary artery in pulmonary hypertension (Chazova I *et al.*, 1995. Pulmonary artery adventitial changes and venous involvement in primary pulmonary hypertension. *American Journal of Pathology* **146**, 389–97). (See also Plate 1.)

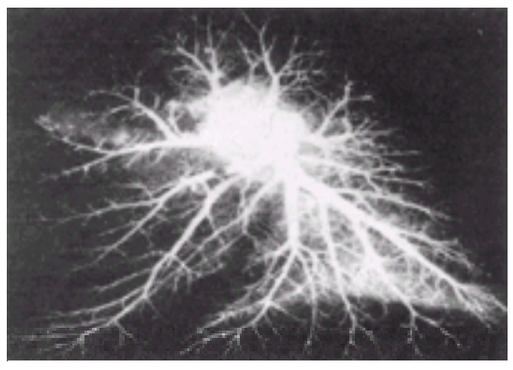

Fig. 2 Loss of precapillary arteries in the lung of a patient with primary pulmonary hypertension.

The physiological consequences of the dramatic loss of small arteries are that the pulmonary vascular resistance is increased, as is the ability of the pulmonary circulation to adapt to the increased blood flow associated with exercise. The resting pulmonary artery pressure is raised; by definition pulmonary hypertension is defined as a mean pulmonary artery pressure in excess of 25 mmHg at rest. More importantly, during exercise there is a rapid rise in pulmonary artery pressure as the pulmonary blood flow increases with cardiac output (Fig. 3).

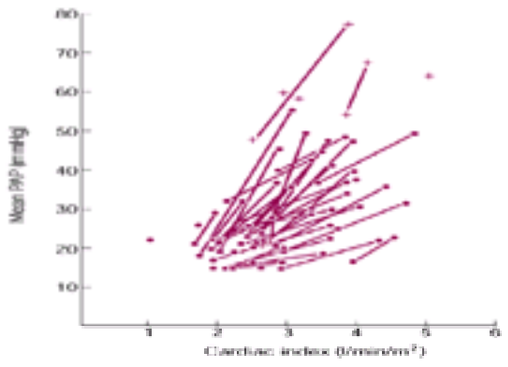

Fig. 3 The increase in pulmonary artery pressure (PAP) with increase in cardiac output (index).

Exercise limitation as a result of breathlessness is the most common symptom in primary pulmonary hypertension and probably caused by acute right ventricular failure. Because the cardiac output fails to rise appropriately with exercise, the mixed venous oxygen saturation ($S\bar{v}O_2$ per cent) falls through increased tissue extraction of oxygen and the arterial oxygen saturation (SaO_2 per cent) also falls. In the later stages of disease the SaO_2 per cent falls even at rest. Right ventricular failure is the most common cause of death.

Clinical features

Pulmonary hypertension should be considered when there is unexplained breathlessness, with no obvious heart or lung disease. In the later stages of the disease symptoms of right ventricular failure become obvious, including syncope, angina-like chest pain, and peripheral oedema. General malaise and cachexia of cardiac failure are endstage symptoms.

In 85 per cent of patients a loud second heart sound is heard. The ECG shows right ventricular strain and RBBB pattern. Also in 85 per cent of patients chest radiography shows large pulmonary arteries.

The screening test is transthoracic echocardiography with Doppler estimation of the tricuspid valve regurgitant flow velocity, which allows the systolic pulmonary artery pressure to be estimated.

At this point it is appropriate to refer all patients with severe pulmonary hypertension—where exercise limitation is a result of pulmonary hypertension—to a specialist centre because of the complexities of diagnosis and the difficulties in managing long-term treatments (Fig. 4). All require a ventilation and perfusion lung scintigraphy followed by a diagnostic right heart catheter. At this the right atrial pressure is measured along with the pulmonary artery pressure, the pulmonary wedge pressure, the cardiac output, and the $S\bar{v}O_2$ per cent. A pulmonary angiogram is undertaken in those patients whose V/Q shows unventilated perfusion defects, although as an alternative investigation it is becoming common to use high-speed spiral CT with an injection of contrast media to assess proximal pulmonary artery obstruction in chronic thromboembolic pulmonary hypertension.

Fig. 4 The investigation and treatment pathway for a patient with pulmonary hypertension.

Classification of pulmonary hypertension

In 1973 the World Health Organization (**WHO**) sponsored the first meeting on pulmonary hypertension. This considered in detail the pathology of the condition and presented the first approach to the classification of the disorder. Unexplained or primary pulmonary hypertension was considered separately from secondary pulmonary hypertension, where an additional disease could be identified in association with pulmonary hypertension. Twenty-five years later the second WHO sponsored meeting focused more upon the common features of the different forms of pulmonary hypertension, in particular their response to treatments such as prostacyclin and the common histopathological changes. Five types of pulmonary hypertension were recognized (Fig. 5).

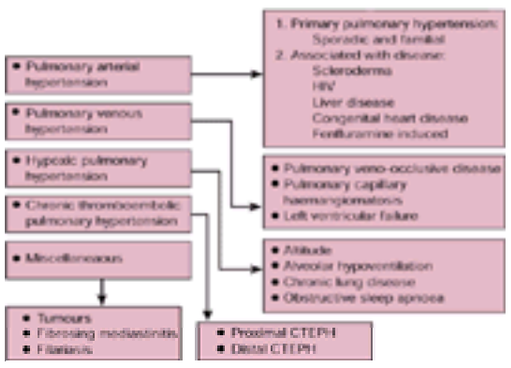

Fig. 5 Types of pulmonary hypertension. CTEPH, chronic thromboembolic pulmonary hypertension (Rich SE, 1998. Primary pulmonary hypertension: executive summary from the world symposium—Primary Pulmonary Hypertension. Available from the World Health Organization via the internet http://www.who.int/ncd/cvd/pph.thml).

Pulmonary arterial hypertension

Pulmonary arterial hypertension was defined as the type of disease where the intimal proliferative changes are found in the arteries alone. In addition there is medial hypertrophy of the muscular arteries and, in advanced disease, changes also include plexiform lesions that it has been suggested are neovascular structures which 'bypass' the obstructed precapillary arteries. Primary pulmonary hypertension is the exemplar and is divided into the sporadic and the familial forms. A necrotizing arteritis has also been described in primary pulmonary hypertension. Peripheral arterial thrombi are often present. Pulmonary arterial hypertension associated with

other diseases includes that seen with HIV infection, liver disease, congenital heart disease (Eisenmenger's syndrome), scleroderma, and other connective tissue diseases. Up to 60 per cent of the pulmonary vascular bed can be obstructed before the symptoms of pulmonary hypertension develop.

The progressive reduction in number and narrowing of the lumen of precapillary arteries initially causes a loss of capacity of the pulmonary circulation to accommodate the increased pulmonary blood flow of exercise. Whilst the resting pulmonary artery pressure may not be raised initially, with exercise the pressure rises rapidly. Right ventricular failure, defined as an inability to sustain the required cardiac output, contributes to the exercise intolerance and the patient experiences breathlessness.

As the disorder advances the pulmonary artery pressure begins to rise, even at rest. The higher systolic and diastolic pressures in the right ventricle can limit diastolic filling of the right ventricular coronary arteries: angina can result, even in the absence of coronary artery disease. Sudden failure of the right ventricle accounts for the exercise-induced syncope seen in the late stages of the disorder. Palpitations on exercise are not uncommon and cardiac dysrythmias are the cause of sudden death in advanced disease.

With failure of the right ventricle at rest the right atrial pressure rises and failing venous return results in the development of peripheral oedema and ascites. Gross hepatic engorgement may occur which impairs the liver's metabolic role.

In addition to these predominately vascular effects, many patients with primary pulmonary hypertension have impaired gas exchange. There is evidence of extensive ventilation/perfusion mismatch, in the main resulting from perfusion of regions of the lungs that are normally poorly ventilated, but also from ventilation of poorly perfused regions. Furthermore, as the cardiac output falls, the mixed venous oxygen level falls as a result of greater extraction of oxygen in the peripheries of the body. Selective flow of this profoundly deoxygenated blood through a limited number of perfused areas of the lungs leaves insufficient time for oxygen uptake to occur, particularly during exercise when the arterial oxygen level can fall profoundly.

In about 15 per cent of patients with primary pulmonary hypertension the foramen ovale of the atrial septum opens as a result of high right ventricular pressure, leading to a right-to-left intracardiac shunt of blood. This adaptation has been shown to prolong survival, as does the fashioning of an atrial septal defect in advanced primary pulmonary hypertension, particularly in infants. The mechanism of this effect is the opportunity for excessive right ventricular pressures during exercise to be released through the defect into the left side of the circulation. This means that the right ventricle does not fail acutely, but the cost is further reduction of arterial oxygen content. However, whilst being more hypoxic than their counterparts without septal defects, these patients can undertake more exercise and live longer.

Pulmonary venous hypertension

Pulmonary venous hypertension is where the intimal proliferation is found in the veins rather than the arteries. There are three main forms—two rare and one very common. Pulmonary veno-occlusive disease and pulmonary capillary haemangiomatosis are the rare conditions, whilst pulmonary venous hypertension from left ventricular failure and left-sided valvular heart disease are common. Any increase in left atrial pressure, pulmonary vascular resistance, and capillary blood flow can lead to a chronic increase in pulmonary venous pressure.

Distinction between pulmonary arterial and pulmonary venous hypertension can be clinically challenging. However, in pulmonary venous hypertension the pulmonary wedge pressure measured with a Swan/Ganz balloon catheter is elevated. On high-resolution computed tomography the lung fields show extensive interstitial lines in the interlobular septi, an appearance akin to left ventricular failure.

Hypoxic pulmonary hypertension

Acute pulmonary hypoxic vasoconstriction

The precapillary arteries of the lungs are sensitive to falls in both alveolar and capillary oxygen partial pressure. At values of oxygen partial pressure below 7.2 kPa, their vascular smooth muscle cells contract, dependent on the activity of voltage-dependent potassium channels, ensuring a matching of the distribution of perfusion of the capillaries to ventilation of the alveoli.

Chronic hypoxic pulmonary hypertension

Whilst transient pulmonary hypertension is often a feature of acute lung disease, normal distribution of perfusion is restored when the alveolar oxygen levels are returned to normal. However, in chronic lung disease (see Chapter 17.6 and Chapter 17.7) the structure of the walls of the precapillary arteries changes. As in pulmonary arterial hypertension the intima proliferates and there may be smooth muscle hypertrophy and adventitial fibrosis. These changes are extensive and not simply localized to those regions of the lungs that are predominantly under-ventilated. In other words the chronic changes in structure of the pulmonary arteries in hypoxic lung disease do not necessarily facilitate close matching between the distribution of ventilation and perfusion.

The increased pulmonary vascular resistance in patients with chronic hypoxic lung disease is usually less severe than in primary pulmonary hypertension, but it does contribute to ill health. There is evidence on echocardiographic studies that right ventricular function is impaired: this is exacerbated by exercise and could contribute to reduced exercise tolerance.

Chronic thromboembolic pulmonary hypertension

Chronic thromboembolic pulmonary hypertension is where the peripheral or proximal pulmonary arteries are occluded by thrombus and emboli, causing widespread segmental and subsegmental defects in lung perfusion. These areas are usually normally ventilated and so gas exchange is impaired. Patients compensate with increased rates of ventilation: $P\mathrm{aO_2}$ is often maintained with a lower than normal $P\mathrm{aCO_2}$ level. As in all forms of pulmonary hypertension, resting cardiac output may be reduced or is reduced when exercise is undertaken.

Miscellaneous

Finally there is the miscellaneous type of pulmonary hypertension. This includes pulmonary hypertension with fibrosing mediastinitis, pulmonary artery tumours, and obstructions associated with protozoal and nematode infestation, such as filariae and schistosomes.

Prognosis

The development of pulmonary hypertension shortens life. This is best seen in primary pulmonary hypertension, where the untreated 3-year post-diagnosis survival is less than 35 per cent (Fig. 6), but pulmonary hypertension also reduces survival when it is associated with other disease such as chronic obstructive bronchitis. This is a result of alveolar hypoxia, as survival is enhanced when the partial pressure of oxygen is restored to normal by long-term oxygen therapy (LTOT).

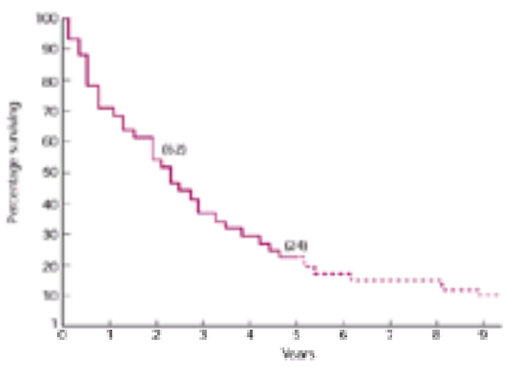

Fig. 6 Survival in primary pulmonary hypertension (Fuster V *et al.*, 1984. Primary pulmonary hypertension: natural history and the importance of thrombosis.

Circulation **70**, 580–7).

The cause of death in pulmonary hypertension depends on the severity of right ventricular failure. In patients with primary pulmonary hypertension it is possible to predict survival from haemodynamic measurements at right heart catheter studies: the presence of a cardiac output less than 2.5 litre/min, mean right atrial pressure more than 10 mmHg, and SvO_2 less than 63 per cent all being poor prognostic factors. For ease it is valuable to use the New York Heart Association Grade III or IV and pulmonary vascular resistance greater than 15 units to predict the chance of survival to be very low without treatment (Fig. 7). A very similar prediction can be made on the basis of haemodynamic measurements in patients with Eisenmenger's syndrome. Sudden death from right ventricular failure is responsible for 47 per cent of the deaths from primary pulmonary hypertension.

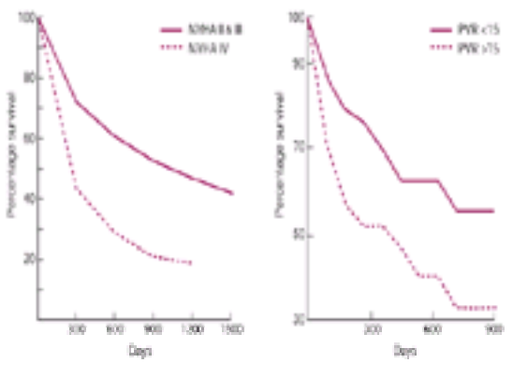

Fig. 7 Survival of patients with primary pulmonary hypertension in the NIH registry according to their New York Heart Association (NYHA) Grade and pulmonary vascular resistance (PVR) (D'Alonzo GE *et al*., 1991. Survival in patients with primary pulmonary hypertension. Results from a national prospective registry. *Annals of Internal Medicine* **115**, 343–9).

Treatment

All patients with pulmonary arterial hypertension should receive anticoagulation treatment as uncontrolled studies have shown overall survival to be improved by their use (Fig. 8). The treatment of chronic thromboembolic pulmonary hypertension with proximal obstructions is surgical thromboendarterectomy: for other types of pulmonary hypertension—with the exception of pulmonary venous hypertension—the use of vasodilators should be considered.

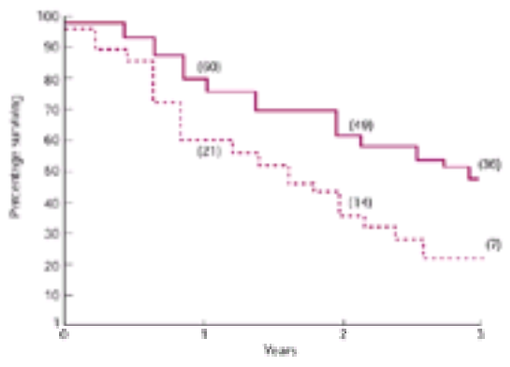

Fig. 8 Survival of patients with primary pulmonary hypertension treated (solid line) or not treated (broken line) with anticoagulation (Fuster V *et al*., 1984. Primary pulmonary hypertension: natural history and the importance of thrombosis. *Circulation* **70**: 580–7).

Early disease

In early/mild disease (cardiac output greater than 2.5 litre/min, mean right atrial pressure less than 10 mmHg, and SvO_2 greater than 63 per cent) decisions about other treatment are made following an acute vasodilator trial, most commonly using inhaled nitric oxide, intravenous prostacyclin, or adenosine. Only if there is evidence of a greater than 20 per cent drop in pulmonary vascular resistance are oral vasodilators considered. This response is found in less than 25 per cent of patients with primary pulmonary hypertension, and for these nifedipine, diltiazem, or amlodopine are used in therapeutic doses. Survival is improved, although the studies are uncontrolled (Fig. 9).

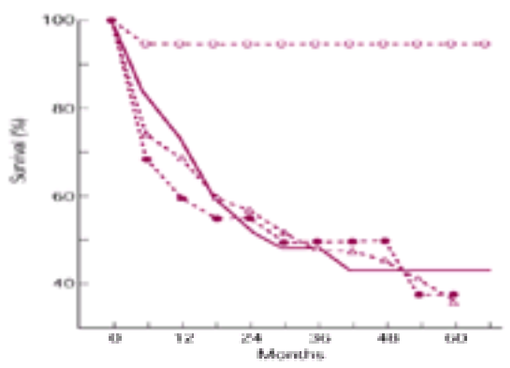

Fig. 9 Kaplan–Meier estimates of survival among patients who responded to treatment (open circles), those who did not respond (solid line), patients enrolled at the NIH registry who were treated at the University of Illinois (solid circles), and the NIH registry cohort (triangles).

Severe disease

In patients with severe disease (cardiac output below 2.5 litre/min, right atrial pressure greater than 10 mmHg, or SvO_2 less than 63 per cent), long-term continuous infusions of prostacyclin improve survival and enhance the quality of life. Actuarial survival at 2 years has been increased to 80 per cent, which exceeds that of untreated patients and the survival following lung transplantation (Fig. 10). Of special interest is the recent report that prostacyclin may, when used long-term, reverse the disease to some extent, with pulmonary vascular resistance falling below the lowest level achieved during the initial right heart catheter study (Fig. 11). This has raised the hope that medical treatments may be able to reverse the disease process.

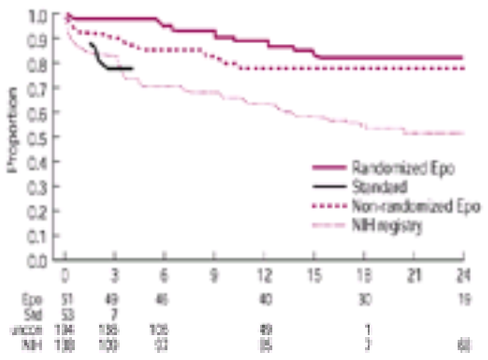

Fig. 10 Long-term continuous infusions of prostacyclin improve survival. Epo, epoprostanol; std, standard; uncon, uncontrolled non-randomized Epo; NIH, National Institute of Health Registry.

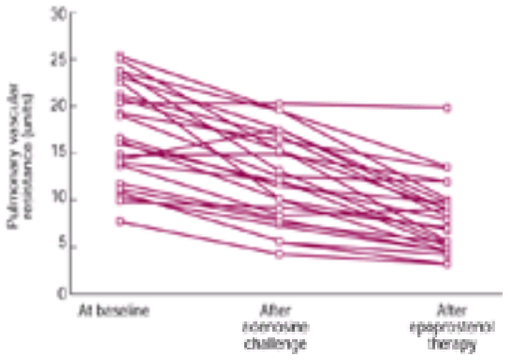

Fig. 11 Long-term prostacyclin may reverse pulmonary hypertension (McLaughlin VV *et al*. (1998). Reduction in pulmonary vascular resistance with long-term epoprostenol (prostacyclin) therapy in primary pulmonary hypertension. *New England Journal of Medicine* **338**, 273–7).

Primary pulmonary hypertension and Eisenmenger's syndrome have the poorest outcomes of any diseases after lung transplantation, the 3-year actuarial survival being only just in excess of the untreated patients. However, the introduction of prostacyclin has delayed the need for lung transplantation by on average 17.5 months and has improved the success of subsequent lung transplantation, with 1-year survival rate in excess of 80 per cent.

Use of vasodilators

Prostacyclin

In pulmonary hypertension the phenotypes of many cells that make up the blood vessels are changed: endothelium, the cells of the matrix tissues, and the vascular smooth muscle cells. In patients with primary pulmonary hypertension, urinary excretion of prostacyclin metabolites is reduced and endothelial cells from the pulmonary arteries express a reduced level of prostacyclin synthase, the enzyme that forms prostacyclin, hence it would seem appropriate to supplement the reduced endogenous production of prostacyclin with exogenous therapy.

The success of intravenous prostacyclin in primary pulmonary hypertension has led to its use in other forms of pulmonary arterial hypertension. In isolated pulmonary hypertension from scleroderma, prostacyclin also improves the quality of life, and in pulmonary arterial hypertension associated with congenital heart disease it improves survival. In those patients with chronic thromboembolic pulmonary hypertension who are not suitable for surgery, prostacyclin also achieves an equivalent improved survival chance to that seen in patients with primary pulmonary hypertension. By contrast, in pulmonary venous hypertension—that is, pulmonary veno-occlusive disease, pulmonary capillary haemangiomatosis, and left ventricular failure—long-term intravenous prostacyclin worsens the survival chances and should not be used. The increased perfusion leads to pulmonary oedema, respiratory failure, and death.

Analogues for prostacyclin have been developed. Iloprost, which is more stable, is of equivalent effect to prostacyclin when given intravenously and has also been used orally and by inhalation. Beroprost is another oral analogue, whilst UT-15 was introduced for continuous subcutaneous infusion. All are in clinical trials, with encouraging early results. There is evidence that inhaled iloprost achieves the same degree of 'reversal' of pulmonary hypertension as intravenous delivery when used long term.

Nitric oxide

As with prostacyclin synthase, expression of nitric oxide synthase and release of nitric oxide is also reduced in the pulmonary arteries in both primary and other types of pulmonary hypertension. Basal nitric oxide release seems normal from pulmonary hypertensive lungs, but stimulated release of the gas is reduced, particularly in hypoxic pulmonary hypertension. In advanced primary pulmonary hypertension there are clusters of new vessels, called plexiform lesions, branching from precapillary arteries. Nitric oxide synthase is overexpressed in these lesions, which develop in the region of the 'obstructed' precapillary pulmonary arteries, perhaps bypassing the obstruction and providing a route from pulmonary artery to the pulmonary veins.

In 1987 inhaled nitric oxide was shown to be a selective pulmonary vasodilator (Fig. 12). However, a problem of handling and using nitric oxide is its speed of oxidation to form nitrogen dioxide, which can injure the epithelial lung surfaces even at low concentrations of 5 parts per million (ppm). This rate of reaction is dependent on the concentration of the gas and the concentration of oxygen, hence it is necessary to mix the nitric oxide (which is stored in nitrogen) carefully with air or oxygen just before it is inhaled. This is straightforward when the patient is receiving mechanically assisted ventilation, but difficult when ventilation is spontaneous. It may be achieved, however, using a 'spiked' delivery system that adds nitric oxide as a small bolus of gas at the beginning of the breath using a patient triggered device. This can reduce the pulmonary vascular resistance by the same amount as when the breath is filled with 40 ppm of nitric oxide, but with only a fortieth of the dose with each breath.

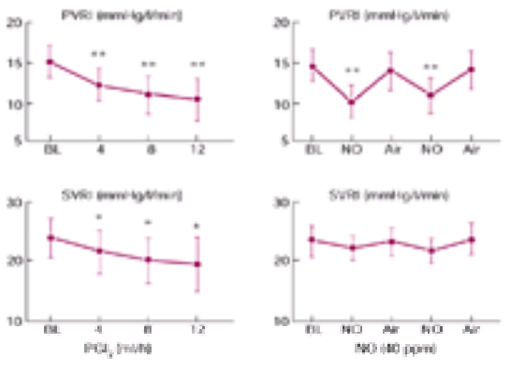

Fig. 12 Inhaled nitric oxide is a selective pulmonary vasodilator. PVRI, pulmonary vascular resistance index; SVRI, systemic vascular resistance index; ppm, parts per million (of inhaled nitric oxide); PGI_2, prostaglandin I_2; *, significantly different from baseline (Pepke Zaba J *et al.* (1991). Inhaled nitric-oxide as a cause of selective pulmonary vasodilatation in pulmonary-hypertension. *Lancet* **338,** 1173–4).

Inhaled nitric oxide is about half as effective as a vasodilator as prostacyclin. It has not yet found a place in the treatment of primary pulmonary hypertension in general, although in some case reports it seems to 'reverse' established primary pulmonary hypertension when given long term. In chronic obstructive pulmonary disease, the pulmonary vascular resistance is reduced in patients receiving long-term oxygen therapy when nitric oxide is administered for 3 months, and in this group inhaled nitric oxide may have a part to play in reducing the pulmonary hypertension and right ventricular dysfunction seen during exercise. Long-term, randomized, controlled trials are awaited. As a therapy inhaled nitric oxide has recently been granted a licence for the treatment of pulmonary hypertension of the neonate, here avoiding the use of extracorporeal oxygenation.

Phosphodiesterase inhibitors

In the lungs the breakdown of cGMP, formed in vascular smooth muscle cells by nitric oxide, is predominately by the phosphodiesterase-5-enzyme that is especially expressed in lung and in the vascular cells of the corpus cavernosum. By use of the inhibitor sildenafil (Viagra) it is possible to induce pulmonary vasodilatation. Given orally long-term this reduces pulmonary vascular resistance and improves exercise tolerance in patients with pulmonary arterial hypertension.

Endothelin-1 antagonists

There have been numerous reports that endothelin-1 is expressed to a greater degree than normal in most types of pulmonary hypertension and that circulating levels of endothelin-1 are also elevated, especially in acute hypoxia of altitude and in chronic hypoxic lung disease. These findings have led to the suggestion that endothelin receptor antagonists might be effective treatments for pulmonary hypertension, and some 32 are in development. One agent, bosentan, has been shown to reverse structural abnormalities in experimental models of pulmonary hypertension. Anxieties about teratogenicity and liver injury have limited the widespread use of these compounds in clinical practice, but encouraging results have been observed in reports of series of patients with isolated pulmonary hypertension and scleroderma. Long-term, randomized, controlled trials have now reported improved exercise tolerance.

Particular causes of pulmonary arterial hypertension

Pulmonary hypertension in fenfluramine and dexfenfluramine users

In the late 1980s a physician in Paris, Francois Brenot, noticed an increasing number of patients with primary pulmonary hypertension being referred who had been treated with the anti-obesity drug fenfluramine or its isomer dexfenfluramine. This observation led to a case–control study of all patients with primary pulmonary hypertension diagnosed over a period of 18 months. For each of 192 patients with this condition three controls were found who were matches for gender, age, and district of residence. An independent panel of doctors checked the entry criteria for each patient with primary pulmonary hypertension. All had a detailed questionnaire administered on past and present therapies, including anti-obesity treatments. It was found that an excess number of patients had taken one of the two drugs, for at least 3 months. Indeed, 1 in 8000 was the calculated risk for developing primary pulmonary hypertension when either fenfluramine or dexfenfluramine was taken for more than 1 year, suggesting a causal relationship. By contrast, the appetite suppressant phentermine was not associated with pulmonary hypertension. Of note, in the 1960s a similar association had been found between the use of another anti-obesity drug, aminorex, and the development of primary pulmonary hypertension.

What is the mechanism by which fenfluramine/dexfenfluramine might cause primary pulmonary hypertension? Both accumulate in the lungs through uptake by the serotonin transporter for which they have a high substrate affinity, and both are metabolized by the cytochrome P450 enzyme CYP2D6 that is expressed in the liver, lungs, and right side of the heart. In part the susceptibility of certain individuals to develop primary pulmonary hypertension when taking fenfluramines can be accounted for by polymorphism of the CYP2D6 enzyme. About 8 per cent of Caucasian and 1 per cent of Asian people express little or no active enzyme, hence they will have little ability to metabolize these drugs within the lungs, with local lung toxicity a possible explanation for the development of pulmonary hypertension. Within the population of patients with primary pulmonary hypertension who have taken dexfenfluramine and fenfluramine there is a higher proportion of poor metabolizers compared with controls (20 per cent compared with 7 per cent). High concentrations of dexfenfluramine and fenfluramine are able to induce vascular smooth muscle contraction in humans as a result of inhibition of membrane potassium channels. In addition, fenfluramine at high concentration can inhibit expression of the 1.5Kv subunit of the voltage-dependent potassium channel of vascular smooth muscle cells.

Familial primary pulmonary hypertension

About 6 per cent of all patients with primary pulmonary hypertension have a family history of the condition, exhibiting an autosomal dominant pattern of inheritance with incomplete penetrance. The histopathology of the pulmonary vascular disease is identical to that found in sporadic primary pulmonary hypertension.

In 1998 two laboratories identified a region on chromosome two associated with familial primary pulmonary hypertension after detailed linkage analysis of extended families. Further work led to identification of mutations of a gene encoding for bone morphogenetic protein receptor II (*BMPR 2*) as the cause. This is a member of the superfamily of transforming growth factor-b receptors.

Transforming growth factor-b is an important cytokine regulator of pulmonary angiogenesis. It inhibits cell growth, cell differentiation, and stimulation of collagen deposition. In the inherited illness hereditary haemorrhagic teliangectasia, new vessels in the lungs and mucosa lead to bleeding. Mutations of the gene encoding endoglin, which is a transforming growth factor-b receptor-complex accessory protein, and of the transforming growth factor-b type 1 receptor ALK-1, have been identified in this disease. A 'failure' of signalling by transforming growth factor-b could account for the new vessel formation. By contrast, mutations of *BMPR 2* appear to enhance the effects of transforming growth factor-b, perhaps promoting vessel 'loss' and synthesis of collagen. Much needs to be learnt about the key ligands, receptors, and downstream signalling pathways. However, this lead from familial primary pulmonary hypertension could have identified a common mechanism for many different types of pulmonary hypertension. Overexpression of transforming growth factor-b is often found in both experimental and human forms of pulmonary hypertension. Lessons learnt from genetics could offer useful clues as to how we might 'fully' reverse pulmonary hypertension in the future.

15.15.2.2Pulmonary oedema

J. S. Prichard (revised by J. Firth)

Introduction

Acute fulminant pulmonary oedema is a terrifying event in which patients literally drown in their own body fluids. Much more commonly, the clinician is called to treat pulmonary oedema in its less acute form, for breathlessness disturbs the patient long before serious alveolar flooding has begun.

Because pulmonary oedema is very commonly seen as a manifestation of left-sided heart disease—where its relief by diuretics is so effective—there is a temptation to forget the very wide range of other causes. Indeed, it is prudent to make the diagnosis of hydrostatic pulmonary oedema of cardiac origin only when other manifestations of heart disease are present, and to consider wider possibilities in all other circumstances. Pulmonary oedema has many possible causes, which occur in combination more often than is usually recognized (see Table 1). Only by careful and clear analysis of clinical and pathophysiological data can the contributing factors be identified and the clinical situation fully understood.

Physiological and experimental aspects of pulmonary oedema

Fluid balance between the capillaries and the interstitial space

The continuous movement of water from the lung capillaries into the interstitium is regulated by the permeability of the endothelium to water and protein and by the imbalance of hydrostatic and osmotic forces across the membrane. The Starling hypothesis suggests that perturbation of any one of five factors could lead to oedema (Fig. 1 and Fig. 2). These are capillary hydrostatic pressure (P_{cap}), interstitial tissue pressure (P_{int}), plasma colloid osmotic (oncotic) pressure (P_{cap}), endothelial permeability (expressed by k and s), and lymphatic function. Abnormalities in the first four will cause oedema by increasing water entry to the interstitial space, whilst impaired function of the last will diminish drainage. Interstitial colloid osmotic pressure (P_{int}) has not been included as an independent variable as it is determined by the plasma protein concentration and endothelial permeability.

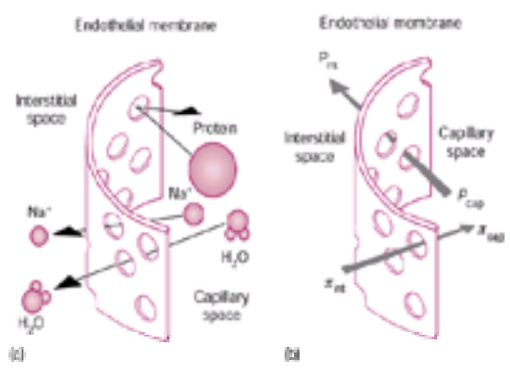

Fig. 1 (a) The lung endothelial membrane is permeable to water and electrolytes but less permeable to macromolecules. (b) The Starling equation: $Q_1 = K(P_{cap} - P_{int}) - Ks(p_{cap} - p_{int})$, where Q_1 is the net fluid filtration rate, K is the filtration coefficient, s is the reflection coefficient, ($P_{cap} - P_{int}$) is the hydrostatic pressure gradient from the capillary lumen to interstitial space, and ($p_{cap} - p_{int}$) is the oncotic pressure difference across the capillary membrane.

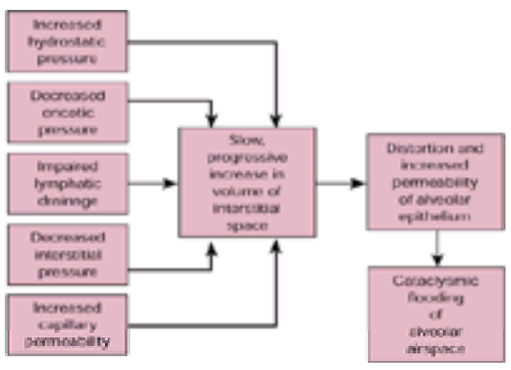

Fig. 2 The initiation of pulmonary oedema and the sequence of development.

Experimentally, the development of pulmonary oedema may be characterized by the relationship between tissue water and microvascular hydrostatic pressure (Fig. 3). In the normal lung, the water content rises only slowly until the capillary pressure reaches 25 to 30 mmHg: thereafter, the rise is rapid. The curve is shifted leftwards by decreased interstitial pressure, increased endothelial permeability, decreased plasma oncotic pressure, or impaired lymphatic drainage. Figure 3 illustrates the interactions between these factors: at low and normal hydrostatic pressures, changes in oncotic pressure, permeability, and lymphatic drainage do not readily cause oedema but, at higher hydrostatic pressures, their effect is much more dramatic. The fact that pulmonary capillary pressure may be raised to 25 to 30 mmHg before there is any significant accumulation of water in a normal lung is a considerable 'safety factor', due principally to the behaviour of the lymphatic system. In response to faster transcapillary water flux from whatever cause (see below), the lymphatic system can increase its activity so much that flow accelerates to between three and ten times the basal level before the drainage becomes overwhelmed. The situation in which the lung water content has increased only little whilst

the transcapillary and lymph fluxes have increased considerably emphasizes that pulmonary oedema is a dynamic phenomenon, in which tissue swelling is but the endstage reached when lymphatic drainage capacity is exceeded. Only then does fluid accumulation begin—slowly at first in the interstitial space, but then rapidly as alveolar flooding begins.

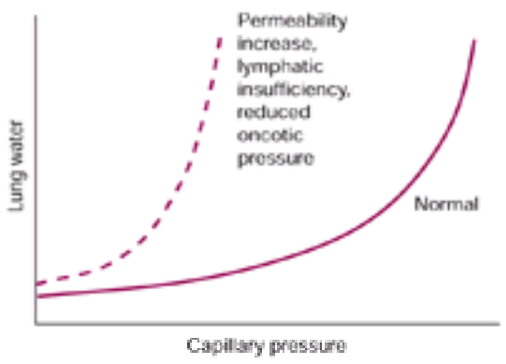

Fig. 3 Lung water content and capillary pressure. In the normal lung tissue, the water content does not begin to increase until the capillary pressure is approximately 30 mmHg. Where colloid osmotic pressure (e.g. plasma protein concentration) is reduced, endothelial permeability is increased or the lymphatic pump is impaired, the whole curve is shifted to the left. (Reproduced from Prichard JS (1982). *Edema of the lung*. Charles C. Thomas, Springfield, Illinois, with permission.)

Hydrostatic pulmonary oedema

Any increase in capillary hydrostatic pressure, whether from cardiac failure, fluid overload, or pulmonary venous occlusion, speeds the rate of water flow into the interstitium. Provided the increase in pressure is not too great, this process will be self-limiting. Thus, molecular sieving, by allowing water to enter the interstitial space more readily than macromolecular solutes, will reduce p_{int}. Increased interstitial water increases the interstitial hydrostatic pressure P_{int} and decreases the macromolecular exclusion volume—again increasing P_{int}. So, as long as lymphatic pumping can keep pace, the tissue water will expand only slightly. However, once the capacity of the lymphatic drainage is exceeded, accumulation of an oedema fluid with a low protein content begins. This starts in the lower parts of the lung (because it is here that hydrostatic pressures are greatest) and is associated with a characteristic redistribution of blood flow away from the lung bases.

The activity of lung lymphatics is critical in determining the onset and extent of hydrostatic oedema, and therefore it is not surprising to find that, in conditions where pulmonary vascular pressures are chronically elevated, the lymphatics undergo hypertrophy as a protective mechanism. Consequently, acute elevations of pulmonary vascular pressure will produce acute life-threatening oedema at levels that, when reached chronically, cause little distress and are registered clinically only by the characteristic radiological changes of lymphatic hypertrophy.

High permeability pulmonary oedema

Endothelial damage speeds water flux into the interstitial space. But, unlike hydrostatic oedema, there is also an increase in protein flux so that the oedema fluid has a high protein content. This has four consequences:

1. The oncotic pressure of the interstitial fluid increases and one of the major mechanisms for limiting the progress of oedema becomes unavailable.
2. Much of the protein reaching the tissue and alveoli is fibrinogen, which coagulates. Initially, the damage from interstitial coagulation is limited by fibrinolysis by plasminogen, but this defence is soon exhausted and mobilization of the coagulum ceases.
3. The residual coagulum impairs lymphatic drainage.
4. The residual coagulum becomes the skeleton on which lung fibrosis develops.

By far the most common cause of high permeability pulmonary oedema is the acute respiratory distress syndrome, which is discussed in Chapter 16.5.1. Less common causes include toxic gases and fumes (Chapter 17.11.17) and drugs (Chapter 17.11.19).

Pulmonary oedema and reduced plasma oncotic pressure

A reduction in plasma oncotic pressure increases fluid transudation into the lung and leads to pulmonary oedema at lower hydrostatic pressures than would otherwise be expected. Although this is readily demonstrable experimentally, it is frequently overlooked in clinical practice, where it may be of importance following myocardial infarction, after transfusion of crystalloids, and in adult respiratory distress syndrome. A useful clinical guide to the danger is the difference between pulmonary wedge pressure (measured by a Swann–Ganz catheter) and colloid osmotic pressure (the **COP–PAW** gradient). The normal lower limit of this index is about –12 mmHg, but at levels below –9 mmHg the risk of oedema is considerably enhanced. A practical problem in applying this method has been the difficulty in standardizing and maintaining protein oncometers. The alternative of using serum protein measurements is valuable but slower.

Lymphatic oedema and the role of the lung lymphatics

The lymphatic system provides the lung with its major 'safety factor'. It is capable of increasing the tissue clearance rate at least 10-fold before becoming overwhelmed. In chronic venous and capillary hypertension, as in mitral stenosis, even larger lymph flows occur because of lymphatic hypertrophy.

Oedema soon develops when lymphatic drainage is occluded experimentally. This has clinical relevance for patients with lung transplants, whose lung lymphatic pathways are severed and in whom initial alveolar flooding is common. Lymphatic oedema also plays a part in pulmonary oedema from lymphangitis carcinomatosa and in facilitating oedema in patients with silicosis and malaria.

Reduced interstitial pressure and pulmonary oedema

Tissue pressure within the interstitial space is one of the determinants of transendothelial fluid movement. It can be altered independently of intravascular events by changes in the intrapleural pressure. Thus, when extreme negative intrapleural pressures occur, the interstitial perialveolar tissue pressure can fall considerably below its normal subatmospheric level and accelerate the rate of fluid movement into the interstitium. Oedema will appear if the rate of fluid entry exceeds the rate at which it can move through the interstitium and be removed by the lymphatics.

The sequence of oedema accumulation

When oedema fluid begins to accumulate in lung tissue—irrespective of the underlying cause—it does so first around fissures, blood vessels, and airways because these tissues are 'loose' and swell easily without great change in tissue pressure. When this 'sump' has become near maximally dilated, swelling and thickening of the alveolar wall begin. Finally, after a phase of progressive alveolar wall thickening, fluid begins to accumulate in the alveoli themselves. This final phase begins at a point where total lung water has increased by about 30 per cent (Fig. 4).

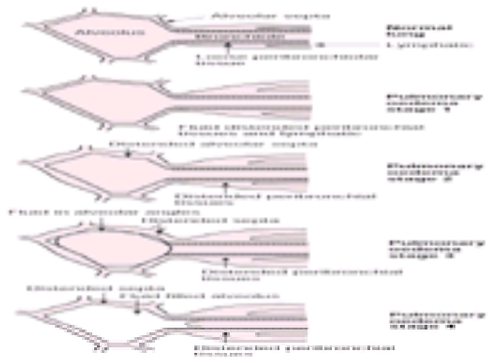

Fig. 4 Stages in the development of pulmonary oedema. Stage 1: peribronchial swelling; stage 2: distended alveolar septa; stage 3: limited accumulation of fluid in alveolar angles; stage 4: alveolar flooding. (Reproduced from Prichard JS (1982). *Edema of the lung*. Charles C. Thomas, Springfield, Illinois, with permission.)

At first, the fluid in the alveoli is confined to the alveolar angles. Subsequently, complete flooding of individual alveoli occurs. A striking feature of the microscopic appearance at this stage is the way in which alveoli are either completely filled with fluid or else have only minimal accumulation in the angles. There are no half-filled alveoli: flooding is a 'quantal' event, with flooded alveoli scattered at random throughout the affected area. Atelectasis is uncommon and air is rarely trapped, although the volume of each alveolus is smaller when fluid-filled than when air-filled.

The quantal nature of alveolar flooding arises from the interaction of surface and tissue forces (Fig. 5). The immediate precipitating factor is probably an increase in alveolar epithelial permeability caused by the distortion and swelling of the alveolar wall, which allows water to flood from the interstitium into the air space. An alternative, less likely, hypothesis is that fluid entry occurs via pores in the epithelium of the terminal airways. Irrespective of the route, the ease of fluid entry now makes the relationship between pressure and volume inverse and unstable, as explained in the legend to Fig. 5.

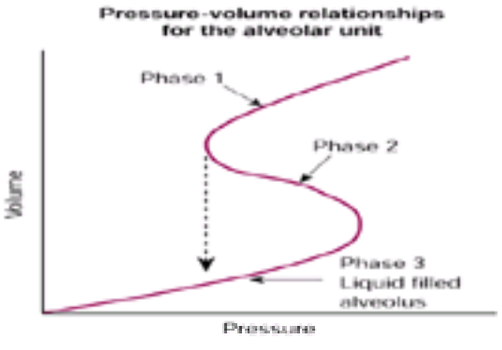

Fig. 5 Pressure–volume relationships in the alveolus. Phase 1 represents the normal alveolus lined by surfactant. Tissue elasticity, osmotic balance, and the presence of surfactant combine to produce a direct, mechanically stable relationship between pressure and volume. Phase 2 represents the situation in which alveolar permeability has increased. Any influx of fluid into the alveolus decreases the overall surface area. At these lower dimensions, surfactant is inoperative and surface tension is independent of area. The relationship between volume and pressure is that of an air bubble in liquid ($P = 2T/R$) and is unstable, a situation only resolved when the alveolus has flooded. The air volume therefore shrinks as air is expelled until phase 3 is reached. Here the remaining air is a 'bleb' at the bronchiolar orifice.

The resolution of pulmonary oedema

The extent and rapidity of resolution of pulmonary oedema depend upon its cause. Hydrostatic oedema and that due to low oncotic pressure can resolve completely and rapidly, but this is rarely the case with permeability oedema, where slow disappearance and permanent lung damage are the rule.

Resolution of hydrostatic oedema occurs in two phases: return of the capillary pressure towards normal, and then lymphatic and osmotic resorption of tissue and alveolar fluid. In cardiac failure, the shift of blood from the pulmonary to the systemic circulation by sitting up is the most powerful method of reducing capillary pressure, but other mechanisms have also been suggested, including:

1. progressive hypovolaemia (from fluid extravasation into the lung);
2. increasing plasma oncotic pressure from the relatively greater transendothelial loss of water than of plasma protein;
3. hypoxic vasoconstriction of the muscular pulmonary arteries causing a fall in capillary pressure;
4. exhaustion of sympathetic neurotransmitter in the systemic circulation with reduction in venomotor tone and left heart afterload.

The first three are all known to occur, but quantitatively their contributions are uncertain. The fourth is conjecture.

In hydrostatic oedema, once hydrostatic pressure has been reduced, fluid is removed from the interstitial space by lymphatic drainage, which can be increased for as long as 24 h after an acute episode in experimental models. Oncotic resorption into the circulation can also play a significant part. However, the mechanism of alveolar clearance is not well understood. Much fluid is removed by coughing and ciliary drainage and final resorption seems to occur as a result of active sodium ion transport, although it is uncertain whether this takes place in the alveolar or terminal airway epithelium.

The clearance mechanisms in high permeability oedema are considerably less efficient than in hydrostatic oedema because fibrin has coagulated in the interstitium, lymphatics, and alveoli, and because the tissues have often been damaged. Regeneration of epithelium and endothelium is frequently necessary. In the case of the alveolar epithelium, cell replacement is by transdifferentiation from type II pneumocytes and this is rarely complete. Whether the transdifferentiated cells are able to play an efficient part in active transport and fluid removal is unknown.

Clinical aspects

Causes of pulmonary oedema

Table 1 lists the main causes of pulmonary oedema classified according to the predominant pathophysiological mechanism. However, the clinician should never forget that more than one cause may be operating (Table 2), and must not neglect one remediable factor at the expense of another, or allow therapy itself to intensify the problem. For example, overvigorous fluid replacement following pulmonary endothelial damage may be the very factor that accelerates water and protein flow into the interstitium and provokes oedema.

Descriptions of the clinical manifestations and management of the more common diseases listed in Table 1 are provided elsewhere, but certain aspects need particular comment.

Pulmonary oedema in heart failure

Heart failure, discussed in detail in Chapter 15.2.2, is the cause of the commonest form of pulmonary oedema, but two features deserve comment. The first is the symptom of orthopnoea in which the oedema either first appears or, if already present, intensifies after a period of lying down. The cause is a shift of blood from the

systemic to the pulmonary circulation, which occurs because of the change in posture. This leads to an increase in intracapillary hydrostatic pressure, which in turn triggers oedema. The symptom is at its most dramatic in paroxysmal nocturnal dyspnoea. The second feature—and one that frequently causes confusion because it is contrary to expectation—is the tendency of the blood pressure to rise as the patient progresses into left heart failure. The cause is probably increasing sympathetic activity and circulating catecholamines, which lead to intense systemic arterial and venous vasoconstriction, thereby increasing afterload and central venous pressure inappropriately and so intensifying the development of oedema.

Loculated constrictive pericarditis

Loculated constrictive pericarditis, predominantly involving the left ventricle, can occur in patients with chronic renal failure who are undergoing dialysis. Echocardiography is helpful in diagnosis, which may be difficult because the characteristic signs of pericardial tamponade may be missing. When located posteriorly, the fluid is difficult to aspirate percutaneously, but open drainage is rarely necessary because strict attention to fluid regulation during and between dialyses usually leads to resolution.

Pulmonary venous thrombosis

This is a rare condition that is difficult to diagnose. It may be idiopathic or may be a manifestation of conditions such as polyarteritis nodosa, other vasculitic disorders, and occult neoplastic disease. The idiopathic condition is most common in middle-aged women: symptoms of increasing lassitude and breathlessness, sometimes with a low-grade fever, are the presenting symptoms. Gross-effort dyspnoea and pulmonary oedema, usually with pleural effusions, develops later. Signs of pulmonary hypertension are present. Difficulty in obtaining a clear pulmonary artery wedge pressure tracing and normal left atrial pressure (measured directly by the trans-septal route) should alert suspicion. Pulmonary artery angiography demonstrates poor segmental drainage in the regions affected by thrombosis. Open lung biopsy will confirm the diagnosis, but this is dangerous and should be undertaken only when there is real fear of missing an alternative cause of the oedema.

Left atrial myxoma, ball thrombus of the left atrium, and cor triatriatum

These are rare, but must not be missed as they are remediable by surgery. Their clinical presentation may be very similar to that of pulmonary venous thrombosis. All three conditions also enter into the differential diagnosis of tight mitral stenosis. Echocardiography is the key investigation.

High-altitude oedema

Some apparently normal people who ascend rapidly to high altitude experience acute pulmonary oedema. The condition develops only in that minority of individuals who have an exaggerated acute pulmonary arterial pressor response to hypoxia. These develop pulmonary hypertension at high altitude, with oedema possibly resulting from transarterial fluid leakage, but alternatively due to inhomogeneity of vasoconstriction and consequent extreme hyperperfusion of those areas not vasoconstricted. A further contribution may arise from the effects of vasoactive amines on the contractile filaments of endothelial cells leading to separation of endothelial junctions.

Pulmonary oedema with pulmonary arterial hypertension

Pulmonary arterial hypertension secondary to high output states, such as large shunts, can occasionally be associated with pulmonary oedema (possibly from transarterial leakage), especially following exercise. This is usually avoided because acute breathlessness is such a prominent early symptom.

Pulmonary oedema following acute intracranial lesions

A large variety of intracranial lesions may occasionally be associated with acute pulmonary oedema. It is probable that damage to the nucleus of the tractus solitarus and the hypothalamus lead to severe systemic vasoconstriction ('sympathetic storm'), which shifts blood to the pulmonary circulation, causing an extreme paroxysm of pulmonary hypertension. In addition, there is evidence to suggest that pulmonary venoconstriction also occurs, thus causing a rise in pulmonary capillary pressure even in excess of that predicted from the pulmonary arterial pressure measurements. The extreme high blood pressure in the capillaries first induces hydrostatic oedema and if sufficiently severe also damages the endothelium, leading to a less easily resolved permeability oedema.

Pulmonary thromboembolism

This may occasionally lead to florid pulmonary oedema, for which two hypotheses have been proposed: (1) local overperfusion caused by diversion of blood flow away from the occluded site; and (2) humoral alteration of permeability. It is possible that both mechanisms may play a part, and also that the causes may be different in micro- and macroemboli. Evidence for the overperfusion mechanism originates from experiments in which balloon occlusion of the major pulmonary vessels leads to oedema and increased flow of low protein lymph from other areas. As in high-altitude oedema, the site of fluid transudation is unclear: the arterial vessels have been proposed, but without strong evidence. In favour of permeability change is the observation that the lymphatic fluid following experimental microembolization is of high protein content, even when the microemboli are pharmacologically inert glass microspheres.

Expansion pulmonary oedema

Pulmonary oedema after expansion of a collapsed lung is rare, but more likely when the lung (or lobe) has been collapsed for some time. The likelihood may be reduced by ensuring that negative pressure in the pleural space during re-expansion does not exceed 10 cmH2O, that the procedure is terminated if cough develops, and that not more than 1500 ml of fluid is aspirated at any one time when collapse is related to an effusion. The mechanism is uncertain. Permeability change is likely as high protein oedemas have been found in both clinical and experimental situations. The mechanism of damage may be from toxic oxygen free radicals, as in cardiac reperfusion injury. Additional contributing factors could be loss of surfactant during the period of collapse and increased negativity of interstitial pressure during re-expansion.

Postobstructive pulmonary oedema

The initiating event is a markedly negative intrapleural pressure generated by forceful inspiratory effort against an obstructed upper airway, which is then transmitted to the pulmonary interstitial space. During normal breathing, intrapleural pressures rarely fall below –5 cmH_2O, but in upper airway obstruction the value may be as low as –50 cmH_2O. Postobstructive oedema should therefore be suspected wherever there is the rapid onset of dyspnoea, cyanosis, frothy pink sputum production, and radiological pulmonary infiltrates after the rapid relief of upper airway obstruction. The onset is usually immediate but, occasionally, delays of up to 2 h have been reported. The chronic form occurs in patients with obstructive sleep apnoea, in whom negative intrapleural pressures as low as –100 cmH_2O have been recorded.

Lymphatic oedema and lymphatic obstruction

Although, in one sense, all pulmonary oedema can be thought of as lymphatic failure, surprisingly little is known of pulmonary lymphatic failure in clinical practice. Lymphatic occlusion underlies the oedema and dyspnoea of lymphangitis carcinomatosa. In cases where cardiac failure and pneumoconioses coexist it has been found that oedema develops at lower capillary pressures than would be expected, and this has been attributed to lymphatic blockage. Mechanical lymphatic disruption is probably a contributing factor to the ease with which lungs develop oedema immediately after transplantation.

Disorders of capillary permeability

Many of the conditions associated with adult respiratory distress syndrome (see Chapter 16.5.1) can also be associated with less dramatic degrees of oedema. It is a good rule always to consider the possibility that a permeability abnormality might exist as an associated cause in all cases of pulmonary oedema. The history can be particularly helpful, particularly with regard to possible infections, use of drugs, and occupational chemicals. The possibility of oxygen toxicity should be borne in mind in all patients in intensive care.

Unilateral oedema

This frequently causes diagnostic confusion. Unilateral oedema on the same side as pre-existing lung abnormalities (ipsilateral oedema) may arise from posture (lying on one side during oedema development), increased perfusion of one lung secondary to a systemic to pulmonary shunt, unilateral venous occlusion (either from unilateral veno-occlusive disease or from extrinsic compression), or unilateral lymphatic pathology such as lymphangitis carcinomatosa. Contralateral oedema is seen where the pre-existing pathology protects that lung. Instances include congenital unilateral pulmonary artery, wyer–James–McLeod syndrome, unilateral thromboembolism, and unilateral fibrosis causing unilateral hypoxia and vasoconstriction.

The diagnosis of pulmonary oedema

The diagnosis of pulmonary oedema is by clinical observation and chest radiography.

Clinical features

The characteristic symptom of pulmonary oedema is breathlessness, probably generated by an awareness of inappropriate respiratory effort and by firing of 'J' (juxta-alveolar) receptors. This dyspnoea comes on more or less acutely in the first instance, often following exercise. Later, paroxysmal nocturnal dyspnoea develops because of postural hydrostatic factors. Only then are signs of diminished breath sounds at the bases and fine lung crepitations found. The crepitations (crackles) characteristic of pulmonary oedema are intermittent explosive sounds that each last for less than 20 ms. They are probably caused by the sudden opening of a succession of small airways, the acoustic wave being produced either by equalization of downstream and upstream pressures or by sudden alterations in the tension of the airway walls. They thus relate to the 'all-or-none' features of alveolar flooding observed physiologically. The rhonchi (musical sounds) that are sometimes heard, and which may cause considerable diagnostic confusion in the dyspnoeic patient, can arise either from bronchiolar wall oedema or from vagally mediated reflex bronchospasm.

Pulmonary oedema is never a static condition, but always either developing or regressing. The observations of Altschule, who over 40 years ago recorded the sequence of events as a patient progressed into ever greater left heart failure, are worth recalling.

1. *premonitory*: anxiety, pallor, tachycardia, raised blood pressure, cold sweaty skin;
2. *interstitial oedema*: dyspnoea, orthopnoea, cyanosis, congested neck veins, wheezing and rales;
3. *intra-alveolar oedema*: crackling rales progressing to general bubbling; cough, sputum—becoming frothy then blood-stained;
4. *shock*: clouding of consciousness;
5. *terminal*: cardiac and respiratory arrhythmias.

The clinical features of the non-haemodynamic oedemas are not dissimilar but are generally less florid.

Chest radiography

The chest radiograph is a sensitive and easily available tool for spotting early pulmonary oedema (Fig. 6 and Fig. 7). The majority of radiographical studies have been made during cardiogenic oedema where changes of oedema are necessarily superimposed on other circulatory alterations. Three successive and overlapping phases can be identified.

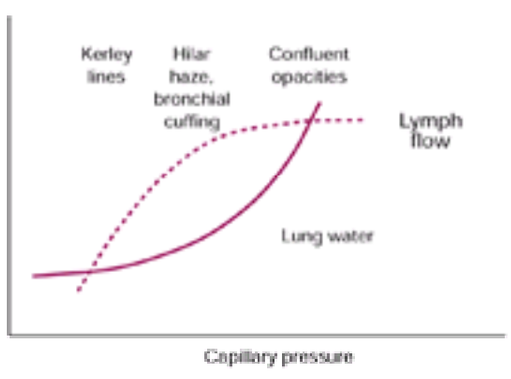

Fig. 6 Radiological signs and pulmonary pathophysiology. Kerley lines are a particularly useful radiological sign, as they occur at a stage where lymph flow and transinterstitial water flow have both increased but where appreciable tissue swelling has not yet appeared. (Reproduced from Prichard JS (1982). *Edema of the lung*. Charles C. Thomas, Springfield, Illinois, with permission.)

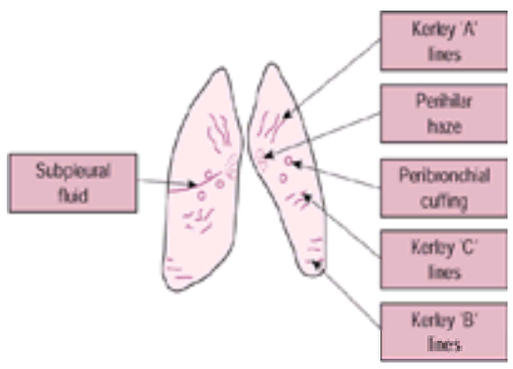

Fig. 7 Characteristic radiological appearances in interstitial oedema (see text). (Reproduced from Prichard JS (1982). *Edema of the lung*. Charles C. Thomas, Springfield, Illinois, with permission.)

Preoedema

This reflects cardiac and circulatory changes and the increased flow of fluid that occurs through the lymphatics before swelling of the tissue takes place. Usually, the cardiothoracic ratio on a posteroanterior film is more than 0.5 (>0.57 for an anteroposterior film is standard when geometry is preserved). Distension and engorgement of blood vessels occur, particularly in the upper zone with inverse changes at the bases leading to reversal of the usual pattern. Distended lymphatics subsequently become identifiable as septal lines, perilobular lines, and rosettes. Septal lines were originally identified by Kerley: type A lines are ragged, unbranched, and run centripetally towards the hilum; type C lines are fine, interlacing, and seen most easily in the central and perihilar regions; type B lines are the best known and most commonly seen. They are short, sharp, horizontal, and found in the costophrenic angles. They occur most often in pulmonary oedema due to chronic pulmonary venous hypertension. Indeed, there is excellent correlation between the density of Kerley B lines and left atrial pressure in mitral stenosis. The lines are rarely seen below a mean left atrial pressure of 13.5 mmHg, are commonly found in the region of 22 mmHg, and are invariably present when the left atrial pressure exceeds 30 mmHg. Perilobular lines and rosettes are found on close inspection in about 3 per cent of radiographs and probably represent the lymphatics running around the respiratory acini.

Interstitial oedema

This first appears in areas of 'loose' connective tissue when wedge pressure begins to rise above 15 mmHg (see sequence of oedema accumulation, above). Visible

interlobar and accessory lung fissures are the first manifestations. They are followed by perivascular and peribronchial cuffs, which contribute, respectively, to the homogeneous circular shadows formed by the already distended vessels and to the 'ring' shadows around bronchi seen close to the hilum. Micronoduli consist of small, round densities (<3 mm) arising from the accumulation of fluid around the smaller blood vessels. Blurring and hazing of the hilar regions represent the beginning of true alveolar septal interstitial oedema and, in hydrostatic oedema, begin at wedge pressures of around 20 mmHg. A diffuse increase in lung density (clouding) represents the final phase.

Alveolar oedema

This starts when wedge pressure reaches 25 to 28 mmHg. It is seen as a 'fluffy' loss of lucency, either around the hila in a 'butterfly' or 'batswing' pattern, or predominantly in the lower zones, usually reflecting a 'gravitational' distribution. Associated changes are the development of effusions and a loss of lung volume caused by a fall in lung compliance.

Radiologically, the permeability oedemas follow the pattern of the hydrostatic except that: (1) the distribution of alveolar oedema tends to be patchy; and (2) the characteristic vascular and cardiac changes are not present.

The presence of pre-existing lung disease—particularly chronic obstructive pulmonary disease—may modify the radiological appearance of pulmonary oedema considerably. Hyperinflation may render the silhouette of a large heart unremarkable; with the onset of interstitial oedema, a hyperinflated lung may shrink to normal size; the distribution of oedema shadowing may be patchy and only evident where parenchyma is sufficiently preserved; Kerley lines may be difficult or impossible to identify.

Other investigations

Computed tomography (**CT**) scanning is not necessary for the diagnosis of pulmonary oedema, but the appearances are characteristic, with thickening and increased visualization of interlobular septa and associated thickening of subpleural and peribronchial interstitial spaces. Alveolar oedema leads to varying degrees of alveolar consolidation. As in the plain radiograph, there may be associated heart and vascular changes and pleural effusions.

Pulmonary function in oedema of the lung

The oedematous lung shows a mixture of restrictive and obstructive defects, although the former dominate. The restrictive component arises from decreased compliance, which is a result of vascular congestion (in cardiogenic and fluid overload oedema), interstitial oedema, and surfactant washout. Of these, the interstitial oedema contributes surprisingly little, so that, to start with, restrictive changes are indicative of an engorged vascular system and later, of alveolar flooding.

Sometimes, airflow resistance may cause easily audible rhonchi and a reduction in forced expiratory volume in 1 s/forced vital capacity (**FEV1/FVC**), but, more usually, it is difficult to detect by simple methods because it occurs predominantly in the small airways of 1 to 2 mm diameter, which contribute relatively little to overall resistance. There could be a number of causes for such airflow obstruction. In the preoedematous phase of heart failure the smallest airways may be compressed by the distension of adjacent vessels in the bronchovascular bundle. In frank interstitial oedema it has been suggested that perivascular cuffing could do the same, but this has not been substantiated. However, submucosal oedema and vagally mediated reflex bronchoconstriction are proven and probably responsible for most of the effect. Restriction and obstruction may combine to reduce vital capacity, and serial measurements of this can be a good index of severity of and recovery from pulmonary oedema.

Tachypnoea is a prominent feature of all forms of pulmonary oedema. This is associated with a low tidal volume, but total ventilation (V_E)—both at rest and during exercise—is high relative to the prevailing level of carbon dioxide consumption. Most of this increase is accounted for by deadspace ventilation hence, unless the patient is progressing into severe alveolar oedema (see below), he or she remains normocapnic. The mechanism underlying this tachypnoea is uncertain. Hypoxic effects upon the central carbon dioxide chemostat do not appear to be an explanation, and recent evidence using perialveolar local anaesthetic suggests that the 'J' (juxta-alveolar) receptor—an unmyelinated nerve ending in the vicinity of the alveoli, which responds to interstitial swelling and distension—is only involved at more severe levels of oedema. Respiratory muscle fatigue is a possibility.

In acute, severe oedema the usual blood gas abnormalities are hypocapnia and hypoxia. The hypoxia is a result of ventilation/perfusion mismatching. The hypocapnia is accounted for by the reflex tachypnoea leading to an increased alveolar ventilation, which more than compensates for the increased pulmonary deadspace (volume of deadspace/volume of tidal air ratios, V_D/V_T ratio). However, in about 20 per cent of severe cases, hypercapnia (with respiratory acidosis) is seen, even when no chronic airflow disease coexists. A number of mechanisms have been proposed, including uncontrolled oxygen administration accompanied by low central carbon dioxide sensitivity, respiratory muscle fatigue, and severe ventilation perfusion imbalance. In acute oedema, blood gas abnormalities are usually accompanied by a mild metabolic acidosis, but occasionally the base excess may exceed –15 mmol/l. This frank metabolic acidosis is most likely in patients with severe oedema who already have carbon dioxide retention.

In the more chronic permeability oedemas—as in adult respiratory distress syndrome—the overwhelming problem is continuing severe hypoxaemia. Three mechanisms have been proposed: (1) diffusion impairment; (2) low ventilation/perfusion $_2$ ($_A$/) values; and (3) shunt ($_A$/ <0.005). Using both the arterial oxygen response to changing fractional inspired oxygen concentration (**FiO2**) and the inert gas technique, it has been shown that diffusion impairment plays little part. Shunt and ventilation/perfusion mismatch are more important, but their contribution varies greatly from patient to patient.

Treatment of pulmonary oedema

Pulmonary oedema may result from increased microvascular hydrostatic pressure, decreased tissue interstitial pressure, decreased plasma colloid oncotic pressure, increased microvascular permeability, or impaired lymphatic drainage. Treatment of each form should include measures designed to reverse the specific cause. However, with the exception of a reduction of elevated hydrostatic pressure and relief of upper airway obstruction, these are rarely available and the clinician has to rely upon general supportive measures combined with meticulous attention to fluid balance and monitoring of plasma oncotic pressure. (See Chapter 16.1 and Chapter 16.5.2 for discussion of the clinical approach to the severely ill and breathless patient.)

Acute cardiogenic and fluid overload pulmonary oedema

By far the most common causes are acute and chronic left-sided heart disease, although the overenthusiastic use of intravenous fluid regimen containing normal saline are frequently an additional factor. The patient is most comfortable in the 'trunk up, legs down' position to help pool blood in the dependent parts and reduce central venous pressure. Oxygen, diuretics, intravenous nitrates, and morphine are the fundamentals of treatment. Thigh cuffs inflated to occlude venous return can help as a form of a bloodless phlebotomy and venesection, and removal of 200 to 500 ml of blood is an effective treatment when other measures are not available.

Hypoxia is relieved with a standard face mask, nasal prongs, or reservoir bag, delivering oxygen at high flow rates—up to 10 litres/min—providing an inspired concentration of up to 60 per cent. The fractional inspired oxygen concentration given should be as high as is necessary to keep the arterial partial pressure of oxygen near to the normal level—and no more—because, in permeability oedema: (1) high oxygen levels may lead to absorption atelectasis in areas of low ventilation/perfusion; (2) oxygen toxicity may become a problem where prolonged administration is necessary. If oxygen administration at normal airway pressure cannot maintain the arterial partial pressure of oxygen and/or hypercapnia develops, then application of a continuous positive airway pressure (**CPAP**) mask, non-invasive ventilation, or tracheal intubation and intermittent positive pressure ventilation will need to be considered (see Chapter 16.5.2).

A bolus dose of furosemide (frusemide) (or other loop diuretic), administered intravenously, is usually given. This acts both as a venous dilator, and as a diuretic. Diuretics are at their most valuable where pulmonary oedema is a component of congestive cardiac failure and where the volume of extracellular fluid is generally increased. By contrast, when left ventricular failure has come on acutely, significant fluid retention has not occurred and pulmonary oedema is a result of fluid shift from the systemic circulation, then overvigorous use of diuretics runs the risk of causing hypovolaemia. If the patient is *in extremis* or heavily sedated, it is wise to catheterize the bladder for, as a result of the diuresis, bladder distension may induce intense reflex systemic vasoconstriction leading, on occasion, to disastrous cardiac overload.

Intravenous nitrates, in particular isosorbide dinitrate at a dose between 2 and 20 mg/h, can effectively reduce venous pressure and alleviate pulmonary oedema.

Arterial hypotension is the effect that usually limits dosage, the combination of heart failure with low blood pressure and pulmonary oedema being difficult to treat and of grave prognosis (see Chapter 16.2).

Morphine acts centrally to relieve the distress of dyspnoea and also dilates the systemic venous system. This reduces venous filling pressure to the heart and shifts blood from the pulmonary to the systemic circulation. It is best administered by slow intravenous injection in a total dose of 2 to 10 mg at a rate of 2 mg/min, together with an appropriate antiemetic.

Aminophylline has diuretic, bronchodilator, cardiac inotropic, and respiratory muscle inotropic effects. Its use would seem logical, but it is now scarcely ever given because of its capacity to induce arrhythmias and the availability of other effective treatments. If it is to be administered, a dose of 250 to 500 mg should be given intravenously in not less than 20 min.

Other types of pulmonary oedema

A reduction in oncotic pressure may contribute to pulmonary oedema, as in crystalloid fluid overload, hepatic failure, or nephrotic syndrome. In fluid overload, the most appropriate therapy is the use of diuretics, for these not only reduce the extracellular and blood volumes but also return osmotic pressure towards normal. It is more difficult to be certain about therapy in true hypo-oncotic states. Even where there is no evidence of endothelial damage, the effects of salt-free albumin and plasma concentrate are disappointing.

In high-permeability pulmonary oedema the best form of management would be to block the inappropriate activation and progress of the cascades that are responsible for the condition (see Chapter 16.5.1). Unfortunately, there is no therapy that allows this at present and management, aside from aiming to treat any precipitating disorder, is supportive (see Chapter 16.5.2).

15.15.3.1 Deep venous thrombosis and pulmonary embolism

Paul D. Stein and J. Firth

Introduction

Pulmonary embolism is a complication of deep venous thrombosis. Among patients with pulmonary embolism, the thrombi in 80 per cent or more originate in the legs. Deep venous thrombosis and pulmonary embolism are sometimes described together, using the term 'thromboembolism'. Strategies of management have been developed which are based on the diagnosis of either pulmonary embolism or deep venous thrombosis, provided the patient has good respiratory reserve. Treatment with anticoagulants is the same for both. Some believe, however, that patients can be managed better if it is known whether acute pulmonary embolism is present, even if a diagnosis of deep venous thrombosis is already established.

Mortality of untreated deep venous thrombosis and pulmonary embolism

The frequency of fatal pulmonary embolism in patients with untreated deep venous thrombosis has diminished as diagnostic tests have made it possible to diagnose deep venous thrombosis before it becomes extensive. In 1955, prior to the use of sensitive non-invasive tests for the early detection of deep venous thrombosis, the risk of fatal pulmonary embolism in untreated patients with clinically apparent deep venous thrombosis was 37 per cent. With the use of radioactive fibrinogen scintiscans, the risk of fatal pulmonary embolism in patients with untreated deep venous thrombosis, most of which was subclinical, was approximately 5 per cent.

Early diagnosis has also reduced the risk of death in those with pulmonary embolism. In the early 1960s, the mortality in untreated patients with acute pulmonary embolism, diagnosed on the basis of clinical features, was 26 to 37 per cent. An additional 36 per cent died of recurrent pulmonary embolism. In recent years, among patients with mild pulmonary embolism who inadvertently escaped treatment, the mortality was 5 per cent. The mortality of untreated patients with mild pulmonary embolism was comparable with the mortality from fatal pulmonary embolism in untreated patients with subtle deep venous thrombosis.

Deep venous thrombosis

Incidence and pathology

Deep venous thrombosis is often silent. In one study of those with deep venous thrombosis detected by screening with ^{125}I-labelled fibrinogen scans, clinical evidence was present in 49 per cent. The percentage of patients with acute pulmonary embolism who have clinically detectable deep venous thrombosis decreases with decreasing severity of pulmonary embolism, which implies more subtle disease. Of patients who died from acute pulmonary embolism, 53 per cent had clinically identified deep venous thrombosis. In patients with massive or submassive acute pulmonary embolism, most of whom survived, 34 per cent had clinically identifiable deep venous thrombosis. Among patients with mild as well as severe acute pulmonary embolism, only 15 per cent had clinically apparent deep venous thrombosis.

Proximal deep venous thrombosis was found at autopsy in 22 per cent of patients who died in a tertiary care hospital. Thrombosis of the leg veins usually occurs without inflammation. Inflammation of the walls of the veins, when it occurs, is usually secondary to the thrombus. No clear evidence indicates that inflammation of the veins prevents embolization, or that embolization is more frequent in those patients with thrombi not associated with venous inflammation.

In the past, patients who had thrombosed leg veins accompanied by signs of inflammation were diagnosed as having thrombophlebitis, based on the presumption that the primary event was inflammation of the walls of the veins. Patients with no clinical signs in the lower extremities who had thrombosis that resulted in pulmonary embolism were said to have phlebothrombosis. Histological investigations have not supported a distinction between the clinical diagnoses of thrombophlebitis and phlebothrombosis. Thrombus can induce inflammation in the underlying wall of the vein, and this inflammation in some patients is extensive enough to produce pain, tenderness, swelling, and fever.

The valve pockets are a frequent site of origin of thrombi. At autopsy, clinically unsuspected deep venous thrombosis is often extensive, causing collateral circulation around occlusions and dilatation of collateral veins. When the veins of the thigh and the calf are thrombosed in continuity, the thrombi in the calf are older than those in the thigh, which suggests that the thrombosis extended from the veins of the calves to the veins of the thighs.

Clinical diagnosis

Patients may complain of pain or swelling of the leg, but physical examination remains the means by which attention is usually drawn to the potential diagnosis of deep venous thrombosis.

Deep venous thrombosis sometimes, but not always, leads to swelling of the leg. If restricted to the popliteal and calf veins, swelling is confined to below the knee, but if thrombosis involves the femoral and pelvic veins (or inferior vena cava), then swelling of the thigh is also expected. A difference of circumference of the calves of greater than 1 cm, measured 10 cm below the tibial tuberosity, is abnormal. It is important to repeat the measurement of diameter of the calves and thighs at frequent intervals: proximal extension of a thrombus is likely to cause increased swelling. To allow repeated measurements to be made from a fixed point, it is good practice for the position of the first measurement to be marked indelibly on the patient's skin.

Homans' sign is positive when active and/or passive dorsiflexion of the foot is associated with any of the following: (i) pain, (ii) incomplete dorsiflexion (with equal pressure applied) to prevent pain, or (iii) flexion of the knee to release tension in the posterior muscles with dorsiflexion. This sign was present in 44 per cent of patients with deep venous thrombosis of the lower leg, and in 60 per cent of patients with femoral venous thrombosis. The elicitation of pain with inflation of a blood pressure cuff around the calf to 60 to 150 mmHg has been recommended as a test for deep venous thrombosis. This test, however, has not been shown to be more helpful than the assessment of direct tenderness or leg circumference.

In one study the sensitivity of oedema, erythema, calf tenderness, palpable cord, or Homans' sign alone, or greater than 1 cm calf asymmetry alone was 55 to 80 per cent, but the specificity only 49 per cent. The combination of one of these signs plus greater than 1 cm ipsilateral calf asymmetry increased the specificity to 87 per cent, but decreased the sensitivity to 15 to 33 per cent. The specificity increased to 91 per cent with one of these signs in combination with greater than 2 cm calf asymmetry. Only 3 to 10 per cent of patients had one or more qualitative signs plus greater than 3 cm ipsilateral calf asymmetry: in these, the specificity for deep venous thrombosis was 96 per cent.

Other clinical features of deep venous thrombosis, whose sensitivity and specificity have not been tested, include increased temperature on the affected side, cyanotic discoloration of the limb, and persistent engorgement of superficial veins. Superficial varicose veins almost always empty when the patient lies down: if they remain engorged, this suggests problems with drainage through the deep veins. In very rare cases, tense venous oedema can cause arterial compression and venous gangrene.

The clinical diagnosis of deep venous thrombosis is not always straightforward. Many of the findings described above can also be found in those with muscular strains and bruising, ruptured Baker's cyst or plantaris tendon, superficial thrombophlebitis, cellulitis, and other traumatic conditions. Given the sinister nature of untreated deep venous thrombosis, it is important to confirm or refute (so far as is possible) the diagnosis with appropriate investigations whenever clinical suspicion is aroused, unless the general condition of the patient makes this inappropriate.

Investigation

Detection of the physical presence of thrombus in leg veins

The 'gold standard' is contrast venography, but this can be unpleasant for patients, time consuming for radiology departments, and is expensive. This has driven the search for acceptable non-invasive methods of diagnosis. Among patients with deep venous thrombosis proven by contrast venography, B-mode ultrasonography using compression showed a 95 per cent sensitivity in symptomatic patients. In asymptomatic patients who were evaluated because of a high risk of deep venous thrombosis, venous compression ultrasound showed a sensitivity of only 67 per cent. Regarding veins of the calves, venous compression ultrasound was 93 per cent sensitive in symptomatic patients, but only 26 per cent sensitive in asymptomatic high-risk patients with deep venous thrombosis. In all instances, specificity was 97 to 99 per cent. Impedance plethysmography was 86 to 94 per cent sensitive for detection of deep venous thrombosis of the thighs, but the sensitivity was only 25 per cent for the veins of the calves. Specificity was high, 97 per cent. In most centres contrast venography and impedance plethysmography have been replaced by B-mode ultrasonography as the preferred first-line diagnostic technique.

Venous phase contrast enhanced spiral computed tomography (CT) appears promising for imaging the veins of the pelvis and thighs. Spiral CT imaging of the veins of the lower extremities and pelvis in combination with spiral CT imaging of the chest potentially offers a comprehensive study for thromboembolism. The sensitivity and specificity of contrast enhanced spiral CT, however, are still being evaluated.

Magnetic resonance imaging, tested in small numbers of patients, was 100 per cent sensitive for veins of the thighs and pelvis and somewhat less sensitive (85 per cent) for veins of the calves. Specificity in all regions was 95 to 100 per cent. Its problem is cost and availability.

Fibrinogen-uptake radionuclide scanning was used extensively in the 1960s. It is more sensitive for deep venous thrombosis in the calves than in the thighs. In view of the greater risk of pulmonary embolism with deep venous thrombosis of the thighs than of the calves, the value of fibrinogen-uptake scanning is limited.

Lately, technetium apcitide labelling of glycoprotein IIb/IIIa receptors expressed on activated platelets has permitted radionuclear imaging of acute proximal deep venous thrombosis and pelvic vein thrombosis. Its sensitivity has been incompletely evaluated.

Detection of evidence of thrombus within the circulation: D-dimer

D-Dimer is a specific degradation product released into the circulation by endogenous fibrinolysis of a cross-linked fibrin clot. A D-dimer measured by enzyme-linked immunosorbent assay (ELISA) below a cut-off of 300 to 540 ng/ml (the values differ slightly from one study to another) make the diagnosis of deep venous thrombosis (or pulmonary embolism) unlikely. A concentration of D-dimer above any particular cut-off level is not useful for making a positive diagnosis because of the large number of false positive tests. However, conventional ELISA assays are cumbersome and not suited for emergency use, which limited the practical utility of D-dimer measurements until the development of rapid ELISA assays. These provide the best balance of sensitivity and specificity among the various assays for the safe diagnostic handling of patients with suspected deep venous thrombosis and pulmonary embolism.

Strategy for diagnosis

For reasons given above, subjecting all patients who might have a deep venous thrombosis to contrast venography is not an attractive option for patients, physicians, radiologists or those who pay for health care. Much effort has therefore been expended in trying to develop management algorithms that will identify those at very low risk of deep venous thrombosis (or pulmonary embolism), who can then be spared invasive tests. These algorithms typically use scoring systems to stratify the clinical probability that the particular patient has a deep venous thrombosis (or pulmonary embolus), and then proceed to D-dimer testing of those with low probability. Patients with a low clinical probability and a negative D-dimer test are not investigated further. Patients with either a high clinical probability or a low clinical probability but elevated D-dimer proceed to tests for the presence of thrombus in the leg veins, typically by ultrasonography. Examples of a pre-test scoring system and management algorithm are shown in Table 1.

Prevention, treatment, and complications of deep venous thrombosis

The prevention of deep venous thrombosis is critical in the prevention of pulmonary embolism. Deep venous thrombosis itself carries extensive morbidity irrespective of pulmonary embolism. Severe postphlebitic syndrome (venous ulcer or combinations of pain, cramps, heaviness, pruritus, paraesthesia, pretibial oedema, induration, hyperpigmentation, venous ectasia, redness or pain with calf compression) occurs in 9 per cent of patients by 5 years after a 3-month course of treatment with anticoagulants. There is some evidence that the likelihood of this problem developing can be reduced by use of elastic stockings at the time of acute deep venous thrombosis and afterwards.

Proximal deep venous thrombosis leads to pulmonary embolism more frequently than deep venous thrombosis confined to the calf. Even so, symptomatic isolated calf vein thrombosis, limited to the calves and diagnosed by non-invasive testing, should be treated with anticoagulation for 3 months. If anticoagulation cannot be given, serial non-invasive studies of the leg veins should be performed over the next 7 to 14 days to assess for proximal extension of the thrombus.

Risk factors for deep venous thrombosis are almost certainly the same as those for pulmonary embolism (see later). Recommendations for the prevention of deep venous thrombosis are shown in Table 2, Table 3, Table 4 and Table 5, and for treatment in Table 6.

Acute pulmonary embolism

Incidence

Acute pulmonary embolism is the third most common cardiovascular problem after coronary heart disease and stroke. The incidence of objectively diagnosed acute pulmonary embolism in a tertiary care hospital is probably higher than in most short-stay hospitals, but in one such centre a definitive diagnosis of pulmonary embolism was made in 0.3 to 0.4 per cent of patients. Inclusion of extrapolated data from autopsy studies and the estimated frequency of pulmonary embolism in patients with non-high probability lung scans increases the calculated incidence of acute pulmonary embolism to 1.0 per cent of patients admitted to hospital. Silent pulmonary embolism was not included in these calculations, and this has been reported in 38 to 51 per cent of patients with deep venous thrombosis.

In one major study, the incidence of acute pulmonary embolism was linearly related to age: more than half of patients were between 65 and 85 years of age, while fewer than 5 per cent were under age 24. Occasionally, however, young adults or adolescents had pulmonary embolism. In patients 50 years of age or older, the incidence of pulmonary embolism was higher among women. By contrast, the incidence was comparable in men and women under age 50 years, suggesting that

childbirth and oral contraceptives had little impact.

In autopsy studies, when the pathologist judged that pulmonary embolism contributed to death or caused death, the diagnosis was unsuspected ante-mortem in 70 per cent. This was true in several series, encompassing university as well as non-university hospitals. Some of the unsuspected pulmonary embolism was in patients who died of malignancy, in whom a diagnosis of pulmonary embolism may (appropriately) not have been actively pursued. But the time-honoured point remains as valid today as ever: a high index of suspicion is necessary to reduce the number of patients with unsuspected pulmonary embolism.

Predisposing factors

Immobilization, irrespective of the cause, is the most frequent predisposing factor (Table 7). Immobilization of even 1 or 2 days may predispose to pulmonary embolism and most patients with pulmonary embolism are immobilized for less than 2 weeks.

Whether obesity is a predisposing factor is controversial. Most patients with pulmonary embolism had smoked at one time or continued to smoke at the time of their pulmonary embolism.

Thromboembolic events have been linked to high oestrogen content in oral contraceptives (greater than 50 µg), but this association has been questioned. Irrespective of whether the risk ratio is increased among women who take oral contraceptives, the absolute risk of venous thromboembolism is low. The United States Food and Drug Administration (**FDA**) in 1980 recommended the use of the lowest possible dose of oestrogen for birth control. Childbearing and oral contraceptives did not result in a higher incidence of pulmonary embolism among women under 50 years of age compared with men. The combination of surgery and oral contraceptives may increase the risk of thromboembolism. This is true even with oral contraceptives that have a low oestrogen content. For further discussion of these and other risks associated with oestrogen use, see Chapter 13.19 and 13.20.

There has been much recent interest in the subject of genetic predisposition to thromboembolism. Heterozygosity for the Factor V Leiden mutation increases susceptibility three- to eightfold in a variety of circumstances. Other genetic and acquired thrombophilic factors include protein C deficiency, protein S deficiency, antithrombin deficiency, prothrombin 20201A, high concentration of factor VIII, hyperhomocystinaemia, heparin cofactor II deficiency, dysfibrinogenaemia, decreased levels of plasminogen, decreased levels of plasminogen activators, antiphospholipid antibodies, heparin-induced thrombocytopenia, and myeloproliferative disorders. For full discussion of this and related issues, see Chapter 15.15.3.2.

Patients with the nephrotic syndrome are known to be at particularly high risk of deep venous thrombosis and pulmonary embolism.

Syndromes of acute pulmonary embolism

Pulmonary embolism can present in diverse ways. The syndrome of pleuritic pain or haemoptysis, in the absence of circulatory collapse, is the most frequent mode of presentation of acute pulmonary embolism. It occurred in 60 per cent of patients recruited in a collaborative investigation, the Prospective Investigation of Pulmonary Embolism Diagnosis (**PIOPED**). A syndrome of dyspnoea in the absence of haemoptysis or pleuritic pain or circulatory collapse occurred in 25 per cent. Circulatory collapse (systolic blood pressure less than 80 mmHg or loss of consciousness) was an uncommon mode of presentation, occurring in 15 per cent. Recognizing that patients with circulatory collapse may not be candidates for recruitment into trials of diagnostic investigations or therapies, and patients with circulatory collapse often die within the first few hours, it may be that the incidence of circulatory collapse as determined from such investigations is falsely low. Patients with pulmonary infarction have less severe pulmonary embolism than those with isolated dyspnoea, and those with circulatory collapse probably have the most severe of all. The clinical characteristics of patients with acute pulmonary embolism often reflect the severity of the syndrome.

Symptoms of acute pulmonary embolism

The clinical characteristics of acute pulmonary embolism have been derived from prospectively acquired data of patients recruited in trials of diagnostic investigations or therapies. Such trials clearly only include those in whom there was sufficient clinical suspicion to lead physicians to obtain diagnostic tests: whether subtle pulmonary embolism was overlooked is undetermined. The specificity of signs, symptoms, and ordinary clinical tests, among patients with suspected pulmonary embolism in whom the diagnosis was eventually excluded by pulmonary angiography, was low. The specificity of such tests when evaluated in a normal population, however, would be higher.

To characterize the diagnostic features of acute pulmonary embolism, it is useful to evaluate patients in whom the diagnosis is not confused by pre-existing cardiac or pulmonary disease. When manifestations related to coexistent disease are excluded, dyspnoea is the most common symptom, occurring in 73 per cent (Table 8). Pleuritic chest pain (66 per cent of patients with pulmonary embolism) occurred much more often than haemoptysis (13 per cent of patients with pulmonary embolism).

Cough was common (37 per cent) among patients with pulmonary embolism and could be non-productive, or productive of purulent or bloody sputum. When haemoptysis occurred, the sputum typically was blood-streaked, but can be pure blood or blood-tinged. Purulent sputum was present in 7 per cent of cases.

The angina-like pain that occurred in a few (4 per cent) patients with pulmonary embolism did not radiate to either arm or to the jaw, which can assist in distinguishing it from true angina. It was usually located in the anterior chest and it was described as heavy.

Signs of acute pulmonary embolism

Tachypnoea (respiratory rate 20/min or greater) was the most common sign of acute pulmonary embolism among patients with no prior cardiac or pulmonary disease (70 per cent of patients) (Table 9). Tachycardia (heart rate greater than 100/min) occurred in 30 per cent; the pulmonary component of the second sound was accentuated in 23 per cent; and deep venous thrombosis was clinically apparent in 11 per cent. A right ventricular lift, third heart sound, or pleural friction rub were uncommon, each occurring in 4 per cent or less of patients with pulmonary embolism.

Most patients with pulmonary embolism who had rales (crepitations) had pulmonary parenchymal abnormalities, atelectasis, or a pleural effusion on the chest radiograph. Rales, therefore, appeared to relate to the effects of pulmonary infarction or atelectasis.

Among patients with pulmonary embolism and no other source of fever, a temperature below 39.9°C was present in 12 per cent and fever of 39.9°C or higher occurred in 2 per cent. Fever in patients with pulmonary haemorrhage/infarction was not more frequent than among those with no pulmonary haemorrhage/infarction. Clinical evidence of deep venous thrombosis was often present in patients with pulmonary embolism and otherwise unexplained fever.

Combinations of signs and symptoms

Dyspnoea or tachypnoea (respiratory rate 20/min or greater) were present in 90 per cent of patients with acute pulmonary embolism. Dyspnoea or tachypnoea or pleuritic pain were present in 97 per cent. Dyspnoea or tachypnoea, pleuritic pain, radiographic evidence of atelectasis, or a parenchymal abnormality were present in 98 per cent of patients. The remaining 2 per cent had either deep venous thrombosis or an unexplained low PaO_2. In the absence of dyspnoea or tachypnoea or pleuritic pain, pulmonary embolism was rarely diagnosed.

Accuracy of clinical assessment

To emphasize the point that the diagnosis of pulmonary embolism is difficult to make, senior staff physicians and postgraduate fellows taking part in the PIOPED study were uncertain of the diagnosis in the majority of patients. Using individual clinical judgement without any specific predetermined criteria, senior staff were correct in the diagnosis in 88 per cent of cases when their clinical assessment indicated a high probability of pulmonary embolism. When their clinical assessment indicated a low probability of pulmonary embolism, senior staff correctly excluded pulmonary embolism in 86 per cent. Postgraduate fellows, on the basis of clinical assessment, were more accurate in excluding pulmonary embolism than they were in making the diagnosis.

Differential diagnosis of pulmonary embolism

The commonest presentation of acute pulmonary embolism is with dyspnoea and/or pleuritic chest pain. There are, however, several other possible causes of these symptoms, the commonest being musculoskeletal pain and pneumonia. Musculoskeletal chest pain can be very similar to that caused by pleurisy, and splinting of the chest can lead to a perception of breathlessness, which may be exacerbated by anxiety. If there is an obvious history of local trauma to the chest, then patients will rarely present to the physician, but it is worthwhile to ask specifically whether there has been any trauma or unaccustomed physical activity, whether the pain can be brought on by particular movements, and to examine carefully for local tenderness of ribs, muscles, or costal margins. Tenderness can sometimes be found in cases of pleurisy, but with appropriate history clearly supports a diagnosis of musculoskeletal pain. Pneumonia complicated by pleurisy can cause dyspnoea and chest pain. Important features to look for in the history include preceding systemic upset ('flu-like' symptoms), high fever, and rigors; and on examination, high fever, 'toxic' appearance, and chest signs of pneumonic consolidation. If a positive diagnosis of another cause of dyspnoea and/or pleuritic chest pain cannot be made, then the default position should be to assume that the patient has pulmonary embolism until proven otherwise.

Investigation

Simple laboratory tests

Among patients with pulmonary embolism in whom a possible or definite cause for leucocytosis was eliminated, 80 per cent had a normal white blood cell count, 6 per cent had a count of 10 100 to 11 900/mm^3, and 13 per cent had a count of 12 000/mm^3 or greater. None had a white blood cell count that was 20 000/mm^3 or greater. Leucocytosis was not more frequent in patients with the pulmonary haemorrhage/infarction syndrome than in other patients with acute pulmonary embolism.

Electrocardiogram

Electrocardiographic abnormalities are described among patients with pulmonary embolism who had no prior cardiopulmonary disease (Table 10). A normal electrocardiogram was shown in 30 per cent of patients with acute pulmonary embolism. Only 5 per cent of the patients with acute pulmonary embolism had atrial fibrillation or atrial flutter. Atrial flutter or atrial fibrillation in patients with acute pulmonary embolism is nearly always limited to individuals with prior heart disease.

Abnormalities of the ST segment and T wave are by far the most frequent electrocardiographic manifestation of acute pulmonary embolism. Non-specific ST-segment or T-wave changes were observed in 49 per cent of patients in whom the severity of pulmonary embolism ranged from mild to severe.

Electrocardiographic manifestations of acute cor pulmonale (S1Q3T3, complete right bundle branch block, P pulmonale, or right axis deviation) were less common than ST-segment or T-wave changes. One or more of these abnormalities occurred in 26 per cent of patients with submassive or massive acute pulmonary embolism not associated with cardiac or pulmonary disease (32 per cent of patients with massive pulmonary embolism).

The electrocardiogram may simulate inferior infarction with Q waves and T-wave inversion in leads II, III, and aVF or anteroseptal infarction characterized by QS or QR waves in V1 and T-wave inversion in the right precordial leads. The development of Q waves and extensive T-wave inversion in the anterior and lateral leads has also been observed. A pseudoinfarction pattern, however, was seen in only 3 per cent of patients with no prior cardiopulmonary disease who had pulmonary embolism that ranged in severity from mild to massive.

New leftward shifts of the frontal plane axis in pulmonary embolism are frequent. Among patients with acute pulmonary embolism, left axis deviation was more frequent than right axis deviation. Low-voltage QRS complexes were observed in 3 per cent.

Inversion of the T waves was the most persistent electrocardiographic abnormality. Inversion of the T wave disappeared in only 22 per cent of patients 5 or 6 days after the pulmonary embolism was diagnosed, although it resolved in 49 per cent by 2 weeks. Depression of the ST segment tended to resolve somewhat faster. Abnormalities of depolarization resolved more quickly than abnormalities of repolarization. Well over half of the electrocardiograms that showed pseudoinfarction, S1S2S3, S1Q3T3, right ventricular hypertrophy, or right bundle branch block, no longer showed these abnormalities 5 or 6 days after the diagnosis was made.

Patients with ST-segment abnormalities, T-wave inversion, pseudoinfarction patterns, S1Q3T3 patterns, incomplete right bundle branch block, right axis deviation, right ventricular hypertrophy, or ventricular premature beats had larger perfusion defects on the lung scan or larger defects on the pulmonary arteriogram than those with normal electrocardiograms. Such patients had higher pulmonary arterial pressures and in general had low partial pressure of oxygen in arterial blood. Acute ventricular dilatation is speculated to be the most likely cause of the electrocardiographic changes.

Chest radiograph

The findings on the plain chest radiograph, when used together with the history, physical examination, electrocardiogram, and simple laboratory tests assist in identifying a syndrome of pulmonary embolism. The chest radiograph, when normal in a patient who is dyspnoeic, may hint that pulmonary embolism is a diagnostic possibility. Abnormalities on the plain chest radiograph may suggest a need for further diagnostic evaluation.

Among patients with pulmonary embolism who had no prior cardiopulmonary disease a normal chest radiograph was shown in 16 per cent (Table 11). Atelectasis or a pulmonary parenchymal abnormality were the most frequent abnormalities (68 per cent). When present, pleural effusions were usually small. The majority were limited to blunting of the costophrenic angle. In some studies, an elevated hemidiaphragm was the most frequent abnormality. The Westermark's sign (prominent central pulmonary artery and decreased pulmonary vascularity) was identified by radiologists in only 7 per cent of patients with pulmonary embolism.

In cases of pulmonary embolism, those with a normal plain chest radiograph had the lowest pulmonary artery mean pressures. The highest pulmonary artery mean pressures were in patients with a prominent central pulmonary artery or cardiomegaly.

Arterial blood gases and alveolar–arterial oxygen difference

A low partial pressure of oxygen in arterial blood (PaO_2) is typical of acute pulmonary embolism and supports the diagnosis, but patients with acute pulmonary embolism can have a normal PaO_2. Among patients with acute pulmonary embolism and no prior cardiopulmonary disease who had measurements of the PaO_2 while breathing room air, 24 per cent had a PaO_2 of 80 mmHg (10.5 kPa) or higher. Even among patients with submassive or massive acute pulmonary embolism, 12 per cent had a PaO_2 of 80 mmHg or higher. A normal alveolar–arterial oxygen difference (alveolar–arterial oxygen gradient) does not exclude acute pulmonary embolism. No value of the alveolar–arterial oxygen difference was diagnostic of pulmonary embolism, and no value excluded pulmonary embolism.

D-Dimer

As when considering the diagnosis of deep venous thrombosis, a 'negative' D-dimer test is useful for excluding pulmonary embolism in patients who are clinically thought to be at low risk, but a 'positive' result does not establish the diagnosis. Hence, when used in the appropriate clinical context, D-dimer testing is useful in defining a group of patients with suspected pulmonary embolism who do not require further investigation.

Ventilation–perfusion lung scans

The ventilation–perfusion lung scan in pulmonary embolism, if high probability, indicates pulmonary embolism in 87 per cent of patients (Table 12 and Fig. 1). If normal, pulmonary embolism is excluded. If intermediate probability, the scan contributes no useful diagnostic information, pulmonary embolism being present in about 30 per cent. If low probability, pulmonary embolism is present in 14 per cent. A low probability ventilation–perfusion scan, therefore, by the criteria used in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) does not exclude pulmonary embolism, and intermediate and low probability interpretations may be grouped as 'non-diagnostic'. Criteria for a very low probability lung scan (positive predictive value less than 10 per cent) have been developed since the conclusion of PIOPED.

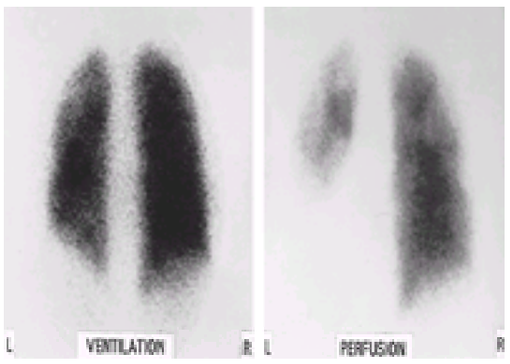

Fig. 1 Ventilation lung scan (left) and perfusion lung scan (right), posterior views. Left (L) and right (R) lungs are indicated. Ventilation scan, equilibrium phase, shows nearly normal ventilation. Perfusion scan shows absent perfusion in the left lower lobe and mismatched perfusion defects in the left upper lobe. Perfusion defects (grey areas) are also shown in the right lung. The ventilation–perfusion lung scan was interpreted as high probability for pulmonary embolism.

Prior clinical assessment in combination with interpretation of the ventilation–perfusion scan improves the diagnostic validity (Table 12). If the ventilation–perfusion scan is interpreted as high probability for pulmonary embolism, and if the clinical impression is concordantly high, then the positive predictive value for pulmonary embolism is 96 per cent. If the ventilation–perfusion scan is low probability and the clinical suspicion is concordantly low, then pulmonary embolism is excluded in 96 per cent of patients.

The probability of pulmonary embolism can be determined based on the number of mismatched defects. A further refinement of probability can be made if the ventilation–perfusion scan is interpreted after being stratified according to prior cardiopulmonary disease. Fewer mismatched perfusion defects are required to diagnose pulmonary embolism among patients with no prior cardiopulmonary disease. Adding clinical assessment to the stratification results in a more accurate evaluation.

Repeat ventilation–perfusion lung scanning

A residual abnormality of perfusion 1 year after acute pulmonary embolism is more frequent among patients with prior cardiopulmonary disease than among patients with none. It is useful to obtain a post-therapy baseline ventilation–perfusion lung scan for use in the event of suspected recurrent pulmonary embolism. This will assist in determining if abnormalities on a ventilation–perfusion scan are new or residual from prior pulmonary embolism.

Pulmonary angiography

Pulmonary angiography is associated with serious complications in about 1 per cent of patients. When needed, pulmonary angiography is useful and remains the diagnostic reference test for pulmonary embolism (Fig. 2, Fig. 3, and Fig. 4). Patients in whom the risk of complications of pulmonary embolism are greatest are patients referred for angiography from the medical intensive care unit. Frequently such patients are on respiratory support and in an unstable condition. The presence or absence of pulmonary embolism and the magnitude of pulmonary hypertension did not relate to the frequency of morbidity from angiography. Elderly patients (70 years or older) are at greater risk of renal impairment than younger patients as a result of the injection of contrast material. A retrospective analysis of complications, among patients in whom angiography was performed with non-ionic low-osmolar contrast material, showed fewer (0.1 per cent) major complications.

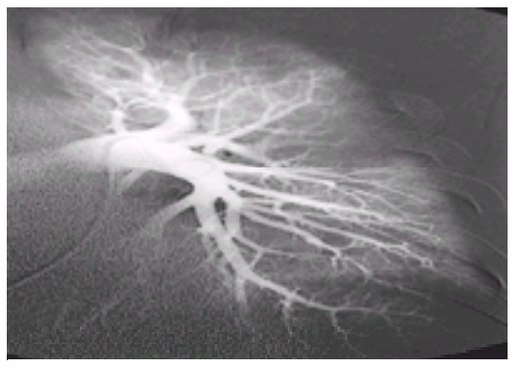

Fig. 2 Normal selective digital subtraction pulmonary angiogram of the left pulmonary artery. Vessels fill completely, taper gradually, and show numerous fine branches. This film and other pulmonary angiograms were supplied by Dr P.C. Shetty, Hurley Medical Center, Flint, Michigan, United States.

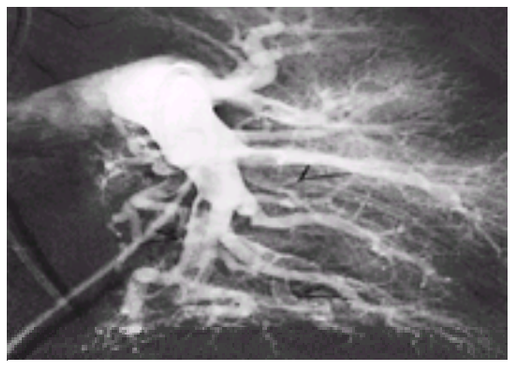

Fig. 3 Selective digital subtraction pulmonary angiogram of the left pulmonary artery showing multiple intraluminal filling defects indicative of pulmonary thromboemboli. Some of these have been identified by arrowheads.

Fig. 4 Selective pulmonary angiogram of the left pulmonary artery showing a large intraluminal filling defect with a saddle embolus at the bifurcation.

Contrast-enhanced spiral computed tomography

The results of imaging with contrast-enhanced spiral computed tomography (**CT**) (Fig. 5) compared with pulmonary angiography or autopsy are sparse. Results of individual small case series varied widely, with reported sensitivities ranging from 50 to 93 per cent. These studies all utilized 5-mm CT sections. With newer equipment, thinner sections with less breathing artefact are available. The sensitivity and specificity should, therefore, improve. However, the sensitivity and specificity of contrast enhanced spiral CT with multidetector scanners have not yet been determined. Investigation is in progress.

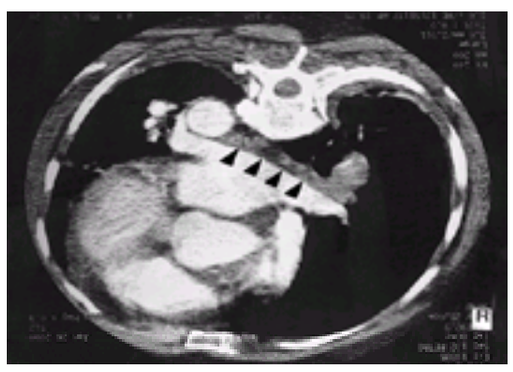

Fig. 5 Contrast-enhanced spiral computed tomogram showing a large intraluminal filling defect (arrowheads).

Magnetic resonance imaging

Magnetic resonance imaging, including magnetic resonance angiography and gadolinium-enhanced magnetic resonance angiography for acute pulmonary embolism are 'evolving' techniques. Preliminary observations suggest that gadolinium-enhanced three-dimensional magnetic resonance angiography during a single breath hold shows promise as a potentially useful imaging technique. Among the potential advantages are rapidity, avoidance of nephrotoxic iodinated contrast agents, and minimal invasiveness. Potential disadvantages include lack of sensitivity in detecting subsegmental pulmonary embolism and the fact that some patients may have a contraindication to magnetic resonance imaging.

Echocardiography

Echocardiography may show right ventricular dilatation and evidence of pulmonary hypertension, which, in the proper clinical setting, may strengthen the clinical impression that pulmonary embolism has occurred. Transoesophageal echocardiography sometimes may show proximal pulmonary emboli, but it has limited value in this regard.

Clues for the diagnosis of pulmonary embolism

With increasing severity of pulmonary embolism, from pulmonary infarction to isolated dyspnoea to circulatory collapse, trends suggest that the prevalence of a high probability ventilation–perfusion lung scan increases, as does the pulmonary artery mean pressure, while the PaO_2 decreases. However, making the diagnosis of pulmonary embolism is difficult, and depends on consideration of clinical, laboratory, and imaging data. Clues that can assist the physician in assessing the possibility of pulmonary embolism and avoiding inadvertent exclusion of the diagnosis are as follows.

1. Some patients with pulmonary embolism and circulatory collapse do not have dyspnoea, tachypnoea, or pleuritic pain.
2. Rales (crepitations) are common among patients with pulmonary infarction, but less so in those with isolated dyspnoea or circulatory collapse. They occur in those with radiographic evidence of a parenchymal abnormality.
3. A normal electrocardiogram is frequent in patients with the pulmonary infarction syndrome, but uncommon in those with isolated dyspnoea.
4. Abnormalities on the chest radiograph, although more common among patients with pulmonary infarction, are often observed in those with isolated dyspnoea.
5. Patients with circulatory collapse may have a normal chest radiograph.
6. A high probability interpretation of the ventilation–perfusion scan occurs in a minority of patients with the pulmonary infarction syndrome, but it is found in the majority of patients with the isolated dyspnoea syndrome.
7. A low probability ventilation–perfusion scan can occur in patients with pulmonary embolism and circulatory collapse.
8. A PaO_2 higher than 80 mmHg (10.5 kPa) is not uncommon in patients with the pulmonary infarction syndrome, but such levels are uncommon in those with the isolated dyspnoea syndrome.

Strategy for diagnosis

There are clear parallels with the situation when the diagnosis of deep venous thrombosis is considered. Subjecting all patients who might have a pulmonary embolus to complex, expensive and/or invasive tests is best avoided, such that management algorithms have been developed to identify those at very low risk, who can then be spared invasive tests. These algorithms typically use scoring systems to stratify the clinical probability that the particular patient has a pulmonary embolus, proceeding to D-dimer testing of those with low probability. Patients with a low clinical probability and a negative D-dimer test are not investigated further. Patients with either a high clinical probability or a low clinical probability but elevated D-dimer proceed to tests for the presence pulmonary emboli, typically by ventilation-perfusion lung scanning or contrast-enhanced spiral computed tomography. Examples of a pre-test scoring system and management algorithm are shown in Table 13.

Management algorithms of the type described in Table 13 are now employed in many hospitals, but a note of caution is appropriate. Their use has not been well validated. When there is genuine clinical doubt and a ventilation perfusion lung scan is reported as of low or intermediate probability, then there is a considerable diagnostic problem. In many centres contrast-enhanced spiral CT has become the diagnostic method of choice for suspected pulmonary embolism, or is used as the next line of investigation if ventilation perfusion scanning does not produce a clear-cut result. However, some would argue that the method has not been tested sufficiently and the physician should weigh the value of angiography (if available) against its hazards in the context of the whole clinical situation. The finding that 57 per cent of positive angiograms in the PIOPED study occurred in those with intermediate and low probability scans strengthens the case for an angiogram. An alternative strategy is to image the veins in the legs if ventilation perfusion scanning does not allow confident exclusion of the diagnosis of pulmonary embolism. If imaging reveals thrombus, then treatment is given. If imaging is negative, then this does not exclude the diagnosis of venous thromboembolism (the thrombus may have gone into the lungs), but the patient can be followed safely with serial non-invasive imaging of the leg veins. The risk of pulmonary embolism is low in patients in whom serial investigations of the legs show no deep venous thrombosis.

Treatment

General measures

All patients who are hypoxic should be given supplementary oxygen at high concentration (enough to restore normal PO_2), excepting those few with coincident chronic chest disease where carbon dioxide retention is problematic. In the early stages, continuous monitoring of arterial oxygen tension by pulse oximetry is advised.

Resuscitation

Most patients with acute pulmonary embolism do not have substantial circulatory compromise, but those presenting with massive pulmonary embolism may have circulatory collapse. They may look as though they are about to die, with cool peripheries, cyanosis, profound hypotension, and marked elevation of the jugular venous pulse. Features typical of long-standing pulmonary hypertension (palpable right ventricular heave, right ventricular gallop, loud P2, hepatomegally, ascites, peripheral oedema) are unlikely to be present. This dramatic haemodynamic picture may not be simply due to the direct anatomical effects of occlusion of main pulmonary vessels (the same picture is not seen after pneumonectomy, when one pulmonary artery is tied off completely), but also secondary to pulmonary neurogenic reflexes and local release of vasoactive substances, including 5-hydroxytryptamine and thromboxane from activated platelets.

Even though the jugular venous pulse is markedly elevated in acute massive pulmonary embolism, volume expanders should be administered rapidly to increase right ventricular filling pressure still further. The aim is to support the circulation until measures designed to deal with the embolus (usually thrombolysis—see below) can be applied and take effect.

Antithrombotic treatment

Unless there are serious concerns about the potential side-effects of anticoagulation or imaging is immediately available, it is common and sensible practice to begin anticoagulant treatment as soon as the diagnosis of pulmonary embolism is suspected. The antithrombotic regimen is the same as for deep venous thrombosis: see Table 5 and Chapter 15.15.3.2. This treatment is effective: the mortality from acute pulmonary embolism or recurrent pulmonary embolism during the first 3 months among 297 patients treated only with anticoagulants in the PIOPED study was 1.7 per cent. An additional 2.0 per cent suffered non-fatal recurrent pulmonary embolism during the first 3 months. Among all patients, irrespective of the treatment, the mortality from pulmonary embolism during the first 3 months was 2.4 per cent and an additional 3.5 per cent suffered non-fatal recurrent pulmonary embolism.

Thrombolytic therapy

Thrombolytic therapy is not indicated for the routine treatment of pulmonary embolism. Hypotension and continuing hypoxemia while receiving high fractions of inspired oxygen (FiO_2) are indications for intervention. Right ventricular dysfunction on the echocardiogram may also be an indication.

More rapid lysis of pulmonary thromboemboli occurs with thrombolytic agents than occurs spontaneously in patients treated only with anticoagulants. However, pulmonary reperfusion, as shown on perfusion lung scans, is similar after 2 weeks in patients treated with thrombolytic agents and those given anticoagulants.

A large prospective randomized trial in 1973 using urokinase showed no improvement of mortality and no difference of the rate of recurrence of pulmonary embolism among stable patients treated with thrombolytic therapy as opposed to anticoagulants. There have been no subsequent prospective randomized trials which contradict these results. A trend suggesting a lower rate of recurrent pulmonary embolism has been shown among patients with right ventricular dysfunction who were treated with tissue plasminogen activator.

Thrombolysis has risks. The frequency of major bleeding from tissue plasminogen activator among patients with pulmonary embolism diagnosed by angiography, based on pooled data, is 13 per cent. All investigations excluded patients at a high risk of bleeding, such as those with recent surgery, recent biopsy, peptic ulcer disease, blood dyscrasia, or severe hepatic or renal disease. The reported patients, therefore, had a low risk of bleeding. The risk of intracranial haemorrhage with tissue plasminogen activator (2 per cent) was higher among patients with pulmonary embolism than among patients who received tissue plasminogen activator for myocardial infarction.

Regimens of thrombolytic therapy

Regimens approved by the United States FDA for treatment of acute pulmonary embolism are:

1. streptokinase, 250 000 IU over 30 min followed by 100 000 IU/h for 24 h;
2. urokinase, 4400 IU/kg/h over 10 min followed by 4400 IU/kg/h for 12 to 24 h; or
3. tissue plasminogen activator, 100 mg(50 million IU)/2 h.

Potentially advantageous regimens of thrombolytic therapy, not fully evaluated, are:

1. urokinase, 15 000 IU/kg over 10 min; or
2. tissue plasminogen activator, 0.6 mg/kg (max. 50 mg) over 2 min.

It is recommended that heparin be discontinued during thrombolytic therapy and reinstituted upon discontinuation of thrombolytic therapy. None of the FDA approved regimens utilize concomitant heparin.

Inferior vena cava occlusion

An inferior vena cava filter is recommended in a patient with proximal deep venous thrombosis or pulmonary embolism if:

1. anticoagulants are contraindicated;
2. pulmonary embolism has recurred while on adequate anticoagulant therapy; or
3. pulmonary embolism is severe (right ventricular failure on physical examination, hypotension) and any recurrent pulmonary embolism may be fatal.

Insertion of an inferior vena cava filter is also strongly recommended in patients following pulmonary embolectomy.

Routine insertion of an inferior vena cava filter is not indicated only on the basis of a continuing predisposition for deep venous thrombosis. In special circumstances, however, this may be the best approach. Prophylactic insertion of vena cava filters may be considered for high-risk patients with deep venous thrombosis, severe pulmonary hypertension, and minimal cardiopulmonary reserve.

A number of vena cava filters have been designed for percutaneous insertion. They differ in outer diameter of the delivery system, maximal caval diameter into which they can be inserted, hook design, retrievability, biocompatability, and filtering efficiency. Filter migration, thrombosis, and cava wall perforation occur. Anticoagulant therapy after insertion of a filter is recommended. The filter alone, however, may be effective.

Symptomatic occlusion of the inferior vena cava is the most frequent complication, occurring in about 9 per cent of patients. Pulmonary embolism after insertion of an inferior vena cava filter is uncommon (1 per cent), and fatal pulmonary embolism is rare. Possible mechanisms that can explain pulmonary embolism after filter insertion are: (i) ineffective filtration, especially with tilting of the filter; (ii) growth of trapped thrombi through the filter; (iii) thrombosis on the proximal side of the filter; (iv) filter migration; (v) filter retraction from the caval wall; (vi) embolization through collaterals; (vii) embolization from sites other than the inferior vena cava; and (viii) incorrect position of the filter.

Complications of vena cava filters include filter deformation, filter fracture, insufficient opening of the filter, and improper anatomical placement of the filter. Filter-related complications include migration, angulation of the filter, caval stenosis, caval occlusion, erosion of the caval wall, and leg oedema. Complications at the site of insertion of the catheter do not differ from complications observed locally with other catheter techniques. Deep venous thrombosis at the puncture site generally has been reported in 8 to 25 per cent of cases.

Catheter interventions

Catheter-tip devices for the extraction or the fragmentation of embolus have the potential of producing immediate relief from massive pulmonary embolism. Such interventions may be particularly useful in patients in whom there is a contraindication to thrombolytic therapy. A suction-tip device for extraction of pulmonary embolism has been used in some patients. Thrombus fragmentation with a guide wire, angiographic catheter or balloon catheter, or specially designed devices have

been reported in small case series or case reports. The release of fragmented thromboemboli into the distal pulmonary arterial branches is not a problem. A registry of management strategies used by hospitals throughout Germany showed use of thrombus fragmentation in 1.3 to 6.8 per cent of patients with pulmonary embolism, depending on the severity. Catheters also have been developed that deliver high-velocity jets in the region of the thrombus, causing the thrombus to be sucked into the adjacent low pressure zone and undergo fragmentation due to the powerful mixing forces.

Pulmonary embolectomy

Medical therapy is likely to give better results than embolectomy. The operative and perioperative mortality related to surgical pulmonary embolectomy ranges between 28 and 74 per cent. A candidate for pulmonary embolectomy should meet the following criteria: (i) massive pulmonary embolism, angiographically documented if possible; (ii) haemodynamic instability (shock) despite heparin therapy and resuscitative efforts; and (iii) failure of thrombolytic therapy or a contraindication to its use.

Chronic pulmonary thromboembolic hypertension

In a very few patients with extensive embolization, the emboli fail to resolve and undergo fibrovascular organization, causing chronic obstruction to pulmonary arterial blood flow. Subsequently this can result in chronic pulmonary thromboembolic hypertension. This occurs in about 0.1 to 0.2 per cent of survivors of acute pulmonary embolism. In most of these patients, a procoagulant abnormality or defect in the fibrinolytic system cannot be shown. In many patients, both acute and chronic emboli are simultaneously present. A proliferation of fibrous connective tissue and small blood vessels penetrate a variable distance into the thrombus and attach it to the intimal surface of the vessel wall. Pulmonary hypertension develops as the result of a critical reduction of cross-sectional area for blood flow. The relatively high flow through non-occluded vessels may cause secondary hypertensive changes in the resistive or precapillary vessels. Patients with mean pulmonary artery pressures over 30 mmHg had a 5-year survival of 30 per cent and if the mean pulmonary artery pressure was over 50 mmHg, the 5-year survival was 10 per cent.

Most patients do not have an obvious history of venous thrombosis or pulmonary embolism. Dyspnoea is present in virtually all, but in the early stages may occur only on exertion. Compensatory right ventricular hypertrophy develops, and there may be a period of months to years when symptoms remain stable, but ultimately right ventricular function deteriorates. Symptoms then include worsening dyspnoea, fatigue, presyncope, syncope (rarely), pleuritic pain, angina-like pain, abdominal swelling, and peripheral oedema. Signs of respiratory and right ventricular failure develop, with cyanosis, grossly elevated jugular venous pulse, palpable right ventricular heave, right ventricular gallop, loud P2, hepatomegaly, ascites, and peripheral oedema. Bruits may be heard over the pulmonary arteries.

Ventilation–perfusion lung scans typically show one or more mismatched segmental or larger perfusion defects, and most patients have several bilateral mismatched perfusion defects. Pulmonary angiography is the most definitive diagnostic test. It shows narrowed segmental pulmonary arteries, sometimes accompanied by post-stenotic dilatation, irregularity of the intima, luminal narrowing of the central arteries, and oddly shaped vessels. Pulmonary fibreoptic angioscopy is useful to define surgical accessibility.

Pulmonary thromboendarterectomy is the treatment of choice. The procedure is highly specialized and postoperative management is difficult and complex. Such surgery is performed only at a limited number of centres. At the most experienced centre, the operative mortality is 8.7 per cent.

Medical therapy is adjunctive and should not delay the assessment for surgery. Medical therapy fails to address the underlying problem of fixed pulmonary vascular obstruction. In patients awaiting surgery, it is important to prevent further emboli and to treat cor pulmonale. Anticoagulation should be initiated immediately and maintained for life. Insertion of an inferior vena cava filter is generally advisable. There is no role for thrombolytic therapy. Angioplasty has not been successful. The potential role of pulmonary vasodilator therapy is speculative.

For fuller discussion of the management of pulmonary hypertension see Chapter 15.15.2.

15.15.3.2 Therapeutic anticoagulation in deep vein thrombosis and pulmonary embolism

David Keeling

Introduction

Deep vein thrombosis and pulmonary embolism are aspects of the same disease, venous thromboembolism. Forty per cent of patients with deep vein thrombosis without clinical evidence of pulmonary embolism have evidence of emboli on lung scanning. The principles of therapeutic anticoagulation are the same for both. In proximal deep vein thrombosis and pulmonary embolism this involves immediate anticoagulation with heparin followed by a period of anticoagulation with warfarin (or other oral vitamin K antagonist). Distal deep vein thrombosis can be managed in the same way, but an alternative strategy is to use serial non-invasive testing (e.g. ultrasound), which only reliably detects proximal thrombosis, to ensure that suspected distal thrombosis does not extend above the knee, withholding treatment if it does not.

There is clear evidence that heparin is needed in the initial phase and that anticoagulation with oral anticoagulants alone is inadequate. Warfarin can be commenced on the first day and heparin is continued for 5 days or until the international normalized ratio (**INR**) is greater than 2.0 for 2 consecutive days, whichever is the longer. Extending the period of heparinization from 5 to 10 days is not more effective and increases the risk of heparin-induced thrombocytopenia. However, for massive pulmonary embolism or severe ileofemoral thrombosis a longer period of heparin therapy may be considered.

Heparin

Heparin, a glycosaminoglycan, is composed of alternating uronic acid and glucosamine saccharides that are sulphated to a varying degree. Its mode of action is to potentiate the activity of the serine protease inhibitor (serpin) antithrombin, whose main mode of action is to inhibit thrombin, but which also inhibits several other coagulant proteases such as factor Xa. A specific pentasaccharide sequence determined by the sulphation pattern along the heparin chain binds to antithrombin and causes a conformational change, giving it full activation against factor Xa but only partial activation against thrombin. Heparins of 18 saccharides (MW 5400) or more can extend across the intermolecular gap and also bind to thrombin giving full antithrombin activity, which is lost if the chains are shorter. Unfractionated or standard heparins are a mixture of chains of different lengths (MW 5000 to 35 000, mean 13 000) and low-molecular-weight heparins (MW 2000 to 8000, mean 5000) are derived from them by enzymatic or physicochemical cleavage. Low-molecular-weight heparins have, with good reason, largely replaced unfractionated heparin for the treatment of venous thromboembolism, but the use of the latter will be discussed first.

Anticoagulation with unfractionated heparin

Unfractionated heparin has most often been given by continuous intravenous infusion, the rate of which has to be adjusted, usually by measuring the activated partial thromboplastin time (**APTT**). An inadequate APTT response in the first 24 h may increase the risk of recurrence of thromboembolism, though this does not seem to be critical if the starting infusion rate is at least 1250 IU/h. A validated regimen is to give a bolus dose of 80 IU/kg and to start the infusion at 18 IU/kg.h, performing the first APTT estimate after 6 h. The dose is then usually adjusted to maintain the APTT between 1.5 to 2.5 times the average laboratory control value. With older APTT reagents this corresponded to a therapeutic heparin level of 0.2 to 0.4 IU/ml by protamine titration or 0.3 to 0.6 IU/ml by anti-Xa assay. However, many current APTT reagents show an increased sensitivity to unfractionated heparin and with these higher ratios should be aimed for. The local laboratory should advise on the appropriate therapeutic range with its reagent. When the dose is therapeutic the APTT should be checked daily.

An alternative is to give unfractionated heparin subcutaneously once every 12 h, and a meta-analysis suggested that this might be more effective and at least as safe as continuous intravenous infusion. A reasonable starting dose is 250 IU/kg, adjusting the dose according to the mid-interval APTT.

Anticoagulation with low-molecular-weight heparin

Although much is made of the greater anti-Xa to antithrombin ratio of the low-molecular-weight heparins, their key clinical property is that they produce a much more predictable anticoagulant response than unfractionated heparin. This, combined with the fact that they have very high bioavailability after subcutaneous injection, means that the dose can be calculated by body weight and be given subcutaneously without any monitoring or dose adjustment. The actual dosage used differs slightly with the different low-molecular-weight heparins and the manufacturers' recommendations should be followed, but a typical dose is 200 IU/kg once a day. They are at least as effective and at least as safe as unfractionated heparin, even when given once a day. Their widespread use has enabled many patients with deep vein thrombosis to be managed as outpatients. Low-molecular-weight heparin is renally excreted so should be used with caution in renal failure (anti-Xa levels can be checked if necessary).

Complications of heparin treatment

If a patient on intravenous unfractionated heparin is excessively anticoagulated, it is usually sufficient simply to stop the infusion, the half-life being 1 to 2 h. If bleeding is severe the heparin can be neutralized with protamine sulphate, giving 1 mg for every 100 IU that have been infused over the previous hour. The reversal of low-molecular-weight heparin is more problematic. Although protamine sulphate may not neutralize the smaller chains it is often clinically effective, though estimating an appropriate dose is more difficult (the maximum dose is 50 mg, so this is often given if the subcutaneous injection was recent).

Heparin-induced thrombocytopenia is a feared complication, but much less common now short courses of low-molecular-weight heparin are used. It is due to the development of an antibody to the heparin–platelet factor 4 complex and can be associated with serious venous and arterial thrombosis. Patients on heparin for 5 or more days should have their platelet count checked. If heparin-induced thrombocytopenia is suspected, then heparin must be stopped and an alternative substituted (danaparoid or hirudin being most suitable).

Long-term treatment, for example in pregnancy, is associated with osteopenia, but this may be less of a problem with low-molecular-weight heparin.

Warfarin

The oral vitamin K antagonists are the mainstay of long-term anticoagulant therapy. Warfarin is the commonest vitamin K antagonist given, though the shorter acting nicoumalone and the longer acting phenprocoumon are also used. Phenindione is used less commonly because of a high incidence of skin rashes. The procoagulant factors II, VII, IX, and X (and the anticoagulants protein C and protein S) need vitamin K for the g-carboxylation of the glutamic acid residues that form their gla domains. Without this post-translational modification they cannot bind calcium, and as a consequence cannot bind to anionic phospholipid surfaces, such that assembly of the key coagulation complexes is disrupted.

Warfarin takes about 4 days to become effective, during which period heparin is given. When warfarin is started the vitamin K-dependent factors fall according to their half-lives. Factor VII and protein C have the shortest half-lives, so that despite a prolongation of the INR due to factor VII deficiency, warfarin may initially be

procoagulant. This is the mechanism for the rare problem of warfarin-induced skin necrosis, most often described in those with protein C deficiency.

Anticoagulation with warfarin

Initiation and monitoring

Monitoring of warfarin treatment is by the international normalized ratio (INR). This is a manipulation of the prothrombin time (**PT**) to allow for the different sensitivities of various laboratory reagents to the warfarin-induced coagulopathy. The INR equals (PT/MNPT) ^{ISI} where MNPT is the (mean normal) control PT and ISI is the international sensitivity index of the thromboplastin used in the assay. For the treatment of deep vein thrombosis and pulmonary embolism the target INR should be 2.5 (target range 2.0 to 3.0). If a recurrence occurs despite an INR of 2.0 to 3.0, then the dose is usually increased to a target INR of 3.5 (target range 3.0 to 4.0).

If the initial coagulation tests are not prolonged it is usual to give 10 mg of warfarin on the first evening and check the INR the following morning. Warfarin dose is adjusted according to the daily INR results until the patient is stable. Stable anticoagulation is more quickly and safely achieved if a dosing algorithm is followed (Table 1).

When patients are stable they may go for up to 8 weeks between INR checks. If the INR is unstable, patients are seen more frequently, but it should be noted that with warfarin it takes approximately 1 week (five times the half-life of 36 h) to reach a new steady state after dose adjustment and more frequent dosage alteration is inadvisable.

How long should the patient take warfarin?

It is a difficult clinical decision to decide how long to continue warfarin, a matter of balancing the risks of recurrence against the risks of warfarin. The latter are well known, 1 to 2 per cent of people on warfarin have a major bleed each year and 0.5 per cent suffer an intracranial bleed, of which 50 per cent die, giving a fatality rate of 0.25 per cent per annum. However, warfarin is highly (90 to 95 per cent) effective at preventing recurrence. The risk of a recurrent venous thromboembolism after a first deep vein thrombosis is approximately 5 per cent per year, when a case–fatality rate of 5 per cent (and some estimates for recurrent venous thromboembolism have been this high, though the overall rate for all venous thromboembolism is probably 1 to 2 per cent) would also give a fatality rate of 0.25 per cent per year. Other factors can be taken into account: the risk of recurrence is higher for the first 6 months, it is higher for proximal deep vein thrombosis and pulmonary embolism than for distal deep vein thrombosis, and it is lower if a transient risk factor was present (e.g. recent surgery, use of the contraceptive pill). Six months of anticoagulation has been shown to be more effective than 6 weeks of anticoagulation in all subgroups. Whether an inherited thrombophilia should influence the long-term management is not clear. Although they predict first events, the commoner defects (factor V Leiden and prothrombin G20210A) may not predict recurrence. Taking all this into account a reasonable approach is indicated in Table 2.

Complications of warfarin treatment

The only major complication of warfarin treatment is bleeding. Risk factors for bleeding are an age of 65 years or more, a history of stroke, a history of gastrointestinal bleeding, anaemia, renal impairment, diabetes, and recent myocardial infarction. A major problem in control is the starting and stopping of other medication. Many drugs interact with warfarin (see Table 3 for those with the most evidence) and patient education and constant vigilance is essential. Close monitoring of the INR is advised when concomitant medication is altered.

The approach taken to reverse over-anticoagulation with warfarin depends on the circumstances (see Table 4). Prothrombin complex concentrates, unlike fresh frozen plasma, reliably and rapidly correct the defect and should be used in life-threatening situations such as intracranial bleeding. Small doses of phytomenadione (vitamin K_1) can lower a high INR without making subsequent anticoagulation difficult, as is the case if high doses are given.

Fibrinolysis

Thrombolytic agents dissolve thrombi by directly or indirectly activating the zymogen plasminogen to plasmin. Plasmin then degrades fibrin to soluble peptides, but cannot distinguish fibrin in pathological thrombi from fibrin in haemostatic plugs and it may also degrade and so deplete plasma fibrinogen. The use of thrombolytic agents for venous thromboembolism requires careful individual assessment. It is rarely given in deep vein thrombosis though its use can be considered in massive ileofemoral thrombosis. Although thrombolytic therapy for pulmonary embolism achieves more rapid resolution than heparin alone, there is no clear evidence of lasting benefit. Patients with pulmonary embolism who survive long enough to have the diagnosis made and treatment with heparin begun have an excellent prognosis, unless they have associated severe medical disease. Thrombolytic therapy, which carries a much greater risk of bleeding, is therefore reserved for those cases of massive pulmonary embolism with haemodynamic instability threatening the patient's life (see Chapter 15.15.3.1).

Streptokinase (which forms a complex with plasminogen that then activates free plasminogen), urokinase, and tissue plasminogen activator (**tPA**) have all been used. For pulmonary embolism, streptokinase is recommended as a 250 000 IU loading dose followed by an infusion for 24 h at 100 000 IU/h. Urokinase is given as a 4400 IU/kg loading dose followed by 2200 IU/kg.h for 12 h. Following the success of rapid fibrinolytic regimens in myocardial infarction, tPA given as 100 mg over 2 h has been used for pulmonary embolism, and the use of more rapid regimens with the other two agents has been suggested (see Chapter 15.15.3.1 for further discussion).

Treatment of venous thromboembolism in pregnancy

Heparin does not cross the placenta and can be used in pregnancy, as described above, but higher doses of unfractionated heparin are sometimes needed to achieve therapeutic levels. As pregnant women are excluded from clinical trials, experience with low-molecular-weight heparin is limited. However, the evidence seems to indicate that low-molecular-weight heparin, with all its logistical advantages, can be used effectively and safely in pregnancy.

The real problem is warfarin, which crosses the placenta and can cause an embryopathy if given between 6 and 12 weeks' gestation. At any time it can cause fetal bleeding and has been associated with central nervous system abnormalities. The usual treatment recommended for venous thromboembolism in pregnancy is to continue with full-dose heparin until term (long-term treatment with unfractionated heparin can be given by subcutaneous injection once every 12 h, and with low-molecular-weight heparin by injection once daily). As heparin may cause osteopenia (possibly less of a risk with low-molecular-weight heparin) some would consider the use of warfarin after the first trimester, switching back to heparin at 36 weeks. Warfarin can be used for the 6 weeks of the puerperium, and women taking warfarin can breast feed.

15.16.1.1 Prevalence, epidemiology, and pathophysiology of hypertension

C. G. Isles

Definitions of hypertension

The simplest and most widely accepted definition of hypertension in an adult is that hypertension is present when clinic systolic pressure exceeds 140mmHg and/or clinic diastolic pressure exceeds 90mmHg. The American and World Health Organization International Society of Hypertension definition of hypertension, reproduced in Table 1, gives a more detailed classification of blood pressure for adults aged over 18 years. Any definition of abnormality that is based on a measurement distributed within the population as a continuous variable, such as blood pressure, serum cholesterol, or height, must necessarily be somewhat arbitrary, and so it is with hypertension.

Prevalence

United Kingdom studies

Estimates of prevalence vary. The number of measurements made, the method used, and the circumstances in which measurements are made all influence prevalence. Also important here are age, gender, race, and socio-economic status. In a representative population sample of 10359 Scottish men and women aged 40 to 59 years between 1984 and 1986, and based on the average of two measurements at a single screening visit in a primary care setting, 1262 (25 per cent) men and 1061 (20 per cent) women were considered to be hypertensive, defined in this study as a blood pressure of 160/95mmHg or higher or receiving antihypertensive drug treatment. A more recent survey of 12116 English adults aged 16 years or more in 1994 yielded similar results. Based on the average of the second and third of three readings at a single screening visit in the respondent's home, 19 per cent of men and 20 per cent of women had a blood pressure of 160/95mmHg or higher or were receiving antihypertensive drug treatment. Both surveys probably overestimate the prevalence of hypertension in the United Kingdom because they were based on the average of readings at a single screening session.

United States studies

The value of repeated measurements at different visits in determining prevalence of hypertension is apparent in a study of 158906 mixed-race individuals aged 30 to 69 years examined in their homes or work places in the United States in the early 1970s. Twenty-five per cent had a diastolic blood pressure of 90mmHg or higher at the first screen. When these subjects were rescreened in a clinic setting, there was a substantial fall in blood pressure such that only 25 per cent (6.4 per cent of the original cohort) remained hypertensive. The majority (75 per cent) were mildly hypertensive with a diastolic blood pressure in the range 90 to 104mmHg. Put another way, in this large population survey most individuals with hypertension identified had a mild to moderate elevation of blood pressure, with less than 2 per cent of those screened having sustained hypertension with a diastolic blood pressure higher than 105mmHg after two measurements.

The importance of age as a determinant of prevalence of hypertension is evident from data collected during the 1988 to 1991 National Health and Nutrition Examination Survey. The proportion of the United States population having a systolic blood pressure of 140mmHg or higher, or a diastolic blood pressure of 90mmHg or higher, based on the average of six measurements at two visits, or currently being treated with an antihypertensive drug, was 4 per cent for young adults aged 18 to 29 years, increasing to 65 per cent for those over 80 years (Fig. 1).

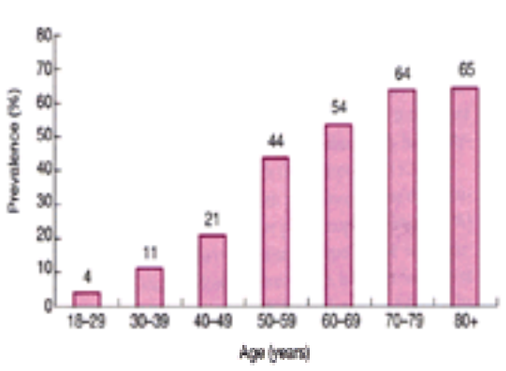

Fig. 1 Prevalence of hypertension, defined as a systolic blood pressure of 140mmHg or higher, or a diastolic blood pressure of 90mmHg or higher in the United States. Prevalence increases with advancing age. Adapted with permission from NHANES III.

Recent data from Framingham, United States suggest that the increasing use of antihypertensive medication has resulted in a decline in the prevalence of hypertension. In an analysis of 10333 subjects aged 45 to 74 years, examined over a 40-year period from 1950 to 1989, using definitions of 160mmHg systolic or 100mmHg diastolic on or off treatment, and based on an average of two separate measurements at each visit, the prevalence of hypertension decreased from 18.5 to 9.2 per cent for men, and from 28.0 to 7.7 per cent for women (Fig. 2).

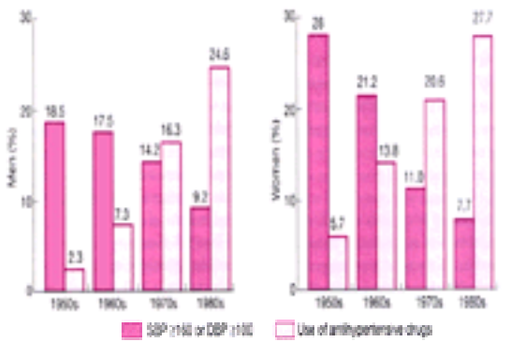

Fig. 2 Age-adjusted temporal trends in prevalence of raised blood pressure and use of antihypertensive drugs among men and women 45 to 74 years of age in Framingham, United States. Adapted with permission.

Measuring blood pressure

If blood pressure is to be measured precisely, a device with validated accuracy that is properly maintained and calibrated must be used. For a long time the mercury sphygmomanometer has been the gold standard in clinical practice but—for health and safety reasons related to mercury—is likely to be replaced by aneroid, semi-automatic and automated devices in the near future. Information on the accuracy of the alternatives to mercury sphygmomanometers can be obtained from the British Hypertension Society Information Services (e-mail: bhsis@sghms.ac.uk; website: www.hyp.ac.uk/bhs/).

Cuff size

Whatever method is employed, a cuff with an appropriately sized bladder should be applied to the upper arm, leaving adequate space for the bell of a stethoscope to be positioned in the antecubital fossa. The arm should be supported at the level of the heart and unrestricted by tight clothing. For most patients an appropriately sized bladder is 14 by 35cm, sometimes known as the alternative adult cuff. Smaller bladders will over-read blood pressure in fat arms, while larger bladders as used in thigh cuffs are too unwieldy for routine use. It is good practice to measure the blood pressure in both arms at the first visit and then to select the arm with the higher reading for future measurements; also to record pressure both seated and standing initially to exclude a significant postural fall, more likely in elderly and diabetic subjects.

Clinic/doctor's office (surgery)

If a mercury sphygmomanometer is being used, the correct procedure for measurement is to deflate the cuff at 2mm/s and read blood pressure to the nearest 2mmHg, recording diastolic pressure at the disappearance of the sounds (phase V). Patients in whom the sounds never disappear probably have arterial disease of their upper limb vessels causing turbulent flow and should have their pressure recorded as systolic/diastolic phase IV (muffling)/0mmHg. At least two measurements should be made at each visit. Because blood pressure tends to fall with repeated measurements, patients whose pressure is found to be greater than 140/90mmHg should be brought back for further measurements at intervals that may vary from 1 day to 1 month, according to the level of their pressure, before a diagnosis of sustained hypertension is made.

Home/ambulatory

Interest in home and ambulatory blood pressure measurement continues to grow. Both techniques permit the recording of numerous values in settings that are closer to daily life than the clinic or office. By averaging up to 60 readings taken at intervals of 20 to 30min over the course of 24h, ambulatory blood pressure measurement improves precision and reproducibility in blood pressure measurement. It also correlates more closely than clinic blood pressure with risk, as judged by evidence of target organ damage, but lacks the authority of an outcome trial, which means that it is not possible to recommend ambulatory blood pressure measurement over clinic pressure in routine practice.

White coat hypertension

Despite the reservations expressed above, ambulatory blood pressure measurement is widely used and can be valuable in a number of circumstances. Foremost among these is the evaluation of the patient with suspected white coat hypertension, also known as isolated clinic or office hypertension. White coat hypertension is present in up to 10 per cent of the hypertensive population and is usually defined as persistent clinic or office hypertension greater than 140/90mmHg in the face of consistently normal readings less than 135/85mmHg at home. Because white coat hypertension carries much less risk of cardiovascular disease, the decision to recommend or withhold drug treatment must be based on the overall risk profile. Subjects whose risk is low require continued monitoring only, whereas patients who already have vascular disease or are at high risk of developing vascular disease, for instance because they have diabetes or target organ damage, should be given antihypertensive drug therapy.

Other indications for ambulatory blood pressure measurement

Ambulatory blood pressure measurement may also be indicated in a number of other circumstances: when clinic blood pressure is unusually variable; when patients complain of postural symptoms related to their drug therapy; and in resistant hypertension, defined here as blood pressure greater than 150/90mmHg despite lifestyle measures and three or more antihypertensive drugs. Whatever the indication for ambulatory blood pressure measurement, the average daytime pressure is recommended for decisions on treatment, rather than the average 24-h pressure or the percentage of readings that lie above a certain threshold. It must also be recognized that ambulatory blood pressure is systematically lower than clinic or office blood pressure by an average of at least 10/5mmHg. This means that treatment thresholds and targets for achieved blood pressure should be adjusted downwards when using ambulatory blood pressure measurement. Pending the outcome of further prospective observational studies, average daytime ambulatory pressure of less than 135/85mmHg should be regarded as probably normal, and average daytime ambulatory pressure of greater than 140/90mmHg as probably abnormal and requiring drug treatment.

Epidemiology

Renfrew Paisley survey

Hypertension is an important contributor to morbidity and mortality from cardiovascular disease, particularly when present in combination with other cardiovascular risk factors. This is apparent from any one of a number of observational studies. The data shown in Fig. 3 are from the Renfrew and Paisley Survey in Scotland and show quite clearly that in this Western population, the relative risk of diastolic pressure for both coronary heart disease and stroke is approximately two to three in both sexes, when comparing high-risk with low-risk subjects; also that the rates of coronary heart disease are higher than those of stroke at all levels of blood pressure; and that coronary deaths are more common in men than in women, while gender differences in stroke mortality are much less apparent.

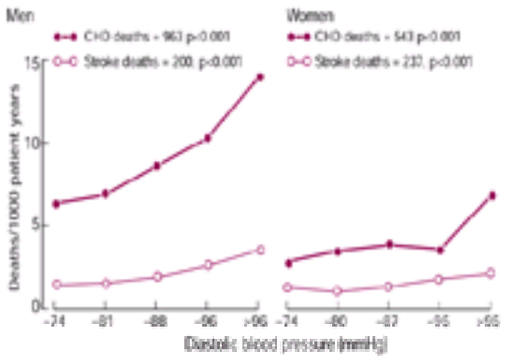

Fig. 3 Deaths per 1000 patient years among men and women aged 45 to 64 years after 17 years of follow-up in Renfrew and Paisley, Scotland. *P* value indicates significance of trend across quintiles of diastolic blood pressure. Reproduced with permission.

Framingham

Some authorities have suggested that the combined effects of risk factors are multiplicative rather than additive. Thus in Framingham, the probability of a 40-year-old male with a systolic pressure of 195mmHg developing coronary heart disease over 6 years is said to be 10-fold greater if he smokes and has plasma cholesterol of 9mmol/l with glucose intolerance and electrocardiographic left ventricular hypertrophy. The problem with data such as these is that very few subjects in Framingham (or elsewhere) possess so many risk factors. This means that the estimates of risk must necessarily be based on mathematical models rather than on actual numbers of events: indeed the authors of the Framingham study concede that the models used assume a degree of non-linearity (Kannel WB, personal communication).

Oxford meta-analysis

The most powerful and persuasive study of the association between blood pressure and risk remains the Oxford meta-analysis of 843 strokes and 4856 coronary heart disease events in 420000 individuals followed in nine major prospective observational studies for an average of 10 years (Fig. 4). The results of this meta-analysis were corrected for a phenomenon known as regression dilution bias by using repeated measurements to determine an individual's long-term average blood pressure, and showed that the relation between diastolic blood pressure, stroke, and coronary heart disease was at least 60 per cent stronger than had previously been thought. Within the range of diastolic blood pressure 70 to 110mmHg, the risk of stroke and coronary heart disease was positive, continuous, and independent of other risk factors, even when diastolic pressure was supposedly normal, namely 70–90mmHg. This raises the intriguing possibility, recently confirmed by the results of PROGRESS, that lowering blood pressure in 'normotensive' high-risk subjects might reduce their risk of vascular disease.

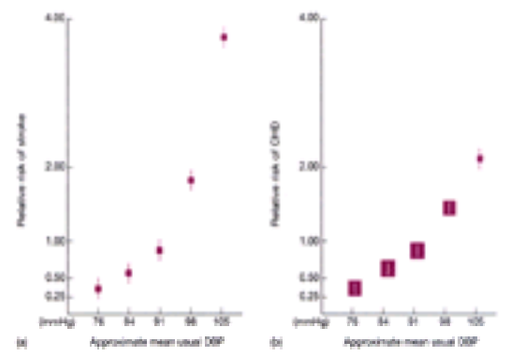

Fig. 4 Relation between diastolic blood pressure, stroke, and coronary heart disease during an average of 10 years follow-up. (a) Stroke and usual diastolic blood pressure. Seven prospective observational studies: 843 events. (b) Coronary heart disease and usual diastolic blood pressure. Nine prospective observational studies: 4856 events. (Reproduced with permission.)

Systolic hypertension and pulse pressure

Systolic blood pressure rises in a linear fashion with age, whereas diastolic pressure increases until the age of 50 then levels off and even begins to fall. This leads to an important transition in the form of hypertension with age. Isolated diastolic hypertension is more common in younger subjects, whilst isolated systolic hypertension emerges as the most common form of hypertension in the elderly. The underlying pathological process is loss of arterial elastic tissue, which means that the pressure wave created by left ventricular contraction can no longer be damped by the aorta and major vessels. Although clinicians have tended to focus on the diastolic component of blood pressure in the past, systolic blood pressure is a better predictor of cardiovascular risk and isolated systolic hypertension is now recognized to be an independent risk factor of cardiovascular disease. A wide pulse pressure has a similar influence on prognosis (Fig. 5).

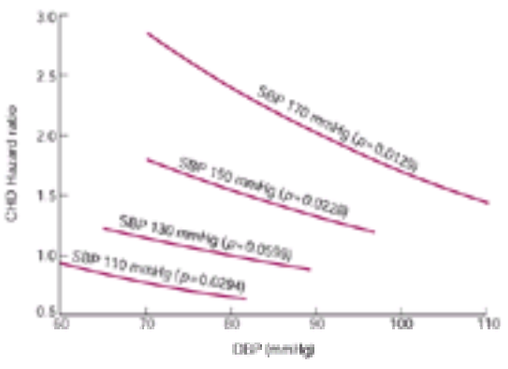

Fig. 5 Adjusted CHD risk in 1924 Framingham men and women between 50 and 79 years with no clinical evidence of CHD at baseline. At any given level of systolic pressure, risk was higher in those whose diastolic pressure was lower, highlighting the predictive power of pulse pressure..

Likely benefits of treatment

The relative risk of high blood pressure for heart attack and stroke is higher among younger subjects and decreases with age. Absolute risk, by contrast, increases with age. This means that attributable risk, which is the number of events that would be avoided if blood pressure were lower, is likely to be higher in the elderly. A similar logic can be applied to the likely impact of interventions that reduce mean blood pressure by even a few millimetres of mercury. The steepness of the slope relating diastolic blood pressure and stroke in the Oxford meta-analysis suggests that more strokes might be avoided than coronary heart disease events. However, the attributable risk of diastolic blood pressure for coronary heart disease, that is the number of coronary heart disease events that would be avoided if diastolic blood pressure were lower, is likely to be as great simply because coronary heart disease is more common than stroke in most Western populations.

Heart failure, renal disease, and recurrent events

Blood pressure is a powerful determinant not only of heart attack and stroke but also of heart failure and renal failure. A non-linear or J-shaped association between blood pressure and recurrent events has been reported for patients with previous myocardial infarction. Despite concerns that this might represent an adverse consequence of treatment, it is is now considered more likely to reflect the effect of disease on blood pressure—the bigger the myocardial infarction the bigger the fall in pressure—than the effect of blood pressure or its treatment on the disease.

Hypertension in black populations

Ethnic variations in the incidence, pathophysiology, and complications of hypertension are well described. Hypertension is more common in black than white populations, and more common in urban than rural black populations. Black individuals have a higher incidence of salt-sensitive hypertension than white individuals, and retain more sodium leading to expanded plasma volumes and lower plasma renin activity. The complications of hypertension also tend to be different in black populations with a higher incidence of left ventricular hypertrophy, stroke, and renal failure, and lower risk of coronary heart disease. The increased frequency of left ventricular hypertrophy, stroke, and renal failure may relate to the severity of hypertension in black individuals, and their relative lack of coronary heart disease may be due to more favourable lipid profiles.

Gender differences

Hypertension is an important risk factor for cardiovascular disease in women. Although premenopausal women have lower blood pressure than age-matched men, the prevalence of hypertension is higher in women than men after the age of 65. Obesity is significantly more common in middle-aged and older women, and is likely to contribute to the crossover in prevalence. Oral contraceptive use increases the risk of hypertension in younger women. Hormone replacement therapy (HRT) does not raise blood pressure in women who are normotensive at the start of treatment, but more research is required to determine whether blood pressure rises when hypertensive postmenopausal women are given HRT.

Pathophysiology

When asked to define hypertension, the clinician may reply 'that level of blood pressure above which treatment does more good than harm'. The response of the pathophysiologist is likely to be more complex, reflecting the fact that we don't fully understand the mechanisms involved. Most individuals with hypertension have essential hypertension, which is best thought of as a progressive rise in pressure with age, as a result of an interplay between genetic factors, environmental influences, and blood pressure control mechanisms. A much smaller number of patients (certainly less than 5 per cent of the hypertensive population) will have a renal or adrenal cause for their high blood pressure (see Chapter 20.10.2).

Genetic factors

The fact that high blood pressure runs in families does not tell us whether the genes or environment are responsible, because families usually share both. Helpful in sorting this out are studies of adopted children within a family, and of twins living apart. The twin studies suggest that approximately 50 per cent of the blood pressure variability between individuals is related to inheritable factors. The genetic component of the development of high blood pressure may not itself necessarily cause hypertension. Rather there may be a genetic predisposition to develop raised blood pressure in response to various environmental factors. For further information on the genetics of hypertension see Chapter 15.16.1.2.

Environmental influences

Environmental influences are more easily studied than genetic factors. Evidence of their importance comes from a number of sources, including studies of migrants, comparison between different communities, prospective population studies, and randomized trials of behaviour modification.

Migrant studies

Adults who migrate adopt the level of blood pressure, frequency of hypertension, and coronary heart disease risk of their destinations. Primitive Kenyan Luo tribespeople moving in search of work from their villages in rural Kenya to the urban slums of Nairobi show marked increases in blood pressure and body weight within a month of migration. Similar findings have been reported for Australian Aborigines migrating from the bush to Melbourne.

Comparison between different communities

In developed countries such as the United Kingdom, the rise in blood pressure that occurs with age is well recognized. The mechanisms responsible for this are not physiologically inevitable because primitive rural populations, most notably the Yanamamo Indians of Brazil and certain New Guinea tribes, show only a tiny rise in blood pressure with advancing age. These observations suggest that the rise in blood pressure seen with advancing age in urban societies must be due to some very powerful environmental factors.

Prospective population studies

A classic study compared Italian women entering a nunnery with a control group of women from the same town. In the control group, blood pressure rose normally with age whereas the nuns showed no rise in blood pressure over 20 years of follow-up. In another example, blood pressure did not rise as expected with age in long-term residents of a psychiatric hospital who entered with normal blood pressure. Studies such as these also provide evidence of which environmental influences might be important.

Specific environmental factors

The best known environmental influences on blood pressure are obesity, alcohol, and salt. Early nutritional deficiency may be important, and recent evidence suggests that psychosocial factors are likely to play a role in the development of essential hypertension. A small socio-economic gradient of blood pressure has been observed: inverse for developed and positive for developing countries. This probably reflects the higher prevalence of obesity, alcohol, and salt intake among those of lower socio-economic status in developed countries, and higher socio-economic status in developing countries. Recent evidence, to be discussed later, suggests that diets rich in fruit and vegetables with low total and saturated fats may protect against hypertension. Low calcium intake, although associated with hypertension in population studies, is now considered to play no part in pathogenesis.

Obesity

Fat people have higher blood pressures than thin people. This is not merely a consequence of cuff artefact, which is the tendency to overestimate blood pressure in fat arms when small cuffs are used, because the relation persists after correcting for arm circumference. Most studies have used body mass index (normal range 20 to 25kg/m^2) as a measure of obesity, although it is probable that high blood pressure correlates more closely with an android (apple-shaped) rather than a gynoid (pear-shaped) fat distribution. This suggests that at least some of the association between blood pressure and obesity is due to sex hormones, which are an important determinant of these body features.

Epidemiologically there is an association between high blood pressure, obesity, impaired glucose tolerance, and dyslipidaemia (particularly low high-density lipoproteins with high triglycerides). The possibility that obesity causes insulin resistance which leads in turn to the other metabolic disturbances in the so-called insulin resistance syndrome is the subject of a great deal of research, and may explain why fat people are more prone to heart disease. The cause and effect relationship between obesity and hypertension has been confirmed in randomized trials, which show that blood pressure falls when hypertensive obese patients are given calorie restricted diets. The degree of blood pressure reduction is variable, but a 1mmHg fall in diastolic blood pressure for each kilogram reduction in body weight might reasonably be anticipated from the data in these trials.

Alcohol

Epidemiological data have consistently shown an association between alcohol intake and blood pressure, while intervention trials confirm that blood pressure falls when alcohol is withdrawn from heavy drinkers. Moderate drinking (2 to 3 units daily where 1 unit is equivalent to 8 to 10g of ethanol) does not appear to exert a pressor effect, and is likely to be beneficial in coronary heart disease. The mechanism of the pressor effect in heavy drinkers is unknown. In a prospective study of 490000 men and women in the United States, the relative risk of death from cardiovascular disease in moderate drinkers compared with non-drinkers was 0.7 for men and 0.6 for women.

Salt

The role of dietary sodium intake in the pathogenesis of essential hypertension, and of dietary sodium restriction in its treatment, is probably more controversial now than it was at the time of the last edition of this textbook. The failure to observe a rise in blood pressure with ageing and the absence of essential hypertension in some non-Westernised cultures has been attributed to very low sodium intake. However, there are other reasons why blood pressure in primitive societies may differ from blood pressure in the United Kingdom, United States, and Europe. Opinions on the merits or otherwise of sodium restriction are similarly polarized.

Those who favour the sodium hypothesis point to the results of randomized controlled trials of sodium restriction in hypertensive subjects. These suggest that sodium intake can be halved to less than 100mmol/day with a fall in blood pressure of approximately 4/2mmHg, leading to a worthwhile reduction in the number of individuals requiring antihypertensive therapy. By contrast, those who argue against the sodium hypothesis can claim that a systolic pressure reduction of less than 1mmHg in normotensive subjects does not support a general recommendation to reduce sodium intake; and that a low sodium diet may have adverse effects on plasma renin, aldosterone, noradrenaline, total cholesterol, and low-density lipoprotein cholesterol.

Ultimately the health effects of a low sodium diet will only be resolved by trials relating nutrition to morbidity and mortality. Until such time as these have been completed, public policy recommendations regarding sodium intake for the general population should probably be withheld. Moderate salt restriction can still be recommended as a supplementary therapy in hypertensive individuals requiring drug treatment.

Fetal and infant growth

Babies who are small at birth have higher blood pressures during adolescence and are more likely to be hypertensive as adults. The relationship strengthens with advancing age such that subjects in their 60s show a decrease of approximately 5mmHg for every 1kg increase in birth weight. This has been interpreted as evidence that differences in blood pressure are initiated *in utero* and then amplified during adult life, and may explain a number of important clinical findings, including the higher prevalence of hypertension in black individuals, who are more likely to have small babies than white individuals, and also the increased risk of coronary heart disease seen in adults of low birth weight. For further discussion of this and similar issues see Chapter 15.4.1.1.

Psychosocial stress

It is well known that acute stress can raise blood pressure acutely—the act of taking blood pressure for example can increase systolic by up to 75mmHg—and it has long been suspected that chronic stress may be a risk factor for hypertension. However, the role of chronic stress has been difficult to assess, partly because stress means different things to different people, and partly because stress is not easy to measure.

Recently, using sophisticated measures of assessment including ambulatory monitoring, it has been shown that in men, but not in women, job strain is associated with an elevated blood pressure, not only at work but also while at home and during sleep. Job strain is defined here as the result of a highly demanding job with low control, as in a shop-floor worker. Subjects in demanding jobs who are able to exert control over their work patterns (e.g. doctors !), do not show the same elevation of blood pressure. The effect of job strain on blood pressure is independent of other environmental influences, and is as strong as that of obesity.

Blood pressure control mechanisms

The third components of the triad leading to essential hypertension are the blood pressure control mechanisms. Necessarily, these become involved as hypertension develops. The challenge for the researcher is to know whether abnormalities of the regulatory mechanisms are cause, consequence, confounder, or coincidental change. By comparison with our knowledge of environmental influences, this is an area fraught with difficulty.

Importance of the kidney

Transplantation experiments in genetically hypertensive rats, and observations following renal transplantation in humans, suggest that hypertension must result at least in part from renal mechanisms. For example, if a kidney from a genetically hypertensive rat is given to a control rat then that animal develops high blood pressure. Conversely, transplantation of a control kidney into a genetically hypertensive rat prevents the development of hypertension. Further studies have suggested that the genetic abnormality in the kidney expresses itself as a difficulty in handling sodium.

The resistance vessels

Blood pressure (BP) is a haemodynamic variable that depends on two other haemodynamic factors— cardiac output (CO) and total peripheral resistance (TPR), where BP = CO × TPR. The hallmark of essential hypertension is increased peripheral resistance with a normal cardiac output, and because of this any discussion on the pathogenesis of essential hypertension must centre on the resistance vessels. These are not the large arteries or capillaries, but the small arterioles.

The walls of small arterioles contain smooth muscle cells that respond to both circulatory and local hormonal influences, and to neural input through the sympathetic nervous system (Fig. 6). There is evidence that increased pressure within these small vessels leads to structural changes in vascular morphology, particularly an increase in the ratio of media thickness:lumen diameter. Recent data suggest this occurs mainly as a result of vascular remodelling (the rearrangement of existing material around a small lumen) and to a lesser extent by myocyte hypertrophy.

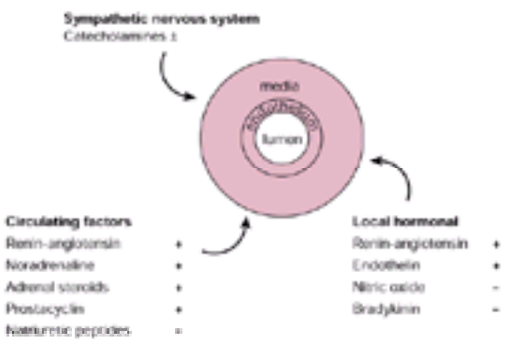

Fig. 6 Arteriolar tone is determined by circulatory and local hormonal influences, also by neural input through the sympathetic nervous system. + vasoconstriction, - vasodilation.

The possibility that these structural changes might act as vascular amplifiers in the hypertensive circulation, both contributing to and maintaining the rise in pressure, has been the subject of much debate. While undoubtedly attractive, the amplifier theory is not supported by results of studies that show no increase in pressor responsiveness when vasoconstrictor stimuli are infused into chronically hypertensive rats; or by restoration of normal pressure in rats when a pressor stimulus is

withdrawn, before structural changes have reversed. The clinical significance of the structural changes in small blood vessels is therefore uncertain.

Atrial natriuretic peptides

A bewildering number of homeostatic mechanisms interact in a complex fashion to maintain blood pressure and adjust it in response to changing circumstances. Atrial natriuretic peptide (**ANP**) is one of a family of natriuretic peptides whose other members are brain natriuretic peptide (**BNP**) and C-type natriuretic peptide (**CNP**). ANP is secreted primarily by the right atrium when the atrial wall is stretched. BNP was identified initially in the brain but is also present in the ventricles and circulates in the blood at approximately one-fifth of the plasma level of ANP. CNP is produced by vascular endothelial cells and in the kidney.

The actions of ANP, which are mediated by its attachment to a specific receptor on the cell membrane, the natriuretic peptide receptor A, include natriuresis, diuresis, decreased secretion of renin and aldosterone, vasodilatation, and a modest fall in blood pressure. These effects raise the possibility that ANP may be involved in the development and maintenance of high blood pressure in essential hypertension. ANP is indeed implicated in the regulation of arterial pressure, but a lack of ANP is unlikely to be the cause of essential hypertension. From a therapeutic viewpoint, however, it is now possible to reduce blood pressure using a new class of drugs that combine neutral endopeptidase inhibition (which blocks the breakdown of ANP) and ACE inhibition.

Endothelial-based systems

The endothelium is known to play an important role in the regulation of vascular tone. Endothelial cells form nitric oxide from L-arginine via the activity of nitric oxide synthase. Nitric oxide, formally known as endothelium-derived relaxing factor or EDRF, is a powerful local vasodilator that also inhibits platelet aggregation and vascular smooth muscle cell proliferation. The action of nitric oxide is opposed by endothelin, a powerful vasoconstrictor peptide also secreted by endothelial cells, and a host of other vasoconstrictor influences. For further discussion see Chapter 15.1.1.2.

Using an analogue of arginine called L-NMMA which inhibits the action of nitric oxide synthase, it has been possible to show a decrease in nitric oxide production in the vasculature of patients with high blood pressure. However, the evidence suggests this is more likely to be a consequence than a cause of hypertension in humans. Equally, the demonstration that endothelin receptor antagonists reduce blood pressure does not prove that an excess of endothelin is the cause of hypertension.

Renin–angiotensin systems

Renin is an enzyme produced by the juxtaglomerular apparatus of the kidney in response to falls in renal perfusion pressure, sodium depletion, and increased sympathetic nerve activity. Renin acts on its substrate angiotensinogen to produce the decapeptide angiotensin I, which in turn is cleaved by angiotensin-converting enzyme to give angiotensin II. Angiotension II is the effector component of the system, with a number of important actions on blood vessels (contraction), heart (hypertrophy), kidney (glomerulosclerosis), and drenal cortex (release of aldosterone). In health, aldosterone feeds back on the kidney to cause sodium retention and potassium excretion, and in this way homeostasis is maintained (Fig. 7).

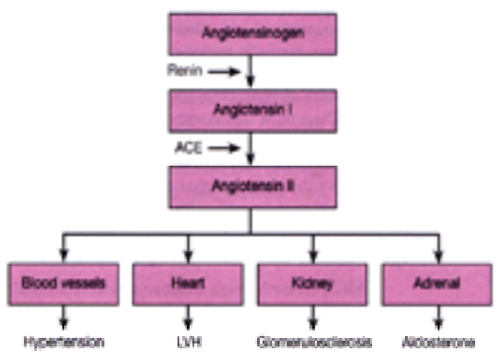

Fig. 7 The renin–angiotensin system.

Recent interest in the renin–angiotensin system has focused on the demonstration that renin may be synthesized in a number of tissues apart from the kidney, including adrenal, heart, the blood vessel wall, and brain. Tissue renin–angiotensin systems have been implicated in the regulation of mineralocorticoid secretion by the adrenal cortex, left ventricular hypertrophy, resistance vessel hypertrophy, and central nervous control of blood pressure.

The role of the renin–angiotensin system in the pathogenesis of essential hypertension is unclear. Plasma renin levels vary widely in essential hypertension from low (30 per cent), to normal (50 per cent), to high (20 per cent). Hypertensive individuals with low renin are usually considered to have volume-dependent hypertension (that is their renin levels are suppressed), whereas high renin in hypertensive individuals may reflect increased levels of sympathetic nervous system activity. Black individuals and the elderly have a high prevalence of low renin hypertension, which may be the reason these groups respond best to diuretics. In everyday clinical practice, however, baseline renin measurements are hardly ever requested or needed.

Sympathetic nervous system

The sympathetic nervous system is known to be involved in the regulation of arteriolar resistance (Fig. 6), also of cardiac output, renin release by the kidney, and catecholamine and mineralocorticoid release by the adrenal gland, and as such might reasonably be expected to have a role in the pathophysiology of essential hypertension. There is no evidence however of sustained overactivity of the sympathetic nervous system in essential hypertension, and even though drugs that block the sympathetic nervous system can lower blood pressure, this does not prove that overactivity of the system is the cause of the disease. In summary, it seems unlikely that a defect in any one of the regulatory mechanisms is directly responsible for the rise in blood pressure in essential hypertension. More probably essential hypertension is a consequence of interactions between several mechanisms, the exact nature of which remain to be determined.

15.16.1.2Genetics of hypertension

N. J. Samani

Historical perspective

The concept that genetic factors may be involved in causing hypertension goes back more than two hundred years and predates the ability to measure blood pressure. In 1769, Morgagni observed that the father of a patient who had died of cerebral haemorrhage had himself died of 'apoplexy' (stroke). The history of the genetics of hypertension is marked by a celebrated debate in the 1950s and 1960s between Platt and Pickering, two doyens of British medicine. On the basis of a finding of a bimodal distribution of blood pressures in some families of patients with hypertension, and evidence of hypertension transmitted over three generations in a few pedigrees, Platt argued that hypertension was a distinct genetic disorder with a likely autosomal dominant mode of inheritance. By contrast, Pickering and colleagues showed that in the general population there was no obvious discontinuity of blood pressure distribution and that the familial resemblance of blood pressure spanned the whole range of blood pressures, and was not different for those with hypertension. Thus, Pickering argued that blood pressure, like height and weight, was a quantitative trait, and that although there was a significant genetic contribution, this was polygenic and that hypertension represented one extreme of the trait but was not a distinct disorder, except perhaps for rare monogenetic forms embedded in the blood pressure distribution curve. Today, the overwhelming mass of evidence supports the Pickering concept.

Genetic epidemiology of blood pressure

The extent of familial aggregation of blood pressure has been studied in diverse ethnic groups living in different places, ranging from Polynesians to Middle Americans. A remarkably consistent level of correlation of around 0.2 between first-degree relatives has been found, that is, if the blood pressure of one member of the family deviates from the norm by +10 mmHg, the first-degree relative will deviate +2 mmHg on average. Studies in children and infants suggest that the familial resemblance in blood pressure starts very early and is maintained throughout the rest of life.

Attempts to partition the familial resemblance of blood pressure between shared genes and shared environment have been made through studies of adoptees and twins. In the Montreal Adoption Study, correlations between natural siblings compared with adoptive siblings and between parents and natural children compared with parents and adopted children were at least twice as great. Similarly, several studies have documented much higher correlations in blood pressure between monozygotic twins (0.55 to 0.85) compared with dizygotic twins (0.25 to 0.50), although the results from twin studies have to be viewed with some caution as there is substantial evidence of excess sharing of sociocultural environments by twin pairs, especially monozygotic twins.

However, taken together the epidemiological data suggest that genetic factors account for about 30 to 35 per cent of the population variability of blood pressure, common household environment for about 10 to 15 per cent, and non-familial factors for the remaining 50 to 55 per cent.

Genetic predisposition to hypertension

Although determination of familial correlations of blood pressure provides an overall view of the impact of heredity in determining blood pressure, a more relevant measure of the importance of genetic factors in determining susceptibility is relative risk. This is the ratio of the risk of an individual developing the condition given its presence in a first-degree relative compared with the overall population risk. For relatively rare monogenetic conditions such as cystic fibrosis, relative risk is as high as 500. For common and complex polygenic disorders, relative risk tends to be much lower. For hypertension, relative risk estimates vary between 2 and 5 depending on the criteria used to define family history. Values are highest when both parents have hypertension before the age of 55 years.

Apart from the increased familial risk, two other observations provide support for an important contribution of genetic factors in the pathogenesis of hypertension. First, spontaneous as well as salt-dependent hypertension can be inbred into animal strains. Second, there are a number of rare monogenetic forms of hypertension and hypotension, where the presence of a single defective gene is sufficient to cause altered blood pressure (Table 1). The molecular basis of several of these disorders has now been elucidated.

Mendelian forms of hypertension

Hypertension and hypokalaemia are features of 11b-hydroxylase and 17b-hydroxylase deficiency—two rare recessive gene disorders of adrenal steroid-synthesizing enzymes that, among others, cause congenital adrenal hyperplasia (see Chapter 12.7.2). 11b-Hydroxylase deficiency usually presents in infancy or early childhood with virilization of both sexes, while presentation of 17b-hydroxylase deficiency may be delayed until adolesecence or adulthood. Hypertension due to a phaeochromocytoma may also be a feature of multiple endocrine neoplasia type 2 (Sipple's syndrome), which when familial is inherited in an autosomal dominant pattern, or rarely be a feature of neurofibromatosis (von Recklinghausen's disease).

Apart from these conditions, several other mendelian disorders (glucocorticoid remediable aldosteronism, syndrome of apparent mineralocorticoid excess, Liddle's and Gordon's syndromes) where hypertension is the predominant manifestation have now been characterized at the molecular level. Although diverse in their molecular basis, all of them, interestingly, impact ultimately on the homeostatic role of the kidney in maintaining sodium balance.

Glucocorticoid-remediable aldosteronism (GRA)

GRA is a form of mineralocorticoid hypertension. It is inherited in an autosomal dominant fashion. The hypertension is accompanied by hypokalaemia (not invariably), a tendency to metabolic alkalosis, an elevated plasma aldosterone level, and a suppressed renin level. The hypertension often responds to thiazides or spironolactone. Patients are usually suspected of having primary aldosteronism (Conn's syndrome), although the age of onset, usually in the first two decades of life, is younger than typical of primary aldosteronism. The two hallmark features of GRA are the presence of large amounts of two abnormal steroids—18-hydroxycortisol and 18-oxocortisol—in the urine, and the paradoxical response of the hypertension, with return of plasma aldosterone to a normal level and disappearance of the abnormal steroids following treatment over a few days with a low dose of exogenous glucocorticoid, such as 0.5 to 1.0 mg of dexamethasone per day (hence the name).

The molecular basis of GRA was solved by Lifton and coworkers in 1992. Patients with GRA have a chimeric gene due to an unequal crossing-over event at meiosis between two adjacent and highly homologous genes involved in adrenocorticosteroid synthesis—aldosterone synthase (CYP11B2) (involved in aldosterone synthesis and normally regulated by angiotensin II) and 11b-hydroxylase (CYP11B1) (involved in glucocorticoid synthesis and normally regulated by ACTH). In the chimeric gene, the regulatory elements of CYP11B1 have become attached to the aldosterone synthase coding region of CYP11B2 (Fig. 1(a)). Thus, the gene produces

aldosterone (and the other abnormal hormones), but under the control of ACTH and hence is suppressible by glucocorticoids, thereby explaining the clinical behaviour.

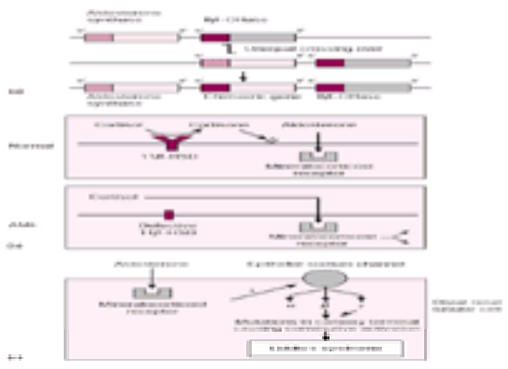

Fig. 1 Mechanisms underlying three forms of monogenetic hypertension. (a) Glucocorticoid-remediable aldosteronism—In GRA an unequal crossing-event leads to a chimeric gene where the coding region of aldosterone synthase (light pink bar) becomes attached to the regulatory region for 11b-hydroxylase (magenta bar). The chimeric gene produces excess amounts of aldosterone under the regulation of ACTH. (b) Syndrome of apparent mineralocorticoid excess—Normally, the mineralocorticoid receptor in the distal renal tubule is protected from stimulation by cortisol by the activity of the 11b-hydroxysteroid dehydrogenase enzyme. In AME, mutations in the enzyme allow cortisol to gain access to the receptor. (c) Liddle's syndrome—The trimeric epithelial sodium channel mediates sodium reuptake in the distal renal tubule under regulation by the mineralocorticoid receptor. In Liddle's syndrome, mutations in the b- and g-subunits of the channel render the channel constitutively active.

Syndrome of apparent mineralocorticoid excess (AME)

AME is an autosomal recessive disorder that usually presents in childhood with hypertension, hypokalaemia, and low renin activity. Despite the clinical features of mineralocorticoid excess, levels of all known mineralocorticoid hormones are low, yet the hypertension responds to spironolactone or amiloride. Patients with the disorder cannot metabolize cortisol to its inactive metabolite cortisone normally, resulting in a prolonged half-life of cortisol and a characteristic increase in urinary cortisol compared with cortisone metabolites.

Elucidating the defect causing AME first required the solution of another paradox—why cortisol, which circulates at a level several-fold greater than aldosterone, does not overwhelmingly activate the renal mineralocorticoid receptor *in vivo*, despite the two having equal affinity *in vitro* for the receptor. The reason relates to the enzyme 11b-hydroxysteroid dehydrogenase (**11b-HSD**), which has two isoforms. Type 1 11b-HSD is located in the liver, adipose tissue, and gonad and converts cortisone to cortisol. Type 2 11b-HSD is expressed in the mineralocorticoid target tissues—kidney, colon, and salivary gland—and inactivates cortisol to cortisone. In the kidney, the enzyme plays the crucial role of protecting the mineralocorticoid receptor on the distal tubule from activation by cortisol. In subjects with AME, a variety of disabling mutations in the type 2 11b-HSD gene cause a deficiency of the enzyme, allowing cortisol access to the mineralocorticoid receptor (Fig. 1(b)).

AME resembles the syndrome observed in subjects ingesting large amounts of liquorice or taking the now redundant antiulcer drug carbenoxolone. Both liquorice and carbenoxolone contain glycyrrhetinic acid, which inhibits type 2 11b-HSD. This, therefore, explains the hypertension and hypokalaemia observed with these compounds. Spillover access of cortisol to the mineralocorticoid receptor may also, at least in part, explain the hypertension accompanying some forms of Cushing's syndrome and glucocorticoid resistance.

Liddle's syndrome

Liddle described a family in which the siblings were affected by early-onset hypertension and hypokalaemia, but with low renin and aldosterone levels. The clue to the nature of the molecular defect underlying this autosomal dominant disorder came from the observation that the hypertension does not respond to spironolactone, the mineralocorticoid receptor antagonist, but does respond to direct inhibitors (such as triamterene or amiloride) of the epithelial sodium channel which mediate the effects of activation of the mineralocorticoid receptor. This indicated that the defect lay downstream of the mineralocorticoid receptor, and Lifton and coworkers subsequently showed that the syndrome arises due to activating mutations in the b- or g-subunits of this trimeric channel (Fig. 1(c)). All mutations identified so far cause an alteration or deletion of a proline-rich (PY) motif in the carboxy-terminal cytoplasmic tails of the subunits. This motif is necessary for regulatory proteins such as Nedd4 to bind and internalize the channel, and when its function is impaired the channel remains constitutively active at the cell surface.

Gordon's syndrome

Pseudohypoaldosteronism type II (PHA-II, also known as Gordon's syndrome), is an autosomal dominant disorder characterized by hyperkalaemia despite normal renal glomerular filtration, hypertension, and correction of physiological abnormalities by thiazide diuretics. Mild hyperchloraemia, metabolic acidosis, and suppressed plasma renin activity are variable associated findings. Genes for PHA-II have been mapped in different families to chromosomes 17, 1, and 12. Recently, the causative genes on chromosomes 12 and 17 have been identified as two members, WNK1 and WNK4, of the WNK family of serine-threonine kinases. Both proteins localize to the distal nephron and gain-of-function mutations are thought to be responsible for causing the abnormalities, although the precise mechanisms leading to the disturbance in electrolyte transport remain to be determined.

Other monogenetic forms of hypertension

A missense mutation in the ligand-binding domain of the mineralocorticoid receptor (MR) has been found to cause an autosomal dominant form of hypertension that is markedly accelerated in pregnancy. The mutation, MR S810L, causes partial, aldosterone-independent, activation of the receptor, causing carriers to develop hypertension before age 20. More interestingly, compounds such as progesterone that normally bind but do not activate MR are all potent agonists of the mutant receptor. Since pregnancy is accompanied by a 100-fold rise in progesterone, MR S810L carriers have dramatic acceleration of hypertension during pregnancy. Although the MR S810L mutation is extremely rare, the finding does raise the question of whether related mechanisms may underlie other forms of hypertension in pregnancy.

A gene causing autosomal dominant hypertension in conjunction with type E brachydactyly in a large Turkisk kindred has been mapped to chromosome 12p. The hypertension in this syndrome, unlike most of the disorders described above, closely resembles essential hypertension with no evidence of volume expansion or electrolyte imbalance. Elucidation of the genetic defect is keenly awaited.

Genetic defects causing hypotension

Just as single-gene disorders have been identified that cause hypertension, a number of mendelian syndromes where hypotension is a feature have recently been characterized at a molecular level (Table 1). Many are mirror images of the genetic abnormalities causing the mendelian forms of hypertension described above. Pseudohypoaldosteronism type 1 (PHA-I) occurs in two forms, autosomal recessive and autosomal dominant. Both are characterized by life-threatening dehydration in the neonatal period, hypotension, salt wasting, hyperkalemia, metabolic acidosis, and marked elevation of renin and aldosterone. The autosomal recessive form is due to inactivating mutations (compare with Liddle's syndrome) in any of the subunits of the epithelial sodium channel, while the autosomal dominant form is due to loss-of-function mutations in the mineralocorticoid receptor.

Gitelman's syndrome is also an autosomal recessive disorder. It is characterized by hypotension, neuromuscular abnormalities, hypokalaemia, metabolic alkalosis, and an activated renin–angiotensin system. It arises due to inactivating mutations in the gene encoding the renal thiazide-sensitive NaCl cotransporter.

Bartter's syndrome is distinguished from Gitelman's syndrome by hypercalciuria and presentation in the neonatal period with life-threatening hypotension. This

disease is caused by mutations in one of several genes that are required for normal salt absorption in the thick ascending loop of Henle.

Does my patient have a recognized form of monogenetic hypertension?

Finding that a patient has GRA, AME, Liddle's syndrome, or Gordon's syndrome has important consequences for treatment (see above) and family screening. However, all of these syndromes are extremely rare and suspicion will usually go unrewarded. Phenotypic expression is highly variable. Features that may suggest a diagnosis of mendelian hypertension include a young age of onset, moderate to severe hypertension, strong family history, and electrolyte abnormalities, particularly of potassium (although this is not invariable). A good starting point is the measurement of plasma renin activity (suppressed in all three syndromes) and plasma aldosterone. If the aldosterone is significantly elevated then the differential diagnosis lies between the various forms of Conn's syndrome and GRA. Diagnosis of GRA would be supported by the finding of elevated 18-hydroxycortisol and 18-oxocortisol in the urine, and can now be relatively easily confirmed by finding a chimeric gene fragment with DNA testing. If the aldosterone level is suppressed, then finding an increased ratio of cortisol/cortisone metabolites in the urine would support a diagnosis of AME. The presence of hyperkalaemia, hyperchloraemia, and metabolic acidosis would suggest a diagnosis of Gordon's syndrome. No biochemical abnormalities specifically support a diagnosis of Liddle's syndrome. Ultimately, diagnosis of AME, Liddle's syndrome, and Gordon's syndrome also requires DNA confirmation, but this is not as straightforward as it is with GRA since several different mutations can give rise to each syndrome.

Progress towards identifying genes that increase susceptibility to essential hypertension

The genetic contribution to essential hypertension (and the population variability in blood pressure) is polygenic. However, little is known about the number of genes involved, their mode of transmission, their quantitative effect on blood pressure, their interaction with other genes, or their modulation by environmental factors. Further, the impact of genetic factors may be dependent on age, gender, and ethnicity, and may only influence specific blood pressure phenotypes such as systolic or diastolic blood pressure. Such complexities have contributed to the difficulty in elucidating the genetic basis of essential hypertension.

Despite evidence that the same genes that increase susceptibility to essential hypertension most likely also contribute to normal blood pressure variation, much of the work to date has focused on the former. Two main approaches have been used: (i) association studies in which the frequency of specific alleles are compared in hypertensive and normotensive subjects, (ii) sibling-pair linkage studies, which test whether specific alleles or markers are shared more often by hypertensive sibling pairs than would be expected by chance. Association studies are most suited to study candidate genes, while with affected sibling pairs the whole genome can also be scanned using anonymous microsatellite markers to identify areas of linkage.

Association studies

Variants in over 30 candidate genes have been associated with hypertension (MEDLINE search under hypertension x genetics), although for the majority the findings are as yet far from robust. However, data for a number of genes are sufficiently persuasive, or otherwise interesting, to merit specific mention.

Angiotensinogen

Cleavage of angiotensinogen (**AGT**) by renin is the rate-limiting step in the generation of angiotensin II, the effector molecule of the renin–angiotensin system. Evidence for the involvement of the AGT gene comes from both linkage of the AGT locus to hypertension in Caucasian and Afro-Carribean hypertensive sibling pairs and association of a polymorphism (M235T) in the gene with hypertension. In a meta-analysis of 32 case–control studies corresponding to 13 760 patients, the TT genotype conferred a 31 per cent increased risk of hypertension compared with the MM genotype. Other estimates suggest that mutations in the AGT gene might be predisposing factors for hypertension in 3 to 6 per cent of subjects with onset before the age of 60. Data showing that the TT genotype is also associated with higher plasma and possibly tissue AGT levels, with its potential impact on angiotensin generation, provides a plausible explanation for the association of the AGT gene with hypertension.

Angiotensin- converting enzyme

Angiotensin converting enzyme (ACE) cleaves angiotensin I to form the vasoactive peptide angiotensin II. A common variant in the ACE gene, the insertion/deletion (I/D) polymorphism, is strongly associated with differences in plasma ACE levels. Although initial linkage and association studies were negative, recent analyses have shown significant association of the I/D polymorphism with blood pressure at least in males. Given the widespread and increasing use of ACE inhibitors and angiotensin receptor antagonists in treating hypertension and related cardiovascular diseases, these observations, if confirmed, could have pharmacological implications.

a-Adducin

Adducin is a ubiquitous a/b heterodimeric cytoskeletal protein that promotes the assembly of actin with spectrin. In the Milan hypertensive rat, point mutations in the adducin a- and b-subunits affect actin assembly and Na–K pump activity and possibly explain up to 50 per cent of the blood pressure difference compared with the Milan normotensive rat. In humans a polymorphism changing glycine for tryptophane at codon 460 in the a-adducin gene has been found to be more common in individuals with hypertension in Italian, French, and Japanese populations, although other studies have not shown an association. More persuasive are data showing a direct functional impact of the 460Trp variant. In an acute salt-sensitivity test, where change in blood pressure from a state of salt-loading to one of salt-depletion was measured, hypertensive individuals heterozygous for the 460Trp allele had a much greater decrease in mean arterial pressure than hypertensive individuals homozygous for the 460Gly allele (15.9 [SE 2.0] compared with 7.4 [SE 1.3] mmHg). Similarly, heterozygous hypertensive individuals showed a much greater fall in mean arterial pressure in response to 2 months' treatment with hydrochlorthiazide than did 460Gly homozygote individuals (14.7 [2.2] compared with 6.8 [1.4] mmHg). Consistent with these observations, the 460Trp variant was associated with a reduced-slope (more salt sensitive) pressure–natriuresis curve. Further confirmation is required, but these findings suggest that variation at the adducin locus may contribute to salt sensitivity and through it to susceptibility to hypertension in some populations.

G protein b3 subunit

Increased activity of the pH-regulating transporter system, the sodium-proton exchanger, is seen in some patients with essential hypertension. Siffert and coworkers found that this was due to enhanced intracellular signal transduction via pertussis toxin-sensitive heterotrimeric G proteins. Sequencing revealed a polymorphism (C825T) in the gene encoding the b3 subunit (GNB3), which although itself silent, appears to cause a biologically active splice variant, Gb3-s, missing 41 amino acids in those carrying the T allele. In an initial study of 426 hypertensive and 427 normotensive subjects, there was a significant association of carriage of the T allele with hypertension (53 compared with 44 per cent). In a further study, where hypertensive subjects were recruited on the basis of a very strong family history of premature hypertension affecting both parents, the association of hypertension with the T allele was even stronger. These early findings suggest that in some patients hypertension may be related to inherited dysfunction of G proteins.

Epithelial sodium channel

Attempts to show that less severe mutations in the genes responsible for monogenetic forms of hypertension (see above) may underlie essential hypertension have by and large met with disappointment. One exception may be the epithelial sodium channel involved in Liddle's syndrome, where a variant in the C-terminus of the b-subunit (T594M) was found to be four times more frequent in hypertensive black subjects resident in London compared with normotensive black subjects (8 compared with 2 per cent). Subjects carrying the mutation demonstrate increased activity of the nasal epithelial sodium channel (a possible surrogate marker of the renal channel) and lower plasma renin activity, supporting the notion of increased sodium reabsorption and volume-dependent hypertension. In turn, this could at least partly explain the generally poor response of black hypertensive subjects to angiotensin-converting enzyme inhibitors.

Epistatic interactions

Current findings (see above) suggest that individually, gene variants will, at best, only contribute a small amount to the risk of hypertension. Interest is therefore turning to additive and epistatic interactions. There are only a few publications, but in one recent study by Staessen and coworkers, possession in combination of the ACE DD genotype, the a-adducin Trp allele, and the aldosterone synthase CC genotype (at the –344C/T polymorphism), increased the risk of developing hypertension by 252 per cent compared with other genotypes. Over a median follow-up of 9.1 years the cumulative incidence rates for hypertension were 71.0 cases

per 1000 person-years in those carrying the three risk genotypes compared with 20.2 cases per 1000 person-years in those without. If confirmed, the findings could have implications for prediction and primary prevention

Linkage studies

These have lagged behind association studies. However increasing numbers are being reported. The most consistent data have been found for a region on chromosome 17 where linkage has been found, not only to hypertension analysed as a qualitative trait in a panel of French and United Kingdom affected sib pairs (Julier and coworkers), but also to blood pressure analysed as a quantitative trait in subjects from the Framingham Heart Study (Levy and coworkers). Involvement of a gene in this region in blood pressure regulation is further supported by the fact that the syntenic interval is also linked to blood pressure in several strains of genetically hypertensive rats. Interestingly, the region overlaps with the chromosome 17 locus for Gordon's syndrome where a mutation in the WNK4 gene has recently been identified to be the cause. Whether other mutations in WNK4 are responsible for the reported linkage to essential hypertension and blood pressure variability remains to be determined.

Future perspectives

Recent progress suggests that in the next few years much more will be understood about the nature of individual genetic factors that influence susceptibility to hypertension and the environmental/genetic context in which they exert their effect on blood pressure. It may prove possible to sub-categorize patients with essential hypertension on the basis of molecular mechanisms. Although this information will not help with diagnosis (we already have an accurate tool– the sphygnomanometer), there could be several important applications. Preventive measures, such as salt restriction, could be better targeted if findings, for example with a-adducin, are confirmed. The information would almost certainly influence choice of antihypertensive medication (pharmacogenetics). Several studies have shown that individuals show significant variation in their response to different classes of antihypertensive agents. At present the choice of drug is largely empirical. The early findings with a-adducin and the epithelial sodium channel gene illustrate how the presence of a particular genetic variant could influence this choice. Finally, there is increasing experimetal as well as some clinical data to show that genetic factors not only contribute to the development of hypertension but also influence the development of end-organ damage. The ultimate goal of hypertension management is not just to lower blood pressure but to prevent complications, and strategies based on a more refined assessment of risk will undoubtedly be more cost-effective.

Pathology

Introduction

High blood pressure induces changes in the heart and blood vessels. These are partly the direct effect of cyclic stress on the arterial wall and also due to indirect trophic effects. In addition, turbulence and shear stress influence endothelial function. Secondary changes may then occur in the organs served by these vessels, giving rise to the clinical features of hypertension. However, not all the pathological changes observed in the cardiovascular system are the result of pressure (Table 1). Hypertension is associated with risk factors for atheroma such as dyslipidaemia and insulin resistance. Smooth muscle growth is enhanced in some animal models of hypertension, probably as a result of genetic factors. There may be other cellular influences at work. Most of the powerful vasoconstrictors such as angiotensin II, catecholamines, vasopressin, and endothelins are also mitogens and may therefore have trophic effects.

Blood vessel changes

Aorta and large arteries

Recurrent pulsatile stress produces uncoiling, disruption and calcification of elastic fibres. At the same time, relatively inelastic collagen is increased. This is a result of ageing as well as hypertension: both processes therefore cause loss of the normal elastic reservoir function of the aorta and large arteries. The effects are additive, so that changes occur at an earlier age in hypertensive than in normotensive subjects. Another reason for the loss of arterial compliance in hypertensive patients is that, as pressure increases, the elastic fibres become fully stretched, causing the inelastic collagen fibres to bear the load. As a result of these changes, the pressure wave generated by left ventricular contraction is no longer buffered by the aorta and proximal arteries, but is transmitted into the arterial tree with greater amplitude. This is manifested clinically as increased pulse pressure, with higher systolic and lower diastolic pressures. In addition, loss of compliance produces increased pulse wave velocity. Pulse waves are reflected back from peripheral sites, normally returning in late diastole as a secondary wave visible on the aortic trace. When the arterial tree is stiffened the return of these waves amplifies the aortic late systolic wave. This is not demonstrable when brachial artery pressure is measured, but throws an additional load on the left ventricle. In addition, lower diastolic pressure reduces coronary artery perfusion.

Large artery changes in hypertension were ignored for many years. However, it is now clear that pulse pressure is an important risk factor in cardiovascular disease. This explains one curious feature of elderly hypertensive patients. Diastolic blood pressure in patients with isolated systolic hypertension is inversely related to prognosis, that is, for any given systolic blood pressure, the lower the diastolic, the worse the risk.

Decreased compliance of the large arteries also has an important effect on the carotid and aortic baroceptors which normally buffer rapid changes in blood pressure. These become less sensitive. As a result, circulatory adaptation to rapid changes in posture may be impaired. This rarely causes problems, except in elderly hypertensive subjects, when age and blood pressure have additive effects. The clinical manifestation is as postural hypotension or post-prandial hypotension in elderly patients whose blood pressure has been overtreated.

Medium-sized arteries

These arteries perform a conduit rather than reservoir function, reflected in their lower elastin content. The predominant pathological change is wall thickening caused by increased deposition of collagenous material.

Resistance vessels

The characteristic structural change in the smaller arteries and arterioles responsible for peripheral vascular resistance is an increase in wall:lumen ratio. This has important functional consequences. The vessels can still dilate in response to stimuli such as warmth or drugs, but maximal vasodilatation is reduced. This change is a response to pressure; it can be prevented by protecting vessels from the increased pressure load in hypertension by means of a mechanical constriction. There may be a genetic factor in hypertension which regulates the structural response, the evidence for which is largely based on animal studies.

In recent years it has become clear that what was thought to be a trophic response is largely if not entirely due to rearrangement of smooth muscle cells around a smaller lumen. There is little if any evidence of hypertrophy and no evidence of hyperplasia (i.e. increased number of cells). The mechanism of this is entirely unknown. Local growth factors, such as angiotensin II have been implicated. Thus lowering blood pressure by angiotensin-converting enzyme (**ACE**) inhibition is better at reversing remodelling than lowering it by b-blockade.

Atheroma in hypertension

The increased prevalence of atheroma in hypertensive patients reflects the cumulative effect of several contributory factors. The importance of local mechanical consequences of increased pressure and turbulence on the arterial wall are demonstrated by the distribution of lesions and the absence of atheroma in the pulmonary vessels of hypertensive patients. Endothelial dysfunction is probably the first stage in initiating a complex chain of local cellular processes leading to the formation of the atheromatous plaque. Increased adhesion molecule expression, increased permeability, and cell migration, accumulation, and proliferation are all involved. Most studies in patients with essential hypertension have shown impairment of endothelium-dependent vasodilatation, although animal studies have shown more complex changes in endothelial function.

Systemic factors are also of importance in the development of atheroma in hypertensive patients. Atheroma cannot usually be produced in hypertensive rabbits unless their lipid levels are raised by feeding them cholesterol. A combination of high perfusion pressure above induced aortic constriction and a high cholesterol diet induces atheroma above, but not below the constriction. A low cholesterol diet prevents it. This is analogous to the situation in humans, where the presence of insulin resistance or diabetes in a hypertensive patient further increases the risk of atheromatous complications.

It has also been postulated that the renin–angiotensin system plays a role in atherogenesis. Renin and angiotensin II levels are often raised in severe hypertension and in hypertension associated with increased sympathetic nervous system activity. In laboratory studies angiotensin II enhances the smooth muscle proliferative response observed in atheroma. High renin levels have been shown to be associated with a worse prognosis in some studies, although this finding is still controversial. Since drugs may either block or activate the renin–angiotensin system, this debate has important therapeutic implications which will only be resolved

when the relevant trials report.

Vessels in malignant hypertension

The characteristic pathological lesion in malignant hypertension is fibrinoid necrosis (necrotizing arteriolitis). The normal structure of the vessel wall is lost and replaced with fibrin-like material. A variable cellular reaction takes place. Fibrinoid necrosis is usually associated with focal areas of vasodilatation and increased permeability. These changes are probably a primary mechanical effect. The endothelium of the dilated segments is disrupted and the vessel wall becomes permeable to particles as large as colloidal carbon. The increased permeability permits exudation of plasma into the media and local tissue destruction. The intima may become massively thickened by concentric collagenous rings as a result of locally released growth factors until the lumen is almost obliterated.

Specific organ changes in hypertension

The heart

Angina and myocardial infarction in the hypertensive patient are usually due to coronary atheroma. Coronary perfusion may also be lowered as a result of reduced diastolic pressures in patients with isolated systolic hypertension (see above). In a minority of patients, anginal pain occurs in the absence of significant coronary atheroma ('syndrome X'). A possible explanation is luminal narrowing of the coronary vessels associated with an increased wall:lumen ratio. Other explanations which have been put forward are increased vasomotor tone and increased pressure on the left ventricular wall causing subendocardial ischaemia. The most likely explanation for syndrome X in hypertensive patients is impairment of endothelial-dependent relaxation in the coronary vascular tree.

Left ventricular hypertrophy is demonstrable in about 50 per cent of untreated hypertensive patients when echocardiography is used, and in 5 to 10 per cent with electrocardiography using conventional criteria. Histologically, it is caused by an increase in size of cardiomyocytes with an increase in intercellular matrix. Its role as a powerful independent risk factor for cardiovascular disease and death has led to intensive research into its causes and reversal by treatment. Pressure load on the left ventricle is unquestionably important, as evidenced by the observation that ambulatory monitoring of blood pressure is much better correlated with left ventricular hypertrophy than clinic measurements of pressure. Furthermore, lowering blood pressure consistently produces regression of left ventricular hypertrophy. However, local trophic factors may also play a role. The sympathetic nervous system and renin–angiotensin–aldosterone system have been implicated by both clinical and experimental studies. Meta-analyses of clinical trials in which blood pressure was lowered by different classes of antihypertensive agent have suggested that ACE inhibitors have a greater effect in reversing left ventricular mass, even when other factors such as duration of therapy and degree of blood pressure reduction are taken into account. However, there have been no adequately sized trials in which agents have been formally compared, and this clinically very important possibility still remains to be demonstrated convincingly.

The bad prognosis carried by left ventricular hypertrophy in the hypertensive patient could have several explanations. These include:

1. Arrhythmias—there is increased prevalence of simple and complex ventricular arrhythmias in hypertensive left ventricular hypertrophy;
2. Relative ischaemia produced by increased muscle mass;
3. Decrease in ventricular compliance causing pulmonary oedema; and
4. Ventricular hypertrophy is also a marker for integrated exposure of the circulation to high blood pressure over a prolonged period.

Central nervous system

Cerebral (atherothrombotic) infarction in a hypertensive patient is usually attributable to atheroma of one of the larger cerebral arteries (usually the middle cerebral artery) and accounts for about 80 per cent of the strokes which these patients suffer. Intracerebral haemorrhage accounts for 10 to 15 per cent, usually the result of rupture of a small intracerebral degenerative microaneurysm (Charcot–Bouchard aneurysm). These lesions develop in the small (less than 200 μm diameter) perforating arteries in the region of the basal ganglia, thalamus, and internal capsule. Hyaline degeneration (lipohyalinosis) occurs in the aneurysmal wall with a defect in the media at the neck of the aneurysm. The incidence of Charcot–Bouchard aneurysms is closely correlated with age and blood pressure, the two factors acting additively so that lesions are rarely if ever seen in younger normotensive people. The remaining strokes in hypertensive patients are due to subarachnoid haemorrhage. Transient ischaemic attacks due to disease of extracranial vessels are also more frequent in hypertensive subjects.

More diffuse changes account for the cognitive decline that may occur, particularly in untreated hypertension and in older patients. Functional imaging studies have shown relative reductions in blood flow in parietal and forebrain areas in hypertensive patients during memory tasks and areas of cortical and subcortical hypometabolism. More advanced vascular disease gives rise to multiple, punctate, hyperintense white matter lesions on MRI. These are due to focal ischaemia, either as a result of lipohyalinosis or microatheromatous disease, tortuosity, and narrowing of the perforating arteries. All degrees of impairment of cognitive performance may occur as a result of these lesions, ranging from effects only detectable with sensitive psychometric testing to lacunar strokes and Binswanger's disease.

Hypertensive encephalopathy

The cerebral vessels usually constrict in the face of increased pressure and dilate in the face of decreased pressure to maintain a constant flow (autoregulation). Resistance vessel remodelling and hypertrophy seem to have a protective function in this respect, so that the autoregulatory range is raised in long-standing hypertension. When blood pressure rises above the autoregulatory range, however, focal areas of vasodilatation and localized perivascular oedema and fibrinoid necrosis occur. Focal haemorrhages, ischaemia, and infarction may result, giving rise to the clinical picture of encephalopathy.

The kidney

In non-malignant hypertension, glomerular filtration rate is well preserved. However, filtration fraction is increased since efferent glomerular arteriolar resistance increases more than afferent resistance, causing a rise in intraglomerular capillary pressure. The long-term renal damage produced by glomerular hypertension probably accounts for progressive glomerulosclerosis in essential hypertension. Thus, the decline in glomerular filtration rate with age is more rapid in hypertensive than normotensive subjects. This phenomenon is not usually significant in mild to moderate essential hypertension where endstage renal disease in the absence of any other lesion is unusual.

Hypertension-induced glomerulosclerosis is much more important, however, in severe and malignant hypertension and in the presence of intrinsic renal disease due to (for instance) diabetes or glomerulonephritis. Effective control of blood pressure arrests or retards the process, and acute hypertension-induced renal failure can be partially or completely reversed by early treatment in many cases. Hyaline degeneration is particularly observed in the afferent arterioles of the kidney in association with ageing and hypertension. Involvement of the juxtaglomerular baroceptor may account for the decline in renin secretion which is demonstrable in elderly and hypertensive populations. In malignant hypertension, glomerular hypertension and vascular necrosis produce proteinuria, haematuria, and progressive renal failure.

Atheromatous renal vascular disease much more commonly causes renal impairment in elderly hypertensive subjects than younger patients with treated mild to moderate hypertension.

Clinical features

Symptoms

Elevated blood pressure is usually asymptomatic until organ damage occurs. However, most patients labour under the illusion that any concurrent symptom is attributable to high blood pressure or its treatment. In some cases, the knowledge that a patient has high blood pressure creates a fertile soil for the growth of functional symptoms. Thus, patients who have been told that they are hypertensive have a much higher incidence of headache than hypertensive patients who are unaware of the fact. In some studies, 'labelling' a patient as hypertensive has led to an increased absenteeism from work, although no target organ damage had occurred. It is a common lay fallacy that a patient can recognize when their blood pressure is elevated, usually on the basis of such symptoms as plethoric features, palpitations, dizziness, or a feeling of tension. A screening survey in the United States examined the frequency of such symptoms as headache, epistaxis, tinnitus, dizziness, and fainting in healthy subjects. None of these symptoms was more prevalent in subjects with diastolic blood pressures over 100 mmHg.

In spite of such evidence, it should be borne in mind that target organ damage can occur and may not be clinically obvious. This may be particularly relevant in the elderly patient with diffuse cerebrovascular disease, whose fairly non-specific symptoms may be dismissed. Functional imaging has shown this to be much more frequent than was once believed (see above). Additionally, higher blood pressure levels may be responsible for some symptoms, such as headache.

Headache

The classic hypertensive headache is present on waking in the morning, situated in the occipital region of the head, radiating to the frontal area, throbbing in quality, and wears off during the course of the day. Most headaches in hypertensive patients are tension headaches not directly related to blood pressure at all. The incidence of such symptoms rises when patients become aware of the diagnosis. Nevertheless, effective treatment of hypertension reduces the incidence of headache. How far this is a specific consequence of blood pressure lowering and how far it is due to reassurance is uncertain. Morning headaches in obese hypertensive patients may be due to sleep apnoea.

Epistaxis

Whilst epistaxis is not associated with mild hypertension, it is much more common in moderate to severe hypertension. When patients present with epistaxis and high blood pressure, it is particularly important to dissociate hypertension as a cause of epistaxis from a pressor response to an alarming episode.

Nocturia

This is one of the most frequent clinically apparent consequences of blood pressure elevation resulting from reduction in urine-concentrating capacity.

Impotence

Erectile dysfunction occurs frequently in hypertension, but is usually not spontaneously mentioned by the patient or enquired about by the physician. It is often attributed by both patient and doctor to drug therapy. Although this may be the case with some classes of drug, untreated hypertension has been associated with an increased incidence of erectile dysfunction in the few studies that have specifically addressed this issue. It is probably a consequence of structural change in the peripheral vasculature limiting the capacity for acute increase in penile perfusion.

Symptoms associated with target organ damage

Cardiovascular system

Effort dyspnoea and orthopnoea suggest cardiac failure. Increased left ventricular mass is associated with decreased compliance and impaired cardiac output response to exercise. This is more likely in elderly patients whose cardiac reserves are less. Claudication suggests peripheral atheromatous vascular disease and is usually associated with atheroma elsewhere, such as the renal or carotid arteries. Angina of effort is also usually due to atheroma, although the coronary vascular tree may be free of plaques in a few cases.

Central nervous system

Scotomas suggest fundal haemorrhages or exudates, whilst blurring of vision is associated with papilloedema. These symptoms therefore deserve particular attention. Decline in cognitive performance detectable only by formal psychometric testing is more common than was once believed. It occurs particularly in long-standing untreated hypertension and in the elderly. More clinically apparent failure in concentration and memory may be due to more advanced cerebrovascular disease, depression, or centrally acting antihypertensive drugs. Extensive disease of the perforating arteries may give rise to a lacunar state characterized by progressive pseudobulbar palsy and dementia. The presence or absence of diffuse cerebrovascular disease can have important consequences for the development of dementia in Alzheimer's disease. Patients without such vascular lesions are less likely to show cognitive impairment than those with vascular lesions in the presence of the characteristic pathology of Alzheimer's disease.

Renal system

Haematuria or haematospermia suggest the malignant phase of hypertension in the absence of any other cause. Advanced renal failure in the absence of malignant hypertension suggests bilateral atheromatous renovascular or other forms of renal disease.

Clinical examination

The objectives of clinical examination are to assess blood pressure, any consequences of its elevation, and any associated disease which might modify its treatment.

Blood pressure measurement

Direct blood pressure measurement

The most accurate way to measure blood pressure is by direct arterial cannulation. Portable recording devices enable continuous arterial blood pressure measurements to be made with this technique, which antedates the modern indirect ambulatory devices. The advantages are precision, independence of arterial wall changes, the absence of any 'white coat effect' as a result of cuff inflation, and the ability to observe beat by beat variability in blood pressure and pulse. Until recently, this was not possible with indirect instruments. However, the inconvenience and morbidity caused by indwelling arterial catheters have prevented their use in routine clinical practice. The only role for direct blood pressure measurement by arterial cannulation in essential hypertension is when calcification of the arterial wall in elderly patients is suspected of causing spuriously high systolic blood pressure measurements. It is also used to monitor blood pressure in severely hypertensive patients during parenteral therapy.

Indirect manual measurement

The 'gold standard' for clinical measurement is still the mercury sphygmomanometer, using the Korotkoff sounds. However, concerns about the toxicity of mercury and the greater reliability of more recent electronic devices is now leading to their increasing usage.

The manual auscultatory technique is based upon the sounds described by Korotkoff in 1905 and uses the inflatable air-filled cuff constructed by Riva-Rocci in 1897. The brachial artery is occluded by inflating the cuff above the pressure at which the radial pulse disappears to palpation. Pressure in the cuff is estimated by a mercury or aneroid manometer. The pressure is then slowly lowered through the valve on the inflating bulb, whilst listening for the Korotkoff sounds.

Although frequently employed, auscultatory measurement of blood pressure is often carried out badly: inter- and intraobserver variability is often unacceptably high. Training videos and CDs are available for doctors and nurses and have been shown to improve measurement technique. Important points to note include the following.

Bladder and cuff

If the cuff is too small (usually as a result of an obese arm) inadequate pressure will be applied and blood pressure will be overestimated. The length of the bladder should be at least 80 per cent and the width of the bladder 40 per cent of the arm circumference. The optimal size is 26 × 12 cm for normal-sized arms and 40 × 12 cm for obese arms. Minor overlap of the ends of the bladder on thinner arms does not significantly influence readings.

Manometers

Mercury manometers should be vertical and should read zero when no pressure is applied to the cuff. Aneroid manometers require calibration every few months.

Bulb and tubing

These require checking for significant leaks (i.e. more than 1 mmHg/s) and for smooth working of the valve and inflation systems.

Technique of blood pressure measurement

The patient should be seated or supine and allowed a minimum of 2 to 3 min rest. On initial assessment or when excessive postural falls are suspected, standing pressures should be measured as well. The patient should be relaxed and the arm supported in the horizontal position with the cuff at heart level. The arm should not be constricted by tight clothing. The bladder mid-point should be placed over the brachial artery. Blood pressure should be recorded in both arms on initial examination and the arm found to have the higher pressure subsequently used. Systolic blood pressure is initially determined by palpation and then the stethoscope is lightly placed over the brachial artery and the cuff pressure raised to approximately 30 mmHg above the point at which the radial pulse disappears and then released at the rate of 2 to 3 mm/s. Both systolic and diastolic pressures should be read to the nearest 2 mm mark. The point of disappearance of sounds (Korotkoff phase V) is preferable to the point of muffling (phase IV). The reasons for this are as follows.

1. Direct arterial blood pressure measurements indicate that the phase of muffling is 5 to 10 mmHg higher than actual diastolic pressure. Korotkoff phase V is 3 to 7 mmHg higher.
2. There are fewer observer errors in identifying the disappearance of sounds.
3. Most of the epidemiological data and multicentre trials of treatment used phase V as the criterion for diastolic blood pressure.

In some clinical situations where blood flow through the brachial artery is high (immediately after exercise, in hyperthyroidism, pregnancy, and anaemia), sounds can be detected down to zero cuff pressure. Under these circumstances, the fourth phase should be recorded, with a note of the fact. Blood pressure in infants and neonates should be measured using a small cuff and Doppler ultrasound as a detection device.

Pseudohypertension in elderly people is due to an incompressible brachial artery wall. Suspicions should be raised when a high systolic pressure is associated with little in the way of target organ damage (particularly echocardiographic left ventricular hypertrophy), postural symptoms on treatment, and a firm radial artery despite cuff occlusion (Osler's phenomenon). Proof depends upon measurement of blood pressure by a method which does not depend upon arterial compression, such as arterial cannulation, finger volumetric, or automatic oscillometric devices.

Home blood pressure monitoring

Patients can usually be taught to measure their own blood pressure by electronic devices which use the Korotkoff sounds or oscillometry. A large range of cheap devices is now available. These are of varying reliability. Only those tested by specialist or consumer bodies and approved should be used. They should also be checked against manual blood pressure measurements. Home blood pressure monitoring has three advantages:

1. Blood pressure can be measured at the end of a dosing interval of an antihypertensive drug, even when this occurs in the evening or early morning.
2. 'White coat effects' as a result of measurement by a doctor or nurse are avoided, although occasional patients find measurement stressful even when carried out by themselves.
3. By encouraging participation in treatment, self-recorded blood pressures are useful both for encouraging compliance and giving reassurance.

Readings should be taken at a consistent time each day. After work in the evening is usually optimal. Blood pressures measured during stressful work are difficult to interpret and provide no useful guidance for treatment. Home blood pressure monitoring gives somewhat higher readings than 24-h ambulatory monitoring, which includes blood pressures during sleep. However, they are usually substantially lower than clinic or office blood pressures. Current evidence suggests that readings of 135/85 mmHg or higher should be considered elevated.

Indirect ambulatory blood pressure monitoring

These devices automatically inflate a cuff at set intervals during the day and night. A recording device is suspended on a belt or sling and the record subjected to computer analysis and print-out at the end of the recording period. One device ('Portapress') measures volumetric change in the finger with each heart beat and therefore offers a means to measure beat to beat variability without requiring large artery compression. At present its use is confined to research, but potentially it offers a novel approach to blood pressure evaluation.

Blood pressure falls during sleep, hence it is preferable to analyse daytime and night-time readings separately using fixed times. Alternatively, an activity meter can detect when the patient is actually asleep. The patient should keep a diary during the day so that blood pressures can be correlated with activity. Night-shift workers rapidly reverse their diurnal rhythm. A reduced or absent nocturnal fall in pressure is associated with a worse cardiovascular prognosis. Pooled analysis of population studies has yielded a figure of 138/87 mmHg for the upper 95 percentile level for daytime blood pressures. The difference between ambulatory daytime pressures and clinic blood pressures is, on average 12/7 mmHg, but individual variability is great. Suggested criteria for abnormality are shown in Table 2.

Ambulatory blood pressures have been shown repeatedly to be more closely correlated with target organ damage than clinic blood pressures. This is true of left ventricular hypertrophy, carotid wall thickness, fundal vessel changes, and microalbuminuria. There is also increasing evidence that ambulatory blood pressure monitoring is better at predicting cardiovascular events when clinic and ambulatory blood pressures diverge. However, this may partly be due to the fact that many more readings contribute to the calculated average. Multiple measurements of blood pressure have more prognostic value than a few.

Indirect ambulatory blood pressure monitoring is labour intensive and costly. Its place in routine practice therefore lies in situations where it adds information to clinic blood pressures which influences treatment. Where the decision to treat is based upon cardiovascular complications or target organ damage, or where the overall cardiovascular risk is below the level for drug treatment, there is no indication for carrying it out. On the other hand, where clinic blood pressures are sustained at high levels (such as 160/100 mmHg or higher) and treatment is not justified by high cardiovascular risk, ambulatory monitoring may be useful in confirming the presence of blood pressure elevation meriting therapy in its own right. Normal readings suggest 'white coat hypertension' under these circumstances. Other indications for ambulatory monitoring are to confirm resistance to antihypertensive medication in the absence of target organ damage, to assess 24-h control of blood pressure and episodic hypertension, and to investigate hypotensive symptoms in treated patients with no supporting evidence from clinic blood pressures.

'White coat hypertension'

Some patients have consistently elevated clinic blood pressures in the treatment range but unequivocally normal ambulatory blood pressure readings. Clearly the proportion depends critically on the criteria used. However, it is probable that about 20 per cent of patients who would be treated on the basis of high clinic blood pressures have normal ambulatory blood pressures. Almost all patients show blood pressure falls with repeated clinic measurement, so the need for sustained elevation of clinic blood pressures is critical. The prognostic significance of 'white coat hypertension' (some authorities use the term 'isolated office hypertension') is uncertain. Some of the cardiovascular changes observed in hypertension have been described in some studies and not others. There is little in the way of end-point data. Such as there is suggests that the cardiovascular risk is low compared with patients who have elevated ambulatory and clinic blood pressures. Where 'white coat hypertension' is diagnosed, the best advice is to monitor blood pressure and target organ damage and not treat unless ambulatory blood pressures become elevated.

Fundal examination

Fundal appearances provide vital information on vascular pathology and prognosis in hypertension. The Keith Wagener classification is still frequently used, although it has serious shortcomings. Chief amongst these is that grade I and II changes are produced by arterial wall thickening as a result of ageing as well as high blood

pressure. Clinically, the main requirement is to differentiate between malignant and non-malignant hypertension on fundal appearances.

Non-malignant hypertension

The earliest effects of blood pressure elevation are generalized reduction in arterial calibre with consequent reduction in arteriovenous ratio. Focal arterial narrowing is seen less often, usually when an acute rise in blood pressure has occurred. The remaining changes are frequently seen in older patients with arteriosclerosis, where their value in assessing hypertensive organ damage is small. They only have significance when seen in younger patients. The light reflex from the arterial wall is increased as a result of thickening. Nipping of the retinal veins occurs largely as a result of the optical effect of the thickened arterial walls preventing visualization of the columns of blood within the veins. Thus the veins appear to taper until they disappear before actually being crossed by the arteries. The veins may also be displaced laterally or posteriorly. Venous obstruction is much less common.

Malignant hypertension

Flame-shaped haemorrhages are superficial and owe their character to constraints imposed by nerve fibres. Dot and blot haemorrhages are deep to nerve fibres and so are not limited in the same way. Haemorrhages usually disappear after a few weeks of effective blood pressure control. There are two types of exudates. Hard or waxy exudates represent the end result of fluid leakage into the fibre layers of the retina from damaged vessels. Fluid is resorbed leaving a protein–lipid residue that is slowly removed by macrophages. Soft exudates or cotton-wool patches are aetiologically and ophthalmoscopically quite different. They are usually larger than hard exudates and have a woolly, ill-defined edge. They are not true exudates, but nerve fibre infarcts caused by hypertensive vascular occlusion. Unlike hard exudates, these lesions disappear within a few weeks of establishing adequate antihypertensive therapy.

Papilloedema is associated with raised pressure in the disc head secondary to severe vascular damage and increased permeability. Venous distention is followed by increased vascularity of the optic disc, which has a pink appearance with blurring of the disc margins and loss of the optic cup. Raising of the optic disc with anterior displacement of the vessels occurs later. The surrounding retina often shows oedema, small radial haemorrhages, and cotton-wool exudates.

The presence of haemorrhages and exudates (grade III), or papilloedema (grade IV) in essential hypertension all carry the same prognosis and the terms 'accelerated' and 'malignant' hypertension should therefore be considered synonymous.

Other physical signs

Clinical evidence of left ventricular hypertrophy and a loud aortic second sound indicate moderate or severe hypertension. Other physical signs indicate target organ damage to the cardiovascular, renal, or central nervous systems.

Investigations

Concentrations of urea, electrolytes, creatinine, and uric acid are usually normal in essential hypertension unless renal damage has occurred. Severe hypertension may be associated with elevated plasma renin and aldosterone levels, which can give rise to a modest hypokalaemic alkalosis. Serum sodium is usually low normal or low under these circumstances. This is an important differentiating point from primary aldosteronism, in which hypokalaemic alkalosis is usually associated with a high or high normal serum sodium concentration.

Microalbuminuria (20 to 200 µg/min or 30 to 300 mg/24 h) in hypertensive patients is prognostic of target organ damage. Other urinary changes, such as urinary casts, haematuria, and proteinuria, usually indicate that hypertension has entered the malignant phase or reflect primary renal disease.

Electrocardiographic left ventricular hypertrophy in the absence of any other cause indicates moderate or severe hypertension and is a valuable independent risk factor in hypertension. Echocardiography is much more sensitive in detecting early changes of left ventricular hypertrophy and provides the best independent evidence of severity in mild to moderate hypertension. Chest radiography is insufficiently sensitive as a measure of left ventricular hypertrophy. 'Unfolding of the aorta' is often observed in moderate and severe hypertension.

Management of essential hypertension

A number of national and international expert bodies have drawn up guidelines for the management of hypertension. Although these differ in detail, the overall structure of the recommendations is similar (Fig. 1). Initial clinical assessment is followed by a period of observation and monitoring depending upon the level of cardiovascular risk. During this period treatment of other cardiovascular risk factors and non-pharmacological measures are undertaken. If, at the end of this period, the patient is still at sufficient risk, antihypertensive drugs are recommended.

Fig. 1 Treatment plan for hypertension.

Assessment

The patient with essential hypertension may present in one of three ways:

1. As an asymptomatic individual whose blood pressure has been measured at routine examination for employment, insurance, or as a result of screening or preoperatively;
2. As a patient presenting with an unrelated disorder; or
3. Much less commonly, as a result of symptoms produced by hypertension or by the complications of hypertension.

Clinicians who deal with hypertension are at a great disadvantage. Whilst treatment of most symptomatic conditions leads to subjective improvement, drug treatment of hypertension may create unpleasant symptoms in an individual who was previously, to the best of their knowledge, perfectly well. It is imperative, therefore, to explain the significance of high blood pressure at the earliest opportunity. It is important to point out that in most cases it does not have a single cause. Many patients find difficulty in grasping the concept of blood pressure variability. Often they are alarmed by the inevitable occasional high reading. Discussion of the rationale for evaluation and treatment and an explanation of the nature of high blood pressure and its very high prevalence serves to reassure patients and improve compliance. Much literature is now available to help.

Establishing the diagnosis

History and examination usually provide few positive features in the uncomplicated hypertensive patient. The usually quoted range for age of onset is 35 to 55 years,

but this of course reflects the arbitrary criteria for diagnosis, and many patients who subsequently develop unequivocal hypertension have a blood pressure in the upper part of the 'normal range' below the age of 35. Moderate or severe hypertension first occurring outside the 35 to 55 age range suggests a secondary cause. The presence of hypertension in parents or siblings is of modest value in making the diagnosis. Often a negative family history simply reflects ignorance or failure to diagnose hypertension, particularly in the previous generation when health checks were less common. In addition, a positive family history can often be obtained fortuitously for a condition of very high prevalence such as essential hypertension. Positive indications of a cause for hypertension are of more value, for example a history of oestrogen-containing contraceptive pill exposure or exposure to other medications which elevate blood pressure, previous renal disease or clinical features suggestive of phaeochromocytoma, renal disease, or primary aldosteronism. Specific enquiries should be made regarding heavy alcohol intake.

Clinical evaluation

This provides essential information in the decision to treat. A history of smoking, diabetes, dyslipidaemia, or cardiovascular disease should always be sought. The presence of cardiovascular target organ damage in the form of coronary artery, cerebrovascular, or peripheral vascular disease, generalized or focal fundal arterial narrowing, or clinical left ventricular hypertrophy, all place the patient in a high-risk category. Fundal changes of malignant hypertension, left ventricular failure, encephalopathy, and hypertensive renal failure place the patient in a very high-risk category. Obesity is important as a factor in hypertension and is an independent cardiovascular risk factor.

The presence of conditions such as obstructive airways disease, diabetes, or gout may play a role in the selection of antihypertensive drug.

Investigations

When there is no clinical suspicion of secondary hypertension, extensive investigation for a primary cause is unnecessary, because the prevalence of secondary hypertension is so low. Measurement of serum urea, sodium, potassium, and creatinine, urinary microscopy, and dip-stick testing for protein are sufficient. Risk factor assessment should include an ECG, which is an important but insensitive indicator of left ventricular hypertrophy. Echocardiography is preferable as a more sensitive but expensive alternative. Where left ventricular hypertrophy is present, it offers an excellent means of excluding white coat hypertension. Fasting glucose and total cholesterol (preferably together with high-density lipoprotein cholesterol) should always be measured to define the patient's cardiovascular risk profile.

Initial advice

Except for patients who are at very high risk, or present as hypertensive emergencies, repeated measurements of blood pressure on several occasions should be carried out. The plan should be explained to the patient and advice given to improve cardiovascular risk and lower blood pressure before antihypertensive medication is considered. Cessation of smoking is probably the most important feature of advice at this stage. Other advice is directed at non-pharmacological blood pressure lowering by lifestyle modification, including dietary and behavioural measures. Dietary methods include weight reduction, sodium restriction, reduced alcohol intake in heavy drinkers, and increased fruit and vegetable intake. Behavioural methods include physical training, biofeedback, and relaxation. Successful non-pharmacological treatment may allow patients with milder degrees of hypertension to avoid drug treatment and enable lower doses of antihypertensive medication to be used in others.

Weight reduction

The epidemiological relationship between weight and blood pressure is reflected in a number of trials which have shown that dietary weight reduction produces a useful fall in blood pressure (Table 3). The mechanism for the fall in blood pressure is debated, but the most likely explanation is a fall in sympathetic efferent output to the cardiovascular system.

Sodium restriction

The average intake of sodium in Westernized cultures is 120 to180 mmol/day. Severe salt restriction (less than 10 mmol/day) produces substantial blood pressure lowering and, together with increased potassium intake, was probably responsible for the efficacy of the Kempner rice–fruit diet, used in the treatment of severe hypertension before the modern drug era. Long-term sodium restriction of this degree is not feasible and carries significant risks. More moderate sodium restriction (70 to 80 mmol/day) can be achieved by abstaining from adding salt at the table, avoiding salt in cooking, and avoiding heavily salted processed foods. As sole therapy, such moderate salt restriction produces a modest reduction in blood pressure, particularly in older subjects and black individuals (Table 3). The individual response is variable: patients showing a more substantial blood pressure fall have been classified as 'salt sensitive'. The reproducibility of 'salt sensitivity' is poor, however, and although a genetic factor has been postulated, the only way of identifying such individuals is by empirically testing the blood pressure response to salt restriction. Salt restriction enhances the blood pressure-lowering action of ACE inhibitors, angiotensin receptor blockers, b-blockers, and diuretics. Curiously, it is ineffective in patients treated with calcium antagonists.

Increased fruit and vegetable intake

Adoption of a vegetarian diet produces a modest fall in blood pressure and increased fruit and vegetable intake has been part of combined regimens of non-pharmacological blood pressure control involving reduction in weight and sodium restriction. However, a recent large trial (DASH—Dietary Approaches to Stop Hypertension) has shown that increased intake of fruit and vegetables can have an important blood pressure-lowering action, equivalent to the effect of a single antihypertensive drug. This was independent of any change in weight or salt intake (Table 3). These effects were produced by doubling the average American intake of 4.3 servings of fruit and vegetables a day. Larger effects were observed when this diet was combined with reduction in total and saturated fats. One contributory factor was probably the increase in potassium intake which occurred. Potassium supplementation has a significant blood pressure-lowering effect, partly at least through natriuresis. There is, however, no justification for potassium supplementation as an independent form of treatment unless the patient is potassium depleted. Although other features of the high fruit and vegetable diet, such as increased fibre and magnesium content, have been claimed to have a blood pressure-lowering action, these actions have not been persuasively demonstrated.

Reduced alcohol intake

The elevated blood pressures shown by heavy drinkers (more than 6 units of alcohol a day) are lowered by withdrawal. This is not related to changes in weight or electrolyte intake. This useful clinical effect has to be differentiated from the pressor response sometimes exhibited by chronic alcoholics on abstention from alcohol, which is mediated by sympathetic overactivity. The optimal intake is 2 to 3 units/day (2 units/day in women). Although some epidemiological studies have shown slightly lower blood pressures in moderate drinkers compared with total abstainers, the individual effect is likely to be small, has not been tested by intervention studies, and it would seem undesirable to advise moderate alcohol intake to teetotal hypertensive patients.

Fish oil and other dietary manoeuvres

Large increases in dietary fish oil (more than 3 g/day of omega-3 fatty acids) lower blood pressure modestly. The effect is only seen in those whose consumption of fish is low. Many patients find the ingestion of such amounts unacceptable, either in the form of oily fish or capsules. Olive oil has been shown to have a very small blood pressure-lowering action in some studies, but there is little evidence to support a therapeutic effect of other unsaturated fatty acids. Claims have also been made for calcium, garlic, protein, and vitamin C, but these are not persuasive.

Physical exercise

Regular aerobic exercise lowers blood pressure independently of any weight loss. Although the overall reduction in blood pressure is impressive, the figures quoted in Table 3 may reflect design flaws in some of the trials, since proper controls are difficult to achieve and the true effect is usually less. Moderate physical activity equivalent to 40 to 60 per cent of maximal oxygen consumption is optimal. This may take the form of, for instance, 30 to 45 min of brisk walking daily. This is also often associated with an improvement in well being attributable to endorphin release.

Other behavioural manoeuvres

Theoretically, interventions which reduce sympathetic efferent output and the alerting response should lower blood pressure. Although superficially attractive as a means of avoiding drug therapy, training in these procedures is labour intensive for professionals and carrying them out is time consuming for patients. A number of controlled trials have claimed such effects, but most have been flawed in design and there is no consistent evidence of efficacy.

Use of non-pharmacological therapy

All patients should receive relevant lifestyle advice. A diet high in fruit and vegetables, and low in salt and saturated fats, together with a recommendation of regular exercise, provide a core management strategy additional to medication, where that is necessary. Weight reduction, even in only marginally overweight patients, is probably the most efficacious manoeuvre of all. Some patients may find it feasible to increase their intake of oily fish. Patients should be advised to reduce heavy alcohol intake.

Although clinical trials have now demonstrated that these various manoeuvres can produce significant blood pressure lowering under rigorous conditions, the effects are often quite small in clinical practice, except perhaps in the case of weight reduction. Some of the dietary advice is expensive for patients (if not for drug budgets), and it is important that those asked to modify their lifestyle substantially are not disappointed by the outcome, or that the uncritical medical enthusiasm which occasionally invests this field does not imply that an aberrant life style is to blame for the development of essential hypertension.

Observation period

A period of observation extending from 1 to 2 weeks up to 1 year before antihypertensive drugs are prescribed is imperative in most patients. There are three reasons for this:

1. Multiple readings on a number of occasions provide a much better estimate of overall risk than readings on one occasion only;
2. Blood pressure usually falls owing to diminution in the alerting response as a result of repeated measurement; and
3. Non-pharmacological management may produce additional blood pressure falls.

The latter two effects may enable substantial numbers of patients with mild hypertension to avoid drug treatment. The observation period is omitted or shortened only if the patient is at high risk. The level of overall cardiovascular risk also determines whether a patient requires antihypertensive medication or not. It is therefore central to the management of essential hypertension.

Cardiovascular risk profile

The epidemiological risks associated with hypertension are not only correlated with sustained systolic and diastolic pressures, but also with:

1. Irreversible factors such as age, race, male gender, family history, and ethnicity;
2. Associated, potentially reversible factors, such as smoking, dyslipidaemia, diabetes, and obesity;
3. The presence of asymptomatic target organ damage such as left ventricular hypertrophy, atheromatous plaques on imaging, or microalbuminuria; and
4. Clinical complications such as ischaemic heart disease, heart failure, cerebrovascular disease, symptomatic peripheral arterial disease, renal disease, and malignant hypertensive fundal changes.

Higher absolute risk conferred by these other factors is translated to greater potential benefit from blood pressure lowering. The blood pressure levels at which drug treatment is initiated should therefore be lower in the presence of additional risk factors.

It is possible to calculate risk using the Framingham epidemiological data. Some guidelines, such as those issued in Britain and New Zealand, recommend this using a printed risk chart (Fig. 2) or computer program. The complexity of the data requires access either to a computer or printed table. Other guidelines—such as those issued by the American Joint National Committee (**JNC**), World Health Organization (**WHO**), and International Society of Hypertension (**ISH**)—use summary tables to assign risk to a limited number of categories (Table 4). The disadvantage of this approach is that it takes no account of differential weighting of risk factors. Age, for instance, becomes a dominant risk factor in the elderly compared with, say, dyslipidaemia.

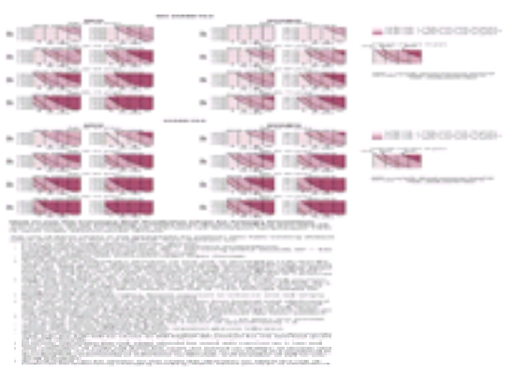

Fig. 2 Coronary risk prevention chart recommended for risk assessment in the British Hypertension Society guidelines. (Reproduced from British National Formulary (2001), **42**, with permission.)

All guidance suggests that the uncomplicated hypertensive patients with no other risk factors above a sustained threshold value for systolic and diastolic pressure should be treated with antihypertensive medication. The British Hypertension Society guidelines recommend values of 160 and 100 mmHg, respectively. The WHO–ISH thresholds are 150 and 95 mmHg, whilst the JNC thresholds are 140 and 90 mmHg.

The presence of added risks modifies both the period of observation and, in some cases, the blood pressure threshold for drug treatment. The British Hypertension Society guidelines reduce the thresholds to 140 and 90 mmHg in the presence of a 15 per cent or more 10-year risk of coronary heart disease (approximately equal to a 20 per cent 10-year risk of coronary heart disease and stroke). Patients with target organ damage, complications, or diabetes associated with hypertension reach this level without further risk-factor calculation. These higher-risk patients and those with high sustained levels (200/110 mmHg or higher) should be observed for shorter periods of 1 to 4 weeks, whilst lower-risk patients should be observed for 12 weeks according to these criteria. The WHO–ISH recommend treating medium-risk patients after observation for 3 to 6 months if blood pressures are 140/90 mmHg or higher, while low-risk patients should be observed for 6 to 12 months before treatment. The JNC risk advice suggests observation periods of up to 12 months in low-risk individuals (most of whom would not be treated on the basis of the other recommendations); other non-urgent patients are treated after two follow-up visits (Table 5).

Patients at the highest risk should be treated more promptly. Accelerated hypertension and hypertension associated with acute complications such as left ventricular failure require immediate treatment. The WHO–ISH recommends treating patients in the 'high' and 'very high' risk groups within a few days, after repeated measurement of blood pressure. The JNC guidelines imply a similar policy.

Adoption of the JNC or WHO–ISH recommendations will result in many more patients receiving drug treatment than the British guidelines. The 10-year level of cardiovascular risk in those who would be given drug treatment according to both sets of recommendations falls below 15 per cent. This is not an issue which clinical trials can resolve. It reflects a balanced judgement of the benefits of treatment set against the cost and inconvenience of life-long therapy, both to the individual and to society. The final decision depends upon the values of both. Often the language of guidelines in the treatment of hypertension has a prescriptive tone. It should not be forgotten that their only objective is to inform the professional so that appropriate options can be presented to the patient.

Treatment of hypertension

Target blood pressure

The one clinical trial which has addressed the issue of target blood pressure suggested no significant differences in outcome when blood pressure control was aimed at different strata below 140/90 mmHg, although the lowest number of events occurred around pressures of 138/83 mmHg. There was no indication of a worse outcome when pressures were reduced to lower levels than this (the so-called 'J-shaped curve'). Rigorous blood pressure control is particularly important in diabetic hypertensive patients, where pressures should be kept below 140/80 mmHg.

Impact of drug treatment

A number of important, large multicentre trials have demonstrated the impact of antihypertensive treatment on cardiovascular disease. Patients recruited have differed, and in particular some trials have been confined to elderly subjects. In addition, drug regimens and protocols have been widely disparate. Nevertheless, the conclusions have shown an impressive degree of concordance. Meta-analysis of the data has demonstrated that in these trials, for a drug-induced fall in systolic blood pressure of 12 to 13 mmHg, coronary heart disease is reduced by 21 per cent, stroke by 37 per cent, and cardiovascular mortality by 25 per cent. A fall in diastolic pressure of 5 to 6 mmHg produced figures of 16, 38, and 21 per cent, respectively. The benefits of treatment were seen in patients with isolated elevation of systolic or diastolic blood pressure. The epidemiological risk of stroke associated with these blood pressure differences was almost identical, so that, at least over the period of the trials, the risk of stroke attributable to hypertension was totally reversed. This does not imply that drug treatment abolishes the life-long risk of stroke, but it does indicate that pharmacological lowering of blood pressure reduces the short-term risks both of atherothrombotic and haemorrhagic strokes. The impact of treatment on coronary events is also significant, but probably falls short of complete reversibility. The reasons for this are still controversial.

Selection of therapy

A number of different classes of hypertensive drug are available and widely used.

Thiazide and related diuretics

Diuretics were used in several of the end-point trials which demonstrated efficacy in treating hypertension. Thiazides are ineffective in patients with a glomerular filtration rate below 40 ml/min. The more potent short-acting loop diuretics have less antihypertensive efficacy over 24 h since rebound sodium retention occurs at the end of the diuretic and natriuretic effect. They are more inconvenient for patients and should not be used except where sodium balance has to be controlled. Their major indication is to control sodium retention associated with hypertension, for example due to renal or cardiac failure. Potassium-retaining diuretics are commonly used in combination with thiazides or, in larger doses, in the treatment of primary aldosteronism. A recent study showing the beneficial effect of spironolactone on morbidity and mortality in heart failure is likely to increase use of this agent. If it, or other potassium-retaining agents, are given to patients with renal impairment, then close monitoring is required because of the danger of hyperkalaemia. This may also occur in patients who are receiving treatment which blocks the renin–angiotensin–aldosterone system. An incidental advantage of thiazides may be reduction in osteoporosis as a result of calcium retention.

Only low doses of diuretics should now be used for uncomplicated hypertension. These have a degree of patient acceptability similar to placebo in more recent studies. The dose–response curve is flat and dose titration is not required. The adverse metabolic effects on potassium balance, plasma lipids, and insulin resistance have attracted attention, since these worsen the cardiovascular risk profile. They are minimal on low-dosage regimes, even in patients with diabetes. Urate retention may precipitate gout in predisposed patients. The incidence of erectile dysfunction (which is elevated in untreated hypertension) is increased. In long-term cohort studies the risk of renal cell carcinoma has been reported as doubled, although the absolute incidence remains very low. Sodium and fluid depletion with prerenal failure is very unusual with low-dose thiazide therapy, but is much more common with loop diuretics, particularly in elderly subjects.

Dosage regimens of selected diuretics are shown in Table 6.

b-Blockers

b-Blockers have also been shown to reduce cardiovascular events in trials of the treatment of hypertension.

There are clinically important differences between the pharmacological properties of different members of the class. b_1-Selective blocking agents have less action upon bronchial and vascular b_2-adrenergic receptors, and so are less likely to cause bronchospasm or vasoconstriction in susceptible patients (for example patients with chronic obstructive airways disease or Raynaud's phenomenon). There is, however, still significant risk as tissues have mixed populations of receptors. Some b-blockers have partial agonist action at the b_1-receptor (intrinsic sympathomimetic activity) so that there is less slowing of the heart, although the heart rate response to exercise is still blunted. The clinical significance of this is uncertain. Heart rate is a risk factor for cardiac mortality and slowing might therefore be thought to be advantageous. However, bradycardia is associated with increased stroke volume and pulse pressure, which constitutes an adverse risk factor. There have been no comparative trials to address this issue in hypertension, although prevention of secondary infarction has been observed only in trials of agents without intrinsic sympathetic activity.

b-Blockers are contraindicated in hypertensive patients with asthma, chronic obstructive airways disease, heart block greater than grade 1, and sick sinus syndrome. They should be used with great caution in cardiac failure, although low-dose b-blockade with carvedilol or metoprolol has reduced morbidity and mortality in end-point trials. The combination of b-blockade with the calcium-channel blockers verapamil and diltiazem may have additional depressant actions on the sinatrial and atrioventricular node and have negative inotropic effects in patients with cardiac disease, and therefore should be avoided.

b-Blockers can have a large number of side-effects. Exercise capacity is decreased and fatiguability increased, most frequently causing problems in athletes and enthusiasts for regular physical training. They probably cause erectile dysfunction, although the incidence is not as high as that reported with diuretics where this has been recorded in trials. Non-selective b-adrenergic blockers inhibit b_2-induced vasodilatation. This may cause cold extremities and worsening of symptoms in peripheral vascular disease and Raynaud's disease. This action may also become important when there are high circulating concentrations of noradrenaline, for instance in patients with phaeochromocytoma, or after clonidine withdrawal, or in patients treated with sympathomimetic medication. Under these circumstances, non-selective b-blockade worsens hypertension. Serum triglycerides are slightly elevated and high-density lipoprotein cholesterol is reduced. This effect is not seen with drugs having intrinsic sympathomimetic activity and is less marked with cardioselective agents. b-Blockade delays the recovery from hypoglycaemia in diabetic patients and may worsen glucose intolerance. These effects are less with cardioselective drugs. b-Blockade may also mask symptoms of hypoglycaemia due to adrenaline. These are relative disadvantages in patients with diabetes and glucose intolerance that have to be balanced against benefits, for example in patients with ischaemic heart disease.

Some members of the class—such as propranolol, metoprolol, and timolol—are lipid soluble: entry into the brain appears to be associated with nightmares and sleep disturbances. These effects are unusual with water-soluble agents such as atenolol, nadolol, celiprolol, and betaxolol. Sudden discontinuation of b-adrenergic blockers in patients with cardiac disease has been associated with sudden death and it is preferable to tail off treatment in such patients over a week or two.

Pharmacological properties and dosage regimens of b-adrenergic blocking drugs are shown in Table 7.

Calcium antagonists

This class of drugs has been extensively used in treating hypertension since the 1970s. There is evidence of reduction in cardiovascular disease in end-point trials of systolic hypertension in elderly patients.

The dihydropyridine channel blockers act mainly upon vascular smooth muscle, causing vasodilatation. The non-dihydropyridines include diltiazem, a benzothiazepine, and verapamil, a phenylalkylamine. These cause less marked vasodilatation but have more pronounced effects upon cardiac contractility and atrioventricular conduction. Short-acting dihydropyridines (such as nifedipine) cause reflex baroreceptor-mediated tachycardia. If vasodilatation is not maintained, the baroreceptors do not reset, and so there may be a sustained increase in pulse rate, with other features of sympathetic activity such as sweating, palpitations, and

headache. These side-effects occur in a substantial number of patients. Sustained release preparations, or dihydropyridines with prolonged action (such as amlodipine), do not usually produce these effects. Flushing and ankle oedema occur frequently with all dihydropyridines. Oedema reflects local increase in pressure distal to dilated precapillary resistance vessels causing transudation of fluid into the tissues.

Considerable controversy was generated in 1995 by a case–control study and a meta-analysis of clinical trials which suggested that calcium-channel blockade in hypertension was associated with an increased incidence of coronary events. Although this finding was hotly disputed, it does seem likely that the first-generation, short-acting dihydropyridines were producing an adverse outcome through repeated sympathetic activation. For this reason they are best avoided in treating hypertension. Other associations with increased incidence of cancer have not been confirmed, and an association with gastrointestinal haemorrhage is still debated.

Verapamil may precipitate cardiac failure in predisposed patients and exacerbate conduction disorders. It should therefore be avoided in patients with sick sinus syndrome and atrioventricular block. Although these dangers are less with diltiazem, it is also best avoided in such patients. An action upon colonic smooth muscle causes constipation with verapamil: this is usually the only adverse effect that interferes with the quality of life with this drug. This side-effect is less commonly seen with diltiazem, although headache is more frequent.

Dosage regimens of calcium-channel blockers are shown in Table 8.

Angiotensin-converting enzyme (ACE) inhibitors

These agents have been used since the late 1970s in treating hypertension. Only one rather inconclusive end-point trial in hypertension has so far been reported, but there has been impressive evidence for reduction of morbidity and mortality in cardiac failure. Their major advantage is that they are very well tolerated with the exception of dry, unproductive cough, observed in about 20 per cent of patients. Since this does not occur with angiotensin-receptor blockers, it is probably due to bradykinin potentiation. Where patients find it unacceptable, there is no alternative to discontinuing ACE inhibitors and substituting another class of drug.

There are two serious side-effects, which are uncommon and avoidable in most cases. First, angiotensin II maintains renal glomerular hydrostatic pressure and filtration fraction by efferent arteriolar constriction. Blockade may therefore reduce glomerular filtration rate, although renal blood flow is increased. This is clinically important when renal blood flow is critically reduced, as for instance in bilateral renal artery stenosis or stenosis of the artery supplying a single kidney. It may also occur when renal perfusion is reduced through salt and water depletion, congestive cardiac failure, or renal microvascular disease. In all these situations, ACE inhibitors may precipitate acute renal failure. When glomerular filtration rate is reduced in the ischaemic kidney in patients with unilateral renal artery stenosis, the effect may not be diagnosed without imaging studies since routine tests of renal function may not be affected. Second, administration of ACE inhibitors to patients with high circulating renin levels due to salt and water depletion may precipitate severe hypotension. Where there is this clinical possibility, a small dose, preferably of a short duration agent such as captopril (6.25 mg), should be administered under supervision.

A small elevation of plasma potassium consistently occurs as a result of reduction in aldosterone secretion. This may be clinically important in those with renal failure. For this reason, ACE inhibitors should not normally be combined with potassium-sparing diuretics. Angioneurotic oedema has occurred rarely.

Dosage regimens of ACE inhibitors are shown in Table 9.

Angiotensin II receptor antagonists

The newest major class of drugs used in treating hypertension are the angiotensin II subtype 1 receptor (AT(1)) antagonists. No hard end-point trials in hypertension have so far been reported. Experience to date indicates a very low incidence of side-effects and very good patient acceptability.

Although, like ACE inhibitors, their prime target is the renin–angiotensin system, they are different in potentially important ways. Thus, while blocking the AT(1) receptor, they stimulate the angiotensin II subtype 2 (AT(2)) and other receptors as a result of high angiotensin II levels. The role of these other receptors is uncertain, and the major actions of angiotensin receptor antagonists reflect inhibition of the 'classic' effects of the renin–angiotensin system mediated by the AT(1) receptor on the blood vessels, heart, adrenal gland, kidneys, brain, and sympathetic nervous system. The actions are in this respect identical with those of ACE inhibitors. The same adverse effects in sodium-depleted patients and in patients with critical reduction of renal blood flow are therefore seen.

Addition of an AT(1) receptor antagonist to an ACE inhibitor has, in some trials, produced additional blood pressure lowering, perhaps due to more complete blockade of the renin–angiotensin system. They have no bradykinin-potentiating activity, accounting for the absence of drug-induced cough and giving these agents an important place as substitutes for ACE inhibitors when unacceptable cough occurs. Losartan is unique in this class of drugs in having a uricosuric effect.

Dosage regimens of AT(1) receptor antagonists are shown in Table 10.

a-Adrenergic blocking drugs

These drugs have been available for over 40 years, but early members of the class were never used routinely in the treatment of hypertension because of severe postural hypotension and the development of tolerance. Prazosin was initially introduced as a direct-acting vasodilator in 1976, but was subsequently found specifically to inhibit post-synaptic a_1-receptors. Initially, the recommended dosage was too high and postural hypotension and syncope proved serious problems which retarded the acceptance of this class of drugs, although the use of lower doses and the development of longer-acting agents has largely overcome this problem. Blockade of sphincteric receptors produces improvement in symptoms in patients with benign prostatic hyperplasia. Occasionally, the sphincteric effects worsen symptoms in patients with stress incontinence. Improvement in penile blood flow is associated with some benefit in patients with erectile dysfunction. Priapism has been reported rarely. Indoramin has additional central effects, causing dry mouth, nasal congestion, and extrapyramidal syndromes. Uniquely amongst antihypertensive drugs, the a_1-antagonists produce favourable changes in plasma lipids, with a reduction in total and low-density lipoprotein cholesterol and triglycerides, and an increase in high-density lipoprotein cholesterol.

Dosage regimens of a_1-adrenoreceptor blocking drugs are shown in Table 11.

Centrally acting sympatholytic drugs

Methyldopa was originally developed in the late 1950s and for many years it was one of the mainstays of antihypertensive therapy. However, it frequently causes sedation, impaired psychomotor performance, dry mouth, and erectile dysfunction. Its unfavourable impact upon quality of life caused it to be replaced by equally effective drugs in the 1970s, although it is still used extensively in the management of hypertension of pregnancy.

The withdrawal syndrome is an occasional but potentially dangerous feature of these drugs. It is most common with clonidine, when discontinuation results in a rebound rise in catecholamines with features that may resemble phaeochromocytoma, such as severe hypertension, tachycardia, and sweating. This is exacerbated when patients are also receiving non-selective b-blockers such as propranolol, which inactivates peripheral b-vasodilator adrenoceptors. The syndrome is treated by readministering the drug and then gradually discontinuing. A combined adrenoceptor inhibitor such as labetolol can be used to control blood pressure in an emergency situation. These central side-effects are shared by guanabenz, guanfacine, and clonidine. Recently, more specific agents such as moxonidine, directed at the imidazoline receptor, have been developed. These have a lower incidence of central side-effects.

Dosage regimens of centrally acting drugs are shown in Table 12.

Direct vasodilators

Hydralazine was extensively used as part of a stepped care regimen. The main disadvantages were sympathetic activation and the development of a lupus-like syndrome, particularly in patients with the slow acetylator genotype. These disadvantages, together with the need for multiple daily dosage, have resulted in the replacement of hydralazine by other agents, except for occasional use in severe hypertension and hypertension associated with pregnancy. No end-point trials have been carried out.

Usage of the more potent vasodilator minoxidil is confined to severe, resistant hypertension because of its side-effects, which include hypertrichosis and severe fluid retention. For this reason, combination with a potent loop diuretic is almost always necessary. T-wave changes and S–T depression may occur in the early phases of treatment with minoxidil due to increased cardiac work as a result of generalized vasodilatation. On these grounds, it is preferable to combine minoxidil with a b-blocker unless contraindicated.

Dosage regimens of oral vasodilators are shown in Table 13.

Drug regimens

Indications and contraindications for specific classes of drugs are shown in Table 14.

Monotherapy on average reduces systolic pressure by 7 to 13 mmHg and diastolic pressure by 4 to 8 mmHg. There is, however, marked heterogeneity in response among individuals to particular drugs. Treatment should normally commence with a low dose of the drug selected. If an adequate response is not obtained, which certainly applies if the blood pressure remains above the level at which treatment was deemed to be indicated in the individual (Table 4 and Table 5), then a number of strategies can be pursued. Firstly, the dose of the initial drug can be titrated upwards against blood pressure, except in the case of diuretics, where a single dose is used. Secondly, a small dose of a second drug can be used either separately or as a combination tablet as a means of limiting dose-related side-effects. Thirdly, the initial drug can be stopped and another class of antihypertensive agent started in the hope of greater efficacy. One study found that a rotational policy of four agents tried sequentially increased the chance of successful control of blood pressure (defined as < 140/90 mmHg) with monotherapy from 39 per cent to 73 per cent. This study also found that the responses to ACE inhibitor (A) and b-blocker (B) were correlated, as were those to calcium-channel blocker (C) and diuretic (D), hence an 'AB/CD' rule was proposed. If the initial drug used did not produce a satisfactory response, it could be substituted with one of the drugs in the other pair of treatments, thus abbreviating the rotation for use in routine practice.

In any situation a drug that is poorly tolerated must be substituted, and when a satisfactory response cannot be produced by a single agent, another class of drug must be added. Three or even four classes of drug may be needed to control more resistant hypertension. However, some combinations of drugs, which share mechanisms of antihypertensive action, have less than additive effects and are best avoided, unless the drugs are indicated on other grounds. Such combinations include a b-blocker and ACE inhibitor or angiotensin receptor antagonist, and a calcium antagonist and diuretic. Effective combinations include:

1. diuretic and b-blocker;
2. diuretic and ACE inhibitor or angiotensin receptor antagonist;
3. dihydropyridine calcium antagonist and b-blocker;
4. a-blocker and b-blocker; and
5. a-blocker with any other class of agent as third-line treatment.

Drug selection

The strong end-point trial data, patient acceptability, and low cost make diuretics or b-blockers the preferred first-line therapy in hypertensive patients who do not have indications for other drugs. The Medical Research Council Trial of Treatment in Hypertension in the Elderly suggested that diuretics were associated with a better outcome in terms of ischaemic heart disease and they should therefore normally be the first-line therapy in elderly patients. There are powerful reasons for using other drugs in the presence of comorbidity, for instance ACE inhibitors in the patient with cardiac failure and b-blockers in the patient with angina. Diuretics or dihydropyridine calcium antagonists are recommended for isolated systolic hypertension on the basis of end-point trials, but it is probable that benefit is common to most classes of drug. The only possible exception to this are rate-limiting b-blockers and calcium antagonists, where cardiac filling and stroke volume may be increased with a consequent rise in pulse pressure.

Follow-up

It is essential that patients are monitored regularly. It is important that they understand the need for this, or default is more likely. The interval between clinic visits may be short initially, usually varying between 1 and 4 weeks. When blood pressure is controlled, it is probably not necessary to see patients more often than once every 6 months.

Other treatment

Other risk factors may need control, such as serum lipids, obesity, and glucose intolerance, all of which are more prevalent in hypertensive patients. Advice about smoking is of paramount importance, since the risks of this habit exceed those of mild hypertension in many patients. Low-dose aspirin (75 mg/day) has been shown to reduce the incidence of myocardial infarction in higher-risk patients over 50 years old and this should be offered routinely to patients who fall in this category and who do not have contraindications. In view of the increased incidence of haemorrhage, it is probably not indicated in lower-risk hypertensive patients.

Resistant hypertension

In the absence of evidence of target organ damage, 'white coat hypertension' should be excluded by 24-h ambulatory monitoring. However, in some cases, blood pressures measured in the clinic, at home, or by ambulatory monitoring may remain high despite therapy with four, or occasionally five, classes of drug in optimal dosage. Minoxidil, in combination with a diuretic and preferably a b-blocker, should be reserved for such cases, titrating the dose against blood pressure, and adjusting the dose of diuretic to control oedema. Possible explanations of resistance should be sought if such measures fail to control blood pressure. These are:

1. Secondary hypertension (e.g. renovascular or endocrine);
2. Ingestion of drugs which may raise blood pressure (e.g. non-steroidal anti-inflammatory agents);
3. Heavy alcohol intake;
4. Sodium and fluid retention as a result of inadequate diuretic therapy; and
5. Poor patient compliance.

Poor compliance is often difficult to detect in hypertensive patients. Clues are provided by an initial reluctance to take medication, absence of expected pharmacological effects (such as bradycardia with some b-blockers, oedema with minoxidil), or evidence of failure to consume tablets, as revealed by tablet counts or prescription frequency. Other forms of poor compliance, such as incorrect dosing intervals, are more frequent but only detectable by electronic pill counting. In some cases it may be necessary to admit a patient to hospital and supervise administration of treatment. Where compliance is obviously poor, a number of manoeuvres can help to improve it. The regimen should be kept as simple as possible, using once daily drugs and combination tablets. A carer needs to be involved in administering medication to those who are confused. Whenever possible, effective communication with full information and involvement of the patient in his or her treatment is essential. Nurses, pharmacists, and other health professionals can play a vital role in this process.

Hypertension in specific groups of patients

Hypertension in Afro-Caribbean patients

Hypertension is more prevalent in black Afro-Caribbean patients and carries a worse prognosis. Meticulous blood pressure control therefore assumes greater importance than normal. Black patients as a group tend to respond better to diuretics, calcium antagonists, and dietary salt restriction than white patients. ACE inhibitors, angiotensin receptor antagonists, and b-blockers are, as a rule, less effective, although there is substantial patient variability in responsiveness. Activation of the renin–angiotensin system by diuretics may restore blood pressure responsiveness to ACE inhibitors or angiotensin receptor antagonists.

Hypertension in the elderly

The elderly are a very high-risk group. Inevitably, therefore, more elderly patients will meet the criteria for antihypertensive medication than will those in younger age

groups. A number of surveys have shown that doctors consistently underestimate the risks of hypertension in the elderly and therefore under-treat. However, the elderly present some particular problems as a result of the changed physiology of ageing. Thus:

1. Arterial wall stiffness gives rise to systolic hypertension and increased pulse pressure (isolated systolic hypertension). This also causes impaired baroreflex sensitivity with increased risk of orthostatic hypotension.
2. Renal conservation of sodium and fluid in the face of depletion is impaired. Elderly patients are therefore more subject to dehydration as a result of diuretic therapy or dietary restriction.
3. Clearance of drugs and their active metabolites is decreased as a result of declining hepatic and renal function.
4. Cardiac compliance and reserve are reduced and patients are therefore much more likely to develop cardiac failure. End-point trials of hypertension treatment have consistently shown reductions in morbidity and mortality from cardiac failure.
5. Comorbidity is much more common.
6. Communication and compliance may be difficult with decline in cognitive function. Some evidence from clinical trials suggests that this decline may be retarded by antihypertensive treatment.

Despite these important considerations, there is no fundamental difference in the approach to treating hypertension in the elderly patient. As a general rule, drug regimens should be as simple as possible and dosages increased more gradually. The greatest danger results from lowering pressure too much and too rapidly. Although trial evidence is limited in the very old (i.e. those over 80), there is no reason to manage these patients any differently from those who are not as old. Biological rather than chronological age should be the deciding factor in initiating antihypertensive treatment.

Essential hypertension in children

Although secondary hypertension is more common in children than in adults, no specific cause is found for hypertension in the majority of adolescents. The criteria for drug treatment, however, have to be modified because of the lower blood pressure range. The American Joint National Committee guidelines recommend that blood pressures above the 95th percentile taking into account age, height, and sex should be considered elevated. In principle, regimens are the same as those recommended for adults, with appropriate dose adjustment.

15.16.2.1 Hypertension—indications for investigation

Lawrence E. Ramsay

Introduction

Sustained hypertension is very common in the general population, with a prevalence of 10 to 20 per cent of adults depending on the definition used. Most of these people will have their hypertension managed entirely in primary care, without referral for specialist investigation or treatment. About 90 per cent have idiopathic or essential hypertension, meaning that no specific cause can be identified. Perhaps 5 per cent of hypertension may be caused by drug therapy (Table 1), particularly non-steroidal anti-inflammatory drugs or oestrogen-containing oral contraceptive preparations; a further 5 per cent may be caused by renal or renovascular disease; while phaeochromocytoma, Conn's and Cushing's syndromes, coarctation, acromegaly, and other even rarer conditions together account for less than 1 per cent of all hypertension.

Note that an identifiable cause does not equate with 'curable' hypertension. In many cases, for example those with bilateral parenchymal renal disease, the cause cannot be rectified. Even when the underlying cause can be corrected, hypertension persists in about 30 per cent of cases regardless of whether the original aetiology was renal, renovascular, or endocrine. Thus, curable hypertension is very uncommon, so much so that routine extensive investigation of all patients with hypertension is unjustifiable. National and international guidelines for hypertension management agree that the investigations for all patients with hypertension should be limited in number and simple, so that they can be done readily in primary care. Detailed investigation should be reserved for patients who have specific indications in the clinical evaluation, and these patients should generally be referred for specialist opinion. This policy for investigation is logical but often not followed: a proportion of patients with hypertension do not receive even very basic tests such as creatinine and electrolyte measurement, while in hospital practice investigations are often done that are unnecessary, costly, inconvenient, and even invasive or potentially harmful.

Clinical evaluation

One consequence of reserving detailed investigation for selected patients is that the detection of uncommon but important cases of curable hypertension relies heavily on thoroughness and clinical acumen in the initial clinical evaluation. The aims of clinical evaluation are to elicit and document:

1. causes of hypertension, such as renal disease and endocrine causes;
2. contributory factors, such as obesity, high salt intake, and excess alcohol;
3. complications of hypertension, such as previous stroke and left ventricular hypertrophy;
4. cardiovascular risk factors, such as smoking, family history, sex, and age; and
5. contraindications to specific drugs, such as asthma (b-blockers) and gout (thiazides).

Those aspects of the clinical evaluation pertinent to detecting possible causes of hypertension are described in more detail in Table 2.

Routine investigations

There is agreement in recent guidelines that routine investigation should be limited to:

- urine strip test for protein and blood
- serum creatinine and electrolytes
- blood glucose
- serum total:HDL cholesterol
- electrocardiogram.

Some guidelines, such as the World Health Organization/International Society of Hypertension and the United States JNC VI guidelines, add 'optional' investigations to those above, implying that these are at the discretion of individual doctors. The British Hypertension Society guidelines do not endorse 'optional' investigations, because any additional investigations performed should be justifiable by evidence that there is some useful influence on clinical management or outcome.

Note that only two of these routine investigations are aimed primarily at detecting underlying causes for hypertension, namely urinalysis (renal causes) and creatinine and electrolytes (for renal causes and for mineralocorticoid excess such as Conn's syndrome). The other routine tests, namely glucose, total:HDL cholesterol, and electrocardiogram for left ventricular hypertrophy, are performed to assess cardiovascular risk, and are combined with other major risk factors (age, sex, smoking, and family history) to estimate cardiovascular or coronary risk formally using a chart, table, or computer program based on the Framingham risk function. Formal cardiovascular or coronary risk assessment is central to decisions on antihypertensive treatment for people with mild hypertension who have no cardiovascular complications, and also central to decisions on aspirin or lipid-lowering drug therapy.

Indications for further investigation

Common indications for more detailed investigation in hypertension are:

1. any evidence of an underlying cause in the history or examination (Table 2);
2. proteinuria, haematuria, or elevated serum creatinine;
3. hypokalaemia not caused by diuretics;
4. accelerated (malignant) hypertension;
5. documented recent onset or recent worsening of hypertension;
6. resistant hypertension (uncontrolled by a regimen of three antihypertensive drugs); or
7. young age, meaning any hypertension in patients less than 20 years old, or hypertension needing treatment in patients aged 20 to 35 years.

In those with accelerated hypertension, a recent onset or worsening of hypertension, or resistant hypertension, the prevalence of secondary hypertension is about 25 per cent, and all should have screening tests for phaeochromocytoma, renal disease, and renovascular disease. Investigation is readily justified in these patients because their hypertension is more difficult to manage, and they often have an impaired prognosis. The chance of curing hypertension is relatively small, but underlying conditions such as phaeochromocytoma, obstructive uropathy, or some parenchymal renal diseases may require treatment in their own right. The 'enrichment' of the patient population that is investigated so as to yield positive findings in about 25 per cent is important for the performance of the screening tests widely used. Tests to screen for renovascular disease and phaeochromocytoma are imperfect, meaning that their sensitivity and specificity are less than 100 per cent. Sensitivity and specificity do not depend on the prevalence of the abnormality sought, but the predictive values of the tests are highly dependent on the underlying prevalence. Screening tests that are valuable in this selected 'enriched' population of patients are often misleading if used to screen all patients with hypertension

indiscriminately.

Hypertension at a young age is generally accepted as an indication for detailed investigation, but note that the yield of underlying causes for hypertension and curable hypertension is disappointingly small when young age is the only indication for investigation. The main justification for more aggressive investigation in young patients is that detection of curable hypertension is more valuable when the alternative is many decades of antihypertensive treatment.

Positive screening investigations will often prompt more definitive tests. These are summarized in Table 3, and discussed in more detail in the chapters dealing with renal and renovascular hypertension (Chapter 15.16.2.2), phaeochromocytoma (Chapter 15.16.2.4), Conn's syndrome (Chapter 15.16.2.3), Cushing's syndrome (Chapter 12.2), and coarctation of the aorta (Chapter 15.16.2.5).

Individual investigations

Renal and renovascular disease

Investigations for renal and renovascular disease are discussed in more detail elsewhere (Chapter 15.16.2.2), but some difficulties surrounding this topic are mentioned here. Policies for renal investigation in hypertension are not uniform, and indeed few institutions or even individual clinicians seem to agree as regards the use of (for example) renal ultrasound, intravenous urogram, isotope renogram (with or without captopril), intravenous digital subtraction angiography, renal artery Doppler, magnetic resonance angiography, or renal arteriography. This unfortunate situation has arisen because those who evaluate different diagnostic methods are not always aware of, or do not address, the diagnostic problem facing clinicians. Investigation of appropriately selected patients with hypertension turns up a wide range of renal problems, among which the most common are renovascular disease, renal scarring (previously called chronic pyelonephritis), and obstructive uropathy. The clinical evaluation does not usually indicate which of these renal pathologies is present, although there are exceptions to this. For example a young patient with hypertension and a family history of polycystic kidney disease is likely to have polycystic kidneys, and the investigation of choice is clearly ultrasound. However, patients with resistant or accelerated hypertension may have any of the renal abnormalities mentioned above. The clinician does not want a test that is specific and highly accurate for renovascular disease, or for scarring, or for obstructive uropathy, but rather needs a screening test or sequence of tests that is general purpose, that is, capable of detecting all the renal abnormalities commonly found in hypertension. Used singly some tests are clearly unsuitable for this purpose, for example the isotope renogram. The best imaging policy now is renal ultrasound, followed by magnetic resonance angiography with gadolinium enhancement where this is available; when magnetic resonance angiography is not available, ultrasound followed by arteriography; and where resources are limited the rapid-sequence intravenous urogram remains a valuable general purpose investigation.

Routine measurement of creatinine clearance is not useful, but is indicated when serum creatinine is elevated and there is uncertainty whether this is related to large muscle mass or a renal abnormality. Measurement of microalbuminuria has no proven value in non-diabetic patients.

Tests for primary aldosteronism

Measurement of the aldosterone:renin ratio to screen for primary aldosteronism (Conn's syndrome) is usually triggered by finding hypokalaemia. However, patients with primary aldosteronism may have intermittent hypokalaemia or even persistent normokalaemia, and primary aldosteronism may be more common than is generally believed. The question arises whether the aldosterone:renin ratio should be measured more often, or even routinely, even without hypokalaemia. From a practical point of view the priority is to detect primary aldosteronism caused by an aldosterone-secreting adrenal adenoma, because surgical removal of the tumour may cure the hypertension and biochemical disturbance. Patients with adrenal hyperplasia causing aldosterone excess are managed medically, and have no prospect of cure of hypertension. The severity of biochemical disturbance relates to the adrenal pathology, so that patients with adrenal adenomas have more marked hypokalaemia. From a pragmatic point of view investigation only of those patients who have hypokalaemia is likely to detect those with surgically curable Conn's syndrome. However, there may be a case for measuring the aldosterone:renin ratio in patients with resistant hypertension, even when hypokalaemia is absent, or for trying the effect of spironolactone in such patients. These issues are discussed in more detail elsewhere (Chapter 15.16.2.3).

Other blood tests

Routine measurement of full blood count is sometimes advocated because of the link between hypertension and polycythaemia, but its value is doubtful. The relation between primary hyperparathyroidism and hypertension might suggest that serum calcium should be measured routinely, but treatment of the primary hyperparathyroidism does not influence the blood pressure or cardiovascular risk. Serum uric acid is often elevated in untreated hypertension, and related to male sex, obesity, alcohol use, and renal impairment. Might routine measurement allow avoidance of diuretic treatment and reduce the risk of precipitating gout? In fact there is little relation between pretreatment uric acid and the risk of gout, and most hyperuricaemic patients do not develop gout on diuretics. Many patients would be denied these valuable drugs unnecessarily with this policy, and routine measurement of serum uric acid is not recommended. Fasting serum triglycerides make no important contribution to cardiovascular risk assessment provided HDL-cholesterol is measured, and need not be measured routinely.

Ambulatory blood pressure measurement

Ambulatory blood pressure measurement should not be used routinely or indiscriminately in the management of hypertension according to current guidelines. Specific indications for ambulatory blood pressure measurement (**ABPM**) are:

1. extreme variability of blood pressure at different visits or in different situations;
2. symptoms suggesting hypotensive episodes;
3. hypertension resistant to a three-drug regimen; or
4. sustained clinic, surgery, or office hypertension in people otherwise at low cardiovascular risk.

The last category is most important because it concerns the phenomenon termed white-coat hypertension (or isolated clinic hypertension). It is not necessary or feasible to perform ABPM to exclude white-coat hypertension in all patients with hypertension. It is not indicated in those who are at high cardiovascular or coronary risk, including patients who already have target organ damage or cardiovascular complications, and those who have an estimated coronary risk of 15 per cent or higher over 10 years. In these patients treatment decisions should be based on clinic pressures rather than ABPM, as was the case in outcome trials of hypertension treatment. ABPM is also unnecessary in patients with mild hypertension (140 to 159/90 to 99 mmHg) who have no target organ damage, no cardiovascular complications, and an estimated 10-year coronary risk of less than 15 per cent. These patients can be left untreated without using ABPM, but should be followed up. ABPM is indicated when the average clinic blood pressure is 160/100 mmHg or higher, but there is no target organ damage or cardiovascular complication, and the estimated 10-year coronary risk is less than 15 per cent. Here elevated blood pressure is the only indication of high cardiovascular risk and for antihypertensive treatment, and normal blood pressure by ABPM may alter the treatment decision. However, any decision to withhold treatment in such patients should be based on appropriately adjusted normal values for ambulatory measurement, and should be confirmed by a second ABPM record because of within-patient variability and limited reproducibility.

Echocardiography

Echocardiography is more 'sensitive' than the electrocardiogram for detecting left ventricular hypertrophy, but this does not mean that it is better or useful. Left ventricular hypertrophy is used to estimate cardiovascular risk, and the relevant question is whether echocardiography is superior to the electrocardiogram for estimating cardiovascular risk. In fact it does enhance the accuracy of risk estimation, but only very slightly, and the gain does not justify routine echocardiography. It is indicated in patients who have 'voltage criteria' for left ventricular hypertrophy, but no T-wave abnormalities. Voltage criteria alone are very unreliable, particularly in young men, and should not be used to diagnose left ventricular hypertrophy without confirmation by echocardiography.

15.16.2.2Renal and renovascular hypertension

Lawrence E. Ramsay

Introduction

Renal or renovascular abnormalities are present in about 5 per cent of all hypertensives, and 25 per cent of those selected appropriately for detailed investigation (see Chapter 15.16.2.1). Some renal lesions are incidental to hypertension, some cause the hypertension but are uncorrectable, some cause the hypertension and are correctable, but without cure of the hypertension, and finally a few cause the hypertension, and are correctable with cure of hypertension. Unfortunately this last category, curable hypertension, is very uncommon. Fibromuscular renal artery stenosis is the only form of renal hypertension that is 'usually' curable, meaning that more than 50 per cent of patients are cured.

Investigation of hypertension often uncovers renal diseases that need management or monitoring in their own right, such as polycystic kidneys, glomerulonephritis, chronic pyelonephritis, or obstructive uropathy. However, policies for investigation and particularly for intervention should be tempered by the knowledge that renal or renovascular hypertension can rarely be cured. Intervention should generally be reserved for patients with a compelling indication, for example severe and resistant hypertension, declining renal function, or 'flash' pulmonary oedema. The outcome is generally best with younger age (under 60 years), normal renal function, and a short history of hypertension.

Causes and mechanisms

Renal abnormalities that may be found in hypertensive patients are shown in Table 1, but note that the relation between hypertension and the renal lesion differs among these. In bilateral parenchymal disorders such as glomerulonephritis, interstitial nephropathy, or polycystic kidneys the prevalence of hypertension in the early stages is about 30 per cent, although it varies with the pathology. For example, hypertension is more common in mesangiocapillary type 1 glomerulonephritis (40 per cent) than in minimal change nephropathy (16 per cent). Again, hypertension is three times more likely in the common form of polycystic kidneys associated with mutations at the *PKD1* locus than in non-*PKD1* disease. The hypertension early in these conditions is probably renin dependent. With progression to renal failure the prevalence of hypertension increases to 80 to 90 per cent, and hypertension then reflects imbalance between volume and vasoconstriction, with the emphasis on volume dependence. Volume-dependent hypertension that is usually curable also occurs in bilateral obstructive uropathy, caused for example by bladder neck obstruction.

The relation of unilateral renal and renovascular abnormalities (Table 1) to hypertension also varies for different entities. Unilateral chronic hydronephrosis is no more common in hypertensive than normotensive subjects and relief of obstruction does not cure the hypertension. It is therefore an incidental finding and should be managed entirely on its own merits. Simple renal cysts or neoplasms are also generally incidental, but very rarely they can cause curable renin-dependent hypertension, either through renin production or by compression of renal tissue leading to renin release. Unilateral chronic pyelonephritis (renal scarring, reflux nephropathy) commonly causes hypertension, yet nephrectomy rarely cures the hypertension. The reason is that the contralateral kidney is usually abnormal also, due either to scarring or to the effects of hypertension itself. Fibromuscular renal artery stenosis is the most convincing cause of reversible hypertension, because correction by angioplasty cures hypertension in at least 50 per cent of cases. The relation of atherosclerotic renal artery stenosis to hypertension is complex. Correction of the stenosis cures hypertension in fewer than 10 per cent of cases, but it is significantly 'treatment sparing'. Thus intervention sometimes improves but rarely cures hypertension. The relation of atherosclerotic renal artery stenosis to hypertension probably differs between patients: in some, renal artery stenosis may be coincidental to, or even a complication of, hypertension; in others, renal artery stenosis may have caused hypertension, which has then become irreversible because of ischaemia or atheroembolic disease (cholesterol embolism); and in a minority (less than 10 per cent) renal artery stenosis is the cause of reversible hypertension. Unfortunately, no tests can distinguish between these. Investigations such as renal vein renin or split function measurements having no useful predictive value.

Clinical evaluation

Pointers to a possible renal abnormality include documented recent onset or worsening of hypertension, onset before 35 years of age, accelerated phase hypertension, resistance to drug therapy, or renal failure precipitated by ACE inhibitor treatment. The physician should enquire about present or past urinary symptoms or loin pain, a family history of renal disease or polycystic kidneys, clues to systemic conditions that may cause renal disease, such as diabetes or vasculitis, and ingestion of drugs that may be nephrotoxic. Examine for palpable kidneys (polycystic kidneys, neoplasm) or bladder (obstructive uropathy), and auscultate the epigastrium and renal angles for a vascular bruit. Systolic bruits are common and have low specificity, whereas continuous or systolic–diastolic bruits are rare but highly suggestive of renovascular disease.

Investigation

Routine investigation for renal disease is limited to serum creatinine and glucose (to exclude diabetes), and a urine stick test for protein and blood. When clinical evaluation and these routine tests are normal, further investigation is not indicated. If they suggest renal abnormality, further investigation may include:

- microscopy and culture of midstream urine; but note that absence of proteinuria, red cells, and casts does not exclude glomerular or interstitial disease with certainty
- quantitation of proteinuria over 24 h to help distinguish between glomerular and interstital disease; proteinuria of more than 1 g/24 h also signals the need for a lower blood pressure target and ACE inhibitor treatment
- renal ultrasound.

Depending on the results of these tests, additional investigation might include tests for systemic causes of renal disease ((for example antinuclear factor (ANF), DNA antibodies, antineutrophil cytoplasmic antibodies (ANCA)), renal biopsy if glomerulonephritis or interstital nephropathy is suspected, or imaging for renovascular disease (see below). However, it is often appropriate to watch rather than investigate further at this stage. For example, a patient with severe hypertension, proteinuria less than 1 g/day, mild renal impairment, and normal renal ultrasound most likely has renal damage caused by previous accelerated hypertension. It is entirely reasonable to control the hypertension, monitor the renal function closely, and investigate further only if the renal function declines.

Unilateral renal disease

Unilateral renal abnormalities should generally be treated on their own merits because nephrectomy rarely cures hypertension. However, lesions such as renal cysts or radiation nephropathy very rarely do cause curable hypertension, and patients therefore have to be considered individually. Nephrectomy should be considered only when:

- hypertension is severe and difficult to control
- hypertension is of recent onset
- the affected kidney has no or very little function

- the contralateral kidney is completely normal on detailed investigation
- serum creatinine is normal
- the patient is young and generally fit
- the patient is willing to accept a small chance of cure or improvement from operation.

In practice these criteria are rarely satisfied, and hypertension is managed medically in almost all patients with unilateral renal disease. Lateralizing tests such as renal vein renin measurements have no useful predictive value in this situation.

Renovascular disease

Aetiology

Only 20 per cent of patients with renovascular disease have fibromuscular dysplasia, but it is important that cases are recognized because patients are often young and hypertension is often curable. The most common dysplastic pathology is medial fibroplasia, in about 70 per cent (Fig. 1), with stenotic lesions that are generally distal, multifocal, rarely cause occlusion, and may affect other vessels such as the carotid or mesenteric arteries. Other forms of medial dysplasia, and perimedial fibroplasia or adventitial fibroplasia, are uncommon. Some of these are unifocal, proximal, and can cause occlusion, and are therefore readily mistaken for atherosclerotic renovascular disease. Fibromuscular dysplasia is five times more common in women than men, bilateral in about 25 per cent of cases, and much more common on the right.

Fig. 1 Selective right renal angiography in a patient with hypertension caused by fibromuscular dysplasia of the common medial fibroplasia type. Note that the lesions involve the distal part of the renal artery, are multifocal, and show the 'string of beads' appearance of alternating stenoses and poststenotic dilatations.

About 80 per cent of renovascular disease is atherosclerotic (Fig. 2). This is strongly associated with vascular disease elsewhere, particularly peripheral vascular disease, and with major risk factors for atherosclerosis including male sex, old age, diabetes, hyperlipidaemia, hypertension itself, and, particularly, cigarette smoking. Atherosclerotic stenotic lesions are usually proximal, often at the ostium of the renal artery, and bilateral in 25 per cent of cases. Atherosclerotic renovascular disease is progressive, leading to arterial occlusion in about 2 per cent of patients per year, and progression to high-grade stenosis in about 10 per cent of patients per year. Loss of about 70 per cent of the artery lumen is necessary for haemodynamic significance, but radiological assessment of the degree of stenosis is imprecise.

Fig. 2 Aortography in a 65-year-old man with severe atherosclerotic renovascular disease. There is total occlusion of the right renal artery, tight stenosis of the left renal artery (arrow), and extensive aortic atheroma.

Less common causes of renovascular disease include neurofibromatosis, transplant renal artery stenosis, aortic or renal artery dissection, embolism, Takayasu's arteritis, arteriovenous fistula, and radiation.

Diagnosis

Patients who have treatment-resistant hypertension or a decline in renal function with ACE inhibitor treatment should be assessed by a clinical prediction method that uses nine simple variables and estimates the probability that renovascular disease is present (Table 2, Fig. 3). This is at least as accurate as many of the non-invasive screening tests in wide use, such as renin measurements or isotope renography with or without an ACE inhibitor. The probability estimate should be considered together with the clinical circumstances to decide on further investigation. For example, a young patient with severe hypertension that is difficult to control, and with side-effects from drugs, would certainly be considered for investigation even if the probability of renovascular disease was only 10 per cent. By contrast, an elderly patient who was well controlled by three drugs, entirely comfortable on treatment, and had normal renal function, would be managed conservatively even if the probability of renovascular disease was much higher.

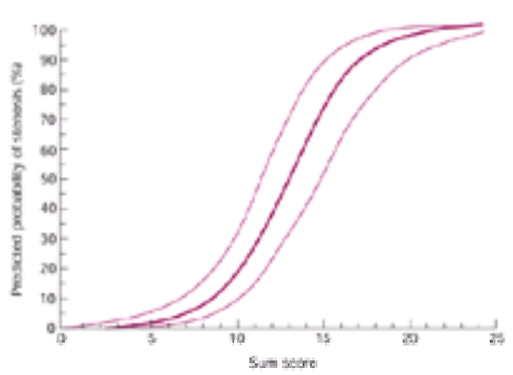

Fig. 3 Predicted probability of renal artery stenosis in patients with drug-resistant hypertension as a function of the sum score. The sum score is derived from the prediction rule in Table 2. The thin lines represent 95 per cent confidence intervals. From Krijnen *et al*. (1998) with permission.

When the probability of renovascular disease and clinical circumstances warrant further investigation, renal ultrasound is done first to exclude other abnormalities. The non-invasive investigation of choice then is magnetic resonance angiography of the renal arteries with gadolinium enhancement. Spiral computed tomography angiography is equally accurate but needs contrast medium and ionizing radiation. Doppler ultrasound examination of the renal arteries is also accurate, but highly operator dependent. Intra-arterial digital subtraction angiography is the gold standard, but is invasive. Magnetic resonance angiography, spiral computed tomography, or Doppler are all valuable methods when they are available: when they are not, ultrasound should be followed by intra-arterial digital subtraction angiography.

Management

Interventional

Stenosis caused by fibromuscular renovascular disease can be corrected completely by angioplasty in 90 per cent of cases, and does not usually require stent insertion. Hypertension is cured completely in around 50 per cent of patients and complications are uncommon. Patients who are not suitable for angioplasty should be considered for surgical bypass or reconstruction in a centre experienced in these techniques.

Atherosclerotic renovascular disease often cannot be corrected completely by angioplasty alone, but stent insertion has greatly increased the technical success and long-term patency rates. However, stenting has not improved the disappointing outcome, with hypertension cured in less than 10 per cent of patients. Complications of the procedure are common and sometimes serious. The effect of angioplasty with stent insertion on renal function in atherosclerotic renovascular disease is unclear, and currently being studied in controlled trials. Limited evidence suggests that renal function improves in one-third, declines in one-third, and remains stable in one-third, and that angioplasty with stent insertion may slow the decline in renal function in some cases. Many patients with atherosclerotic renovascular disease have a very limited prognosis because of their widespread vascular disease. Given these considerations, angioplasty with stent insertion should be considered for atherosclerotic renovascular disease in the following circumstances:

- Hypertension that is severe and uncontrollable by several drugs in combination, including high doses of a loop diuretic.
- 'Flash' pulmonary oedema—patients with critical renovascular disease, meaning severe bilateral stenosis or tight stenosis to a single functioning kidney, may develop fulminant pulmonary oedema even when left ventricular function is normal or near normal. This condition can respond dramatically to correction of atherosclerotic renovascular disease.
- Progressing renal failure in a patient with bilateral renovascular disease, despite adequate blood pressure control, and with no other cause. Intervention hoping to prevent progression is justified pending the outcome of controlled trials in progress.

Surgical correction of renovascular disease should be considered for these same indications when angioplasty with stent insertion is technically impossible, although morbidity and mortality are daunting because of extensive cardiovascular disease.

The combination of hypertension, renal impairment, and one small kidney is a common presentation in elderly patients, and is caused by renal artery thrombosis with stenosis in the contralateral renal artery. This is usually best managed medically. However, in appropriate cases revascularization of a kidney with renal artery thrombosis can restore renal function, and should be considered if the kidney length is more than about 8 cm, the thrombosis is fairly recent, and renal biopsy shows no irreversible fibrosis or glomerular loss.

Medical

Patients with hypertension and atherosclerotic renovascular disease or renal failure usually have severe hypertension that is resistant to drug therapy. As a rule they will need several antihypertensive drugs in combination. Thiazide diuretics are ineffective or insufficiently effective in patients with resistant hypertension or renal impairment, and a loop diuretic is needed, often at high dosage. ACE inhibitors are a two-edged sword in patients with hypertension and renal disease. In critical renovascular disease, defined as severe bilateral renal artery stenosis or tight stenosis to a single functioning kidney, glomerular filtration is entirely dependent on increased efferent arteriolar tone, which is maintained by angiotensin II. Treatment with ACE inhibitors or angiotensin II antagonists abolishes the increased efferent arteriolar tone, stops glomerular filtration entirely, and causes acute renal failure. ACE inhibitors and angiotensin II antagonists should be avoided, or used with extreme caution and close monitoring of renal function, in patients known to have renovascular disease or who may have renovascular disease, for example those with peripheral vascular disease or unexplained renal impairment. On the other hand, ACE inhibitors are renoprotective and positively indicated in patients who have hypertension, renal impairment, and proteinuria over 1 g/day.

Hypertensive patients who have atherosclerotic renovascular disease or renal impairment are at very high cardiovascular and coronary risk. In addition to good blood pressure control they often need treatment with low-dose aspirin, and with a statin if the serum cholesterol is equal to or more than 5 mmol/litre.

15.16.2.3 Primary hyperaldosteronism (Conn's syndrome)

M. J. Brown

Introduction

Conn's syndrome is the eponymous term that embraces the various causes of primary aldosteronism. Although the current trend in medicine is away from eponymous nomenclature and towards names that reveal more of a disease's pathogenesis, there are good arguments for retaining the eponym when there is a need to ensure much wider recognition, and diagnosis, of the syndrome. All drugs receive two names, a generic and brand name: the former is more informative but often forgettable (or unpronounceable), encouraging the use of the memorable brand name after patent life expires. 'Patent life' on Conn's description of primary hyperaldosteronism as a cause of hypertension, in 1966, long since expired, but controversy remains regarding many aspects of the syndrome—prevalence, pathogenesis, treatment—and look-alikes continue to appear.

Within the continuum of hypertension are a number of so-called secondary syndromes, meaning that the hypertension is due to a specific, recognizable cause. The search for secondary causes is sometimes motivated by the aim of finding a curable cause, but it is better to think of the aim as finding the optimal treatment.

The three different types of Conn's syndrome embrace, and illustrate, the spectrum of hypertension. Firstly, adrenal adenoma is the only curable type, but the overlap with hyperplasia contributes to the hazards of predicting cure. Secondly, bilateral hyperplasia can be hard to differentiate from the low-renin end of the spectrum of essential hypertension and on recognition is not curable, but diagnosis is still rewarding because of the usually excellent blood pressure response to spironolactone. Thirdly, the only definite genetic cause of Conn's syndrome identified to date, glucocorticoid remediable aldosteronism, is clearly incurable, but the genetic test provides an infallible diagnosis and predicts a reversal of the hypertension by an otherwise ineffective treatment.

Physiological background

The zona glomerulosa, where aldosterone—the principal salt-retaining hormone—is synthesized, is the outermost of the three secretory zones of the adrenal cortex and the usual site of the tumours or hyperplasia in Conn's syndrome. The zonas glomerulosa and fasciculata, where cortisol is synthesized, are distinguished by their respective expression of the closely related genes, *CYP11B1* encoding 11b-hydroxylase, and *CYP11B2* encoding aldosterone synthase. The secretion of aldosterone is regulated by angiotensin II, whose concentration is determined by that of circulating renin. However, aldosterone secretion also responds in some degree to ACTH, acting both directly on zona glomerulosa cells and through release of endothelin from adrenal endothelial cells and of 5-HT from mast cells. It is these alternative stimuli that may be responsible for aldosterone-dependent hypertension in low-renin patients.

The main receptor for aldosterone, the mineralocorticoid receptor, is a nuclear hormone receptor in the distal tubules and collecting duct of the kidney. Stimulation of the receptor leads to activation of the epithelial sodium channel on the apical (luminal) surface of the tubular cells, through the action of a serine/threonine kinase called serum glucocorticoid kinase, which disappears from the renal tubules after adrenalectomy. As an apparently passive consequence of the increased apical Na^+ flux into the cells, there is also enhanced activity of the basolateral Na^+,K^+-ATPase, which pumps Na^+ into the peritubular interstitium and thereby into the blood.

Of the two main adrenal steroids, cortisol is much the more abundant, by 100- to 1000-fold. Since both steroids have a similar affinity for the mineralocorticoid receptor, it used to be a mystery why aldosterone is the physiological agonist. The explanation became clear with the discovery, in the same distribution as mineralocorticoid receptors, of the enzyme 11-hydroxysteroid dehydrogenase: this enzyme inactivates cortisol to cortisone, preventing access to the receptor. The enzyme is inhibited by liquorice, or the old antiulcer drug carbenoxolone, and is congenitally deficient in homozygotes with the rare syndrome of apparent mineralocorticoid excess (see Chapter 15.16.1.2). The enzyme is also inhibited (or, rather, saturated) by very high plasma concentrations of cortisol, such as occur in patients with the ectopic ACTH syndrome (see Chapter 12.7.1). These patients develop the clinical and biochemical features of Conn's syndrome before (or without) becoming floridly cushingoid. Indeed, the lowest levels of plasma K^+ (less than 2.5 mmol/litre) in the presence of plasma Na^+ over 145 mmol/litre should suggest the diagnosis of ectopic ACTH rather than primary hyperaldosteronism.

Incidence

This is contentious. Until recently, the figure was considered to be 1 to 2 per cent of hypertensives, but this is based on the incidence in patients with the typical electrolyte pattern described below, which is now recognized to be absent in many patients. Selected series of hospital patients have suggested figures as high as 15 per cent of hypertensives. Our own survey of plasma aldosterone to renin ratios in 800 unselected hypertensive patients suggests that the true prevalence is at least 5 per cent, most of whom do not have adenomas. The increased recognition of Conn's syndrome is mainly among patients with plasma K^+ levels within the normal range. Previous algorithms designed to distinguish adenomas from bilateral hyperplasia have emphasized the absolute level of aldosterone as a guide to adenoma: it seems likely that patients with adenomas will therefore have more instantly recognizable plasma electrolyte abnormalities, unless these have been masked by treatment with a calcium-channel blocker.

Clinical characteristics

Adenomas are said to occur more commonly in women and bilateral hyperplasia more often in men, but the differences are too slight to be helpful diagnostically. Except for the rare monogenic syndrome of glucocorticoid remediable aldosteronism, Conn's syndrome is not a cause of childhood hypertension. The main, and essential, clinical feature of Conn's syndrome is hypertension, any other clinical features being secondary to hypertension or hypokalaemia, but the majority of patients are asymptomatic.

Two important features differentiate patients with Conn's syndrome from those with secondary hyperaldosteronism, in which increased aldosterone secretion is driven by elevated levels of renin and angiotensin. First, patients with Conn's do not develop oedema; it is assumed that secretion of a natriuretic hormone, such as atrial natriuretic hormone, leads to escape from the salt-retaining effect of aldosterone (the 'escape phenomenon'). Secondly, and of diagnostic value, the plasma Na^+ concentration is within—or just above—the upper part of the normal range, usually more than 140 mmol/litre, whereas in secondary hyperaldosteronism the reduced free water clearance caused by angiotensin II results in some dilution of the plasma Na^+, whose concentration is therefore less than 140 mmol/litre. Very rarely, primary hyperaldosteronism is associated with phaeochromocytoma, primary hyperparathyroidism, or acromegaly.

Investigation

Who requires investigation?

In patients with hypertension the diagnosis of Conn's syndrome should be suspected in two main circumstances. The conventional one is the presence of hypokalaemia and high normal plasma sodium concentration. Because in general practice K^+ measurements can be unreliable if samples have stood for some hours before separation, routine measurement of bicarbonate is recommended in the initial sample from a hypertensive patient. Conn's patients typically have hypokalaemic

alkalosis because stimulation of the epithelial sodium channel by aldosterone causes exchange of Na^+ for both K^+ and H^+ ions. It is important to have increased suspicion when the plasma K^+ falls (or the bicarbonate rises) substantially on diuretic treatment: the low doses of thiazide diuretics commonly used nowadays in the treatment of hypertension do not usually lower K^+ by more than 0.5 mmol/litre.

The second circumstance under which Conn's syndrome should be suspected is when patients appear resistant to conventional antihypertensive treatment and the electrolytes are 'in the direction' of Conn's, without necessarily being outside the normal range (plasma Na^+ more than 140, K^+ less than 4.0 mmol/litre).

Establishing the diagnosis of Conn's syndrome

When the diagnosis of Conn's syndrome is suspected, it should be pursued by estimation of plasma aldosterone and renin, seeking evidence of elevated aldosterone secretion in the absence of elevated renin production. An aldosterone to renin ratio of over 850 is usually diagnostic, and should at least trigger a trial of spironolactone therapy and an adrenal scan. Application of the ratio, rather than consideration of the absolute level of aldosterone, is useful in encouraging measurement of the hormones under more everyday conditions than is recommended for either hormone alone. Thus, a patient whose aldosterone secretion is elevated by physical activity will have a similar elevation in plasma renin activity. A further important practical point is that most antihypertensive drugs can be continued, provided that the clinician is aware of some potential for interference.

Effects of antihypertensive drugs on plasma renin and aldosterone

ACE inhibitors and angiotensin receptor antagonists markedly reduce the aldosterone to renin ratio in most non-Conn's patients by interrupting the negative feedback inhibition of renin secretion by angiotensin II, but do not prevent detection of an elevated ratio in low-renin patients with autonomous aldosterone secretion (i.e. Conn's). b-Blockers elevate the ratio by suppressing renin secretion more than aldosterone; in patients whose ratio but not absolute level of aldosterone is elevated, a repeat estimation of b-blockade may be worthwhile. Calcium blockers cause variable suppression of aldosterone and renin secretion, sometimes sufficiently to mask the diagnosis of Conn's syndrome. It is not necessary to stop a calcium blocker in order to measure aldosterone except in patients whose electrolyte abnormalities have been corrected by the calcium blocker. Diuretics increase renin and aldosterone in parallel, and the measurement of the aldosterone to renin ratio therefore readily distinguishes Conn's from diuretic induced hypokalaemia.

Further investigations in patients with an elevated aldosterone to renin ratio

Once the probable diagnosis is established, the next question is whether the patient has a unilateral adenoma or a bilateral hyperplasia. The answer clearly has a major influence on the choice of long-term treatment, although it is important to remember that Conn's adenomas are always benign and that some patients will opt for long-term medication in preference to surgery. A number of algorithms have been devised to help distinguish the two conditions. Some of these are based on the relatively greater response of aldosterone secretion from adenomas and hyperplasia to ACTH and angiotensin II, respectively. Thus, there is a greater diurnal rhythm in aldosterone levels in patients with adenomas, but greater response to posture in hyperplasia. The problem with these algorithms is that they usually depend on multiple measurements, requiring admission of patients to hospital, and the result is still only a probability of one or other diagnosis, insufficiently strong to make a decision about surgery. The practicalities of outpatient investigation, coupled with the quality of modern imaging techniques, dictate a more empirical approach. The clinician wants to know the following:

- Is there an operable adenoma?
- Is the contralateral adrenal anatomically normal (i.e. no adenoma)?
- Is aldosterone secretion unilateral and from the side with the adenoma?

A good magnetic resonance or computed tomography scan will usually answer the first two questions, and where imaging reveals an adrenal mass 1–2 cm in size, the probability of adenoma is high enough to justify surgery without further troublesome investigations (Fig. 1). Above this size, the possibility of an adrenal carcinoma should be considered. Below 1 cm, the anatomical scan cannot with certainty exclude non-functioning myelolipomas ('incidentalomas') or large nodules within a hyperplastic gland. Magnetic resonance imaging has the slight edge over computed tomography on specificity, but the choice between the two scans can reasonably depend on local availability.

Fig. 1 Computed tomography scan of a 2 × 1 cm left adrenal adenoma (arrowed) in a patient with Conn's syndrome.

There are two tests for lateralization, neither of which is ideal. The better is measurement of the aldosterone to cortisol ratio in samples from the adrenal veins, with a reference sample from the vena cava. A 'perfect' result is a ratio in blood from the adenoma that is ten times greater than the reference sample, with the suppressed contralateral adrenal having a ratio lower than reference. However, suppression is not always demonstrable, and a serious problem with the test is that cannulation of both adrenal veins is technically demanding; few radiologists can claim a greater than 75 per cent success at cannulating the right adrenal vein, which drains directly into the back of the inferior vena cava. A hooked catheter with side holes should be used.

The alternative test is the radio-isotope scan using selenium cholestenol as a precursor for adrenal steroids. This is less invasive than venous sampling, but in practice can inflict more discomfort and is less accurate. Because most steroid synthesis takes place in the zona fasciculata of the adrenal, this needs to be blocked by pretreatment with dexamethasone for at least a week. In addition, several of the main antihypertensives, including those most likely to be effective in Conn's syndrome, can interfere with the scan and need to be stopped. Scanning is usually performed at 3, 7, and sometimes 14 days after radionuclide administration. For reasons that are not clear, the scan is often misleading, failing to detect any uptake in some patients, and failing to lateralize in some patients with adenomas.

Treatment

Medical

The medical treatment of choice is spironolactone, which is a competitive antagonist of the aldosterone receptor. It can be started once the diagnosis is suspected from the biochemical results, and the blood pressure response is valuable in confirming the presence of increased aldosterone secretion. Most patients will have a substantial fall in blood pressure, and normalization of plasma electrolytes after a month's treatment at a dose of 50 mg daily. This relatively low dose has the advantage of reducing the risk of adverse reactions, of which dyspepsia is the main short-term and gynaecomastia the main long-term problem. However, 50 mg is too small a dose for larger patients, and it is worth prescribing as near as possible to 1 mg/kg (using the available 50 mg and 25 mg size tablets). The dose can sometimes be reduced after prolonged administration.

Not all patients with Conn's syndrome tolerate or respond adequately to spironolactone alone. Usually a dose is tolerated sufficient to permit control of hypokalaemia; if not, high doses (20–40 mg) of amiloride may be required. As mentioned above, the calcium blockers can suppress aldosterone secretion and are a logical addition. However, patients with Conn's syndrome can develop quite resistant hypertension, which is a reason for trying harder to make the diagnosis at an early stage in the

development of hypertension. Spironolactone should be stopped a week before any lateralization tests, because of the risk that suppression of the contralateral adrenal is removed.

Surgical

This is the treatment of choice for patients with the unilateral adenomas. Because the tumours are always small, they lend themselves well to laparoscopic surgery, although patients should always be warned about the possible need to proceed to an open operation. Patients should be on spiro-nolactone (if tolerated) in the period running up to surgery, but there are few risks of uncontrolled hypertension or postoperative hypotension in the surgery of Conn's syndrome.

No steroid replacement is required after surgery, when most patients are able to discontinue all antihypertensive therapy. This may not be possible in older patients, perhaps because the adenoma arose on a background of essential hypertension. There is no need for long-term follow-up.

It seems likely that Conn's is familial more often than has been recognized, or can be currently explained by any known genetic variant, and it is therefore worth considering whether siblings with hypertension should have their plasma renin and aldosterone measured.

15.16.2.4

Phaeochromocytoma

M. J. Brown

Introduction

Phaeochromocytoma is a rare tumour. Estimates of incidence are unreliable because none has been undertaken in an unselected group of patients, but it is probably in the range 0.1–1 per cent of hypertensives. During a study of prevalence of hypertension, we measured blood pressure in 30 000 healthy subjects in general practice, selected only for the absence of known hypertension or vascular disease: 8 per cent were found to have a systolic blood pressure of more than 150 mmHg, and two were subsequently found to have a phaeochromocytoma, giving an incidence of about 0.1 per cent of hypertensives. This fits our parallel experience in 750 patients referred over 10 years by general practitioners following their own diagnosis of hypertension and before initiation of treatment; only one of these patients was found to have a phaeochromocytoma. Both these series will have missed those cases in whom typical symptoms led to correct diagnosis soon after presentation with hypertension, but it is reassuring to know that for a potentially malignant tumour (unlike the situation in Conn's syndrome, see Chapter 15.16.2.3) the typical picture is unlikely to be just the tip of an iceberg.

Despite its rarity, phaeochromocytoma justifies the disproportionate interest and awareness of the condition that exists among physicians. Like a few other rare conditions which share this position, such as infective endocarditis or Addison's disease, phaeochromocytoma combines the potential for being lethal if not diagnosed and treated, and for cure in most patients if diagnosed. The diagnosis of phaeochromocytoma offers the best chance of a cure of all the secondary causes of hypertension (especially those presenting in the second half of life), and avoidance of the need for lifelong antihypertensive therapy.

The need for maintaining a high awareness of the condition is emphasized by the small number of deaths each year, in both anaesthetic and obstetric practice, due to undiagnosed phaeochromocytoma.

Catecholamine biochemistry

An understanding of the tests used to diagnose phaeochromocytoma requires reference to an outline of both the synthetic and degradative pathways of catecholamine metabolism. The term catechol refers to a phenyl ring with hydroxyl groups at adjacent carbons (conventionally, the 3' and 4' positions). The precursor essential amino acid, phenylalanine, is not itself a catechol; neither is tyrosine which has only the 3' hydroxyl. This amino acid is the substrate for the rate-limiting step in the biosynthetic pathway, tyrosine hydroxylase, which yields L-dopa, the first catechol and still an amino acid. Decarboxylation of L-dopa yields the first catecholamine in the pathway, dopamine. This can occasionally be the principal catecholamine secreted by phaeochromocytomas, or more often by childhood neuroblastomas, but in the chromaffin tissue from which phaeochromocytomas originate dopamine is usually further hydroxylated, in the sidechain bearing the amine group, to noradrenaline. The final step in the biosynthetic pathway is the *N*-methylation of noradrenaline to adrenaline, the prefix 'nor' being used for substances that are *N*-demethylated, a common step in degradative metabolism.

N-methylation usually occurs in only two sites in the body: the adrenal medulla and certain hindbrain nuclei involved in blood pressure control. The enzyme responsible, phenylethanolamine-*N*-methyltransferase, may differ between these sites, as outside the central nervous system it is dependent for induction on glucocorticoids, which are provided in the adrenal through the portocapillary circulation. The clinical importance of this is threefold. First, extra-adrenal phaeochromocytomas rarely produce adrenaline, most of the reports to the contrary being in older literature when the methodology was less satisfactory for separating adrenaline and noradrenaline. Secondly, the normal adrenal produces mainly adrenaline, and accounts for less than 2 per cent of circulating noradrenaline concentrations. Thirdly, when a tumour is present in the adrenal, the disruption of the portocapillary circulation causes a reversal of the normal adrenaline to noradrenaline ratio. The relevance of these to the clinical features and diagnosis of phaeochromocytoma will become apparent.

The metabolic breakdown of catecholamines is due to two principal enzymes, monoamine oxidase and catechol-*O*-methyltransferase. The metabolism of catecholamines is different from normal in phaeochromocytoma in that adrenaline and noradrenaline are liberated directly into the bloodstream rather than mainly into the synaptic gap around sympathetic nerve endings. Noradrenaline released into these gaps is largely recaptured by neuronal and extraneuronal uptake, being metabolized before any free amine escapes into the bloodstream. Consequently, the proportion of parent amine to metabolite is usually higher in blood and urine in the presence of a phaeochromocytoma than in any other cause of elevated catecholamine production.

The most abundant product of the action of monoamine oxidase and catechol-*O*-methyltransferase (acting in sequence, in either order) is vanillylmandelic acid. Normetanephrine and metanephrine are produced by catechol-*O*-methyltransferase from noradrenaline and adrenaline, respectively. The products of monoamine oxidase alone are less often used in diagnosis, but in specialized laboratories the ratio of one of these, dihydroxyphenylglycol, to noradrenaline is a useful clue to the origin of noradrenaline, as dihydroxyphenylglycol arises mainly intraneuronally, and relatively little is therefore formed from noradrenaline liberated directly into the bloodstream as in phaeochromocytoma.

Laboratory diagnosis of phaeochromocytoma

Measurements of catecholamine metabolites in 24-h urine samples are the most appropriate screening tests because they offer an integrated measure of total catecholamine release over this period and can be performed in most routine laboratories. Vanillylmandelic acid is the product least prone to interference, L-dopa being the only drug that can crossreact in measurement through its equivalent metabolite, homovanillic acid. Although, for the reasons discussed, quantitation of vanillylmandelic acid is less sensitive than other measures, it remains very rare that a patient with a secreting phaeochromocytoma has a 24-h vanillylmandelic acid result that is normal. High doses of a-methyldopa reduce, and occasionally normalize, vanillylmandelic acid levels by competitively inhibiting catechol-*O*-methyl-transferase. However, there is a problem of distinguishing the true positive from the relatively large number of hypertensive patients with results in the 'grey zone'. Metanephrines are arguably more sensitive than vanillylmandelic acid, but their assay is more prone to interference by drugs, especially by b-blockers.

The measurement of free catecholamines is a more specialized procedure. Assays can be made in plasma or urine, the former generally being more accurate and also allowing variation in secretion to be assessed because of the very short half-life in plasma (around 1 min) of catecholamines. The assay generally used is based on high-performance liquid chromatography separation of the catecholamines, followed by electrochemical or fluorometric detection. However, this technique does not eliminate the possibility of interference, especially in the adrenaline peak, and it is necessary to be particularly suspicious of any result showing a higher adrenaline than noradrenaline concentration. A few centres still undertake the gold-standard radioenzymatic assay in which the catecholamines are converted to their [^{3}H]-methylated derivative in the presence of catechol-*O*-methyltransferase and a [^{3}H]-methyl donor, a double-isotope technique usually being used to ensure accurate quantification.

Pathology

Phaeochromocytomas arise in chromaffin tissue, and their anatomical distribution closely parallels the sites where this tissue is present at the time of birth. These

tumours, like the normal sympathoadrenal tissue, are of neuroectodermal origin. The term phaeochromocytoma reflects the dusky colour of the cut surface of the tumour, whereas the term chromaffin refers to the brownish colour caused by contact with dichromate salts, which oxidize the catecholamines. Much has been written about pathological differences between extra-adrenal phaeochromocytomas at various sites, but this is not relevant to clinical practice except as a possible explanation for the failure of some head and neck phaeochromocytomas to accumulate the noradrenaline analogue used as a radionuclide in scanning, as discussed later.

The pathogenesis of most phaeochromocytomas is unknown. However, at least 10 per cent of patients have inherited, as an autosomal dominant, their susceptibility to phaeochromocytoma. Two syndromes are recognized, both with germline mutations in a tumour suppressor gene. In multiple endocrine neoplasia type 2 syndrome, phaeochromocytoma is most commonly associated (not necessarily at the same time) with medullary carcinoma of the thyroid. In von Hippel–Lindau syndrome, multiple other tumours can occur, most commonly retinal angiomas, but also hypernephroma and central nervous system haemangioblastomas. There is evidence of somatic mutations in the same genes as responsible for these syndromes in some of the sporadic phaeochromocytomas. Given the large size of the von Hippel–Lindau gene, it is likely that many more sporadic phaeochromocytomas have such mutations than have been identified. Familial phaeochromocytoma without other tumours can be caused by mutations in the succinate dehydrogenase complex.

Most phaeochromocytomas are benign. However, the pathologist can rarely provide a clear distinction between benign and malignant phaeochromocytomas: benign tumours can appear to be invading the capsule of the tumour, which is often ill defined, and malignant tumours may show no mitoses because of their slow rate of division.

Clinical features

Hypertension is the most common presentation of phaeochromocytoma in clinical practice; other rare presentations include unexplained heart failure or paroxysmal arrhythmias. Increasingly, small and asymptomatic phaeochromocytomas are detected through regular screening of patients with a genetic diagnosis of multiple endocrine neoplasia or von Hippel–Lindau syndrome.

In the hypertensive patients, a spontaneous history or direct enquiry will usually reveal at least one of a group of characteristic symptoms. The most common are headache, sweating, and palpitations. Less frequent are episodes of pallor, a feeling of 'impending doom', and paraesthesiae. Examination rarely reveals useful signs, but an exception is a Raynaud's-type of discoloration over the extremities and the larger joints in the limbs. This is due to ischaemia and occasionally progresses to atrophic ulceration over pressure points.

A rare initial presentation, pathognomonic of phaeochromocytoma, is with wildly swinging blood pressure, between extremes of hypertension and hypotension, in combination with other signs of retroperitoneal haemorrhage. Even prompt recognition of the diagnosis, spontaneous haemorrhage and infarction of the tumour, is not always sufficient to save patients presenting in this way. By contrast, it is important to emphasize that some patients with large tumours, causing significant hypertension, may be asymptomatic.

Many of the symptoms of phaeochromocytoma can be readily ascribed to the expected effects of the excess catecholamine, and disappear rapidly on initiation of appropriate treatment. Some remain more difficult to explain, including the sweating whose control in healthy subjects is usually ascribed to cholinergic sympathetic innervation. Because large tumours secrete principally noradrenaline, even when arising within the adrenal gland, tachycardia is usually only modest, and can be replaced altogether by reflex bradycardia when episodes of hypertension are triggered by release of noradrenaline alone. The author once treated a 'cardiac arrest' with phentolamine when the arrest call was for an episode of apparent asystole that was in reality a vagal reaction to an arterial pressure of 300/160. Severe bradycardia is also recorded in response to the paradoxical rise in blood pressure when a patient with a phaeochromocytoma is inadvertently given a non-selective b-blocker such as propranolol. In a few patients, excess catecholamine can cause myocardial necrosis, which is probably due to a mixture of a-receptor mediated vasoconstriction and a b-receptor direct toxic effect on the cardiomyocytes. These are rare presentations and it is important to recognize that clinical features are usually less impressive than expected, possibly because the adrenoceptors have been downregulated by years of exposure before the diagnosis is first entertained. Indeed, hypertensive patients who complain of symptoms suggestive of excess catecholamines are more likely to be found to be suffering from side-effects of a vasodilator drug activating the baroreflex than to have a phaeochromocytoma.

Establishing the diagnosis

The diagnosis is not usually difficult once the possibility of phaeochromocytoma has been entertained, and it is important to exclude the diagnosis in patients who have clinical and/or biochemical features of catecholamine excess due to sympathetic overactivity rather than phaeochromocytoma. There are two distinct questions to ask: 'Does the patient have a phaeochromocytoma?' and 'Where is it?'. The tests required to answer the first question are mainly biochemical, as described above, whereas the second is answered by radiological investigation. A golden rule, which saves false positives and negatives, and therefore a large number of unnecessary investigations and sometimes operations, is that the first question should be answered before proceeding to the second. No single radiological investigation is sufficiently accurate to detect more than 80 to 90 per cent of phaeochromocytomas, whilst computed tomography scanning of the adrenal glands can detect non-functional myoleiomas that should not lead to further investigation in the absence of biochemical abnormalities.

The symptoms of a functioning phaeochromocytoma are remarkably variable and may be absent. To avoid missing the diagnosis, therefore, an average size general hospital might expect each year to screen several hundred patients with hypertension, tens of patients with unexplained heart failure, and all their known patients with multiple endocrine neoplasia or von Hippel–Lindau syndromes. Although the diagnosis is often postulated in other patients with isolated features of catecholamine excess, for example patients without hypertension but complaining of palpitation, headaches, sweating, or panic attacks, the chance of such patients having a phaeochromocytoma is very, very small. In a 15-year period during which the author investigated more than 100 phaeochromocytomas and more than 1000 patients referred with a possible phaeochromocytoma, none has proven to have phaeochromocytoma in the absence of hypertension, heart failure, or a genetic syndrome.

The next question is how should screening be performed? There is no single perfect or 'best' test. It is important to recognize the diversity of analyses in use, quite different from the position for most standard endocrine analyses, and reflecting the difficulty of achieving an entirely reliable method in routine laboratories. Our own practice is to use 24-h urine vanillylmandelic acid as the initial screen in most patients, supplemented when necessary with the specialized catecholamine analyses. An entirely normal 24-h urine vanillylmandelic acid measured in a good hospital laboratory is most unlikely in the presence of a phaeochromocytoma. Conventionally, patients are asked to avoid vanilla-containing foods during the collection for assay of vanillylmandelic acid and to undertake three collections in order to exclude the diagnosis of phaeochromocytoma. Both of these precautions are unnecessary in the majority of cases: those with phaeochromocytoma have become relatively insensitive to the effects of catecholamines, hence a patient with 'significant' hypertension (diastolic blood pressure over 100 mmHg) must have a several-fold elevation of catecholamine secretion. Although the urinary vanillylmandelic acid is not proportionally elevated, for the reasons discussed earlier, the elevation is still sufficient to ensure an abnormal result provided that this is correctly measured. A vanilla-free diet is unnecessary because the dietary contribution to vanillylmandelic acid excretion is small compared with that derived from noradrenaline, and is unlikely to push the vanillylmandelic acid excretion into an abnormal range.

Most patients whose vanillylmandelic acid excretion is more than twofold above the upper limit of normal will prove to have a phaeochromocytoma, and a threefold elevation is almost always diagnostic. Patients who need further biochemical analyses are those with a less than twofold elevation of vanillylmandelic acid excretion, of whom only a very small proportion (less than 5 per cent) will have a phaeochromocytoma. Here, the single most helpful investigation is measurement of plasma noradrenaline, which will be at least twofold elevated in those with a phaeochromocytoma, whereas a single resting plasma noradrenaline will often be normal in those without.

Suppression tests

If the urinary vanillylmandelic acid analysis and assay of resting plasma noradrenaline does not resolve whether or not a patient has a phaeochromocytoma, there are two further useful investigations. The most widely used is a pharmacological suppression test, in which physiological elevations of noradrenaline release are temporarily suppressed by administration of either the ganglion-blocking drug pentolinium, or centrally acting a $_2$-agonist, clonidine. The former is more widely used in the United Kingdom and has three advantages:

1. It is most effective at suppressing noradrenaline release in the problem patients—namely those with elevated sympathetic nervous activity but without a phaeochromocytoma.
2. It also suppresses release of adrenaline from the adrenal medulla.

3. It has a short half-life (of approximately 20 min) so that the test can be completed in the outpatient clinic.

Clonidine has the supposed advantage of suppressing release of noradrenaline even when the basal level is normal, but when this is the case a suppression test is rarely necessary. An exception is in patients with von Hippel–Lindau syndrome found to have a small adrenal mass on their annual abdominal computed tomography (**CT**) or magnetic resonance scan: they may have a normal plasma noradrenaline concentration and, unlike the multiple endocrine neoplasia patients with phaeochromocytoma, the tumour secretes little adrenaline. In the multiple endocrine neoplasia patients, by contrast, an elevated plasma adrenaline concentration is the first biochemical abnormality, and biochemical diagnosis is likely to precede radiological diagnosis in multiple endocrine neoplasia, where annual scans are not indicated.

Only patients with normal or near normal renal function (serum creatinine less than 150 µmol/litre) are suitable for the pentolinium test, as this agent is entirely excreted by the kidneys. After the patient has rested supine for 15 to 30 min, plasma catecholamines are measured in two samples taken 5 min apart from an intravenous cannula, and in two further samples taken 10 and 20 min after an intravenous bolus of pentolinium 2.5 mg. They should remain supine for a further 60 min, and their erect arterial pressure should be checked before they are allowed to leave the clinic. A normal response to pentolinium is a fall of both plasma noradrenaline and adrenaline concentrations into the normal range or by 50 per cent from baseline. It should be noted that since ganglion-blocking drugs are less effective at low rates of sympathetic nerve discharge there may be little fall in plasma catecholamine values when the basal levels are already within the normal range.

Another test that can sometimes be helpful is to assay a plasma sample for dihydroxyphenyl glycol, the deaminated metabolite synthesized principally in sympathetic nerve endings. The ratio of dihydroxyphenyl glycol to noradrenaline is reversed from normal (more dihydroxyphenyl glycol than noradrenaline) in patients with phaeochromocytoma, allowing an alternative method to a suppression test for distinguishing patients with borderline noradrenaline results.

Localization of phaeochromocytomas

It is helpful to measure plasma catecholamines even in patients with unequivocal elevation of their 24-h urine vanillylmandelic acid as the adrenaline level is a most useful clue to the location of a phaeochromocytoma. Most adrenal phaeochromocytomas do secrete adrenaline, although the proportion of noradrenaline to adrenaline is reversed from that in normal subjects, whilst it is exceptional for extra-adrenal phaeochromocytomas to secrete adrenaline because of the lack of cortisol stimulation.

Although a major clue to localization can be provided by measurement of plasma adrenaline, CT scanning is the method of choice. The adrenal gland, where 90 per cent of phaeochromocytomas arise (Fig. 1), is easy to visualize, and imaging is able to distinguish cortical tumours such as a Conn's tumour from medullary tumours. These differences should, however, not be used as a basis for diagnosis: mistakes will be made if the differentiation between these tumours is attempted radiologically rather than biochemically. It should also be emphasized that both of these tumours account for a minority of adrenal tumours identified by CT, the majority of which are non-functional adenomas of no significance.

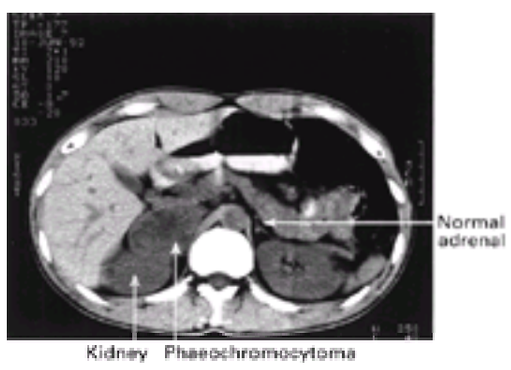

Fig. 1 CT scan of a right adrenal phaeochromocytoma. The phaeochromocytoma has the typical non-homogeneous appearance due to areas of haemorrhage and infarction. The normal left adrenal has the typical tricornuate appearance with concave borders.

While modern CT is capable of whole body imaging at high resolution, it is preferable to withhold CT for extra-adrenal phaeochromocytomas until the radiologist can be given some clue as to where to direct their activities. In about 85 per cent of patients, this can be achieved by radio-isotopescanning, using the iodinated analogue of noradrenaline, *m*-iodo-benzylguanidine. There is a case for undertaking such scanning in addition to CT, even for patients found to have an adrenal phaeochromocytoma, to identify extra-adrenal secondary deposits when tumours are malignant, and because there may be coexisting adrenal and extra-adrenal phaeochromocytomas.

If these investigations fail to localize a phaeochromocytoma diagnosed by biochemical assays, the next step is to undertake selective venous sampling. In this procedure, about 25 samples of blood for estimation of catecholamine concentration are collected under fluoroscopic guidance from various sites in the vena cava and the veins that drain into it. An arterial sample taken at the end of the procedure is invaluable for interpretation of data, as it enables sites with a positive venoarterial difference to be readily detected. Although invasive, venous sampling is free of significant hazard, but it is important that the radiologist is not tempted to undertake a venogram of the phaeochromocytoma, since this can cause immediate infarction of the tumour with release of the stored catecholamines and catastrophic consequences. The procedure is more helpful in the diagnosis of phaeochromocytoma than of other endocrine tumours because of the very short half-life of catecholamines in the circulation (about 1 min), such that most is removed during one passage round the circulation, hence the concentration at the tumour site is usually several fold greater than concentrations elsewhere. This procedure should not usually be used for adrenal phaeochromocytomas because the concentration of catecholamines is much higher than elsewhere in veins draining normal adrenals, and because CT scanning should have already rendered their imaging unnecessary. An exception, once again, is in patients with von Hippel–Lindau syndrome with small adrenal masses. As discussed above, these are the patients in whom all other biochemical tests may be normal, and the diagnosis of phaeochromocytoma is suggested by a reversal of the normal excess of adrenaline to noradrenaline in the adrenal vein. Because in von Hippel–Lindau syndrome the adrenal phaeochromocytomas are frequently bilateral, but asymmetrical, venous sampling may be required to determine whether one or both adrenals need to be removed.

The place of angiography has been much diminished but not entirely removed by the advent of CT scanning. As phaeochromocytomas are vascular tumours, they provide a good tumour blush, and angiography should resolve equivocal CT scans. However, by contrast to venous sampling, this procedure can provoke an outpouring of catechols. Patients must be fully a- and preferably also b-blocked prior to angiography, and their blood pressure, pulse rate, and ECG must be monitored during the procedure with phentolamine and atenolol readily available to treat arterial hypertension or tachycardia.

In some centres, magnetic resonance imaging may be tried before angiography to determine the nature of lesions of doubtful significance on CT. However, the semi-infarcted nature of some phaeochromocytomas can make it difficult to interpret magnetic resonance scans, and in our experience such imaging has only helped with a few head and neck phaeochromocytomas that were not detected by *m*-iodobenzylguanidine or CT scanning.

Other investigations

It is important to check blood glucose in every patient as there may be a mediated inhibition of insulin release prior to effective treatment. All patients should be screened for an associated medullary carcinoma of the thyroid by plasma calcitonin estimation.

Apart from the catecholamines, most phaeochromocytomas also secrete one or more neuropeptides, especially neuropeptide Y (NPY), which is a normal cotransmitter of noradrenaline and adrenaline. There is no need routinely to measure other neurotransmitters that may be cosecreted with the catecholamines, but unusual symptoms may indicate that a gut peptide screen should be undertaken. Although very rare, it is essential to detect (especially preoperatively) coexisting ectopic adrenocorticotropic hormone syndrome that manifests as gross hypokalaemia. A particular catch is that the excess secretion of catecholamines may suppress release

of other peptides until treatment with a-blockade is initiated, hence it is important to recheck the electrolytes after a few days of a-blocking treatment.

Even where there is no suggestive family history, routine slit-lamp examination of the fundi has resulted in a more frequent diagnosis of von Hippel–Lindau syndrome, sometimes as a *de novo* occurrence.

Treatment

The definitive treatment is surgical removal of the tumour or tumours. Even the small number of phaeochromocytomas that can be recognized to be malignant preoperatively (e.g. by the presence of bone or liver metastases) may still benefit from resection of the primary tumour. The task for the physician is to make the surgery safe. The mainstay of medical treatment is a-blockade, but not all patients—especially those without elevated plasma adrenaline levels—require b-blockade. The objective of this treatment is not solely control of blood pressure but also the expansion of blood volume, which is always reduced in those with a phaeochromocytoma. The a-blocker of choice is phenoxybenzamine, the principal reason for this being that it is irreversible, actually destroying the a-receptor by alkylation. More modern a-blockers, such as prazosin, doxazosin, and the mixed a- and b-blocker, labetalol, cause competitive blockade, which can be overcome by a surge of noradrenaline release from the tumour. An additional advantage of phenoxybenzamine is that it will block both a_1- and a_2-receptors. Blockade of the latter is considered disadvantageous in essential hypertension since the main a_2-receptors outside the central nervous system are presynaptic and may serve a useful role in damping neuronal release of noradrenaline, whereas in phaeochromocytoma patients a_2-receptor blockade may be advantageous because a small population of extrasynaptic a_2-receptors mediate direct vasoconstriction by circulating (non-neuronal) catecholamines. The diabetogenic effect of catecholamines is also an a_2-mediated response.

The starting dose of phenoxybenzamine depends on the degree of catecholamine excess, but is usually 10 mg twice daily. The effect of irreversible antagonists is cumulative, and the effect of the drug—and each subsequent dose increment—takes several days to reach maximum. It is reasonable to aim for a diastolic blood pressure of between 90 and 100 mmHg during outpatient treatment, and to admit patients for 5 days preoperatively, during which time the dose is increased until there is at least a 10 mmHg postural fall in blood pressure and little if any variability in arterial pressure. An important objective of preoperative a-blockade is expansion of intravascular volume. Surgery should not take place until a new steady-state weight has been achieved, which usually requires about a month.

The need for b-blockade is indicated by tachycardia, which may become apparent only after treatment with phenoxybenzamine. Lower doses of b-blocking drugs are necessary than used generally in the treatment of hypertension, and it is usually better to use a selective b_1-selective agent so that the peripheral vasodilatation mediated by b_2-receptors is not affected. The reason for using as low a dose as possible is that immediately upon removal of the phaeochromocytoma there may be a period of hypotension despite the preoperative preparation that has been outlined. This is due to the withdrawal of any a-mediated vasoconstriction, and should normally be offset by the ability to mount a tachycardia. It is important to note that if hypotension does occur, it should not be treated with pressor agents; the correct treatment is by volume replacement, supplemented if necessary by b-agonists. Most vasoconstrictor drugs are unlikely to be effective, because of the previous treatment with phenoxybenzamine. Angiotensin is no longer available as a pharmaceutical preparation.

The treatment of malignant phaeochromocytomas remains uncertain and unsatisfactory. As is the case for many endocrine cancers, the rate of growth is usually slow, but outcome can vary from local recurrence at intervals of many years to rapid demise, sometimes precipitated by surgery. These tumours are not particularly sensitive to either chemotherapy or radiotherapy. There has been interest in the use of therapeutic doses of *m*-iodobenzylguanidine, as a means of targeting high doses of radioactivity to the tumour, and some patients show considerable regression after such treatment. Long-term results are less certain. If the primary tumour has been removed or debulked, it is rare for the pharmacological effects of the tumour to be the principal problem. However, if this is the case, then high doses of phenoxybenzamine are greatly preferable to a-methyltyrosine, occasionally used as an inhibitor of noradrenaline synthesis, but which also depletes noradrenaline in the brain, causing sedation and depression.

Prognosis

Ninety per cent of phaeochromocytomas are benign. For adrenal phaeochromocytomas, the proportion is probably even higher, whereas extra-adrenal phaeochromocytomas have a greater than 10 per cent likelihood of proving malignant. However, because of the difficulties already described in ascertaining malignancy, all patients with a phaeochromocytoma should be followed indefinitely with at least an annual measurement of arterial pressure and analysis of one of the indices of catecholamine secretion.

The removal of a phaeochromocytoma cures most patients of their hypertension, especially the younger ones. In only 13 out of a personal series of 76 patients with phaeochromocytoma was the blood pressure greater than 140/85 at 6 and 12 months postoperatively (compared with an average 172/114 at presentation), and these 13 were all aged over 50 (compared with an average age of 37 for all 76 patients).

15.16.2.5Aortic coarctation

Lawrence E. Ramsay

Further reading

Coarctation is a congenital narrowing of the aorta near the junction with the ligamentum arteriosum and usually distal to the left subclavian artery. About 20 per cent of coarctations present in adolescent or adult years, often with hypertension, but coarctation is very rare in unselected hypertensive patients. It is very easy to overlook, but should come to mind in hypertensive patients who are young, male (four times commoner than in females), have isolated or disproportionate systolic hypertension, have a prominent murmur over the precordium or back, have disproportionate left ventricular hypertrophy, or have Turner's syndrome. About 70 per cent have other congenital abnormalities, most commonly a bicuspid aortic valve, but also ventricular septal defect or patent ductus arteriosus. Palpate routinely for delayed or weak femoral pulses in all hypertensive patients. When coarctation is suspected, seek other clinical features which include palpable collaterals in the back, displaced apex beat and systolic thrill, systolic murmurs over the coarctation, collaterals, or aortic valve, and an ejection click or loud aortic valve closure. Measuring blood pressure in the legs with a sphygmomanometer is a nightmare, and Doppler measurement of the ankle–brachial pressure index is much more accurate. A chest radiograph may show rib notching (Fig. 1), cardiomegaly, and abnormal aortic configuration. The diagnosis is confirmed by aortography (Fig. 2) or magnetic resonance imaging (Fig. 3). Echocardiography reveals the state of the aortic valve and left ventricle, and aortography is done before intervention to define the anatomy and haemodynamics.

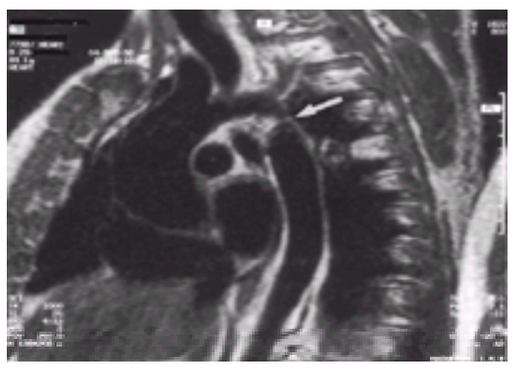

Fig. 3 Sagittal spin echo magnetic resonance image scan showing a well defined coarctation (arrow) in the typical position. (By courtesy of Dr N. Boon.)

Untreated coarctation has a bad prognosis because of heart failure, aortic rupture or dissection, cerebral haemorrhage related to berry aneurysms, bacterial endocarditis or endarteritis, and other complications of hypertension. Correction of coarctation improves survival, but not to a normal life expectancy. The prognosis after correction is affected adversely by correction at an older age, and persistent hypertension after correction. Coarctation should therefore be dealt with as soon as it is diagnosed, provided that this is technically possible and the patient is otherwise fit. Surgical repair may be complicated by postoperative paradoxical hypertension, and mesenteric or spinal ischaemia. Balloon angioplasty has lower immediate morbidity and mortality, and is possible as a primary procedure in about 90 per cent of cases, and also for recoarctation. There is uncertainty about the long-term outcome after angioplasty, particularly as regards development of aneurysms, but data to 5–10 years postangioplasty are reassuring. Nevertheless, indefinite follow-up and monitoring with repeat magnetic resonance scans are needed to detect possible recurrence or aneurysm development. About 30 per cent of patients still need treatment for hypertension after correction, with a higher probability as the age at correction increases. Patients need advice on prophylaxis against bacterial endocarditis before and after correction.

15.16.2.6Other rare causes of hypertension

Lawrence E. Ramsay

Further reading

Identifiable causes of hypertension are commonly renal, renovascular, drug-induced, primary aldosteronism, or a phaeochromocytoma. There are numerous other causes of, or associations with, hypertension (Table 1). Some are rare conditions that usually cause hypertension (for example, liquorice excess, renin-secreting tumour); some are rare conditions that rarely cause hypertension (for example, carcinoid syndrome); some are common conditions that rarely present as hypertension (for example, pregnancy presenting as pre-eclampsia); and some are associations that may not be causal (such as hypothyroidism, acromegaly).

Mineralocorticoid excess is suggested by hypertension, hypokalaemia, and high or high-normal serum sodium levels. Primary aldosteronism (Conn's syndrome, see Chapter 15.16.2.3) is the commonest cause, but rare causes should be suspected (Table 1) if the aldosterone level is low or normal rather than high. Most important among these is excess liquorice ingestion, because asking one simple question may avoid complex and costly investigations and rapidly resolve the hypertension and biochemical abnormalities. Liquorice excess causes hypertension, hypokalaemia, and increased levels of free cortisol in urine through an acquired 11-dehydro-genase deficiency.

Table 1 includes several conditions that can cause paroxysmal hypertension, sometimes with additional symptoms that may closely mimic a phaeochromocytoma. Some also show excess urinary or plasma catecholamines, particularly posterior fossa tumours near the fourth ventricle, which may be tiny and virtually undiagnosable. These causes of paroxysmal hypertension should be considered when investigation of a patient with features suggesting phaeochromocytoma fails to localize a phaeochromocytoma or other catecholamine-secreting tumour.

15.16.3 Hypertensive emergencies and urgencies

Gregory Y. H. Lip and D. Gareth Beevers

Introduction

Hypertensive emergencies occur when severe hypertension is associated with acute end-organ damage. These can take a variety of forms and can occur at any age. They may be acute life-threatening medical conditions, and are associated with either severe hypertension or sudden marked increases in blood pressure (Table 1). Symptomatic patients with complications such as aortic dissection and hypertensive encephalopathy require parenteral antihypertensive therapy to reduce the blood pressure promptly, but in a controlled manner and with careful monitoring. However, over-rapid treatment may itself be hazardous, leading on occasions to ischaemic complications such as stroke, myocardial infarction, or blindness. Thus, in patients who have severe hypertension but are asymptomatic, slower controlled reduction in blood pressure should be achieved with oral antihypertensive agents, making such situations hypertensive 'urgencies' rather than 'emergencies'.

In general, there has been a decline in the incidence of hypertensive emergencies over the past 20 years in the Western world, which may possibly be the result of the more effective detection, diagnosis, and treatment of mild to moderate hypertension.

If patients with hypertensive emergencies are not recognized or treated appropriately, the mortality and morbidity can be very high, with the 1-year mortality being 70 to 90 per cent, and the 5 year mortality 100 per cent. With adequate blood pressure control, the 1-year and 5-year mortality rates decrease to 25 and 50 per cent, respectively. The mortality of untreated malignant phase hypertension (a hypertensive urgency rather than emergency) is around 80 per cent at 2 years, and if managed inappropriately there is also a high rate of progression to renal dysfunction, necessitating long-term dialysis, in addition to strokes and heart failure.

Clinical presentations

Hypertensive emergencies occur most commonly in patients with previous hypertension, especially if inadequately managed. Nevertheless, some patients can present with hypertensive emergencies *de novo*, without any previous history of hypertension.

Very severe and malignant hypertension are more likely to be associated with underlying causes such as renovascular disease, primary renal diseases, phaeochromocytoma, and connective tissue disorders, but malignant hypertension complicating primary hyperaldosteronism (Conn's syndrome) is very rare. Approximately 50 per cent of patients with malignant hypertension have an underlying cause.

Pathophysiology

The common denominator in hypertensive emergencies is intense peripheral vasoconstriction, resulting in a rapid rise in blood pressure and a vicious circle of events, including ischaemia of the brain and peripheral organs. This ischaemia stimulates neurohormone and cytokine release, exacerbating vasoconstriction and ischaemia, further increasing blood pressure and resulting in target organ damage. In addition, myointimal proliferation in the vasculature may exacerbate the situation, as can disseminated intravascular coagulation. Also, renal ischaemia leads to activation of the renin–angiotensin system, causing further rise in blood pressure and microvascular damage.

With mild to moderate elevation of blood pressure, the initial response of the vasculature is arterial and arteriolar vasoconstriction. Thus autoregulation maintains tissue perfusion at a relatively constant level and prevents the raised blood pressure from damaging the smaller, more distal blood vessels. Later, arteriolar hypertrophy also minimizes the transmission of pressure to the capillary circulation. In chronic hypertension, the lower limit of autoregulation of cerebral blood flow is shifted towards higher blood pressures, with impairment of the tolerance to acute hypotension. In normotensive subjects, the upper limit of autoregulation can be a mean arterial pressure of 120 mmHg (equivalent to 160/100 mmHg), but in individuals whose vessels are hypertrophied by long-standing hypertension, this upper limit is substantially higher (Fig. 1 and Plate 1). However, with rapid and severe rises in blood pressure, this process of autoregulation fails, leading to a rise in pressure in the arterioles and capillaries, causing vascular damage. Disruption of the endothelium allows plasma constituents (including fibrinoid material) to enter the vessel wall, narrowing or obliterating the lumen in many tissue beds. The level at which fibrinoid necrosis occurs is dependent upon the baseline blood pressure. In the cerebral circulation this can lead to the development of cerebral oedema and the clinical picture of hypertensive encephalopathy.

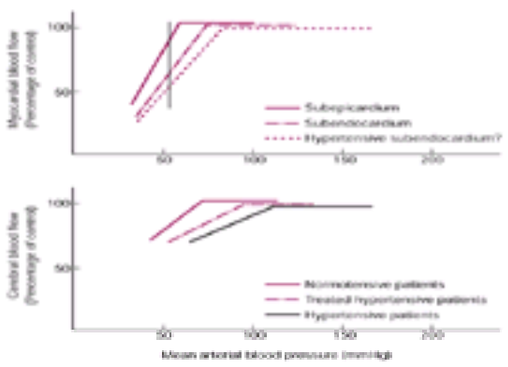

Fig. 1 Autoregulation of myocardial and cerebral blood flow in normotensive and hypertensive patients. (Reproduced from Strandgaard S, HaunsØ S (1987). Why does antihypertensive treatment prevent stroke but not myocardial infarction? *Lancet* **ii**, 658–60, with permission.)

In addition to protecting the tissues against the effects of hypertension, autoregulation maintains perfusion during the treatment of hyper-tension via arterial and arteriolar vasodilatation. However, falls in blood pressure below the autoregulatory range can lead to organ ischaemia, and the arteriolar hypertrophy induced by chronic hypertension means that target organ ischaemia will occur at a higher pressure than in previously normotensive subjects.

Malignant hypertension

The malignant phase of hypertension is a rare condition characterized by very high blood pressures, with bilateral retinal haemorrhages and/or exudates or cotton wool spots, without the added requirement for papilloedema (Fig. 2). This clinical definition of malignant hypertension includes both Keith, Wagener, and Barker grades 3 and 4 retinopathy, previously designated as 'accelerated' and 'malignant' hypertension, respectively. Differentiation between Keith, Wagener, and Barker grades 3 and 4 retinopathy has been shown to be unhelpful, as the presence of papilloedema is an unreliable sign. Furthermore, both categories carry an equally bad prognosis and should therefore be considered the same disease—'malignant' hypertension.

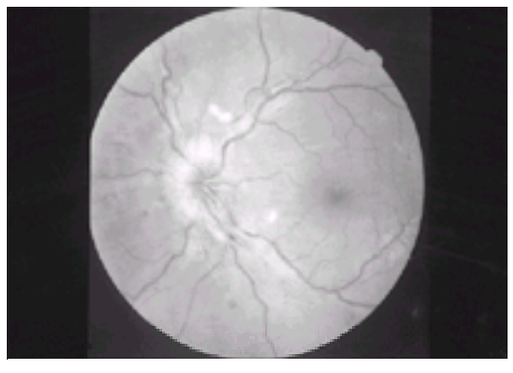

Fig. 2 Ocular fundus in hypertension, showing papilloedema, exudates, and a few haemorrhages. (See also Plate 1.)

The pathophysiological definition of malignant hypertension is based on the histological hallmark of fibrinoid necrosis of arterioles in many tissues, particularly the kidney. The histological changes are broadly similar to those seen in the haemolytic–uraemic syndrome or scleroderma. Mucoid intimal proliferation in renal interlobular arteries and ischaemic collapse of the glomerular tufts may also be seen. In black patients, myointimal hyperplasia is a common finding. The consequent intrarenal vascular disease leads to ischaemia of the juxtaglomerular apparatus and activation of the renin–angiotensin system with further vasoconstriction and wall damage, as well as exacerbation of the hypertension.

Epidemiology

Malignant hypertension has been reported to be becoming rarer in some countries, particularly amongst white populations. However, malignant hypertension still remains a common problem in the Third World and in other populations with health and social deprivation, where it is an important cause of endstage renal failure. Furthermore, in west Birmingham in the United Kingdom, the incidence of malignant hypertension was found to be around 1 to 2 per 100 000 population per year, with no clear reduction between 1970 and 1993 in the number of new cases seen, the mean duration of known hypertension before presentation, presenting blood pressures, or the number of antihypertensive drugs that were being used.

Whilst essential hypertension is usually the most common underlying cause of malignant hypertension in adults, secondary causes are more prevalent among younger patients. In children (aged less than 16 years) with malignant hypertension, parenchymal renal disease is the commonest cause (63 per cent), with 33 per cent having renovascular hypertension (aortoarteritis and fibromuscular dysplasia), and only 5 per cent with essential hypertension.

There is an association between cigarette smoking and malignant hypertension, which remains unexplained. Very rarely, the oral contraceptive pill may be implicated, consistent with the well-recognized increase in blood pressure in some women taking the 'combined' oestrogen/progesterone oral contraceptive pill. It is uncertain whether oral contraceptives di-rectly cause hypertension, or whether they simply exaggerate a tendency in women who already have a propensity to raised blood pressure. Malignant hypertension may also occur in the elderly, and is more common in Afro-Caribbean than white Caucasian and Indo-Asian populations. Possible reasons for the higher proportions of black and Asian people include the relative resistance of black patients to some antihypertensive therapies and perhaps poorer drug compliance.

One reason for the failure of malignant hypertension to decline in some centres may be inadequate medical screening facilities among poorly educated people with a limited understanding of the nature of the disease and the need to comply with antihypertensive therapy. Any reduction in the incidence of malignant hypertension may be because of the increasing use of drug therapy in the milder grades of hypertension preventing progression to the malignant phase. Nevertheless, it is possible that there has been no real decline in malignant hypertension, but merely a failure to recognize this life-threatening condition.

Clinical features

Some patients with malignant hypertension remain asymptomatic, but others present at a late stage of their disease. This proportion ranged from 10 to 75 per cent in one series from Nigeria. The predominant presenting symptom is visual disturbance with or without headaches. In the west Birmingham series, the presenting mean systolic and diastolic blood pressures have remained surprisingly similar over the 24 years surveyed (average blood pressure 228/142 mmHg), despite improvements in antihypertensive therapy. Heart failure, angina, or myocardial infarction are complicating features in approximately 20 per cent of patients with malignant hypertension, and ECG shows a high proportion of patients to have cardiomegaly and left ventricular hypertrophy. Nevertheless, some patients do have normal chest radiographs, ECGs, or echocardiograms despite very high blood pressure, suggesting that hypertension may have been of acute onset.

Investigation of malignant hypertension

All patients with malignant hypertension need a detailed clinical history and examination and investigation with blood tests (full blood count, serum biochemistry—including electrolytes and renal function), 12-lead ECG, chest radiography, and urinalysis. Fundoscopy and retinal photography are mandatory. The kidneys should be imaged by abdominal ultrasound to assess renal size and appearance, with a low threshold for proceeding to renal angiography to look for renal artery stenosis if the kidneys are asymmetric. A 24-h urine collection is necessary for urine catecholamines and protein excretion in all patients. These initial screening tests serve to identify patients in whom additional investigations may be appropriate to detect a secondary cause of hypertension.

The full blood count and film may reveal the anaemia of chronic renal failure or occasionally a microangiopathic haemolytic anaemia, with red cell fragmentation and intravascular coagulation, possibly related to the degree of arteriolar fibrinoid necrosis. Serum urea or creatinine should initially be measured daily, and if stable, creatinine clearance may be measured to give a more precise estimate of renal function. Raised serum creatinine or urea, indicating renal impairment, may have significant prognostic implications. Mild hypokalaemia may be present, due to secondary hyperaldosteronism. This usually resolves after control of the hypertension. Only very rarely does hypokalaemia indicate primary hyperaldosteronism (Conn's syndrome), but if it is extreme or persists despite good blood pressure control, then the characteristic findings of low renin levels but high aldosterone concentrations may be present. More commonly, both plasma renin and aldosterone levels are high in malignant hypertension, usually attributed to juxtaglomerular ischaemia. Urinalysis may demonstrate proteinuria and haematuria, even in the absence of primary renal disease, but the presence of proteinuria is a poor prognostic sign. Inflammatory markers (erythrocyte sedimentation rate and C-reactive protein) are often modestly elevated in malignant hypertension, but measurement of autoantibodies (antinuclear antibodies and antineutrophil cytoplasmic antibodies) can be used to discern uncommon cases due to vasculitis. Renal biopsy is required to make a specific diagnosis in some instances, but should not be performed until after blood pressure is controlled. The chest radiograph may show cardiomegaly and the presence of pulmonary oedema. Cardiomegaly and the presence of left ventricular hypertrophy can also be assessed using echocardiography.

Retinopathy in malignant hypertension

The most widely used classification of hypertensive changes in the fundus is that of Keith, Wagener, and Barker (Table 2). The strength of this classification was the correlation between clinical findings and prognosis, where grades 3 and 4 had a poor prognosis compared with grades 1 and 2. Although widely used, this grading system has some limitations, and has been made obsolete by advances in the understanding of the pathophysiology of arterial hypetension and the availability of

effective antihypertensive therapy. This and other traditional grading systems have therefore become less applicable to clinical practice than previously. The ophthalmoscopic grading can be simplified into two workable groups: grade A (non-malignant)—arteriolar narrowing and focal constriction, which also correlate with age and general cardiovascular status as well as blood pressure; and grade B (malignant)—linear flame-shaped haemorrhages, and/or exudates, and/or cotton wool spots with or without disc swelling.

Similar retinal appearances with haemorrhages and papilloedema can occur in severe anaemia, connective tissue disease, and infective endocarditis. Benign intracranial hypertension may cause bilateral papilloedema, but is usually self-limiting and minimally symptomatic. Nevertheless, severe hypertension and lone bilateral papilloedema may be a variant of malignant hypertension, with similar clinical features and prognosis. The retinal features of malignant hypertension regress over a period of 2 to 3 months if good blood pressure control is achieved.

The kidney in malignant hypertension

Renal involvement in malignant hypertension has been referred to as malignant nephrosclerosis, manifest as haematuria, proteinuria, and (sometimes) acute renal failure. Renal failure was the commonest cause of death in the west Birmingham series, and presenting urea and creatinine levels were independent predictors of survival. The Aberdeen Hypertension Clinic also found that serum creatinine at referral was an independant predictor of survival.

When antihypertensive therapy is initiated and blood pressure control achieved, the effect on renal function is variable. In the short term, renal function stabilizes in 10 per cent of cases, deteriorates progressively in 30 per cent, and deteriorates transiently before improving over a matter of weeks in the remainder. Isles and coworkers have suggested that the renal outcome of patients with malignant hypertension can be considered in three groups, each with a different renal prognosis: (i) patients whose serum creatinine is less than 300 µmol/l at presentation, who do well with effective antihypertensive therapy; (ii) patients with chronic renal failure (serum creatinine greater than 300 µmol/l) who do not require renal dialysis immediately, but are unlikely to maintain or recover renal function, except possibly in the short term, and commonly progress to endstage renal failure; and (iii) a small group with acute renal failure. Some of these patients may have post-streptococcal acute nephritic syndrome, characterized by retinopathy, fluid retention, and usually complete renal recovery. Thus, in the long term, some patients with mild renal impairment at first presentation may improve or even regain normal renal function as fibrinoid necrosis heals, especially with good blood pressure control. This is unlikely to occur in patients with more severe renal impairment at presentation.

There are varying reports of the frequency of renovascular disease in malignant hypertension, and this variation may be due to the frequency of renal angiography. In older patients, renal artery stenosis is more likely to be due to atheromatous disease which itself may be a consequence of chronic hypertension and chronic hyperlipidaemia, as well as cigarette smoking. In younger patients and particularly in women, renal artery stenosis may be due to fibromuscular dysplasia of the renal arteries with the characteristic 'string of beads' appearance on renal angiography. The value of surgical or angioplastic correction of atheromatous disease is debatable, possibly producing no better results than effective blood pressure control with antihypertensive drugs. In patients with fibromuscular dysplasia, however, renal angioplasty is worthwhile and may sometimes lead to a normal blood pressure level.

Practical guidelines for management of malignant hypertension

All patients with malignant hypertension should be admitted for assessment, investigation, and commencement of therapy under supervision. The initial aim of treatment is to lower the diastolic pressure to about 100 to 105 mmHg over a period of 2 to 3 days, with oral therapy and dose escalation at daily intervals if necessary. The maximum initial fall in blood pressure should not exceed 25 per cent of the presenting value. Blood pressure should be measured 4 hourly. Gradual reduction will allow adaptation of disordered tissue autoregulation and avoid target organ ischaemia. More aggressive antihypertensive therapy is both unnecessary and dangerous as it may reduce the blood pressure to below the autoregulatory range, leading to ischaemic events such as strokes, heart attack, or renal failure.

The first-line oral antihypertensive agent is either a short-acting calcium antagonist (such as nifedipine) or a b-blocker (such as atenolol). An appropriate dose of nifedipine is 10 to 20 mg of the tablet formulation, which can be repeated or increased as necessary to bring about gradual reduction in blood pressure. Nifedipine is not absorbed from the oral mucosa, and there have been reports of complications including visual loss, cerebral infarction, and myocardial infarction with nifedipine therapy using the short-acting sublingual capsules. Sublingual nifedipine produces unpredictable falls in blood pressure and should never be used. b-Blockers are useful alternatives, but should be avoided in patients with asthma or where there is a high suspicion of an underlying phaeochromocytoma. It is sensible to start with small doses, such as 25 mg of atenolol, increasing as necessary. The combination of oral atenolol and nifedipine is often a well tolerated and effective regime.

Diuretics should be restricted to those with evidence of fluid overload. Some patients are volume depleted, presumably secondary to a pressure-related diuresis and activation of the renin–angiotensin system. Captopril and the other ACE inhibitors can produce rapid and dangerous falls in blood pressure, particularly in patients with hypokalaemic secondary hyperaldosteronism and hyponatraemia secondary to juxtaglomerular ischaemia or renovascular disease, which may be unrecognized in the acute situation. Over a period of about 1 to 2 weeks, further antihypertensive drugs should be added in to achieve a gradual reduction of blood pressure to less than 140/85 mmHg. Triple or quadruple drug regimens are invariably necessary in the long term.

Prognosis

If malignant hypertension is left untreated, around 80 per cent of patients die within 2 years, hence the name. The importance of early diagnosis is emphasized as patients tend to develop clinical symptoms only at a late stage of their disease. Black male patients with malignant hypertension have a poor prognosis when compared with other ethnic groups or women. These patients also present with more severe hypertension and greater renal damage, which represent independent predictors of outcome and explain the poorer prognosis.

The advent of effective and tolerable antihypertensive drug therapy has meant that this prognosis is greatly improved. For example, in the west Birmingham malignant hypertension series, median survival times for the patients presenting before 1970, between 1970 and 1979, and between 1980 and 1989 were 39.2, 68.6, and 144.0+ months, respectively, suggesting an improvement in prognosis with more recently diagnosed patients (Fig. 3). The series by Scarpelli and coworkers reported a 12-year survival rate of about 69 per cent, although patients with malignant hypertension diagnosed after 1980 had a 100 per cent survival rate. Whatever the cause, progressive renal impairment is still a common complicating factor in malignant hypertension, with many patients needing dialysis in the long term.

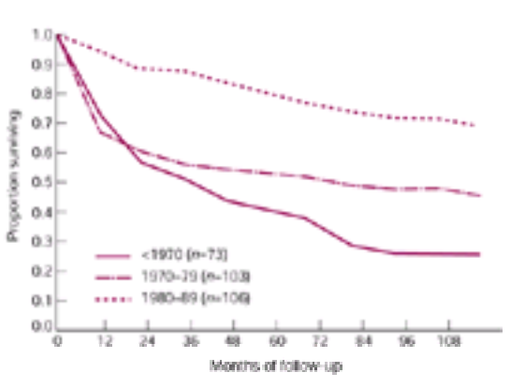

Fig. 3 Prognosis in 282 patients with malignant hypertension, divided into cohorts depending on year of presentation. (Reproduced from Lip GYH, Beevers M, Beevers DC (1995). Complications and survival of 315 patients with malignant-phase hypertension. *Journal of Hypertension* **13**, 915–24, with permission.)

Hypertensive left ventricular failure

Hypertension causes heart failure by a number of mechanisms: these include pressure overload on the heart due to the raised peripheral vascular resistance, reduced left ventricular compliance (for example, in left ventricular hypertrophy), an increased risk for coronary artery disease and the precipitation of cardiac arrhythmias (such as atrial fibrillation). Severe hypertension results in a significant increase in afterload and may result in decompensation of the failing heart.

In addition to the conventional management with opioids and loop diuretics, in very severe hypertension with marked pulmonary oedema, intravenous sodium nitroprusside may be necessary to reduce preload and afterload. Nitrates may also be used, but are less potent than sodium nitroprusside. ACE inhibitors should be considered in these patients only after stabilisation. These drugs are well-established to be life-saving in patients with left ventricular systolic impairment, and in addition they lead to long-term regression of LVH, which may also improve heart failure secondary to diastolic dysfunction.

Hypertensive encephalopathy

Hypertensive encephalopathy refers to the presence of signs of cerebral oedema caused by breakthrough hyperperfusion following severe and sudden rises in blood pressure. There is failure of autoregulatory vasoconstriction with focal or generalized dilatation of small arteries and arterioles. This leads to high cerebral blood flow, dysfunction of the blood–brain barrier, and the formation of brain oedema, which is thought to cause the clinical symptoms. The condition is very rare, and it is essential to ensure that this hypertensive emergency is distinguished from other neurological syndromes associated with high blood pressure, including intracerebral or subarachnoid haemorrhage, ischaemic stroke, or lacunar infarction.

Hypertensive encephalopathy is usually associated with a history of hypertension which has been inadequately treated, or where previous treatment has been discontinued. The condition is characterized by the insidious onset of headache, nausea, and vomiting, followed by visual disturbances and fluctuating non-localizing neurological symptoms such as restlessness, confusion, and, if the hypertension is not treated, seizures and coma. Severe retinopathy is frequently present, but not always.

The cerebrospinal fluid is usually normal but is at an increased pressure. The electroencephalogram may show variable transient, focal, or bilateral abnormalities. The CT scan or MRI may demonstrate white matter oedema: one of these tests is mandatory to exclude cerebral haemorrhage or infarction. Indeed, the increased use of CT scanning has demonstrated that almost all patients who appear to have hypertensive encephalopathy have cerebral infarction or haemorrhage with surrounding oedema and space-occupying cerebral symptoms.

Sodium nitroprusside is the drug of choice for genuine hypertensive encephalopathy but is not usually given if there is a cerebral infarct or haemorrhage. Parenteral labetalol and nitrates have also been used successfully. Rarely, diazoxide and hydralazine have been used, but they can cause precipitate and life-threatening acute falls in blood pressure. Sublingual nifedipine capsules should never be used (see above).

Severe pre-eclampsia and eclampsia are discussed in detail elsewhere. They may present with clinical features similar to hypertensive encephalopathy and treatment is broadly similar with antihypertensive drugs, magnesium sulphate, and early delivery of the fetus.

Hypertension with unstable angina or acute myocardial infarction

In a patient presenting with unstable angina or acute myocardial infarction and severe hypertension, a 'true' hypertensive emergency, such as aortic dissection, must first be ruled out. The risk of bleeding and stroke is significantly increased if anticoagulation with heparin or thrombolytic therapy is administered.

The appropriate initial treatment of patients with severe hypertension (greater than 180/110 mmHg) and an acute coronary syndrome should include the initiation of intravenous nitrates, with intravenous labetalol, sodium nitroprusside, or nicardipine as alternatives. The reduction of blood pressure should not be too abrupt, and (as with malignant hypertension) a gradual reduction is recommended, so that further myocardial or brain ischaemia is avoided. Sublingual nifedipine, which was once considered as a first-line drug, should not be used, in view of the negligible oral absorption and unpredictable hypotensive effects from later gastric absorption. Once the blood pressure is adequately controlled (less than 180/110 mmHg), anticoagulation or thrombolytic therapy can then be administered.

Hypertension with acute stroke

It is common to find modestly elevated blood pressure in patients admitted to hospital following an acute stroke. Cerebral autoregulation is commonly disturbed in this situation and excessive antihypertensive treatment may only serve to worsen the cerebral damage resulting from intracerebral infarction or haemorrhage. Such treatment should only be administered for severe elevation of blood pressure (diastolic blood pressure greater than 130 mmHg). In these cases, oral therapy with small doses of nifedipine or atenolol may be required. Parenteral treatment or sublingual nifedipine is almost always contraindicated. The calcium antagonist nimodipine has beneficial effects on cerebral vasospasm following subarachnoid haemorrhage, but these effects are not related to the small fall in blood pressure with this drug.

Severe hypertension after a stroke is a risk factor for further stokes and long-term treatment is worthwhile. It is unclear whether the immediate treatment of mild hypertension is of benefit. The role of antihypertensive medication before, during, and after a stroke can therefore be summarized as follows.

1. Before a stroke: it is of benefit to have blood pressure reduced to below 140/85 mmHg, as stroke prevention can be achieved.
2. During a stroke: it is detrimental to have hypertension treated aggressively, in view of the disordered cerebral autoregulation.
3. After a stroke: the role of antihypertensive medication remains unanswered, as the value of long-term antihypertensive therapy in mildly hypertensive patients following a stroke remains uncertain. Ongoing trials will answer this question. Nevertheless, drug therapy should be prescribed if blood pressure exceeds 160/100 mmHg.

The management of blood pressure in a patient with aortic dissection

The detailed presentation, diagnosis, and treatment of aortic dissection is discussed elsewhere. On suspicion of the diagnosis, whether or not surgery is indicated, all patients should be treated pharmacologically to reduce the systolic blood pressure to around 110 mmHg and the heart rate to 60 to 70 beats/min, thus reducing the force of systolic ejection to reduce aortic shear stress and limit the size of the dissection. Labetalol is an effective agent, or alternatively, sodium nitroprusside in conjunction with a b-blocker may be used. Patients should have haemodynamic monitoring with an arterial line and a Swan–Ganz catheter in position. Diagnostic tests are then performed on an urgent basis to confirm the dissection, identifying whether the ascending aorta is involved and defining any vascular abnormalities resulting from the dissection.

Summary of drug treatment options for hypertensive urgencies and emergencies

In uncomplicated malignant hypertension, where acute target organ damage is absent, and in uncomplicated severe hypertension, immediate blood pressure reduction with parenteral drugs is not indicated and blood pressure should be gradually reduced with oral agents (Table 3). Thus malignant hypertension, pre-eclampsia, and very severe hypertension without end-organ damage can be classified as hypertensive 'urgencies' rather than emergencies. Parenteral drugs to lower blood pressure may be dangerous and sublingual or capsular nifedipine should never be used.

In hypertensive crises the high blood pressure is directly responsible for a pressing clinical problem (hypertensive encephalopathy, left ventricular failure, or aortic dissection) and controlled reduction with parenteral treatment over a matter of hours is needed (Table 4). All such patients should be admitted to a high dependency or intensive care unit for monitoring. Blood pressure should be reduced by 25 per cent over several hours, depending on the clinical situation, usually with a target diastolic blood pressure of less than 100 to 110 mmHg. Thus, the goal of blood pressure reduction in those with hypertensive emergencies as well as urgencies is not to return blood pressure to a normal value immediately.

While nitroprusside is used in most hypertensive emergencies, its metabolism to cyanide, possibly leading to the development of cyanide or rarely thiocyanate toxicity, may be a limitation, especially in children. Toxicity is manifest by clinical deterioration, altered mental status, and lactic acidosis, and can be fatal; the risk of toxicity is increased with prolonged treatment (more than 24 to 48 h), underlying renal insufficiency, and high doses (greater than 2 µg/kg.min). An infusion of sodium thiosulphate can be used in affected patients to provide a sulphur donor to detoxify cyanide into thiocyanate.

Other parenteral agents such labetolol, hydralazine, and diazoxide are alternatives. Phentolamine is used only in patients with severe hypertension due to increased catecholamine activity, such as that seen in phaeochromocytoma, or after tyramine ingestion in a patient being treated with a monoamine oxidase inhibitor. Direct vasodilators such as diazoxide or hydralazine require concurrent b-blocker administration to minimize reflex sympathetic stimulation and are rarely used. ACE

inhibitors are best avoided in the early stage as they may, even in very low dose, cause precipitate falls in blood pressure and life-threatening reduction in cerebral perfusion. These rapid falls occur when patients are fluid depleted due to diuretic therapy or in renal artery stenosis.

Final summary

Hypertensive emergencies and urgencies carry a poor short- and long-term prognosis unless adequately managed. Initially, reduction of blood pressure to a normal value is dangerous, but in the long term, blood pressure should be reduced to 140/85 mmHg.

Lymphoedema

Peter S. Mortimer

Introduction

Lymphoedema is swelling due to the accumulation of lymph within the tissues and results from a failure of lymphatic drainage. Lymphoedema differs clinically from other forms of chronic oedema by its altered skin texture and the brawny quality of the subcutaneous tissues, which limit pitting. There may be no distinguishing clinical features, particularly in the early stages of swelling.

It is the essential function of the lymphatic system to return to the plasma any proteins which escape from the blood circulation. Impairment of lymph drainage therefore causes the accumulation of protein as well as fluid since both enter the tissues in substantial amounts. The lymphatics act as a safety valve or buffer in the event of fluid overload in the tissues. Therefore, theoretically, oedema should not arise as long as lymph flow can respond to the increased 'lymph load'.

In addition, the lymph drainage pathways are responsible for the removal and processing of foreign organic material, such as microbes, as well as for the trafficking of immunologically active cells such as lymphocytes. Consequently, a predisposition to infection, which can be relapsing, is a common occurrence with lymphoedema. The elimination of dying and mutant cells is via the lymphatic system, but the mechanism by which lymph vessels attract and channel cancer cells is not understood.

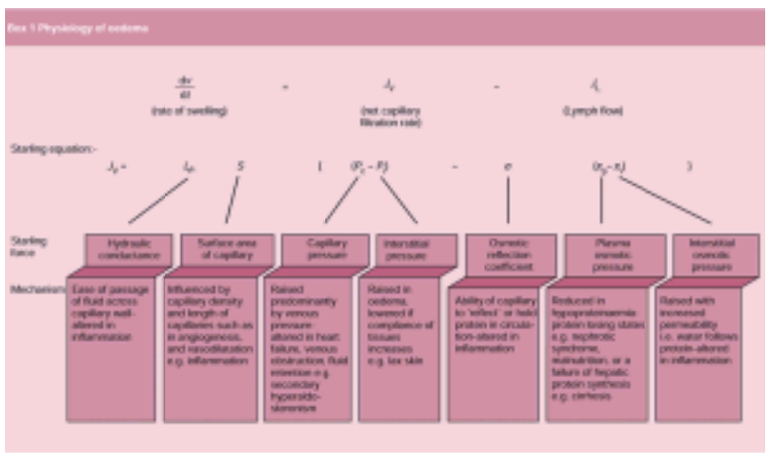
Aetiology/pathophysiology

In practice, the clinician is faced with a problem of oedema, usually a swollen limb, for which the cause may not be obvious. Rather than assemble a list of specific medical conditions, such as heart failure and venous oedema, as differential diagnosis, it is more sensible to consider causes of oedema from physiological principles as there may be more than one reason for the swelling.

Oedema

Oedema is swelling due to the excessive accumulation of fluid within tissues. Interstitial fluid volume must increase by over 100 per cent before oedema is clinically detectable. Oedema develops when the capillary filtration rate exceeds the lymph drainage rate for a sufficient period. All oedema, whatever the cause, results from an imbalance between capillary filtration and lymph drainage. Therefore it follows that the pathogenesis of any oedema results from either a high filtration rate or a low lymph flow or a combination of the two.

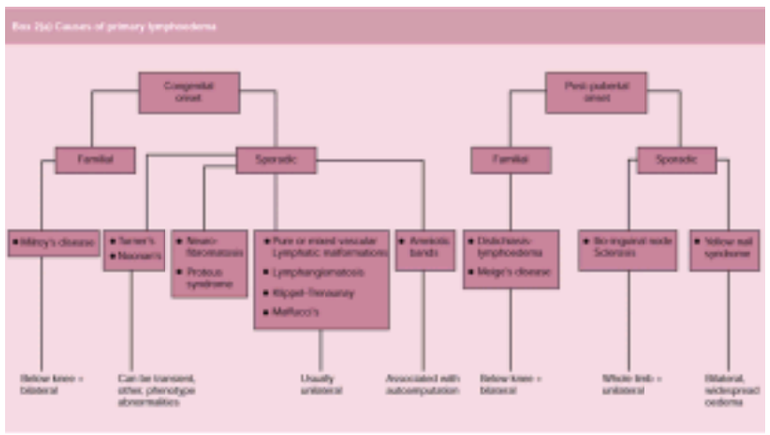
Elevation of capillary pressure is usually secondary to chronic elevation of venous pressure caused by heart failure, fluid overload, or deep vein thrombosis. A rise in blood (arterial) pressure alone should not raise capillary pressure sufficiently to cause oedema. Reduced plasma colloid osmotic pressure, for example in hypoproteinaemia, raises net filtration rate. Changes in capillary permeability, for example due to inflammation, increase the escape of proteins into the interstitium and water follows osmotically. Any change to the Starling forces governing fluid exchange can influence oedema formation (Box 1).



Most oedemas arise from increased capillary filtration overwhelming lymph drainage. To some extent any oedema incriminates the lymphatic system through its failure to keep up with demand (capillary filtration). Lymphoedema, however, is strictly oedema arising principally from a failure of lymph drainage.

Lymphoedema

Lymph drainage may fail either because of a defect intrinsic to the lymph conducting pathways (primary lymphoedema, Box 2(a)) or because of irreversible damage from some factor(s) originating from outside the lymphatic system (secondary lymphoedema, Box 2(b)).



Physiologically there are only a limited number of ways that lymphatics can fail. They may be reduced in number (aplasia/hypoplasia), obliterated (lymphangitis), obstructed, lose contractility (pump failure), or become incompetent (valvular reflux). A lack of sensitive methods for investigation makes it difficult to distinguish between these mechanisms.

Primary lymphoedema

True congenital lymphoedema, which presents at or soon after birth, is rare. Milroy's disease is both congenital and familial: both features are required for the diagnosis. The fault is a hypoplasia of peripheral lymphatic vessels. The gene for Milroy's disease is vascular endothelial growth factor C receptor, which is known to be involved with lymphangiogenesis.

Congenital lymphoedema may present as a result of a developmental malformation either in pure form, such as lymphangiectasia, or in combination with a congenital vascular syndrome. Lymphoedema may coexist with cardiovascular malformations in other genetic syndromes such as Turner's and Noonan's.

Most forms of primary lymphoedema present at or after puberty with distal lower limb swelling, usually bilateral. Familial forms frequently occur (Meige's syndrome) in which lymphangiograms usually demonstrate a reduction in size and number of peripheral leg lymphatic (main collecting) vessels. Familial post-pubertal lymphoedema, associated with an extra row of ingrowing eyelashes (distichiasis–lymphoedema syndrome), seems to be associated with hypertrophy of leg lymphatics (increase in number and size of vessels). Mutations in *FOXC2*, a forkhead family transcription factor, have been found responsible.

Genetic forms of lymphoedema are usually (ultimately) symmetrical with predominantly distal limb swelling. Lymphoedema of the proximal obstructive type with unilateral whole leg swelling is sporadic in type. Lymphangiograms of this form of lymphoedema demonstrate obstruction at the iliac nodes, but no cause can be identified. It is of paramount importance to exclude serious pathology such as tumour or thrombosis. Whole leg swelling can sometimes be bilateral due to megalymphatics. Grossly dilated (varicose) lymphatics with valvular incompetence give rise to lymph and sometimes chylous reflux, indicating the primary fault lies with abdominal lymphatics.

Protein-losing enteropathy and hypogammaglobulinaemia may arise from intestinal lymphangiectasia. The yellow nail syndrome is characterized by yellow, non-growing, over-curved nails, pleural effusions, bronchiectasis, chronic sinusitis, and peripheral oedema, but the mechanism is unknown.

Secondary lymphoedema

Damage to lymph-conducting pathways may be secondary to outside influences. In developed countries, surgical removal or radiation (or both) of lymph nodes as a necessary part of cancer treatment probably represents the largest group. Trauma to lymphatics either from elective surgery or by accident usually needs to be extensive to induce lymphoedema. The experimental production of lymphoedema is extremely difficult owing to the efficient regenerative powers of lymphatics. It is probably the failure of lymphatics to regenerate or regrow through scarred or irradiated tissue which is responsible for lymphoedema following cancer therapy. Cancer rarely presents with lymphoedema, except in advanced disease, but relapsed tumour (after first-line treatment) frequently produces swelling because of infiltration of collateral lymphatic routes which hitherto have prevented oedema.

Filariasis is probably the most common cause of lymphoedema worldwide. Microfilariae are introduced into the skin by mosquitoes and migrate to the lymphatics. Adult worms develop within the main lymphatic vessels proximal to the nodes. Animal studies have shown that within days of infection, vigorous movement by adult worms directly impacts on the endothelial lining of the lymphatic trunks and indirectly distorts the local lymph-node architecture. The result is enlarged lymph nodes and lymphatics with thickened walls and valves, thrombus formation, and perilymphangitis.

Lymphangitis or cellulitis probably only cause lymphoedema when the lymphatics are perilously vulnerable. Any patient suffering recurrent lymphangitis/cellulitis in the same region is likely to have impaired lymph drainage. Proving which came first—the cellulitis or the lymphatic insufficiency—is difficult. Recurrent acute inflammatory episodes frequently lead to a stepwise deterioration in swelling.

Podoconiosis is a form of endemic non-filarial lymphoedema caused by particles of silica dust which penetrate the feet during barefoot walking. The microparticles are taken up by lymphatics and result in fibrosis.

Cellulitis (acute inflammatory episodes)

Evidence supporting the role of the lymphatic route in immunosurveillance was provided during the early days of organ transplantation. Lymphatics convey antigens to lymph nodes. Without intact lymphatics a primary immune response cannot develop. T lymphocytes constantly recirculate between central organs, blood, and tissues for the purpose of immunosurveillance. Disturbances in host defence mechanisms within the lymph drainage area in lymphoedema probably predispose to infections such as cellulitis. However, in some patients even prophylactic antibiotics fail to control recurrent attacks, thus questioning infection as the sole explanation.

Epidemiology

Filarial lymphoedema is a major health problem in tropical and subtropical areas where the disease is endemic. The number of infected people worldwide is estimated to be 750 million. Morbidity is high. Fever ('mumu' attacks) is the earliest symptom followed by enlarged lymph nodes. Damage to central abdominal nodes results in reflux of lymph or chyle into lower limbs and genitalia with swelling and seepage of lymph on to this skin surface (lymphorrhoea). Chyluria may also occur.

The cumulative prevalence of arm swelling following curative treatment for breast cancer has been reported at 28 per cent. Similar values are quoted for incidence in hospital series if surgery and radiotherapy are combined.

Primary lymphoedema is perceived as uncommon, yet chronic ankle oedema—particularly in the elderly—is considered common. Lymphatic insufficiency s likely to be a contributing cause because of the decline in lymph drainage function with age. Lymphoedema can be a difficult diagnosis in mild or early cases and may be underdiagnosed. Primary lymphoedema tends to affect females more than males. In less than 10 per cent of cases is swelling present at birth and most cases present at or soon after puberty. It is estimated that 80 per cent will present before the age of 35 years (lymphoedema praecox) and 10 per cent after the age of 35 years (lymphoedema tarda). In a study of 1000 normal young adults, 8 per cent of women demonstrated signs of lymphoedema in the lower limb.

Clinical features

Lymphoedema most commonly affects the extremities, particularly the lower limb. Midline swelling affecting head and neck or genitalia can be an isolated finding. Truncal oedema is often observed in the adjoining quadrant of the trunk to an affected limb because of the shared lymph drainage route.

Cells, proteins, lipids, and debris accumulate giving a 'solid' as well as a 'fluid' component to the swelling, hence the brawny texture to lymphoedema. Pitting occurs in

most patients and many early cases will pit readily.

History

Swelling frequently develops rapidly—overnight—but may be mild and intermittent at first. Pain may feature initially, prompting diagnoses such as deep vein thrombosis and soft tissue injury. With time, oedema becomes more permanent and painless, although discomfort, aching, and heaviness are common symptoms. Functional impairment is slight until swelling becomes more severe. The major problem is disfigurement (Fig. 1).

Fig. 1 Lymphoedema of the left lower limb exhibiting characteristic skin changes and loss of shape with folds developing around the ankle.

Lymphoedema does not usually respond to elevation or diuretics, except in the early stages or when it is compounded by increased capillary filtration. Chronic oedema that does not reduce significantly overnight is likely to be lymphatic in origin.

Clinical signs

Most swelling occurs in the subcutaneous layer, but it is the skin which exhibits most changes. It becomes thicker, as demonstrated by the Kaposi–Stemmer sign (a failure to pick up or pinch a fold of skin). Skin creases become enhanced and a warty texture develops (hyperkeratosis). Accumulation of stagnant lymph in the dermis can produce surface bulges resembling cobblestones that feel firm to the touch (papillomatosis). The resemblance of the skin texture to elephant hide explains the term elephantiasis. Dilated lymphatics (lymphangiectasia) can also bulge on the surface like a blister from which lymph can leak.

Lymphatic insufficiency has three major consequences: (i) swelling (oedema); (ii) a predisposition to infection, in particular cellulitis; and (iii) the uncommon complication of malignancy arising with the lymphoedema (Stewart–Treves syndrome).

Oedema

Most cases of primary lymphoedema present with bilateral but asymmetrical oedema of the feet, ankles, and lower legs (distal hypoplastic type). However, it may take months to years before oedema manifests in the contralateral limb. Whole limb swelling usually indicates a problem at the level of the regional lymph nodes such as following cancer treatment or in filariasis. Oedema that begins proximally and spreads distally suggests an obstructive process (proximal obstructive type). Abnormalities of central abdominal and thoracic lymphatics may produce lower limb swelling, often bilateral, with lymph or chyle reflux. Lymph and chyle effusions can be observed in the pleural, peritoneal, and pericardial cavities and rarely in joints.

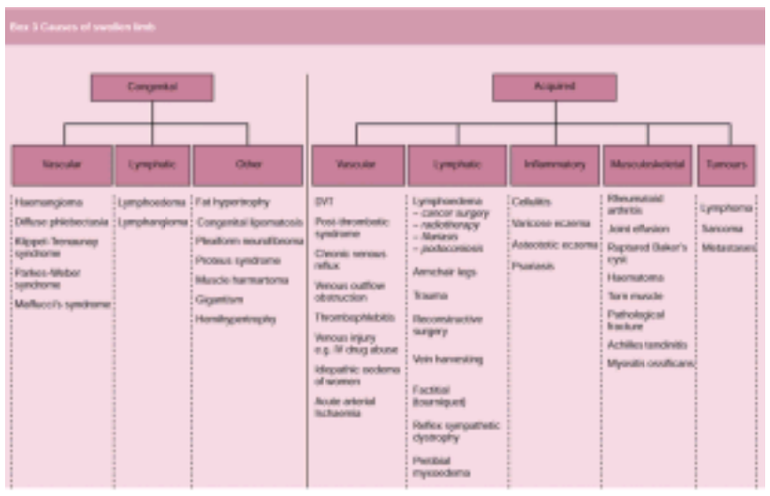
Cellulitis (acute inflammatory episodes)

Acute inflammatory episodes describe the attacks of apparent infection, simulating cellulitis, which afflict patients with lymphoedema. A typical attack starts rapidly, often without warning. Fever, rigors, headache, and vomiting can occur, but patients usually feel as if influenza is starting. A feeling of heat, redness, and increased swelling occurs within the lymphoedematous area. Pain may precede the rash. Areas of clearly demarcated erythema with a migrating border, as seen in classic cellulitis, may not be observed, presumably because of rapid dissemination throughout the oedematous tissue. Sometimes the condition may 'grumble' in a rather chronic manner for days or weeks and only on complete recovery after prolonged antibiotics and rest can the diagnosis be made. A characteristic of lymphoedema is for acute inflammatory episodes to recur. Intervals may be more than 12 months or as short as 3 weeks.

Lymphangiosarcoma

Lymphangiosarcoma (Stewart–Treves syndrome) is the most serious but rarest complication of lymphoedema. Chronic lymphoedema is a major predisposing factor in the development of malignant vascular tumours irrespective of the cause of the lymphoedema. The clinical appearance is usually of a fixed purple or bruise-like discoloration within the lymphoedematous skin. Infiltrated plaques and nodules later appear.

Differential diagnosis of the swollen limb Box 3)



Both excessive capillary filtration and compromised lymph drainage frequent coexist.

'Venous' oedema

Most cases of chronic venous disease do not manifest oedema because of increased lymph flow in response to increased capillary filtration. This suggests that the development of oedema in post-thrombotic syndrome and venous ulceration is as much a failure of lymph drainage to compensate as it is due solely to overwhelming filtration. The expansion of the venous pool in the leg due to dilatation of veins will also contribute to an increase in limb girth independent of oedema.

'Armchair' legs

This syndrome refers to those patients who sit in a chair night and day with their legs dependent. Immobility results in minimal lymph drainage and 'functional lymphoedema' ensues, compounded by increased capillary filtration from gravitational forces. Predisposed are those patients suffering cardiac or respiratory failure

who cannot lie flat, those paralysed from strokes or spinal damage including spina bifida, and those with arthritis, particularly rheumatoid arthritis.

Lipoedema (lipidosis, lipodystrophy)

Frequently misdiagnosed as lymphoedema, lipoedema is peculiar to females with onset at or after puberty. A 'fatty', non-pitting swelling affects legs, thighs, and hips. Characteristic inverse shouldering occurs above the ankle because of sparing of the foot. The skin is soft, tender, and bruises easily. Pain may feature. Lipoedema is not influenced by dieting and is distinct from morbid obesity.

Investigation

The investigation of choice for confirming that oedema is primarily of lymphatic origin is lymphoscintigraphy (isotope lymphography). Conventional direct-contrast X-ray lymphography is now rarely undertaken to investigate lymphoedema. MRI, in preference to CT, is of value in identifying a cause for lymphatic obstruction.

Lymphoscintigraphy

A radiolabelled protein or colloid is administered via a subcutaneous injection and its movement through lymphatic vessels to nodes is monitored. The dynamics of lymph flow, as depicted by tracer removal from injection site and/or trapping in regional nodes, can be captured using a scintiscanner or g-camera. Off-line calculation of time–activity curves from regions of interest permit quantitative analysis of lymph drainage. A normal lymphoscintigram is shown in Fig. 2 and an abnormal one in Fig. 3.

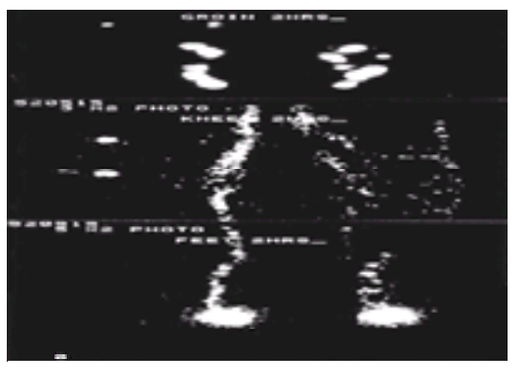


Fig. 2 A normal lymphoscintigram apart from some collateral lymph drainage in the left thigh. Following a web space injection of radiolabelled colloid (^{99m}Tc–antimony sulphide colloid) the transport of radioactivity is imaged by a g-camera. Measurement of radioactivity over the ilio-inguinal nodes for a given time interval can quantify lymph drainage function.

Fig. 3 A lymphoscintigram in a patient with Milroy's disease (congenital familial lymphoedema) demonstrates no migration of tracer in the affected right leg. The left leg (clinically normal) shows normal ilio-inguinal nodal uptake but extravasation of tracer where lymphatics are abnormal.

Direct-contrast X-ray lymphography (lymphangiography)

The technique requires the identification of a peripheral lymphatic (usually in the foot) by subcutaneous injection of a vital dye, such as patent blue. The oily contract medium Lipiodol is then administered into the canulated lymphatic, with subsequent imaging by X-ray as the contrast passes through the main limb lymphatics. The failure to identify a lymphatic with vital dye suggests lymphoedema with distal hypoplasia of vessels, particularly if the dye persists in the tissues for days. Lymphography is an invasive procedure which provides little functional information, but it remains the gold standard for delineating lymph vessel and node anatomy.

Magnetic resonance imaging

MRI (and CT) demonstrates a thicker skin and a characteristic 'honeycomb' pattern in the subcutaneous compartment. Following deep vein thrombosis in the leg the muscle compartment is enlarged, but this remains unchanged in lymphoedema.

Treatment

Physical therapy

This first-line approach is designed to stimulate lymph drainage within main or collateral lymph routes. Intermittent changes in tissue pressure are normally responsible for moving materials and fluid from tissue spaces into initial lymphatics. Lymphatic collecting vessels that possess smooth muscle then actively pump the lymph downstream. In lymphoedema, exercise, through dynamic muscle contractions undertaken while compression is applied to the skin surface, encourages movement of lymph through lymph vessels in a matter akin to external cardiac massage. In practice, this means fitting of compression hosiery or bandages and instruction on exercise. Overexertion and excessive static exercises, such as gripping, increase blood flow and can therefore increase oedema. Compression has the added benefit of opposing excessive capillary filtration should it coexist. Manual lymph drainage, a specific form of lymphatic massage, is added to stimulate lymph flow and redirect the lymph towards the functioning lymph nodes in an unaffected lymphatic basin.

In moderate to severe lymphoedema an intensive period of treatment using multilayer bandaging, exercise, and manual lymph drainage is used to reduce swollen limbs so that subsequent maintenance treatment with hosiery and exercise is more effective at controlling the condition.

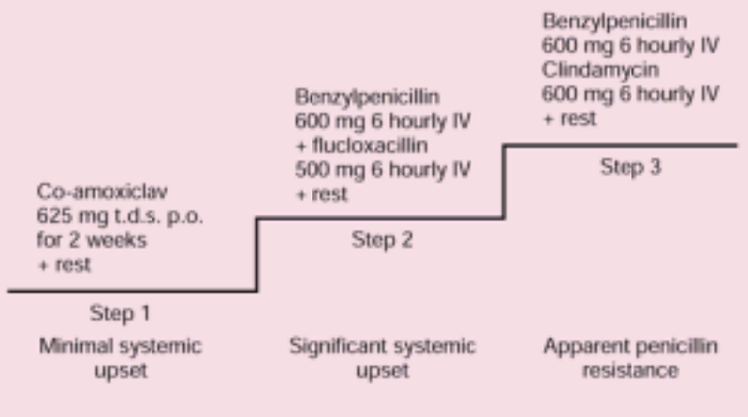
Pneumatic compression therapy, such as Flowtron, softens and reduces limb volume during treatment but it is doubtful that there is any long-term benefit compared with hosiery (and exercise) alone.

Infection

Prevention of acute inflammatory episodes (cellulitis) is crucial to the control of lymphoedema. Care of the skin, good hygiene, treatment of any dermatitis or fungal infection, and antisepsis following minor wounds are important. Prompt administration of antibiotics, such as co-amoxiclav in a dose of 625 mg three times daily at the

onset of an attack, is mandatory (Box 4). For relapsing cellulitis, prophylactic antibiotics, preferably phenoxymethylpenicillin in a dose of 500 mg twice daily, are indicated for an indefinite period. Control of the oedema may help to reduce antibiotic requirements.

Box 4 Stepladder approach to treatment of acute inflammatory episodes (cellulitis)



Drug therapy

Diuretics remain the most commonly used treatment but have very little benefit in established lymphoedema because their main action is to reduce capillary filtration. Improvement with diuretics suggests that the predominant cause of the oedema is not lymphatic. Diuretics, such as spironolactone, may be necessary in circumstances where there is substantial truncal lymphoedema, particularly if venous hypertension coexists.

The benzopyrone group of drugs, for instance rutosides and coumarin, have been advocated, but the clinical effect is minimal.

Surgery

Surgery can involve removal of excess tissue (reducing/debulking operations or liposuction) or bypassing of local lymphatic defects. The defective region may be bridged with omentum or an isolated segment of gut. Microsurgery such as lymphovenous anastomoses remains experimental. All surgery is followed by continued compression therapy, such as hosiery.

Prevention

Primary lymphoedema usually develops spontaneously without warning. A diagnosis of lymphoedema should be entertained if oedema is persistent. Lymphoscintigraphy is the investigation of choice at this stage as clinical signs are few in the early stages. In the future, identification of the genes programming for inherited lymphoedema may help predict those at risk.

Secondary lymphoedema can, in theory, be prevented by avoiding the cause or limiting the damage. Less intervention to lymph nodes for staging and treatment of cancer would help. Patients at significant risk of lymphoedema should receive advice from the appropriate professional, such as a breast-care nurse, and any oedema should be treated early, at a stage when it is more responsive to intervention and when it may even be reversible.

15.18 Idiopathic oedema of women

J. Firth

Definition and diagnosis

In some women fluid retention occurs in the absence of any clear explanation and is termed idiopathic oedema. Since the condition typically fluctuates in severity from one time to another it is sometimes called cyclical or periodic oedema, but these terms mislead; first, because there is rarely any recognizable periodicity, and second, because the condition is not related to menstrual periods. Most women retain fluid just before the menses and lose this fluid immediately afterwards. Idiopathic oedema occurs most commonly in women aged 20 to 40 years, but has no clear relationship with the menstrual cycle and can persist after the menopause or oophorectomy.

The diagnosis of idiopathic oedema depends on the exclusion of other causes of oedema, including cardiac, hepatic, renal, allergic, or hypoproteinaemic disease, venous or lymphatic obstruction, and use of some medications. The role of diuretics, causally or in treatment, is contentious, as discussed below. However, it is always unsatisfactory when a diagnosis is made by exclusion of other conditions rather than on the basis of 'positive' criteria. Such criteria for the diagnosis of idiopathic oedema have not been universally agreed, although both Thorn and McKendry (see Kay *et al*. for discussion) have made proposals. These require evidence of substantial weight gain during the course of the day from morning to evening, with a figure of more than 1.4 kg often quoted, although this does not provide a clear-cut separation from normal. They also demand the presence of emotional or psychological factors. Many authors comment on the aggravation of swelling by prolonged sitting or standing, but this does not feature in the diagnostic criteria mentioned.

Clinical features

The patient's complaint is of swelling, which usually waxes and wanes but can be constant. In the morning the face and eyelids feel swollen and heavy. By the end of the day the areas worst affected are the hands, breasts, trunk, abdomen, thighs, ankles, and feet. Rings no longer fit the swollen fingers and undergarments and clothes can feel uncomfortably tight such that they have to be removed or replaced with something larger. The feet and ankles may be relatively spared, hence the disposition of oedema tends to be different from that in most other oedematous states, where it begins distally in the feet and ankles and progresses proximally.

Episodes or exacerbations of fluid retention often occur unpredictably, but obesity, emotional stress, and consumption of high-carbohydrate food are thought to be triggers in some. Sufferers are often mentally and physically lethargic during periods of fluid retention, frequently expressing the view that they feel bloated and ugly, even though this may not be apparent to the observer. Many appear to be emotionally labile or anxious and some are depressed, invariably (and perhaps correctly) claiming that this is secondary to the fluid retention. Other common symptoms include carpal tunnel syndrome, non-articular rheumatism, palpitations, non-ulcer dyspepsia, and headaches.

Aside from oedema, which may or may not be present at the time of medical assessment, examination is unremarkable, as are routine investigations for the cause of oedema. Those patients that have used diuretics may have a hypokalaemic hypochloraemic metabolic alkalosis.

Pathophysiology

The cause of idiopathic oedema is not known (by definition). Diurnal weight fluctuation of more than 1.4 kg is required for diagnosis, but weight may fluctuate from day to day by up to 4 or 5 kg. During periods of weight gain the patient may be oliguric, passing low volumes of urine in which there is little sodium (less than 20 mmol/l). The blood vessels of women with idiopathic oedema are more permeable to albumin, the fractional catabolic rate of albumin is increased, both intravascular and total body albumin pools are smaller, and the plasma volume decreases by more on standing than in normal controls. Activation of the sympathetic nervous system, renin–angiotensin–aldosterone system, and high levels of ADH in the plasma that are consistent with intravascular volume depletion have all been reported, as has reduction in dopaminergic activity. These changes provide a plausible explanation for why the kidney retains salt and water in idiopathic oedema, but the prime mover remains uncertain. They also form the background to postural water-loading or sodium-loading tests that have been advocated as diagnostic tools, although these are not used routinely in clinical practice. After similar loading on two separate occasions, patients with idiopathic oedema who remain upright throughout the test excrete less water or sodium than they do if they remain supine.

Many patients seen in hospital practice will already be taking diuretics or have taken them in the past, and some will be consuming large doses of loop agents every day. One influential study reported 10 such patients who started to take diuretics because of concern about swelling or their body weight and who continued to take them because cessation provoked rapid weight gain, facial bloating, and abdominal distension. When prevailed upon to stop diuretics they each gained weight (up to 5 kg), reaching a maximum in 4 to 10 days, but by 20 days 7 of the 10 had fallen to below their previous weight, and 9 of the 10 remained free of oedema over a long period of follow-up without taking diuretics. This led the authors to suggest that diuretic abuse might be the cause of all cases of idiopathic oedema. This view is not held by most with experience in the field, but rebound oedema on diuretic withdrawal can undoubtedly be an exacerbating feature, and it is appropriate to look for evidence of diuretic abuse if the patient denies taking such drugs and yet routine biochemical testing of blood and urine suggests the possibility (see Chapter 20.2.2 for further discussion).

Management

Women with idiopathic oedema frequently complain that doctors have not taken their condition seriously, and there is no doubt that it is a frustrating disorder for both patients and their physicians. Sympathetic explanation of the nature of the problem helps management.

If the patient is obese, then they should be given advice as to how to lose weight, and—independent of any effect on weight—some find that reducing dietary carbohydrate helps. They should be advised to avoid long periods of standing or sitting and to wear loose-fitting clothing, although most will have discovered these things for themselves. Avoidance of an excessive dietary intake of sodium is a sensible recommendation. On theoretical grounds the use of elastic stockings would also seem appropriate, since these might reduce the postural reduction in plasma volume seen in idiopathic oedema. However, few find that their benefits outweigh their disadvantages and it is difficult to get most patients to persist with them for long enough to see whether or not they really would be of help.

Diuretics are a real problem. It seems intuitively obvious to most patients and to many doctors that someone who is retaining fluid would benefit from a diuretic, hence many patients with idiopathic oedema end up on very large doses of loop agents, often combined with amiloride or spironolactone. Rather than helping, these may worsen symptoms of tiredness, lethargy, weakness, and dizziness by exacerbating intravascular volume depletion, and attempts to stop typically lead to rebound oedema. Explanation is the key here in that if patients recognize rebound oedema for what it is and relieve oedema with supine rest rather than renewed consumption of high doses of diuretics, then there is a reasonable chance that they can be weaned off diuretics with benefit.

Levodopa, carbidopa, bromocriptine, captopril, and a variety of other agents have been tried in idiopathic oedema, but none is of proven benefit.

16.1 The clinical approach to the patient who is very ill

J. Firth

Introduction—recognizing the problem

As a young doctor, I vividly remember watching a senior physician at a teaching hospital endeavouring to take a history from a middle-aged man who looked grey and very unwell. The man was not giving lucid answers and the conversation seemed increasingly unlikely to lead to a useful conclusion. After a period of silence his breathing became extremely laboured, and within a minute he suffered a cardiac arrest from which he could not be resuscitated.

The first priority in the management of patients who are very ill is to recognize that this is the situation. It is a sensible discipline when dealing with emergency admissions (and sometimes in other contexts) to ask yourself the question: Is this patient well, ill, very ill, or nearly dead? Some physicians will recognize this intuitively, others will have to make a conscious effort, lest they make the sort of error described in the previous paragraph. In general the approach to the patient begins with the history, followed by the examination, and sometimes the ordering and appraisal of the results of investigations, before a diagnosis is reached and treatment commences. This approach can be fatal in those who are very ill or nearly dead at the start.

Key features—summarized as airway, breathing, circulation (ABC)—to assess immediately in the patient who is very ill or worse are shown in Table 1. If in any doubt, the most important of the questions to answer is: 'Do you think that this patient can keep breathing like this for the next 10 min?' If the answer is no, then you need to get help immediately: this will usually involve summoning someone directly from the intensive care unit, or putting out a 'cardiac arrest' call. It is better to do this 10 min before the heart stops than 2 min afterwards, a strategy emphasized by replacing the 'cardiac arrest team' with a 'medical emergency team' in one study. One doctor, with or without one nurse, is not enough to deal optimally with the patient who is *in extremis*.

Immediate management of airway and breathing

The immediate treatment priorities for the patient with cardiorespiratory collapse are shown in Table 2.

Airway and oxygen

If a patient is having problems breathing, then is there a difficulty in maintaining the upper airway? If a head tilt/chin lift manoeuvre is beneficial, then a gentle attempt to insert an oropharyngeal airway should be made. This should not be done against resistance—a fight is much more likely to do harm than good—and if the patient spits the airway out it almost certainly means that it is not necessary.

All patients who are extremely ill should be given oxygen in as high a concentration as possible by face mask. A fraction of inspired oxygen (FiO_2) of around 60 per cent can be obtained using a standard face mask with a reservoir bag and an oxygen flow rate of 10 litre/min. An obvious concern about this recommendation is that it may induce carbon dioxide retention in those who are prone to this (usually patients with chronic obstructive pulmonary disease), but the downside of denying someone oxygen can be substantial: hypoxia kills, hypercarbia merely intoxicates. If blood gas analysis shows that the patient is retaining carbon dioxide, the FiO_2 can gradually be reduced or elective ventilation can be used.

If a patient with respiratory difficulty has received opioids within the past 48 h, or could have done so, then give intravenous naloxone (0.2 to 0.4 mg in those who have received opioids; 0.8 to 2.0 mg repeated to a maximum of 10 mg in case of overdosage). This sometimes produces a dramatic response.

Elective ventilation

The patient should be electively intubated and ventilated if breathing seems to be failing despite the measures indicated above, although in some circumstances non-invasive ventilation may be an appropriate alternative. There is no substitute for wise clinical judgement in deciding when this should be done, and it is easy for the inexperienced to be led astray. Too soon is better than too late. A 'normal' respiratory rate of, say, 12 breaths/min may indicate normality, but is also compatible with near death in the patient with a severe respiratory problem who is becoming exhausted. A blood gas level that 'doesn't seem too bad', meaning perhaps a PO_2 of 9 kPa and PCO_2 of 5.5 kPa, which may not be a cause for any concern at all in a patient who is comfortable and breathing room air, is not at all reassuring if the patient is breathing 60 per cent oxygen and looks very tired.

The work of breathing accounts for up to one-third of the body's oxygen consumption, hence taking this burden from patients by sedating, paralysing, and ventilating them can have a dramatically beneficial effect, whatever the reason for their predicament. However, one note of caution: whilst being ventilated can be very helpful, the minute or two when the patient is being sedated, paralysed, and intubated is a time of very high risk, since the pharmacological agents used can, to varying degrees, induce profound hypotension culminating in a 'crash'. The chances of this happening can be reduced by giving the patient a bolus of fluid (a rapid infusion of 500 ml of 0.9 per cent saline or colloid) immediately before induction, with dilute adrenaline (1:10 000; not 1:1000) given as 1-ml intravenous pushes (up to one push/min) in the event of a dramatic fall in blood pressure. Whilst the anaesthetist is attending to the airway, the match-hardened physician will stand by a site of intravenous access with such a syringe in their hand and not skulk off into a corner.

Tension pneumothorax

If the patient has a tension pneumothorax, then this should be decompressed immediately by inserting a large-bore venous cannula into the chest in the second intercostal space in the mid-clavicular line and then withdrawing the stylet. The response to this is dramatic and satisfying. A chest drain with underwater seal can then be inserted at (relative) leisure.

The prospect of performing chest decompression is daunting for many junior physicians, and even more so for most of their senior colleagues. Remember that the physical signs are not subtle, the patient with '? minor shift of the trachea' as the only relevant sign does not have a tension pneumothorax. If the patient is blue and can't breathe, one side of the chest looks blown up and there are no breath sounds over it, then (after attending to the airway and oxygen and calling the cardiac arrest team) stick in the cannula. There is much to be gained from doing so, and little to be lost if it does not lead to improvement.

Immediate management of the circulation

The patient who is volume depleted

In a patient who is very ill, if the pulse rate is less than about 60 to 70/min, or above 120/min other than with a sinus tachycardia, then manoeuvres to speed it up (atropine, isoprenaline, pacing) or slow it down (DC cardioversion or antiarrhythmics, but avoiding any of the latter that are negatively inotropic excepting in rare

circumstances) are likely to improve the circulation. (See Chapter 16.3 and Chapter 15.6 for further information.)

Most patients who are very ill will have a sinus tachycardia, when there is no advantage in attempting to alter pulse rate and rhythm, indeed there is much to be lost from ill-advised attempts to do so. The key question then becomes: Is the filling pressure optimal? Does the patient need to be given fluid, or is there too much fluid on board? Those who do not see many very ill patients might think that it should be easy to tell the difference, but the answer is not always obvious, and yet the physician must decide rapidly, often without anything other than clinical judgement to guide them. Although they may yearn for a measurement of central venous or pulmonary capillary wedge pressure, or for a chest radiograph to see whether or not there is pulmonary oedema, to delay management might be fatal. The clinical features to look for are listed in Table 3, and the appropriate responses discussed in Table 4.

Obtaining venous access

The need is to insert a cannula into a decent-sized vein quickly, and with as low a risk of complication as possible. Try initially for a peripheral vein in the forearm or antecubital fossa, but if these are constricted and cannot be cannulated and the patient is *in extremis*, then go for the femoral vein, which lies medial to the artery in the groin (NAVY, nerve artery vein Y-fronts). The procedure is easiest if the patient can lie flat, but can be performed with the patient propped up if respiratory difficulty means that lying down is impossible. Feel for the femoral pulse just below the crease of the groin and, after giving local anaesthetic, insert the needle (with the bevel pointing forwards) one finger breadth medial to the point of maximum pulsation at an angle of about 60° to the skin and parallel to the long axis of the leg. The only significant complication of this procedure is inadvertent arterial puncture (Table 5), the consequences of which are much less likely to be severe in the groin than in the neck or below the clavicle.

An attempt to insert a central venous cannula into the internal jugular or subclavian vein of a patient who is *in extremis* has led to more deaths than such catheters have prevented. If the patient's intravascular volume is depleted, then the veins are constricted and small, cannulation is very difficult, and the procedure tends to degenerate into what is known in the trade as the 'sewing machine technique', where multiple stabs culminate in something being hit, often not the vein that was being (increasingly loosely) targeted. If patients are volume overloaded and in respiratory difficulty, then they will not tolerate being laid flat for the cannulation attempt: if you try to make them do so, they won't lie still for long, and if they do become still it might be because they have died.

When the patient who is volume depleted has had intravascular volume restored, or when the situation of the patient who is volume overloaded and breathless has been rendered safe (perhaps by intubation and ventilation), then the insertion of a central venous catheter can be helpful in diagnosis (for example to allow passage of a right heart catheter for measurement of the pulmonary capillary wedge pressure), monitoring (for example fall in the central venous pressure indicating further gastrointestinal haemorrhage), and treatment (for example infusion of inotropes, other drugs, or parenteral nutrition). The approaches for internal jugular and subclavian vein cannulation are shown in Fig. 1 and Fig. 2, with details of safety and reliability in Table 5.

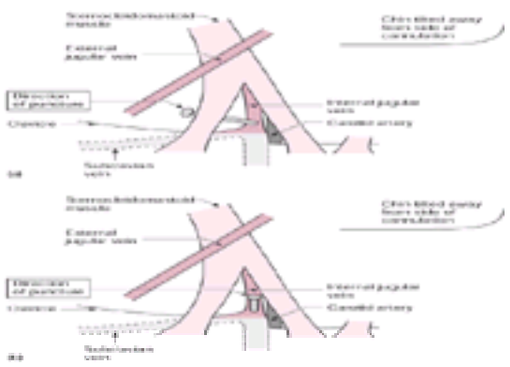

Fig. 1 The low lateral (a) and axial (b) approaches to the internal jugular vein. (a) The patient is supine with the head turned away from the side of the puncture. A towel may be placed under both shoulders to extend the neck. After preparation of the skin and drapes, and insertion of local anaesthetic, the bed is tilted to a 25° head down position. The needle is inserted just lateral to the posterior border of the clavicular head of the sternocleidomastoid muscle, about one finger breadth above the clavicle. It is then advanced parallel to the line of the clavicle and just behind the sternocleidomastoid muscle. The internal jugular vein, which lies superficially at this point, is cannulated close to its junction with the subclavian vein. As soon as the vein is entered the needle is angulated caudally to ease cannulation, the guidewire passing directly into the innominate vein. The risk of complications was lower with this technique than for any other method of central venous cannulation used in one large series (see Table 5). (b) The patient is positioned as described for the low lateral approach to the internal jugular vein. The needle is inserted in the centre of the triangle defined by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle itself. It should be angulated caudally, at about 60° to the skin, and in a line pointing towards the ipsilateral anterior superior iliac spine. See Table 5 for details of complications using this approach.

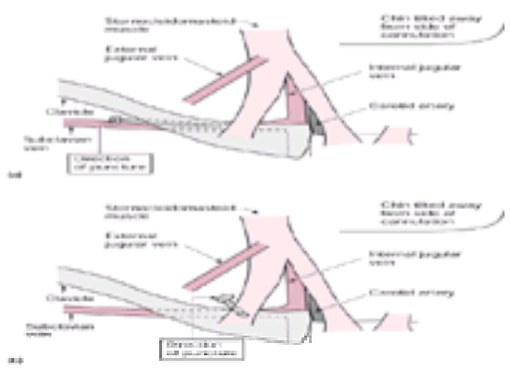

Fig. 2 The infraclavicular (a) and supraclavicular (b) approaches to the subclavian vein. (a) The patient is positioned as described for the low lateral approach to the internal jugular vein (Fig. 1(a)), excepting that instead of a towel being placed under both shoulders it should be positioned under the spine, allowing the shoulders to retract to reduce the risk of pneumothorax. The needle enters the skin below the mid-point of the lower border of the clavicle and is advanced under the clavicle towards the upper edge of the junction of the clavicle with the manubrium. See Table 5 for details of complications using this approach. (b) The patient is positioned as described for the infraclavicular approach to the subclavian vein. The needle is inserted into the angle between the superior border of the clavicle and the posterior border of the clavicular head of the sternocleidomastoid and advanced caudally, medially, and ventrally. See Table 5 for details of complications using this approach.

What fluid should you give, and how much?

A great deal of heat, but little light, has been generated in the literature on the subject of when to replace fluid, what to give, and how much. For patients with penetrating trauma to the torso it has been shown that delayed resuscitation, where venous access is established but fluid is not given until the patient is in the operating theatre, is preferable to immediate resuscitation, but there is no obvious analogy between this situation and that of the vast majority of patients with circulatory collapse and the rule, in general, remains that resuscitation should start as soon as possible.

It is logical that the fluid given to the patient whose intravascular volume is depleted should be one that remains substantially within the intravascular compartment. Solutions based on dextrose (with zero or low concentration of sodium) are most certainly not appropriate, since they partition throughout the body water and relatively little remains in the intravascular compartment, but beyond this it is not possible to make any firm recommendation. If the patient has lost blood, then it would seem sensible to give blood, and most physicians would recommend this. Whether isotonic crystalloid (usually 0.9 per cent saline), hypertonic crystalloid (usually saline), or various types of colloid are best in other situations is not clear. Cochrane reviews have failed to find significant differences between the use in critically ill patients of crystalloid or colloid, between isotonic or hypertonic fluids, and between different types of colloid solution, although there is evidence that albumin infusion

may increase the risk of death in this situation.

At the outset it is not possible to judge precisely how much fluid will be needed to resuscitate a patient. The only way to determine this is by frequent clinical examination as fluid is given. In the patient who is very unwell and clearly volume depleted, standard practice is to give 500 ml of blood or plasma expander (as appropriate and as available) as fast as the giving set and venous cannula will allow (applying pressure to the bag by manual or mechanical compression if the patient is *in extremis*). A second 500 ml infusion is commenced whilst checking peripheral perfusion, pulse rate, blood pressure, and the jugular venous pressure. Rapid infusion is continued until there is clear evidence that the situation is beginning to improve, as manifest by warming of the peripheries, slowing of the pulse rate, and rise in blood pressure. Interpretation of change in the height of the jugular venous pressure requires some care. It rises as fluid starts to be given, but may then fall for two reasons: first, if there is further fluid loss, most typically haemorrhage; and second, as venoconstrictor tone diminishes in the patient who is 'warming up' with adequate resuscitation. Their different effects on peripheral perfusion, pulse rate, and blood pressure easily distinguish these two eventualities.

As soon as it is clear that the patient's circulation is beginning to improve, the rate of fluid infusion should be slowed so as not to risk precipitating pulmonary oedema by forcing very high hydrostatic pressures in a circulation that is still 'tight' due to the effect of endogenous vasoconstrictors. Hence the patient who has lost, say, 2 litres of blood, may be optimally treated by receiving the first litre as quickly as possible, followed by the second litre over the next 2 h or so as the circulation 'relaxes'.

When resuscitation is complete—meaning that peripheral perfusion, pulse rate, blood pressure, and jugular venous pressure have all returned to acceptable levels—fluid input should then be given with regard to fluid output. At this stage it is good practice to insert a urinary catheter into any patient who has presented with severe cardiorespiratory disturbance. Urinary flow rate reflects renal perfusion, which is a marker of the overall state of the circulation, and accurate measurement of urinary output is essential to judge continuing fluid requirement. If patients have developed acute tubular necrosis with oliguria as a result of hypotension, they will not be well served by a 'standard' prescription of 3 litres of fluid per day to follow on from that given to resuscitate. This will inevitably lead to pulmonary oedema if continued in the face of diminished urinary output. A daily input equal to the last 24-hours' output plus 500 to 1000 ml for insensible losses is appropriate in these circumstances.

The patient who is volume verloaded

Acute volume overload manifests as pulmonary oedema, which can be a most terrifying condition. When severe, patients cannot get their breath and, with good reason, think they are going to die. As for patients in extreme respiratory difficulty, they sit up and use their accessory muscles. They are sweaty, cool peripherally, tachycardic, hypertensive (usually), centrally cyanosed, the jugular venous pressure is raised, and there is a gallop rhythm, although this may be hard to appreciate amidst the widespread crackles and wheezes in the chest. In extreme forms, frothy pink oedema fluid may come from the mouth. For further information see Chapter 15.15.2.2. The main features of treatment are shown in Table 4.

The underlying condition

The initial management of patients who are desperately ill does not depend on making a precise diagnosis of the cause of their predicament. However, as soon as resuscitation is underway, attention must turn towards making a diagnosis. Although the naive might think that the more severe the illness, the more obvious the cause should be, the opposite is often the case. When dead, all patients look identical, and the same is true just before they die. Patients who are *in extremis*, whether due to profound hypoxia or with next to no blood pressure, are not lucid historians, and it may be that the only question that they can usefully answer is: 'Do you have any pain?' If they indicate their chest or their abdomen, this might be a helpful clue.

The pragmatic approach to making a diagnosis in the patient with cardiorespiratory collapse is to use a 'surgical sieve' technique, looking systematically for features on examination and investigation to nail the diagnosis of conditions that can kill (Table 6). Details of the management of the many specific disorders listed in Table 6 can be found in the relevant sections of this book, but there is one general point: if initial investigations do not give any clear diagnostic lead, then do not be afraid to start treatment 'on suspicion', especially for those disorders that cannot reliably be diagnosed or excluded by clinical examination or with those tests that are rapidly available. In particular, consider pulmonary embolism and sepsis.

If the clinical context makes pulmonary embolism likely, for instance the patient has collapsed after an operation a week or so ago, then—in the absence of other explanation for the problem—it would not be unreasonable to start anticoagulation with intravenous heparin (which can be reversed if necessary) pending definitive imaging, but it would be unwise to give thrombolytic agents until the diagnosis was established. I began this chapter with a paragraph describing a failing of another doctor, so it is fair and reasonable that I also include details of one of my own. When I was a medical registrar 'on call' 15 years ago, I was asked to see a woman in her 60s from a long-stay psychiatric ward because the nurse looking after her thought that 'she wasn't her usual self'. She would not speak to me, but this was not abnormal since she had not spoken to anyone for many years. I examined her with some difficulty, because she did not co-operate, and could find nothing wrong, except that her systolic blood pressure was 60 mmHg. ECG and chest radiography were unremarkable, blood tests were taken, and I arranged to 'review with the results'. She died 4 h later. The next day the microbiologist phoned to say that streptococci had been grown from all blood cultures. Even awkward patients should have a blood pressure, and serious disease is likely if they don't. Give broad-spectrum parenteral antibiotics as soon as blood cultures have been taken if the cause of cardiorespiratory collapse is not apparent. And with regard to sepsis, ask if patients have travelled recently: if they have, the diagnosis may be malaria.

Communication

Once resuscitation and diagnostic endeavours are underway, and certainly when you have a clear idea what the diagnosis is, do not forget to speak to the patient's relatives and record in the medical notes what you have told them.

16.2 The circulation and circulatory support of the critically ill

David F. Treacher

Introduction

This section considers global and regional oxygen delivery, the concept of shock, assessment and monitoring of the circulation, and the use of vasoactive drugs and in the critically ill patient.

The aphorism 'prevention is better than cure' should guide the management of the circulation, since early identification of circulatory derangement and the prompt diagnosis and treatment of underlying pathology provides the best chance for the rapid and complete recovery of the patient. However, with the limited monitoring and supervision available outside critical care units, early detection may be difficult. Hypotension is widely considered to be the cardinal sign of circulatory dysfunction, but other global features such as poor peripheral perfusion, persistent tachycardia, restlessness, confusion, tachypnoea, respiratory distress, hypoxaemia, and progressive metabolic acidaemia frequently occur earlier. These reflect the activation of powerful homeostatic mechanisms that maintain pressure at the expense of flow.

Features of regional circulatory failure include:

- oliguria with deteriorating renal function;
- confusion and impaired conscious level;
- chest pain, dysrhythmias, and ischaemic changes on electrocardiography (**ECG**);
- nausea, vomiting, and impaired gastrointestinal function: these symptoms of splanchnic ischaemia are often an early manifestation, but their significance is frequently overlooked.

Recent studies have demonstrated that evidence of an impending critical illness is often present—but not acted upon—for over 24 h in many of those patients on general wards who are subsequently admitted to intensive care units (**ICU**) following a cardiorespiratory arrest or with progressive organ failure. Such delay results in mortality rising almost exponentially as the number of organs that fail increases, leading to recommendations that 'rapid-response' or 'patient-at-risk' teams should be created with the aim of ensuring that experienced evaluation is rapidly available and timely admission to a critical care unit is arranged.

In high-risk surgical patients, preoperative 'optimization' of the circulation that ensures an oxygen delivery greater than 600 ml/min per m^2 through fluid resuscitation and, if necessary, inotrope/vasodilator therapy, has reduced mortality in controlled studies from over 20 per cent to less than 5 per cent, and the length of hospital stay by over 30 per cent.

Oxygen delivery and shock

Circulatory problems prompting a patient's admission to an ICU are cardiac arrest, pulmonary oedema, systemic hypotension, metabolic acidaemia, and organ failure, all situations that either threaten or have resulted from a failure of global or regional oxygen delivery. These patients are frequently described as suffering from 'shock'. The term has the advantage of brevity but little else, since it is imprecise and is applied to circulatory states that differ profoundly when analysed pathophysiologically. It can therefore guide neither management nor prognosis, but is irreversibly part of critical care terminology. Shock may be defined as inadequate cellular perfusion and oxygen uptake with consequent tissue hypoxia and organ failure. The terms 'early' and 'late' shock reflect the association between the duration and severity of the circulatory derangement and the prospect for recovery.

The major categories of shock, with examples, are:

- *Hypovolaemic*: haemorrhage, burns, gastrointestinal fluid loss;
- *Cardiogenic*: myocardial infarction, myocarditis, valve dysfunction;
- *Obstructive*: pulmonary embolus, cardiac tamponade, tension pneumothorax;
- *Anaphylactic*: drugs, blood transfusion, insect sting;
- *Septic*: bacterial infection, non-infective inflammatory conditions, e.g. pancreatitis, burns, trauma.

The primary problem in hypovolaemic, cardiogenic, and obstructive shock is a progressive decline in cardiac output and global oxygen delivery (DO_2), which—if not corrected—leads to secondary failure of the peripheral circulation and progressive organ dysfunction. By contrast, in sepsis and anaphylaxis, the primary problem is a failure of control of the peripheral circulation with disruption of the regional distribution of cardiac output, hence the alternative description of peripheral or distributive shock.

The initial physiological goal in the circulatory resuscitation of the critically ill patient is to restore global oxygen delivery while appropriate specific treatment is instituted.

Oxygen delivery

The delivery of oxygen from the external environment via the lungs to the mitochondria within individual cells is summarized in Fig. 1, with typical values quoted for normal activity in a 70-kg individual. Global oxygen delivery (DO_2) is calculated from the cardiac output, the oxygen saturation, and the haemoglobin concentration of arterial blood (Table 1).

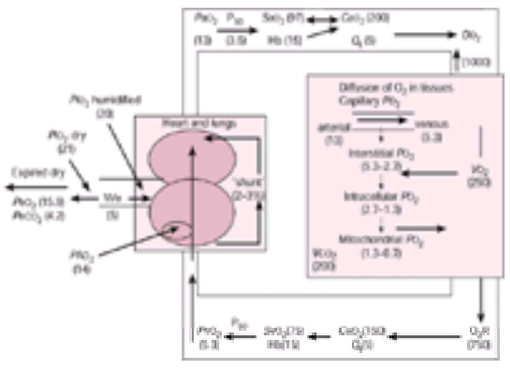

Fig. 1 Oxygen transport from the atmosphere to the mitochondria. Values in parentheses are for a normal 70-kg individual (body surface area (BSA), 1.67 m^2) breathing air (fractional inspiratory oxygen concentration (FiO_2), 0.21) at standard atmospheric pressure (PB), 101 kPa). Partial pressures of O_2, CO_2 in kPa; saturation in per cent; contents (CaO_2,CvO_2) in ml/litre; Hb in g/100 ml; blood/gas flows (Qt, Vi/e) in litres/min; oxygen transport (DO_2, O_2R), VO_2, and VCO_2 in ml/min. Abbreviations: SO_2, oxygen saturation (%); PO_2, partial pressure of oxygen (kPa); PiO_2, partial pressure of inspired O_2; PeO_2, partial pressure of mixed expired O_2; $PeCO_2$, partial pressure of mixed expired CO_2; PAO_2, partial pressure of alveolar O_2; PaO_2, partial pressure of arterial O_2; SaO_2, arterial SO_2; SvO_2, mixed venous SO_2; Qt, cardiac output; Hb, haemoglobin; CaO_2, arterial O_2 content; CvO_2, mixed venous O_2 content; VO_2, oxygen consumption; VCO_2, CO_2 production; O_2R, oxygen return; DO_2, oxygen delivery; Vi/e, minute volume-inspiration/expiration.

Apart from the adequacy of overall DO_2, the regional distribution both between and within organs is important in maintaining normal organ function. If the myocutaneous bed receives a disproportionately high blood flow, but the flow to the splanchnic bed is poor, then the gastrointestinal tract and liver will become ischaemic despite a high DO_2.

The final parts of the oxygen cascade depend on diffusion, determined by the PO_2 gradient and the distance from capillary to cell, and also upon the integrity of cellular metabolic function. Increased levels of DO_2 cannot compensate for either the disruption of regional distribution or impaired diffusion between capillary and cell, or for primary metabolic failure within the cell as occurs in cyanide poisoning and sepsis. This explains why strategies that improve global oxygen delivery may even adversely affect cellular oxygen status—for example: (1) vasoactive agents altering the distribution of DO_2 between and within organs; (2) excessive volume loading producing tissue oedema and impairment of diffusion; (3) inotropes that increase cellular oxygen requirements (for instance, epinephrine (adrenaline) and dobutamine) may increase cellular oxygen debt.

Although achieving and maintaining an adequate global DO_2 is undoubtedly important, particularly in early resuscitation, the ability to measure and control regional distribution is now the challenge in the circulatory management of the critically ill patient.

Relationship between oxygen delivery and consumption

The oxygen extraction ratio (**OER**) is the percentage of the oxygen delivered that is extracted by the tissues, which is normally approximately 25 per cent. As metabolic demand (VO_2) increases or supply diminishes, the OER increases to maintain aerobic metabolism. However, as demonstrated by point B in Fig. 2, there is a maximum extraction ratio (slope AB) that can be achieved. This is around 60 to 70 per cent for most tissues, beyond which a further increase in VO_2 or decline in DO_2 must lead to an inadequate availability of oxygen, at least in certain tissue beds, thus leading to anaerobic metabolism and increased lactic acid production. The dotted line, DEF, represents the altered relationship that may exist during critical illness. The slope of maximum OER falls, reflecting the reduced tissue extraction of oxygen, but the relationship does not plateau as in the normal relationship, that is to say oxygen consumption continues to rise with increasing delivery.

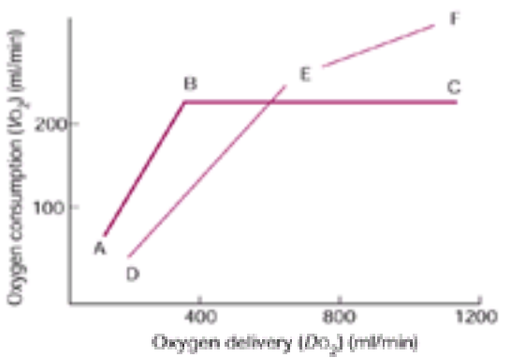

Fig. 2 Relationship between oxygen delivery and consumption. The effects of changing oxygen delivery on consumption. The solid line, ABC, represents the normal relationship and the fine line, DEF, the relationship believed to exist in critically ill patients.

An enthusiasm for achieving supranormal levels of DO_2, so called 'goal-directed' therapy, arose from the concept of shock as a failure of adequate global oxygen delivery and the belief that oxygen consumption had become 'supply-dependent'. Observations of postoperative patients in the early 1980s led to a decade of ICU practice that focused on such goal-directed therapy. Based on studies relevant to postoperative patients, many critically ill patients with established 'shock' in ICU were managed with the aim of achieving oxygen deliveries *above* 600 ml/min per m^2 using vigorous volume loading and inotropic support, frequently with dobutamine, in the belief that this would increase VO_2, relieve tissue hypoxia, prevent multiorgan failure, and improve prognosis. Several major studies have now failed to demonstrate any benefit from this approach in the treatment of established shock, where such aggressive volume loading can be detrimental. In these studies, the patients who failed to achieve the desired DO_2 levels despite volume loading and dobutamine had a poorer outcome than those with a higher DO_2, whether achieved spontaneously or following intervention, as did patients with low levels of DO_2 in the control group. This 'physiological reserve' or ability to increase DO_2 in response to the stress of critical illness is an important prognostic marker, which progressively diminishes with the length of time that the state of shock persists and as the circulatory state changes from early to late or 'irreversible/unresponsive' shock.

Although the relationship DEF of Fig. 2 may be unproven for established or late shock, the concept that a point B exists beyond which a further reduction in DO_2 causes progressive tissue hypoxaemia is valid early in the evolution of shock. This is particularly so for the low cardiac output/high vascular resistance causes (hypovolaemia, cardiogenic, obstructive) and also in early septic shock with intravascular depletion and low flows. In these situations the appropriate treatment is to increase DO_2 promptly by restoring the intravascular volume, relieving obstruction, or augmenting cardiac function. However, in the later stages of established shock from any cause the problem becomes peripheral at the microcirculatory level, with failure of autoregulation, abnormal regional distribution of flow within the organs, and direct cellular toxicity preventing oxygen uptake and utilization despite high levels of global DO_2.

Aside from variations in DO_2, tissue oxygenation may also be improved and aerobic metabolism sustained by reducing oxygen demand—achieved by controlling those factors that increase metabolic rate, such as: sympathetic activation from pain, agitation, shivering, and various interventions (nursing procedures, physiotherapy, visitors), drugs, and pyrexia. For each degree Celsius rise in temperature, oxygen consumption increases by 10 to 15 per cent.

Assessment of global circulatory performance

Cardiac output (Qt) depends upon:

1. ventricular 'preload', i.e. atrial filling pressures (right atrial pressure (**RAP**), left atrial pressure (**LAP**));
2. ventricular 'afterload', i.e. mean pulmonary and systemic arterial pressures (**PAP**, **SAP**);
3. ventricular contractility;
4. heart rate and rhythm.

Preload

Ventricular preload, traditionally assessed from the atrial filling pressures (RAP, LAP), determines the end-diastolic ventricular volume. This, according to Starling's law and depending on ventricular contractility, will in turn determine the work generated by the next cardiac contraction, the resulting stroke volume depending on the afterload.

Both ventricular contractility and afterload will affect the atrial filling pressures, but the predominant factor influencing preload is venous return, which is determined by the intravascular volume and the venous 'tone'. The systemic venous 'tone' or compliance is controlled by the autonomic nervous system and circulating catecholamines and can vary from 30 to over 300 ml/mmHg, such that the normal 70-kg person can compensate through venoconstriction for an intravascular volume loss of up to 1.5 litres without developing overt circulatory disturbance.

If the preload is low and either blood pressure or cardiac output is inadequate, the treatment priority is volume loading to restore the intravascular volume and venous return.

A high preload reflects one or more of the following: (1) high intravascular volume; (2) impaired myocardial contractility; or (3) increased 'afterload'. If treatment to reduce the preload is warranted, the options are therefore: to remove volume from the circulation (diuretics, venesection, haemofiltration) or to increase the capacity of the vascular bed with venodilator therapy (e.g. glyceryl trinitrate, morphine); to improve contractility; or to reduce the resistance of the relevant arterial bed.

In interpreting atrial pressures as measures of preload, two points must be considered. First, if the intrathoracic pressure (**Pt**) is raised, the intravascular pressure (**Pv**) may be misleading as a measure of preload since the true ventricular distending pressure is the transmural pressure (Pv – Pt). This is particularly relevant in situations where there is significant alveolar gas trapping, as in asthma or ventilation with high end-expiratory pressure and an increased ratio of inspiratory to expiratory time. Second, when the ventricle is dilated and poorly compliant the end-diastolic pressure-volume relationship is not necessarily linear, and ideally volume rather than pressure preload should be measured.

Afterload

Afterload influences the tension developed in the ventricular wall during systole, and is determined by the resistance to ventricular outflow from valvular abnormalities and the peripheral vascular resistance. The systemic and pulmonary vascular resistances (**SVR**, **PVR**) are calculated by analogy with Ohm's law as the pressure drop across the resistance bed divided by the flow, making the considerable assumption that flow in the circulation is linear and non-pulsatile.

Appropriate circulatory management requires an appreciation of the relationship between pressure, resistance, and flow: for a constant ventricular stroke work, the cardiac output will be inversely related to arterial pressure and resistance. The drugs used to manipulate pulmonary and systemic resistances are listed in Table 2.

Myocardial contractility

The ventricular stroke work is the external work performed by the ventricle with each beat and is calculated from the stroke volume and the pre- and afterload pressures (Table 1). The relationship between filling pressure, stroke work, and the resulting stroke volume for a constant afterload defines myocardial contractility. Consideration of ventricular work is important since circulatory management involves achieving the necessary pressures and flows to maintain satisfactory perfusion and oxygen delivery to all organs at maximum cardiac efficiency, that is for the least ventricular work, so that myocardial ischaemia is avoided.

Myocardial contractility is frequently reduced in critically ill patients due either to pre-existing cardiac disease, most often ischaemic heart disease, or as a consequence of the disease process, particularly sepsis. If the cardiac output is inadequate and myocardial contractility is poor, as defined by a 'flattened' stroke work/filling pressure equation, the available options are to:

- *reduce afterload* using an arteriolar dilator (nitrates, a-receptor blocker, angiotensin-converting enzyme (**ACE**) inhibitor). However, this may be limited by the consequent fall in systemic pressure.
- *increase preload*. Although appropriate if the preload is low or the intrathoracic pressure is high, the filling pressure will often already be raised and any further increase may not only fail to augment stroke volume but could increase ventricular wall tension, compromise ventricular blood supply, particularly to the endocardium, and potentially cause further impairment of contractility as well as pulmonary oedema.
- *increase myocardial contractility*, either by removing negatively inotropic influences (acidaemia, hyperkalaemia, drugs (for example, b-receptor blockers), or by using an inotrope (Table 2). The possible adverse effects of vasoactive agents on regional distribution of flow must also be considered.

Heart rate and rhythm

If the heart rate is low (<65 beats/min) with a low cardiac output, then increasing the rate either with a b_1-receptor agonist (for example, isoprenaline) or by pacing should be considered. Atrial pacing, or atrioventricular sequential pacing, has the advantage of maintaining co-ordinated atrial contraction that increases ventricular end-diastolic volume and hence stroke volume without increasing myocardial irritability.

Heart rates above 120 beats/min, other than sinus tachycardia, should be controlled either by drugs and/or DC cardioversion after ensuring that low plasma potassium and magnesium levels have been corrected.

Monitoring

The purpose of monitoring the critically ill patient is both to alert staff if a physiological variable is not maintained within preset limits and to guide therapy. Critically ill patients require the following investigations: continuous monitoring of heart rate and rhythm; intravascularly measured blood pressure and RAP; arterial oxygen saturation by oximetry; intermittent blood gas analysis, which usually also provides electrolyte, glucose, and lactate concentrations; and hourly fluid balance measurements.

Pulmonary artery catheterization

Of the six primary circulatory variables measured in an intensive care unit, three (RAP, mean arterial pressure (**MAP**), and heart rate) are routinely available even outside an ICU. Conventionally, the other three (PAP, LAP, and Qt) are measured by the insertion of a pulmonary artery catheter. Apart from the derivation of vascular resistances, ventricular work, and oxygen delivery, the mixed venous oxygen saturation can be measured and used to calculate oxygen consumption (Table 1).

Sampling from the pulmonary artery is necessary to ensure good mixing of the venous blood, since the saturation of venous blood from different organs does vary considerably. Hepatic venous saturation may only be 40 per cent, whereas renal venous saturation may exceed 80 per cent, reflecting the considerable difference between these organs in oxygen delivery compared to their metabolic requirements. Provided the peripheral distribution of DO_2 and cellular metabolic function are normal, a value of SvO_2 above 65 per cent indicates that oxygen delivery is satisfying tissue oxygen requirements.

The focus on 'goal-directed therapy' led to the widespread use of pulmonary artery (**PA**) catheters, with an annual consumption of over 2 million in the United States.

However, their indiscriminate use has been challenged by:

1. evidence that goal-directed therapy, although probably appropriate for under-resuscitated perioperative patients, may be harmful for other critically ill patients;
2. a multicentre case-controlled study of the use of the PA catheter, which suggested that those patients managed with a PA catheter had a poorer prognosis than those managed without such an intervention;
3. doubts about the appropriateness of using pressure preload as reflected by the pulmonary artery occlusion pressure as a surrogate for the volume preload of the left ventricle.

Although the PA catheter is undoubtedly associated with complications, particularly infection (see Table 3), and the measurements subject to significant error, the results of this study probably reflected poor training in the use of the catheter and a failure to respond appropriately to the data obtained. Insertion of a PA catheter should still be considered:

- if the RAP is raised and the relationship with the LAP is uncertain due to a recent myocardial infarction, valvular abnormalities, or high pulmonary vascular resistance—the most useful finding is a low 'wedge' pressure, demonstrating that further volume is indicated, but a high value does not necessarily exclude the need for further volume;
- if the patient's condition fails to improve with initial management;
- to measure cardiac output to guide the appropriate choice of vasoactive drug, particularly when high doses are being used;
- if continuous monitoring of PA pressures and evaluation of right ventricular (**RV**) function is indicated

The PA catheter debate has, however, led to considerable interest in alternative, less invasive methods of assessing cardiac output and the adequacy of left ventricular preload.

Measurement of global cardiac output

Table 4 summarizes the features of the alternative methods available for measuring cardiac output, with an assessment of those aspects other than accuracy that should be considered. Any additional information that is provided, such as continuous mixed venous oxygen saturation with a PA catheter, should be considered when selecting the most appropriate monitor.

The most widely used method for measuring cardiac output remains the thermodilution technique using a PA catheter. Although generally viewed as the 'gold standard', the error is at least 10 per cent and there are potentially serious complications, particularly infection.

Clinical assessment of systemic vascular resistance and pulse volume allows cardiac output to be estimated with sufficient accuracy to direct initial management. This approach is rapid, requires no invasive monitoring, may be performed outside the intensive care unit, and is relevant for use in less-well resourced countries. If the patient does not improve with management based on this initial assessment, more invasive monitoring is indicated.

With the oesophageal Doppler technique an ultrasound transducer probe is positioned in front of the descending aorta and blood flow velocity measured, from which cardiac output is derived using an estimate of the aortic cross-sectional area calculated from the patient's height, weight, and age. Intravascular volume status can also be assessed from changes in the size and shape of the aortic velocity waveform. It can be inserted rapidly and left *in situ* for up to a week without serious complication and is notionally non-invasive. However it is expensive, operator-dependent, and cannot easily be used in patients who are not intubated.

The recently reported technique of lithium dilution cardiac output can be performed with a peripheral venous and arterial line and compares favourably with the thermodilution method.

Pulse contour analysis relies on analysis of the arterial pressure waveform to provide a beat-by-beat estimation of the stroke volume. Regular calibration by thermal or lithium dilution is necessary but only requires a central venous injection of the indicator, and from this both intrathoracic blood volume and lung water can also be derived to provide an assessment of the adequacy of intravascular fluid resuscitation.

Measurement of regional blood flow

Appropriate management of the circulation requires information about regional as well as global flow. Urine output is sensitive to changes in renal perfusion, provided the kidneys have not developed acute tubular necrosis (**ATN**) or been poisoned with drugs, particularly diuretics. The lower limit is 0.5 ml/kg per min, but twice this rate is appropriate in the catabolic patient.

Peripheral perfusion and changes in cardiac output and its distribution can be assessed from the gradient between the peripheral temperature, usually measured over the dorsum of the foot, and the central or core temperature (rectal, oesophageal, or possibly tympanic).

Splanchnic blood flow, which is particularly sensitive to hypovolaemia and vasoconstricting inotropes and which is important in the aetiology of multiple organ failure, can be assessed by tonometry. The gastric tonometer is a nasogastric tube with a second channel connected to a balloon that can be inflated with saline or air. When the PCO_2 within the gastric mucosal cells (PCO_{2i}), stomach lumen, and the balloon have equilibrated, a sample is withdrawn from the balloon to measure PCO_2. From this measurement and the arterial bicarbonate concentration, the intracellular pH (pHi) can be calculated. Some perioperative studies in patients have shown that pHi is valuable both prognostically and in guiding treatment. Its role in the established critically ill patient is less clear. The gastric mucosal and alveolar PCO_2 gradient is probably a more appropriate measure. However, problems remain with obtaining useful data when the patient is being enterally fed, and there is also uncertainty whether gastric PCO_{2i} reflects the energy and oxygen status of other parts of the bowel. Although tonometers can be placed in the small bowel and sigmoid colon, the technique remains predominantly a research tool.

The new technologies of magnetic resonance spectroscopy and positron emission tomography allow more detailed study of the regional circulation, tissue oxygenation, and cellular bioenergetics and will soon become available for clinically based studies in the critically ill patient.

Echocardiography is useful in assessing ventricular volume preload and will also provide information about cardiac function and structure. It is particularly valuable in the diagnosis of obstructive shock and aortic dissection. The transthoracic approach may be difficult in ventilated patients due to a poor 'echo window', but the transoesophageal approach has been a major advance.

Acid–base balance and serum lactate are useful metabolic indices of the circulation and both are sensitive to intravascular volume depletion, particularly in the presence of inotropic support. Progressive metabolic acidaemia requires diagnosis and effective treatment. The serum lactate level reflects the balance between increased production in hypoxic tissues and metabolic clearance, which is predominantly hepatic. High lactate levels often indicate splanchnic ischaemia when there is both increased production and reduced clearance due to hepatic ischaemia. A single measurement is difficult to interpret, but the trend is valuable in assessing the response to treatment.

Key points in monitoring the circulation

- Regular clinical examination should never be forgotten: the symptoms and signs already discussed are as important as impressively displayed numbers on expensive monitors.
- Trends are more useful than a single observation.
- Pressure is no guarantee of flow.
- Although the jugular venous pressure (**JVP**) is traditionally measured from the sternal angle, in ICU pressures are measured from the mid-axillary line in the 5th intercostal space. From this reference point, in the supine position, the normal RAP is between +4 and +8 mmHg and the LAP or 'wedge' between +10 and +14 mmHg.
- If monitor data and clinical judgement conflict, check for common sources of error in the monitoring such as catheter blockage or malposition, failure to re-zero after postural change.
- Critical care monitoring is invasive, potentially hazardous (Table 3), expensive, and mostly of no proven benefit. The device should be used while *in situ*, but it

should be removed as soon as the information obtained is no longer required.
- Outcome benefit from the use of any monitor depends on the data being displayed accurately (zero and calibration), observed promptly, and interpreted appropriately and on an effective intervention being available and rapidly instituted.

Management of the circulation in the critically ill

General principles

The circulation should be assessed as shown in Table 5, which provides examples of the circulatory abnormalities in various conditions. The severity of the condition and pre-existing cardiorespiratory disease will affect the precise figures obtained in individual cases. It is not always necessary to use invasive monitoring to obtain precise measurements, but the discipline of estimating the key variables commits the clinician to a logical analysis of the problem and an awareness of which measurements need to be confirmed, invasively if necessary, if the patient's condition fails to improve.

The six key questions in managing the circulation are:

1. *What are the appropriate targets for blood pressure and cardiac output?* —Despite the emphasis placed on blood flow to the tissues, adequate perfusion pressure is also necessary to achieve the appropriate distribution of cardiac output and oxygen supply. The target for mean arterial pressure should be 65 mmHg but adequate splanchnic and renal perfusion may require higher pressures, particularly in the elderly patient with pre-existing hypertension or widespread atheroma. In treating a patient with cerebral oedema the target pressure should be 65 mmHg *above* the intracranial pressure.
2. A minimum cardiac output of 2.8 litres/min per m^2 should ensure that tissue hypoxia is not due to inadequate global oxygen supply. Thereafter, management of organ dysfunction should concentrate on the regional distribution.
3. *Has sufficient fluid been given?*—Conventionally this is based on measurement of the atrial filling pressures (RAP and LAP, or pulmonary artery occlusion/'wedge' pressure). Before starting inotropic support, fluid should be given to achieve an RAP up to 12 mmHg or a 'wedge' pressure of 18 mmHg. This assumes that the relationship between the atrial filling pressures, the permeability of the pulmonary capillary membranes, and the intrathoracic pressure are all normal, but none of these assumptions is necessarily valid in the critically ill patient. A low value (RAP <10 mmHg, LAP <14 mmHg) is helpful since further volume will improve cardiac work. Higher levels are more difficult to interpret, particularly in the ventilated patient, since, although an inadequate volume preload is not necessarily excluded, further fluid may result in pulmonary oedema.
4. Intravascular volume depletion is suggested by hypotension precipitated by sedation, analgesia, postural change, or during the inspiratory phase of positive-pressure ventilation. Brief disconnection from the ventilator causes the blood pressure to rise and venous pressure to fall: the measurement 'off' the ventilator more accurately reflects the ventricular end-diastolic transmural pressure. This manoeuvre is relatively contraindicated in patients with acute respiratory distress syndrome (**ARDS**), since loss of positive end-expiratory pressure may cause widespread alveolar collapse.
5. The difficulty in interpreting the absolute levels of RAP/LAP can be resolved by a fluid challenge: 200 ml of colloid is administered and the impact on blood pressure, flow, and preload observed. In the volume-depleted patient, blood pressure and flow will increase with only a small, transient increase in filling pressures. While pulmonary gas exchange remains satisfactory there is less anxiety about giving further colloid. Sufficient volume will have been given when either the target pressures are achieved and the evidence of poor peripheral perfusion and organ dysfunction has resolved, or when there is a sustained rise in filling pressures to a level above which there is a risk of pulmonary oedema developing.
6. *Which fluids should be used?*—The previous day's crystalloid and colloid balance should be reviewed, both intravascular and extravascular compartments should be assessed, and the volume of fluid to be given over the following 24 h should be decided. The crystalloid balance should include the planned enteral intake, fluid for central lines and drug infusions, urine output, and correction for both 'insensible' losses (sweat, diarrhoea) and the state of hydration of the extravascular tissue space. A daily target balance ranging from –1.5 to >+3 litres may be appropriate, but typically it will be between –0.5 and +1.5 litres.
7. If the intravascular space is underfilled, the rate of infusion of normal saline should be increased by up to 100 ml/h, but, acutely, the extra volume required to reach the preload target should be given as colloid. With an active haemorrhage or if the haemoglobin concentration is less than 8 g/dl, blood should be used. Traditionally, the target haemoglobin has been 10 g/dl, since this was believed to represent the balance between oxygen content and viscosity that achieved optimum tissue oxygen delivery. However, a prospective randomized study to assess the impact of the haemoglobin level on outcome demonstrated that, for patients without significant coronary artery disease, survival was improved if the haemoglobin was maintained between 7 and 9 g/dl rather than between 10 and 12 g/dl.
8. After appropriate blood transfusion, synthetic colloid rather than albumin should be used. A much-debated meta-analysis comparing the use of albumin with crystalloid or synthetic colloid concluded that, in the critically ill, albumin was associated with an increased mortality. Certainly, attempting to correct a low serum albumin level in such patients exhibiting a significant inflammatory response is futile, since their vascular endothelium will be freely permeable to albumin. There is relatively little evidence on which to base the choice of synthetic colloid (starch or gelatin) but the increase in intravascular volume is sustained for longer with the starch solutions, which also provide a wider range of molecular weight products and a sodium-free option.
9. *Are there metabolic factors that require correction?*—Metabolic acidaemia with a pH below 7.20 or a base deficit above 10 mmol/l should be corrected, as myocardial contractility increases linearly with rising pH to values above 7.40. The suggestion that sodium bicarbonate will produce a damaging paradoxical intracellular acidosis is misleading, since the experiments demonstrating this effect were performed *in vitro* with unphysiological solutions, within a 'closed system' that allowed no correction for any rise in carbon dioxide concentration, and the sodium bicarbonate was given by bolus injection rather than infusion. Sodium bicarbonate, given as a physiological infusion at between 1 and 2 mmol/min, improves myocardial contractility and cardiac output, as demonstrated by several clinical studies and shown by the benefits of bicarbonate haemofiltration in lactate-intolerant, critically ill patients.
10. Hyperkalaemia, hypocalcaemia, and hypophosphataemia also impair myocardial contractility and should be corrected.
11. *Is ventilatory support indicated?*—Hypoxaemia should be corrected promptly to ensure that oxygen saturation is at least 92 per cent, both to prevent myocardial ischaemia and to ensure maximum oxygen delivery. The work of breathing may account for up to one-third of oxygen consumption and, if provided mechanically, circulatory demands will be reduced significantly. Non-invasive ventilatory support should first be considered: both continuous positive airway pressure (**CPAP**) and pressure support ventilation can be provided by a face or nasal mask. If formal mechanical ventilation with intubation becomes necessary, colloid volume should be given and a vasoconstricting inotrope infusion should be available to prevent the potentially catastrophic hypotension that may result from the use of sedative anaesthetic drugs in the volume-depleted patient with high endogenous catecholamine levels and raised SVR.
12. *Which vasoactive agents should be used?*—If the target systemic pressure and cardiac output/oxygen delivery are not achieved with appropriate intravascular filling, a suitable vasoactive agent or combination must be selected (Table 2). The impact of such treatment in individual patients will be influenced by their baseline circulation state (that is, if it is either intensely constricted or dilated the same drug will potentially produce different effects on pressure, flow, and its distribution). The initial choice of vasoactive agent will depend on the mean arterial pressure (**MAP**), cardiac output, and derived systemic vascular resistance (**SVR**). If, for example:
    - cardiac output and MAP are both low with a high SVR, an inotropic and dilating (inodilator) effect is required and epinephrine (adrenaline) with glyceryl trinitrate or dobutamine would be appropriate. If cardiac output rises but MAP falls, as may happen when dobutamine is given, a constricting agent such as norepinephrine (noradrenaline) is required.
    - MAP and SVR are low with a high cardiac output, as frequently occurs in sepsis after volume resuscitation, then arteriolar constriction with norepinephrine is needed.
    - MAP is at or above target but the cardiac output is low with a raised SVR, a dilating agent (glyceryl trinitrate) or an inodilator is appropriate treatment.
13. When the PVR and RAP are acutely raised, a pulmonary vasodilator to 'offload' the right ventricle and maintain cardiac output is required. A nitrate or b-receptor agonist, such as isoprenaline, would be appropriate, but hypotension may result from arteriolar dilatation and hypoxaemia due to increased ventilation–perfusion mismatch.
14. A vasoactive drug that could influence regional flow would be valuable. The belief that low-dose dopamine selectively improves renal blood flow has resulted in its widespread use. However, the evidence to support this belief is scanty, and a study of its use in perioperative patients suggested that it may even be harmful. Its undoubted effect in increasing urine output is probably due to an improvement in MAP and cardiac output together with a natriuretic effect, rather than to any specific effect on renal blood flow. When these effects are required, provided it is not used as a substitute for adequate volume replacement, it remains useful. Dopexamine, with both dopamine (DA1, DA2)- and b-receptor effects, is used to improve splanchnic blood flow. However, despite reported benefits when used with volume loading in perioperative patients, there is little evidence of outcome benefit in the treatment of established shock.
15. Phosphodiesterase inhibitors, such as milrinone, offer a theoretically attractive approach to improving myocardial contractility by increasing intracellular cAMP when there is reduced responsiveness to b-agonists. Useful increases in cardiac output can be achieved, but these agents are powerful vasodilators and hypotension may limit their use and results in the need for a norepinephrine infusion.

Management in specific conditions

Myocardial infarction/pulmonary oedema

The aim should be a dilated circulation to achieve the target cardiac output for the minimum cardiac work, but with a diastolic pressure above 50 mmHg to protect coronary artery perfusion. The preload should be reduced with nitrate therapy, both to reverse pulmonary oedema and to avoid ventricular overdistension and increased wall tension that reduces epicardial to endocardial flow. An ACE inhibitor should be started early, although hypotension and impairment of renal function may cause delay. The intra-aortic balloon pump has the advantage of augmenting cardiac work, improving coronary artery perfusion, and reducing the left ventricular afterload and hence the need for inotropic drugs.

Haemorrhage

During a major haemorrhage, sympathetic activation with intense venoconstriction prevents hypotension developing until 30 per cent of the circulating blood volume is lost, which explains the response to subsequent transfusion. As volume is lost, venous 'tone' increases to maintain venous return and only late is there a marked fall in venous pressure, cardiac output, and finally arterial pressure. If the rate of fluid replacement does not exceed the speed of resolution of the reflex increase in sympathetic tone, the atrial filling pressures will not rise excessively. However, rapid transfusion may produce very high atrial pressures and even pulmonary oedema, even though the volume replaced is less than the volume lost from the circulation.

Major pulmonary embolism

Oxygen delivery should be maintained by oxygen administration, volume expansion, and inotropic stimulation, while the obstruction is relieved by heparinization with thrombolysis or embolectomy.

The RAP should be raised to at least 15 mmHg using colloid to increase right ventricular work, and the resulting expansion of the pulmonary vascular bed may reduce the pulmonary vascular resistance by up to 50 per cent. Hydraulic pulmonary oedema does not occur since the atrial pressure relationship is reversed. An initial intravenous bolus of heparin (15 000 units) should be given to initiate anticoagulation and to reverse the reflex pulmonary vasoconstriction that occurs in the unobstructed pulmonary vascular bed. Digitalization improves right ventricular contractility and is sensible prophylaxis against supraventricular tachycardias.

Sedation, diuretics, haemorrhage, induction of anaesthesia, vena caval ligation, and the administration of contrast material during angiography may produce a disastrous fall in RAP and cardiac output. To prevent such changes, venous return must be maintained with volume expanders and by venoconstriction with a-agonists such as norepinephrine or phenylephrine.

Septic shock

In septic shock the circulatory changes are primarily peripheral, with cytokine release and activated white cells producing both direct cellular toxicity and microcirculatory chaos. As a result of the 'shunting' of blood through the tissues and the failure of cellular oxygen utilization, the tissues remain hypoxic despite high DO_2. This results in a low oxygen extraction ratio, a raised lactate level, and a reduced arteriovenous oxygen difference with a paradoxically high SvO_2. Secondary failure of the global circulation is caused by:

- volume depletion due to the increased leakiness of the vascular endothelium and sequestration secondary to venodilatation; and
- toxic effects on the myocardium impairing both systolic contraction and diastolic relaxation.

The typical circulatory profiles before and after volume resuscitation are shown in Table 5.

Despite a low SVR, the patient may feel cold peripherally and present as having unexplained hypotension with a speed of onset that suggests a major pulmonary embolus or myocardial infarction. However, palpation of a surprisingly large volume yet a rapid central pulse reveals that the cardiac output must be high, effectively ruling out these other causes of shock and indicating the true diagnosis.

Deciding on the 'appropriate' fluid volume to give in sepsis can be difficult. Frequently, the decision represents a balance between giving sufficient volume to prevent the use of excessive doses of constricting inotropes and giving excessive amounts with consequent tissue oedema and deterioration in pulmonary gas exchange.

Norepinephrine and epinephrine infusions will often be necessary, with doses adjusted as previously described to achieve pressure and flow targets. If high doses (>0.15 µg/kg per min) are required, splanchnic ischaemia is a major concern and should be suspected if the patient develops abdominal tenderness, large nasogastric aspirates, and a lactic acidosis. Patients with severe sepsis develop b-receptor desensitization with reduced intracellular cAMP levels, which makes the use of phosphodiesterase inhibitors such as milrinone logical. However, their use may exacerbate hypotension and result in the dose of vasoconstrictor drugs being increased.

Earlier studies suggested there was no role for steroids in the treatment of septic shock. However, there is now evidence that, at a lower dose (100 mg hydrocortisone, three times per day) than previously used, they can reduce the marked vasodilatation associated with a persistent and excessive inflammatory response, so that the doses of constricting inotropes can be reduced with potential benefit for regional perfusion.

Several large studies of anticytokine therapy and of antithrombin III supplementation in patients with severe sepsis have all failed to improve outcome. Similarly, a trial of *N*-monomethyl-L-arginine (**l-NMMA**)—an antagonist of the effects of inducible nitric oxide synthase, an enzyme responsible for the excess production of nitric oxide that is central to the severe peripheral vasodilatation associated with septic shock—had to be stopped prematurely because of an adverse outcome in the treatment group. However, a study in which activated protein C was given as an infusion over 4 days to patients with severe sepsis has now shown a significant reduction in mortality at 28 days.

16.3 Cardiac arrest

C. A. Eynon

Introduction

Cardiac arrest is a clinical syndrome consisting of unresponsiveness, absence of a detectable pulse, and either apnoea or agonal respiration. Cessation of cardiac activity is common to all causes of death and it is important to remember that cardiopulmonary resuscitation (**CPR**) was only developed to treat potentially reversible causes.

From the earliest recorded times it has been recognized that there is a period in which it is possible to reverse the transition from life to death. In Ancient Egyptian mythology, Isis, the goddess of healing, revived her husband Osiris by breathing into his mouth. In the Old Testament, Elijah successfully resuscitated an apparently dead child. The techniques that comprise modern CPR were all described before the end of the 19th century. Accounts of mouth-to-mouth ventilation appeared in the recommendations of the Dutch Humane Society in 1767, and in 1775 Abildgaard described the effects of electricity in first killing, and then resuscitating chickens. The earliest reports of closed-chest compression were in the late 1800s. It was only from the mid-1950s, however, that these individual modalities were combined and evolved into the concept of the 'chain of survival' (Fig. 1).

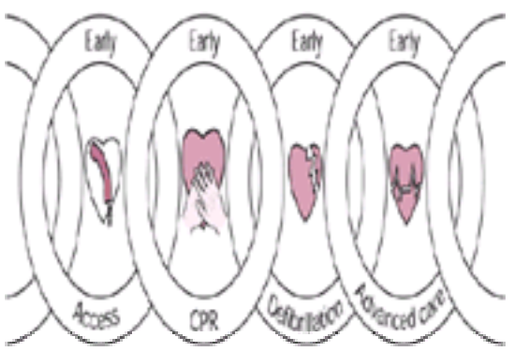

Fig. 1 The sequence of events in emergency cardiac care is displayed schematically by the 'chain of survival' metaphor. (From Cummins RO *et al*., 1991. Improving survival from sudden cardiac arrest: the 'chain of survival' concept. *Circulation* **83**, 1832–47.)

Aetiology

In the adult population, sudden cardiac arrest commonly results from ischaemic heart disease, 30 per cent of victims having evidence of recent myocardial infarction at autopsy. Other cardiac causes include primary arrhythmias, cardiomyopathies, and structural abnormalities. A wide range of non-cardiac conditions can precipitate a secondary cardiac arrest.

Three cardiac arrest rhythms are recognized: ventricular fibrillation (**VF**) or pulseless ventricular tachycardia (**VT**), asystole, and pulseless electrical activity (**PEA**). VF is characterized by a chaotic, uncoordinated waveform on the electrocardiogram (**ECG**). Asystole occurs when no ventricular electrical activity is present. Although atrial and ventricular asystole usually coexist, ventricular asystole may precede atrial asystole by a short time, producing an ECG in which there are isolated p waves. PEA occurs when there are clinical features of cardiac arrest despite an ECG rhythm that would normally be associated with a palpable pulse. Outside hospital, up to 75 per cent of cardiac arrests are due to VF/VT. In hospital, asystole and PEA are more common. This may reflect the greater prevalence of comorbid conditions in the hospital population.

Epidemiology

Sudden cardiac arrest remains the leading cause of unexpected death in the Western world, with 500 000 cases annually in the United States. With resuscitation the rate of return of spontaneous circulation is approximately 30 per cent for patients suffering an in-hospital cardiac arrest, but only around 15 per cent survive to discharge. Patients who suffer an out-of-hospital cardiac arrest have a worse outcome, with 8 to 22 per cent surviving to admission and 2 to 8 per cent being discharged. This variation in outcomes results from differences in emergency medical systems and study methodology. The main determinant of outcome is the initially documented cardiac rhythm. The survival rate for patients in VF/VT is 10 to 15 times that for asystole or PEA.

Pathophysiology

During cardiac arrest there is global ischaemia. Therapy is directed at maintaining perfusion of vital organs and re-establishing organized myocardial activity. Release of endogenous catecholamines and other vasoactive peptides causes redistribution of blood flow to the brain and heart and away from other organs. The brain is the organ most susceptible to ischaemia, and the rate of neurologically intact survival decreases rapidly to virtually zero at 20 min following cardiac arrest.

Myocardial ischaemia causes maximal coronary vasodilatation and myocardial blood flow becomes dependent on the coronary perfusion pressure: the pressure gradient between the aorta and right atrium during diastole. A coronary perfusion pressure of 15 mmHg during resuscitation appears to be the threshold for successful return of spontaneous circulation. Under normal conditions, coronary blood flow is autoregulated and coronary artery stenoses of up to 70 per cent do not compromise flow. However, during cardiac arrest autoregulation is lost and relatively insignificant lesions may reduce distal perfusion.

Following resuscitation there is a period of reversible organ dysfunction. Neurological impairment often persists for 12 to 24 h. Thereafter, two patterns emerge:

progressive improvement, or persisting coma and stable neurological deficit. Myocardial dysfunction contributes to the high mortality from arrhythmias and heart failure in the hours and days after resuscitation. Other organ systems are relatively resistant to periods of ischaemia compatible with successful resuscitation. Although multiple organ support may be necessary, permanent damage of organs other than the brain is uncommon in survivors.

Management

The current European Resuscitation Guidelines for adult basic and advanced life support are shown in Fig. 2 and Fig. 3. The most important factors affecting outcome are the times before institution of CPR, defibrillation, and advanced care. For VF/VT, survival rates correlate with the time to defibrillation. For asystole and PEA, the aim of treatment is to maintain organ perfusion until remediable causes for cardiac arrest can be identified and treated.

Early access/assessment

Immediate activation of the emergency medical systems is essential once it has been determined that the patient is unresponsive. Campaigns have highlighted the need for witnesses of cardiac arrest to notify the emergency services correctly. Awareness of the appropriate telephone number is impaired by the use of different numbers in different countries. The Council of the European Communities has recommended that the number '112' should be used throughout Europe, but this has not been widely implemented, and telephone codes to summon the cardiac arrest team within hospitals have also not been standardized.

After activation of the emergency medical systems, assessment of the patient continues with **ABC** (airway, breathing, and circulation). Airway obstruction commonly results from loss of muscle tone in the tongue and jaw muscles, allowing the tongue and epiglottis to occlude the airway. In the absence of head or neck trauma, the airway should be opened using the head-tilt, chin-lift manoeuvre. The rescuer should then look for chest movement, listen for breath sounds, and feel for air movement on their cheek. Absence of breathing should be confirmed over 10 s. The patient should then be examined for signs of circulation for up to 10 s.

Basic life support

The objective of basic life support is to generate sufficient flow of oxygenated blood to the heart and brain until definitive therapy can be applied and spontaneous circulation re-established. Basic life support at least doubles the chances of survival if applied between the time of collapse and first defibrillation.

Mouth-to-mouth ventilation

Maintenance of the airway and ventilation may be performed concurrently using the mouth-to-mouth method. The rescuer's lips are placed around the patient's mouth and the patient's nose is sealed by pinching the nostrils together. The recommended tidal volume is 400 to 600 ml. Current recommendations are for two ventilations to 15 chest compressions. Normal expired air contains 15 to 17 per cent oxygen and 4 per cent carbon dioxide. Hyperventilation increases the oxygen concentration to 18 per cent and reduces the carbon dioxide concentration to 2 per cent. Enough oxygen can be administered in this manner to maintain an adequate arterial oxygen saturation in the early stages of cardiac arrest.

Closed-chest compression

Closed-chest compressions are performed by placing the heel of one hand over the lower sternum, two fingerbreadths from the xiphisternal junction. The heel of the second hand is placed over the first. The sternum is compressed 4 to 5 cm in the adult, maintaining compression for 50 per cent of the compression–relaxation cycle. The rate should be 100 compressions per minute. Properly performed closed-chest compressions can produce peak systolic arterial pressures of 60 to 80 mmHg, but diastolic arterial pressure and coronary perfusion pressure fall rapidly after the first few minutes. Cardiac output during closed-chest compression ranges from a quarter to a third of normal.

The mechanism leading to blood flow during closed-chest compressions is still debated. The cardiac pump hypothesis proposes that direct compression of the heart between the sternum and the paraspinal structures results in ejection of blood. The aortic and pulmonary valves open during compression, whilst closure of the mitral and tricuspid valves prevents regurgitation of blood. As compression is released, intracardiac pressures fall and the mitral and tricuspid valves open, promoting ventricular filling. In contrast, the thoracic pump hypothesis proposes that the entire thorax is the pump, with the heart being a passive conduit and the pulmonary vascular bed acting as a reservoir for blood. This theory is supported by the finding that patients in cardiac arrest can maintain prolonged consciousness by forceful coughing. Coughing increases intrathoracic pressure which results in antegrade blood flow. Also favouring this theory are studies showing no significant reduction in left ventricular dimensions and patent heart valves, during closed-chest compression.

The major complication from closed-chest compression is trauma. Rib and sternal fractures occur in up to 30 per cent of patients, even with well-trained rescuers.

Incorrectly performed compressions may injure the thoracic or abdominal contents.

Adjuncts to standard CPR

The airway may be maintained using either nasopharyngeal or oropharangeal airways. These hold the base of the tongue away from the posterior pharynx. Pocket masks for mouth-to-mask ventilation reduce possible spread of pathogens and can incorporate supplementary oxygen. Bag–valve–mask devices with a reservoir bag can deliver an inspired oxygen concentration of over 90 per cent.

Alternative methods of closed-chest compression

The poor survival rate following closed-chest compression has driven the search for more effective methods. Interposed abdominal counterpulsation aims to increase venous return to the heart prior to chest compression. Active compression–decompression CPR uses a device applied to the chest wall to reduce intrathoracic pressure and increase venous return during decompression. Vest CPR uses a circumferential vest around the thorax. Sequential inflation and deflation alters intrathoracic pressure resulting in blood flow. Although promising in animal trials and limited human studies, no survival benefit has been seen in larger studies for any of these methods.

Open-chest cardiac massage

The ease of closed-chest compression led to it quickly supplanting open-chest cardiac massage without trials to demonstrate its superiority. Experimental evidence, coupled with reports of patient survival using open-chest cardiac massage after prolonged periods of unsuccessful closed-chest compression, have led to a resurgence of interest in the open-chest method. The American Heart Association recommends open-chest cardiac massage for cardiac arrest associated with penetrating trauma, hypothermia, pulmonary embolus, pericardial tamponade, abdominal haemorrhage, or where chest or vertebral anomalies prevent effective closed-chest compression.

Advanced life support

Defibrillation

The majority of survivors of cardiac arrest are in VF/VT. Defibrillation is the only effective method of terminating these rhythms and its effectiveness falls rapidly with time (Fig. 4). Over 80 per cent of patients successfully resuscitated from VF/VT are resuscitated by one of the first three shocks. A precordial thump may terminate VF/VT and should be considered for witnessed arrests when a defibrillator is not immediately available.

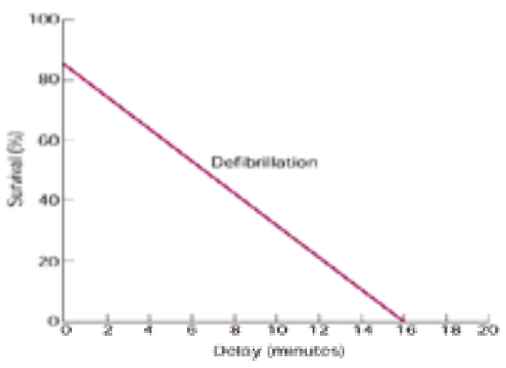

Fig. 4 Effect of time on success of defibrillation. (From Colquhoun MC, Handley AJ, Evans TR, 1998. *ABC of resuscitation*, 3rd edn. © BMJ Books.)

Mechanism of defibrillation

The mechanism of defibrillation is unknown. The critical mass hypothesis suggests that defibrillation occurs when sufficient current passes through the heart to depolarize approximately 75 per cent of the myocardium. This causes arrest of the activating wave and allows a normal rhythm to be re-established. The upper limit of vulnerability theory proposes that fibrillation terminates only when the strength of shock is greater than the threshold limit for the whole myocardium. Sub-threshold shocks induce refractoriness in susceptible tissue but lead to new activation waveforms from regions excited by the shock. This second theory is supported by the finding of a period of electrical silence after a countershock, followed by resumption of fibrillation with a different morphology.

As little as 4 per cent of the current applied using external defibrillation actually crosses the heart. The current applied depends on the energy selected and the impedance of the thorax. Transthoracic impedance is altered by electrode size, the use of couplants (usually preformed gel pads) between electrodes and chest wall, multiple shocks, the phase of respiration, and the pressure with which the electrodes are applied.

The recommended energy level for the initial shock is 200 joules. This aims to produce a high success rate whilst minimizing the risk of damage to the heart. If a second shock is required it should also be 200 J. Transthoracic impedance reduces with successive shocks and each shock should deliver more energy to the myocardium. Subsequent shocks are delivered at 360 J, which is the maximum available on most defibrillators. The most commonly used electrode placement is apex–anterior with one placed to the right of the upper sternum below the clavicle, and the other over the apex of the heart. Alternative placements may result in successful defibrillation in some patients.

Current-based defibrillation uses a microprocessor to measure transthoracic impedance. The operator selects the required current and the defibrillator charges a capacitor to the energy required to deliver that current. Using biphasic waveforms rather than the standard damped sinusoidal waveform may reduce energy requirements. Both of these methods have shown promise in early clinical trials.

Automated external defibrillators

It is important that the first responder at a cardiac arrest can defibrillate. Even small reductions in the time to first shock can dramatically improve survival. Interpretation of ECG rhythms is difficult even for medical professionals and can delay defibrillation. Automated external defibrillators are capable of analysing the ECG rhythm and advise that a countershock be given if VF is present. Fully automated machines deliver the shock after offering an audible warning. By simplifying the training required, they may be used by a wide range of non-medical personnel.

Early advanced care

Advanced care is required if CPR and defibrillation fail to achieve or sustain a spontaneous circulation.

Advanced airway support

Endotracheal intubation remains the gold standard of airway management. Intubation maintains and protects the airway, permits administration of additional oxygen and certain drugs, and allows adjustment of ventilation. Successful intubation requires a high level of skill and regular practice. Laryngeal mask airways are commonly used in anaesthesia and increasingly for airway management during cardiac arrest. Their use requires a lower level of training than does intubation.

Drug therapy

Peripheral venous cannulation is the quickest method of administering medication during cardiac arrest. Peak drug levels are lower and circulation times are longer using peripheral rather than central routes. If there is delay in obtaining venous access, adrenaline, atropine, and lignocaine may be administered via the endotracheal tube. They should be given at 2 to 3 times the normal intravenous dose and diluted in 10 ml of normal saline. Drug absorption and pharmacodynamics are less predictable when given via the endotracheal route.

Vasopressors

Adrenaline has not been proved to improve survival from cardiac arrest. The standard dose of 1 mg originates from studies using 0.1 mg/kg in 10 kg dogs. This was translated into human use without evidence of comparable efficacy. In a dose range of 0.045 to 0.2 mg/kg (3 to 14 mg in a 70 kg man), adrenaline improves the arterial pressures generated during CPR and increases myocardial and cerebral blood flow. High-dose adrenaline has failed to show any survival benefit compared with standard dosage. Currently, the majority of studies support the use of adrenaline for patients who remain in cardiac arrest after CPR and defibrillation.

No other adrenergic agonist has been shown to have advantages over adrenaline in the treatment of cardiac arrest. The vasoconstrictor vasopressin has been used in limited clinical trials with encouraging results.

Antiarrhythmics

The advantage of routine use of antiarrhythmics in cardiac arrest is unproved. Although bretylium and lignocaine are effective in suppressing arrhythmias after myocardial infarction, they have not shown clear benefit in the setting of cardiac arrest. Amiodarone has been used in trials of persistent ventricular arrhythmias with reported improvement. Magnesium sulphate is the treatment of choice for torsade de pointes. Empirical magnesium supplementation has not, however, been shown to be of benefit in cardiac arrest.

Atropine is of value in haemodynamically compromising bradycardia, but the recommendation for its use in asystole is based on limited data. It is hypothesized that excessive vagal tone may inhibit cardiac action. Small-scale studies suggest that atropine has a favourable effect on cardiac rhythm.

Buffers

Cardiac arrest causes a mixed respiratory and metabolic acidosis due to retention of carbon dioxide and lactic acid. Low blood flow during CPR often causes differences between venous and arterial samples with a mixed venous acidosis despite arterial hypocarbic alkalosis. No clinical data support correction of the acidosis by means other than adequate ventilation and tissue perfusion. Addition of bicarbonate causes further increases in venous carbon dioxide and venous respiratory acidosis. Sodium bicarbonate also has the theoretical disadvantages of hyperosmolarity and hypernatraemia. Alternative buffering agents have shown no benefit. Buffers remain of use in cases of cardiac arrest associated with tricyclic antidepressant overdose and pre-existing metabolic acidosis.

Pacing

External pacing of asystole may be beneficial in the small group of patients who arrest shortly before pacing is instituted. For the majority, application of external pacing is too late.

Post-resuscitation care

Following return of spontaneous circulation the cause of the cardiac arrest should be ascertained and tissue perfusion optimized. Emergency thrombolysis or angioplasty may offer benefit for patients with acute myocardial infarction. Prolonged coma following resuscitation is associated with poor outcome. Neurological assessment after 72 h can predict the likelihood of long-term survival. Trials to evaluate treatment that might reduce cerebral damage have been disappointing. Myocardial dysfunction accounts for the majority of early deaths after return of spontaneous circulation. The only method of minimizing post-resuscitation sequelae is to strengthen the chain of survival.

Training in life support measures

Most sudden cardiac arrests occur in the community. For these patients, the highest rates of survival have been achieved when CPR is initiated within 4 min. Well-performed basic life support is more successful than poorly performed basic life support, and some basic life support is better than none. Training in the technique is well established in many communities. The use of automated external defibrillators is now included in the American Heart Association basic life support programme.

Ethics of resuscitation

When resuscitation is not attempted, death is virtually inevitable. Only with evidence that resuscitation is not indicated should it be omitted.

Advanced directives or living wills are becoming more common, especially in the United States. These convey the patients' wishes with respect to specific treatments when they are unconscious or incapacitated. If possible, decisions not to attempt resuscitation (DNR orders) should be made after discussion with the patient. If the patient is not competent to make the decision, factors to be considered include the quality of life prior to the illness, the expected quality of life assuming recovery, and the likelihood of successful resuscitation.

Although doctors are not required to offer a treatment if it is deemed futile, determinations of futility vary greatly between physicians. Resuscitation has been deemed futile for the following reasons.

1. An adequate trial of basic and advanced life support has already been attempted without return of spontaneous circulation.
2. No physiological benefit from basic or advanced life support can be expected because the patient's vital functions are deteriorating despite maximum therapy.
3. No survivors after cardiopulmonary resuscitation have been reported under the given circumstances.

The presence of sepsis, disseminated cancer, or major organ failure is associated with very poor outcome. Lower survival rates in the elderly result from a higher presence of comorbidity rather than from age itself. In practice, doctors must determine the merit of attempting CPR for each patient. If resuscitation is attempted but return of spontaneous circulation does not occur promptly, consideration must be given to termination of the attempt. This decision depends on a number of factors in addition to those cited above.

1. Time intervals to initiation of basic life support and defibrillation—delays of over 5 min to basic life support or 30 min to defibrillation are associated with extremely poor prognosis.
2. Evidence of cardiac activity—termination of resuscitation effort after 15 to 20 min has been suggested for non-VF/VT arrests.
3. Protective factors—hypothermia or ingestion of sedatives, hypnotics, or narcotics confer a measure of protection from the sequelae of cardiac arrest.

Relatives and resuscitation

The presence of relatives in the resuscitation room remains controversial. Whilst common in paediatric practice it is not routine in adult cardiac arrest. However, if properly managed witnessing resuscitation does no harm and probably aids the grieving process should the patient not survive.

Practical skill training using the recently dead

Mannikins have largely replaced the use of the recently dead for training in the practical skills used in resuscitation.

Future developments

End-tidal carbon dioxide levels ($ETCO_2$)

$ETCO_2$ meters are widely used to confirm correct endotracheal tube placement. During cardiac arrest, $ETCO_2$ levels depend primarily on the cardiac output generated by resuscitation. A value of 10 mmHg at 20 min can distinguish patients who may survive from ones who will not. Use of $ETCO_2$ may clarify when resuscitation attempts can be deemed futile.

Invasive support

Cardiopulmonary bypass

Whilst cardiopulmonary bypass is a proven treatment for cardiac arrest associated with hypothermia, its role in routine arrests is likely to be limited by cost as well as the time required to achieve bypass.

Minimally invasive direct cardiac massage

In this technique a plunger device is placed directly on to the pericardium via a small thoracotomy. Manual compression of the ventricles provides an artificial circulation.

Anstadt cup

This is a biventricular assist device placed around the heart. Its role is limited by the requirement for significant surgical skill and equipment.

Retroaortic perfusion

This involves insertion of an aortic occlusion balloon into the descending aorta and infusion of oxygenated blood or blood substitutes into the proximal aorta.

16.4 Anaphylaxis

Anthony F. T. Brown

Introduction

The term anaphylaxis was introduced by Richet and Portier in 1902, literally meaning 'against protection'. It is currently used to describe the rapid, generalized, and often unheralded IgE immunologically mediated events that follow exposure to some foreign substances in those who have previously been sensitized. An identical clinical syndrome involving release of similar potent mediators but not triggered by IgE, and thus not necessarily requiring previous exposure, is termed an anaphylactoid reaction. Despite aetiological differences of vital importance to subsequent follow-up and prevention, the clinical term anaphylaxis is often used to describe both of these syndromes (as in this chapter).

Anaphylaxis is potentially the most severe of the immediate-type hypersensitivity reactions. It is the quintessential medical emergency that may be mild or severe, gradual in onset or fulminant, involve multiple organ systems or cause isolated wheeze or shock. It often occurs without warning in otherwise healthy people, and since there is no immediate confirmatory laboratory test it mandates prompt clinical recognition and treatment to prevent death from hypoxia or hypotension in severe cases.

Epidemiology

The true incidence and prevalence of anaphylaxis are unknown. The literature is heterogeneous, retrospective, and utilizes variable definitions. Emergency department presentations range from 1 in 440 to 1 in 1500 attendances, representing an incidence from 1 per 3400 to 1 per 10 000 catchment population per year. Hospital discharge data suggest 10 per 100 000 admissions are due to anaphylaxis. No age, sex, race, or locality is exempt, with cases occurring from infancy to old age.

Atopy increases the risk of idiopathic anaphylaxis and that caused by ingested antigens, latex, radiocontrast media, and exercise. Asthma increases the risk of dying from anaphylaxis. Patients taking b-blocking drugs develop more severe reactions which may be resistant to therapy, and those taking angiotensin-converting enzyme (ACE) inhibitor drugs are particularly prone to angioedema that can be life threatening. The newer angiotensin-II receptor antagonists cause fewer reactions but are also implicated.

Deaths from anaphylaxis are rare, although penicillins, hymenopteran stings, and radiocontrast media account for the majority.

Aetiology

IgE-mediated anaphylaxis

A vast array of IgE immune-mediated triggers are recognized (Table 1), the most important being b-lactam antibiotics including the penicillins and cephalosporins, hymenopteran stings such as wasps and bees, and foods.

Antibiotics

Penicillins are the most common cause of anaphylaxis in adults, occurring after 1 in 5000 parenteral doses, and are the most frequent cause of death. True cross-sensitivity to the cephalosporins is considerably less than 10 per cent and largely confined to the first-generation cephalosporins. Fatalities to oral penicillins are exceedingly rare.

Hymenoptera

Reactions to hymenopteran venom, such as from wasps, bees, hornets, and fire ants, are second only to antibiotics in frequency, occurring in up to 3 per cent of the population. Large local reactions, toxic reactions, and late serum sickness-like, non-IgE reactions may also occur following a sting.

Foods

Peanuts, other legumes, true nuts, shellfish, milk, and eggs cause the largest number of food-related cases, particularly in children. Reactions occur rapidly and may recur several hours later (biphasic reaction). Cross-reactivity to seemingly unrelated plants is seen. Mislabelling and contamination at the manufacturing stage or in the home cause inadvertent exposure.

Latex

Allergy to latex (rubber) is seen particularly in hospital personnel, children with spina bifida and genitourinary abnormalities, and in workers with occupational exposure. It may occur by contact, parenteral administration, and aerosol transmission and is one cause of perioperative anaphylaxis, along with thiopentone, neuromuscular blocking drugs, antibiotics, protamine, and anaphylactoid reactions to opiates, colloids, or blood.

Non-immune, anaphylactoid reactions

Various less well understood, non-immunological mechanisms lead to the release of similar inflammatory mediators in anaphylactoid reactions. Agents responsible include aspirin, non-steroidal anti-inflammatory drugs (**NSAIDs**), radiocontrast media, and opiates, and in the case of infusions may relate to their rate, concentration, and volume delivered (see Table 2).

Radiocontrast media

These were the most common cause of anaphylactoid reactions, but the incidence has declined to less than 1 in 200 patients receiving the newer low osmolality, non-ionic agents. Asthma, atopy, and patients on b-blockers or with prior reactions are at greatest risk.

Aspirin and NSAIDs

Bronchospasm following these is common in patients with nasal polyps and reactive airway disease, but systemic anaphylactoid reactions may occur in their absence following cyclo-oxygenase inhibition. Cross-reactivity occurs between different NSAIDs and rare reactions have occurred to the newer COX-II (cyclo-oxygenase II) inhibitors.

Pathogenesis

Irrespective of the triggering event, two main groups of mediators are released by mast cells and basophils. These groups include the preformed, granule-associated mediators histamine, neutrophil and eosinophil chemotactic factors, enzymes such as tryptase and b-glucuronidase, and proteoglycans such as heparin. They also include newly synthesized mediators from arachidonic acid metabolism via the cyclo-oxygenase pathway, such as prostaglandin D_2 and thromboxane A_2, and via the lipoxygenase pathway, such as the leukotrienes. In addition, platelet-activating factor and cytokines such as the interleukins are also rapidly formed.

All these mediators act by inducing vasodilatation, increasing capillary permeability and glandular secretion, causing smooth muscle spasm (including bronchoconstriction), and by attracting new cells to the area (see Chapter 5.2 for further discussion).

Clinical features

Anaphylaxis is typically a disease of those who are fit and is rarely seen or described in patients who are critically ill or shocked other than those suffering from asthma. The speed of onset of symptoms and signs is related to the severity of the process, with life-threatening reactions occurring in minutes to parenteral antigen exposure, although deaths have been associated with oral, topical, or cutaneous triggers. Most symptoms occur within 30 min, but may be delayed for some hours, particularly following oral or topical exposure.

Over half the deaths from anaphylaxis occur within the first hour of onset. Seventy five per cent result from asphyxia due to upper airway oedema and hypoxia from severe bronchospasm. The remaining 25 per cent are due to circulatory failure with shock related to vasodilatation and hypovolaemia from plasma volume losses, cardiac arrhythmias, pulmonary hypertension, and (possibly) decreased myocardial activity in the absence of cardiac disease.

Ninety five per cent of patients have cutaneous features, but these can sometimes be absent, particularly in cases presenting with the rapid onset of laryngeal oedema or circulatory shock, or resolve spontaneously or in response to prehospital treatment.

Cutaneous features

A premonitory aura, tingling, or warm sensation may precede generalized erythema, urticaria with pruritus, local oedema or angioedema, and occasionally pallor. Rhinitis and conjunctivitis are also seen.

Respiratory system features

Sudden cough, hoarseness, throat tightness, or the sensation of a 'lump' may precede shortness of breath, dyspnoea, stridor, wheeze, and cyanosis due to oropharyngeal or laryngeal oedema and bronchospasm.

Cardiovascular and neurological features

Apprehension, light-headedness, dizziness, or syncope may precede or accompany cardiovascular collapse with tachycardia, hypotension, and cardiac arrhythmias. Hypoxia, hypoperfusion, and the direct effect of mediators lead to incontinence, confusion or coma, and myocardial or cerebral ischaemia or infarction.

Gastrointestinal and miscellaneous features

Cramping abdominal pain, nausea, vomiting, and diarrhoea are common, but the more obviously life-threatening features described above usually overshadow these gastrointestinal manifestations. In rare instances there may be back pain, watery vaginal discharge, pulmonary oedema, and even disseminated intravascular coagulation.

Differential diagnosis

The protean manifestations of anaphylaxis allow a potentially vast differential diagnosis, although the rapid onset, accompanying cutaneous feature, and relationship to a potential trigger suggest the diagnosis of anaphylaxis in most cases. However, the following alternative diagnoses may be considered.

Facial swelling or oedema

These may result from bacterial or viral infection, although fever and pain should predominate. Traumatic or spontaneous bleeding, particularly in patients on warfarin, usually causes recognizable bruising.

Wheeze and difficulty breathing

Bronchial asthma, cardiogenic pulmonary oedema, foreign body inhalation, irritant chemical exposure, and tension pneumothorax should be distinguished on the basis of associated presenting features.

Light-headedness and syncope

A vasovagal reaction must be considered in the context of a painful procedure such as an injection or local anaesthetic infiltration: bradycardia, pallor, and rapid response to a recumbent position are usual. Panic attacks are common in allergic patients confronted by an unexpected, potential allergen exposure.

Angioedema

Angioedema in the absence of urticaria may be caused by actual or functional C_1 esterase inhibitor deficiency. This may be hereditary with autosomal dominant inheritance or acquired related to lymphoproliferative disorders. A family history, the absence of pruritus, prominence of abdominal symptoms, and recurrent attacks suggest the hereditary cause. C_1 esterase inhibitor concentrate or fresh frozen plasma is used to treat recalcitrant cases.

Investigation

The diagnosis of anaphylaxis is clinical. No immediate laboratory or radiological tests confirm the process and investigation must not delay immediate management.

Disease progress may be monitored by pulse oximetry, arterial blood gases (looking for metabolic or respiratory acidosis), haematocrit level (may rise with extravasation of fluid), and measurement of electrolytes and renal function. These tests together with blood glucose level, chest radiograph, and ECG are necessary if there is a slow response to therapy or when there is doubt about the diagnosis.

Mast cell tryptase

The only direct marker of mast cell activation is an elevated serum tryptase level. Tryptase is released in both anaphylactic and anaphylactoid reactions, beginning to rise within 30 min and remaining high for up to 6 h. It is of value when the diagnosis of anaphylaxis is uncertain clinically, particularly during anaesthesia, and may also be useful after death. Frozen serum specimens must be sent to a specialist laboratory.

Management

Patients with anaphylaxis may present directly to their family doctor or to the emergency department, or the reaction may start in hospital in the radiology department, theatre, on the ward, or even in the outpatient department. Cutaneous features of generalized mediator release may be the first signal, followed by more serious systemic symptoms or signs.

Any causative agent, such as an intravenous drug or infusion, must be stopped immediately. The patient should initially be managed in a monitored resuscitation area, or equipment including at least a pulse oximeter, non-invasive blood pressure device, and ECG monitor brought to them.

After a brief history of possible allergen exposure is obtained, a rapid assessment of the extent and severity of the reaction must be made, particularly looking for upper and lower respiratory tract involvement and the early signs of shock.

Oxygen, adrenaline, and fluids are the mainstay of treatment, with antihistamines and steroids only utilized as second-line agents once the cardiorespiratory status has been stabilized (see Table 3 and Table 4). A more detailed exposure history may be taken at this time.

First-line treatment

Oxygen and airway patency

Oxygen by face mask should be given to all patients, aiming to maintain an oxygen saturation above 92 per cent. Allow the patient to remain upright unless shocked, and call urgently for experienced anaesthetic help if there are signs of impending airway obstruction such as worsening hoarseness or stridor, or rapidly progressive respiratory failure with tachypnoea and wheeze. Cyanosis and exhaustion indicate imminent respiratory arrest, but sedative or muscle relaxant drugs should not be given unless the physician is competent in the management of a difficult airway, since endotracheal intubation and mechanical ventilation may be extremely difficult. As a last resort, a surgical airway via the cricothyroid membrane should be established before hypoxic cardiac arrest occurs.

Adrenaline

Adrenaline is the drug of choice and should be given in all but the most trivial cases, particularly to patients with airway swelling, bronchospasm, or hypotension. It has beneficial a-, b_1-, and b_2-adrenergic effects, including a rise in intracellular cyclic AMP that inhibits further mast cell and basophil mediator release.

When anaphylaxis is treated early, is mild or progressing slowly, if venous access is difficult or delayed, or in an unmonitored patient, give 0.3 to 0.5 ml of 1:1000 adrenaline (0.3 to 0.5 mg) intramuscularly in adults. This has advantages in terms of safety and is usually rapidly effective. The dose may be repeated every 5 to 10 min or longer according to response, and is preferred to the subcutaneous route.

However, in serious or quickly progressing cases, particularly in the presence of vascular collapse and shock, marked airway compromise, or severe bronchospasm, intravenous adrenaline is essential to achieve more rapid and reliable delivery. Although 1:10 000 adrenaline containing 100 µg/ml is readily available, for instance as the Min-I-Jet preparation, it is difficult to give this slowly in small quantities titrated to response. An alternative is to prepare a 1:100 000 dilution containing 10 µg/ml, and to give 1 to 2 ml (10 to 20 µg) per minute at an initial dose of 0.75 to 1.5 µg/kg (see Table 3). Intravenous adrenaline must only be given under ECG control in a monitored resuscitation area by doctors experienced in its use.

Whilst parenteral adrenaline is being prepared, patients may be given nebulized 1:1000 adrenaline from 1 to 4 ml (1 to 4 mg) via an oxygen-driven system. This may dramatically improve upper airway oedema or bronchospam.

Fluids

A large-bore intravenous cannula should be inserted as soon as possible in patients with shock to administer a 10 to 20 ml/kg fluid bolus. Gelatin preparations such as Haemaccel or Gelofusine are best, although normal saline in larger quantities is suitable and there are no outcome data favouring one infusion over another. Further fluid boluses are indicated by the clinical response, although it is important to give adrenaline in addition.

Second-line treatment

Once the cardiorespiratory status and tissue oxygenation have been improved with oxygen, adrenaline, and fluids, other drugs may be given in a supporting role.

Antihistamines

Although popular, antihistamines must never be relied upon as sole therapy. They are only indicated: when the reaction is not life threatening; when it is progressing slowly with predominant cutaneous features such as angioedema and urticaria; to prevent later recrudescence of symptoms or signs; as pretreatment to prevent reactions to radiocontrast media or volume expanders; and finally as prophylaxis during anaesthesia.

Newer, second-generation 'non-sedating' H_1-antihistamines such as loratadine and cetirizine are available orally, but still may cross the blood–brain barrier to cause drowsiness, particularly with alcohol. H_2-antihistamines have been used successfully in protracted anaphylaxis with shock, and increasingly now in combination with H_1-antihistamines. H_1- and H_2-antihistamines given together are supported by improved outcome in both prevention and treatment of acute anaphylaxis, combined with steroids in some instances.

Steroids

Steroids are of limited value despite many theoretical beneficial effects on mediator release and tissue responsiveness. They may prevent or shorten protracted

reactions, particularly those associated with bronchospasm, and may reduce the likelihood of relapse of symptoms, particularly after discharge. They are, however, essential in the management of recurrent idiopathic anaphylaxis.

Salbutamol, aminophylline, and glucagon

Nebulized salbutamol may be given for bronchospasm and has the advantage of familiarity. Aminophylline intravenously has additive effects to adrenaline in refractory bronchospasm. Glucagon may be used, particularly in patients already taking b-blockers, who at the same time may be both therapeutically resistant yet overly sensitive to unopposed a-mediated effects of adrenaline.

Admission, observation, and follow-up

Patients with cutaneous features alone who remain well may be discharged after a short 3- to 4-h period of observation, dependent on the nature and time of the suspected allergen exposure and their response to treatment.

Patients with significant systemic anaphylactic reactions, including all those receiving adrenaline, must be observed for a minimum of 6 to 8 h after apparent full recovery, as late deterioration may occur in 1 to 5 per cent of cases (biphasic response).

Those patients with unstable vital signs or with protracted or resistant anaphylaxis should remain monitored and be admitted to an intensive care area. An adrenaline infusion at 1 to 10 µg/min may be needed as a temporizing measure, and can be given by adding 1 ml of 1:1000 adrenaline to 100 ml of normal saline and infusing this at 6 to 60 ml/h.

Discharge medication

Following a successful period of observation, patients discharged from the emergency or outpatient department should be given combined oral H_1-and H_2-antihistamines and steroids for 2 to 3 days, such as chlorpheniramine at 4 mg 6-hourly, ranitidine at 150 mg 12-hourly, and prednisolone at 50 mg once daily in adults.

Patients who have had a life-threatening reaction, particularly to a food or insect sting, should also be prescribed a self-administered adrenaline syringe. Several devices are available, including the EpiPen that delivers 300 µg intramuscularly via a pressure-activated, spring-loaded needle, or the EpiPen Jr delivering 150 µg. It is essential that the patient and their immediate family are taught how and when to use the device before they are discharged from hospital, and appropriate early follow-up with an allergy specialist must be arranged.

Allergy referral

All patients who have suffered a severe anaphylactic reaction and those with significant attacks, particularly if they are recurrent or the stimulus is unknown or unavoidable, should be referred to an allergy specialist. This must include all those prescribed an EpiPen, and patients suitable for immunotherapy following a wasp or bee sting. Expert knowledge is required to determine whether skin testing, *in vitro* IgE tests, and/or challenge tests should be used to confirm the suspected cause.

A detailed letter of the nature and circumstances of the anaphylactic reaction, the treatment given, and the suspected causative agent(s) should accompany the patient home. If the cause of the reaction was unclear, ask the patient to write a brief diary of events of the immediate 6 to 12 h preceding the reaction, including all foods ingested, drugs taken (including non-proprietary), cosmetics used, and so on, and all activities performed outside as well as indoors. Later recall of events will be flawed unless documented.

Prevention

Education

Patient education about the nature and cause of the reaction and the relevance of carrying an EpiPen is fundamental. Individualized antigen elimination measures must be carefully explained, including hymenopteran avoidance, and recognizing hidden or unexpected sources of antigen such as salicylate in over-the-counter preparations and trace food elements such as nuts, plus possible cross-reactions to unrelated antigens. Latex-sensitive patients may require all future medical care in a latex-controlled environment.

An alert bracelet such as Medic-Alert should be worn, particularly following a severe reaction that may recur and render the patient unable to give a history. This should highlight drug or vaccine allergy to avoid inadvertent iatrogenic exposure.

Pretreatment

Pretreatment is only helpful in limited situations, for example prednisolone at 50 mg orally, with or without an antihistamine, 12 and 2 h prior to radiocontrast media in patients with asthma or those with previous reactions, and 1:1000 adrenaline at 0.25 ml subcutaneously prior to polyvalent snake antivenom. In the latter situation antihistamines are of no proven value.

Skin testing and short-term desensitization

In some clinical circumstances, such as when a penicillin is considered essential and there is a history of possible penicillin allergy, skin testing followed—if positive—by short-term desensitization over several hours with increasing doses at 15-min intervals may be instituted under strict medical control in a monitored area.

Long-term desensitization (immunotherapy)

Hyposensitization immunotherapy is principally reserved for wasp and bee allergy, as these preventable reactions may become life threatening. b-Blockade is a contraindication, and asthma or ACE inhibitor use require careful risk–benefit evaluation. Therapy needs to be continued for at least 3 to 5 years.

Drug avoidance

Wherever possible give therapy orally, and if intravenous use is chosen, always administer a drug slowly. Avoid drugs known to predispose to reactions, particularly aspirin and NSAIDs, as well as b-blockers and ACE inhibitors. Patients at risk of anaphylaxis with hypertension or ischaemic heart disease should ideally be taken off b-blockers, and care taken not to substitute an ACE inhibitor.

Conclusion

Anaphylaxis is a common clinical and diagnostic challenge for physicians. Prompt treatment with oxygen, adrenaline, and fluids to restore cardiorespiratory stability is followed with second-line therapy such as antihistamines and steroids. Proactive discharge planning with allergy referral when appropriate protects against further unheralded or potentially avoidable attacks.

16.5.1 Pathophysiology and pathogenesis of acute respiratory distress syndrome

C. Haslett

Introduction

The acute respiratory distress syndrome (**ARDS**) is a form of acute inflammatory lung injury, initiated as part of an injurious, generalized, systemic inflammatory microvasculature response that may also result in failure of other organs (multiple organ failure). It occurs in an unpredictable fashion after a 'latent' period of several hours or days following a wide range of predisposing events, which may injure the lung directly (for instance, severe pneumonia, acid inhalation, toxic gas inhalation, near-drowning), or indirectly (for example, multiple trauma, sepsis, pancreatitis). Despite the varied causes, there appears to result a common clinical picture of non-cardiogenic alveolar oedema and a common histopathological picture of 'diffuse alveolar damage'.

Although subclinical forms of ARDS are likely to be common, many patients require mechanical ventilation. Mortality is high in this group, with around 50 per cent of patients dying, usually as a result of multiple organ failure, nosocomial infection in the injured lung, and episodes of septicaemia. The only treatment available is supportive. Recent advances in the understanding of pathophysiology, particularly in the role of inflammatory processes, leads to the hope that we will soon see novel mechanism-driven therapies that could perhaps be applied in the early stages of disease, before the full complexity of lung injury has evolved.

Pathophysiology

Oedema

Gas-dilution studies have shown that only one-third to one-half of the total lung volume is gas-filled in patients with acute lung injury. The use of computed tomography (**CT**) scanning has revealed that most of the alveolar oedema fluid is distributed to the dependent parts of the lungs. Sometimes changing the position of the patients to the prone position can improve gas exchange. Other studies have demonstrated that oedema distribution is more uniform in patients who are ventilated by high-frequency jet ventilation, suggesting that the mode of ventilation may also have an important influence on how oedema fluid is distributed.

Changes in surfactant

Other pathophysiological consequences may result from disturbance of surfactant production in acute lung injury, which is disordered both in volume and quality, perhaps the result of dysfunction of type II alveolar epithelial cells. Qualitative changes in surfactant may be sensitive markers of early alveolar injury, and in some studies surfactant alterations during the risk period and early stages of ARDS correlate with the severity of lung function changes in full-blown disease. Progressive alterations in the percentage composition of certain phospholipids during the later stages of the natural history of ARDS have been observed, but their functional significance is uncertain. Surfactant function may also be detrimentally influenced by reactive oxygen intermediates and phospholipases that are released locally by neutrophils and other inflammatory cells, and it is also likely that the high protein concentration in the inflammatory exudate markedly impairs surfactant function. These qualitative and quantitative changes in surfactant composition and adverse influences on its function undoubtedly make a major contribution to the evolution of atelactasis, the reduced functional residual capacity, reduced compliance, and increased shunt found in established ARDS.

Other changes in surfactant function may relate to other aspects of lung disease in ARDS. Little is known about alterations in the protein composition and function of surfactant in patients with ARDS. These surfactant proteins (SpA, B, C, and D) have recently been subjected to detailed study (see Chapter 17.1.3) and have been found to possess a number of properties, including bacterial opsonization, and to exert effects on inflammatory cells including macrophages. It is possible that changes in these proteins could have secondary influences, particularly on host defence in the damaged lung, which we know is particularly prone to secondary and often devastating infections with Gram-negative and other bacteria.

Pulmonary hypertension

Pulmonary hypertension is a common complication of the early stages of ARDS, contributes to the generation of alveolar oedema, and is associated with increased mortality. It probably arises as the result of the release of vasoconstrictor mediators, but in the late stages of ARDS it may occur as a result of pulmonary thromboembolism or remodelling of the injured lung. Pulmonary hypertension may contribute to right ventricular dysfunction, although poorly characterized circulating factors also directly depress the contractility of both the right and left ventricles.

At different stages of ARDS both augmented hypoxic pulmonary vasoconstriction and loss of the normal hypoxic vasoconstrictor response are thought to play a role in the development of pulmonary hypertension and increased right to left shunting, respectively.

Decreased cardiac output in patients with ARDS may lead to impaired oxygen delivery to tissues, even in the presence of the normal arterial PO_2. This problem may be compounded by impaired tissue oxygen uptake that is particularly common in patients with sepsis, and which may occur as a result of tissue oedema, microembolization of capillaries, or loss of local microvascular control mechanisms. Finally, to make matters worse, in many of these patients there is an increased tissue oxygen demand as a result of fever, inflammation, and repair processes.

Pathology

The non-specific acute alveolar injury that characterizes ARDS was first described in detail by Liebow and given the term 'diffuse alveolar damage' (**DAD**). Like the clinical situations in which diverse predisposing conditions appear to result in the common clinical picture described by Asbaugh *et al.*, diffuse alveolar damage can be induced by a wide variety of noxious stimuli. In its early stages the alveoli may show atelactasis and the lung microvessels may appear engorged. The alveolar septa are oedematous with inflammatory exudate and extravasated erythrocytes, and a proteinaceous inflammatory exudate may flood the alveoli in some areas of the lung.

The initiation of lung injury is likely to occur within the pulmonary capillaries (see below). Increased numbers of neutrophils may be seen in these and in the interstitial spaces and, if obtained at the earliest stages, bronchoalveolar lavage fluid shows large numbers of neutrophils. Neutrophil numbers in bronchoalveolar lavage and the concentration of neutrophil secreted products therein appear to correlate with ARDS and its severity. These observations draw attention to the likely role of neutrophils early in ARDS pathogenesis. On ultrastructural examination there is clear evidence of endothelial and epithelial injury: this may be extensive. Hyaline membranes, which are the light-microscopical hallmark of diffuse alveolar damage, are likely to be derived from layers of necrotic epithelial cells.

It is important to recognize that these pathological events do not occur in a strictly ordered sequence, and may appear to have reached different stages in different

parts of the lungs at the same time. It is not unusual to find evidence of continued inflammatory injury concurrent with alveolar type II cell proliferation or other evidence of attempts at repair. In those patients who die after just a few days of mechanical ventilation there is often evidence of a pronounced fibroproliferative response, including fibroblast migration into injured alveoli, and fibroblast proliferation and collagen deposition that within 2 weeks can achieve quite remarkable proportions. Nevertheless, in those patients who survive the initiating condition and who are mechanically ventilated, death is not usually due to progressive respiratory failure. Most patients die from the failure of other organs involved in multiple organ failure that are less easy to support than the lung, septicaemia, or secondary nosocomial infections in the injured lung, although barotrauma from mechanical ventilation of poorly compliant lungs can be a major problem in some patients.

Since case reports describing lung biopsies that have been repeated for clinical indications are extremely rare, very little is known about the pathology of the recovery phase of ARDS. Those that have been done suggest that some pulmonary remodelling had occurred. The remarkable examples of patients with severe ARDS, yet who nevertheless appear to regain virtually normal lung function, suggest that some forms of inflammatory lung injury, and perhaps even fibrosis, have the capacity to resolve and/or become significantly remodelled.

Pathogenesis—cellular and humoral mechanisms

Neutrophils and other inflammatory cells

Neutrophils have long been recognized in the lung tissues of necropsy specimens obtained early in the course of ARDS, and bronchoalveolar lavage cytology shows a high percentage of neutrophils and their products, such as myeloperoxidase, which correlate with the development and severity of ARDS. Other potentially injurious neutrophil products including neutrophil elastase and collagenase are also found; and, of importance, peripheral blood levels of neutrophil elastase in patients at risk of ARDS correlate with subsequent ARDS development. External imaging of radiolabelled neutrophils has demonstrated neutrophil accumulation in the lungs of patients with ARDS. Recent studies have suggested that the neutrophil chemokine interleukin-8 (**IL-8**) may be specifically related to the development of this condition. Studies in animal models of acute lung injury, using stimuli of relevance to the pathogenesis of ARDS, critically implicate the neutrophil.

This is not to suggest that other inflammatory cells are unimportant in the pathogenesis of ARDS. Although this condition has been described in neutropenic patients, histology does show the presence of some neutrophils in the lungs, and it is uncertain how much of a neutrophil 'load' may be required: neutrophil replenishment experiments in neutropenic animals replace only a small proportion of the total neutrophil complement. Nevertheless, studies of neutropenic patients raise the possibility that other cells, perhaps monocytes, play an important ancillary role or may even substitute for granulocytes under some circumstances: these cells possess most (if not all) of the potentially injurious mechanisms and capacity of neutrophils.

It is now generally believed that one of the earliest initiation mechanisms in ARDS is damage to the capillary endothelial cells and the airway epithelial cells that form the delicate alveolar gas-exchange membrane. This is caused by toxic products of inflammatory cells that have become sequestered and activated as a result of inflammatory mediators generated as a consequence of the initiating insult (see Fig. 1). It is uncertain why lung injury is so prominent and often the first clinically obvious event in the multisystem microvascular injury of multiple organ failure. However, this may partly be due to the fact that most of the 'marginating pool' of neutrophils resides in lung capillaries, and even in the healthy state neutrophils (average diameter 7.5 µm) have to squeeze through lung capillaries (mean diameter 5.5 µm), thus presenting a massive surface area of contact between this potentially injurious cell and the at-risk gas-exchange membrane (see below). With regard to this interaction, neutrophils cannot injure cells or degrade matrix proteins without extremely close apposition, and it is essential for us to understand the kinetics and adhesion mechanisms that relate to this critical interaction to gain a full appreciation of the pathogenesis of acute lung injury. Finally, neutrophil secretion is not necessarily an all-or-nothing phenomenon: for maximum release of reactive oxygen intermediates or granule enzymes the neutrophil needs to be exposed to agents that 'prime' the cell, together with those that trigger it.

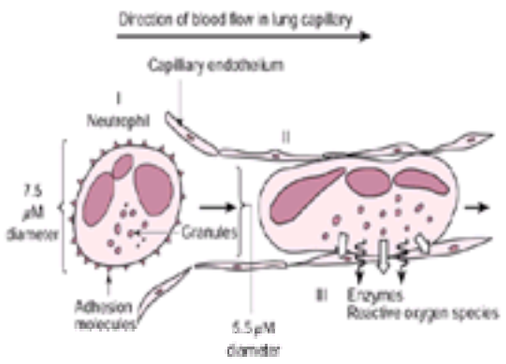

Fig. 1 Initiating insults and toxic products of inflammatory cells that are involved in ARDS. I: Neutrophils became 'primed' by circulating mediators (lipopolysaccharide (**LPS**), platelet-activating factor (**PAF**)) to become 'stiff', 'sticky', and very responsive to secretagogues. II: Primed neutrophils sequester abnormally in the pulmonary capillaries. III: Sequestered primed neutrophils are acted upon by circulating secretagogues (e.g. IL-8) to release injurious reactive oxygen species (**ROS**) and enzymes.

Mediators

A very large number of mediators, indeed several mediator cascades, have been implicated in the pathogenesis of ARDS.

Endotoxin

Endotoxic lipopolysaccharide (**LPS**) is the main 'active' ingredient of the cell walls of *Escherichia coli* and other Gram-negative organisms that cause sepsis syndrome, septic shock, and ARDS. When injected into animals, LPS causes many of the pathophysiological features of septic shock. Low concentrations of LPS may enter the circulation of patients with circulatory shock by the process of 'translocation' through the compromised gut lining. LPS exerts a number of direct influences on neutrophils. In the presence of serum, very low concentrations of LPS (pg/ml) are required to cause enhanced expression of neutrophil surface adhesion molecules that bind the activated endothelium (see Chapter 4.4 and Chapter 5.1) and cause a direct reduction in neutrophil deformability, both of which promote excessive and prolonged neutrophil sequestration in pulmonary microvessels. LPS also causes macrophages to release cytokines, including IL-1 and tumour necrosis factor-a (**TNF-a**), which play key roles in the initiation of inflammation and activate other cascades, including the complement, coagulation, and kinin cascades, as well as generating systemic cytokines including IL-6 that regulate the acute-phase response.

Peptide mediators

The complement peptide C5a is an effective neutrophil chemotaxin and secretagogue *in vitro*, and is found in the blood of patients at risk of ARDS as well as in those with established disease. However, most workers in this field believe that chemokines, especially IL-8, play a more important role in neutrophil chemoattraction to the lung in ARDS. There has been much less study of the role of the contact system, which activates bradykinin, and the clotting and fibrinolytic cascades, but these are also likely to be important in the pathogenesis of ARDS. Activated kinins are vasoactive and cause increased vascular permeability: they can also act as secretagogues for neutrophils and other inflammatory cells.

Cytokines

Cytokines are a diverse group of soluble, hormone-like polypeptides produced by leucocytes and also by some constitutive tissue cells, especially macrophages, endothelial cells, epithelial cells, and fibroblasts. It is likely that cytokines (see Chapter 4.4 and Chapter 5.1) play key roles at all stages of the evolution of ARDS. TNF-a and IL-1 are generated by alveolar macrophages on exposure to LPS and other stimuli of relevance to ARDS pathogenesis, and are likely to play key initiator roles by stimulating other resident cells, particularly epithelial and microvascular endothelial cells, to release IL-8 and other potent neutrophil chemokines. They also act on capillary endothelial cells to induce the expression and activation of adhesion molecules necessary for neutrophil sequestration and for the creation of an

'injury-promoting' microenvironment. Other cytokines—for example, platelet-derived growth factor (**PDGF**), fibroblast growth factor (**FGF**), transforming growth factor-b (**TGF-b**)—are likely to play an important part in the vascular remodelling, fibroblast chemotaxis, and fibroblast proliferation and collagen synthesis that characterize the poorly understood fibroproliferative or 'chronic' phase of ARDS.

Chemokines

This expanding family of small molecular weight peptides has received much recent attention. Depending on the position of cysteine in the molecule they have been subdivided into the 'C–X–C' and 'C–C' chemokines. The C–X–C subgroup contains a variety of peptides that are powerful neutrophil chemoattractants and activators, whereas the C–C group exert their chemotactic influences on monocytes and/or eosinophils.

It is now generally agreed that IL-8 and its family members are responsible for neutrophil attraction to the lung in ARDS. IL-8 is an 8.0 kDa polypeptide that is a potent neutrophil chemoattractant and a powerful stimulus for angiogenesis. IL-8, of a plethora of candidates, was the only mediator to correlate with subsequent ARDS development in studies of patients at the earliest stage of the risk period for ARDS. Other chemokines are likely to play important roles in subsequent monocyte emigration, but these are less well characterized.

Membrane phospholipid derivatives

Membrane-derived phospholipid products, including platelet-activating factor (PAF), leukotrienes, prostaglandins, and prostacyclin, may influence inflammatory cells (PAF is an important neutrophil priming agent, for example), but they also exert major influences on local blood vessels and promote the generation of oedema fluid. Thromboxanes can cause marked pulmonary vasoconstriction and may be partly responsible for the pulmonary hypertension that characterizes the early stages of ARDS.

An injury-promoting microenvironment between abnormally sequestered neutrophils and pulmonary capillary endothelial cells

Neutrophils do not injure endothelial cells *in vitro* without there being direct contact. It is likely that stimulated neutrophils interact with endothelium in a fashion that leads to the formation of a specialized intercellular microenvironment, within which concentrations of histotoxic agents (such as enzymes and reactive oxygen intermediates) would reach high levels, whereas their high molecular weight inhibitors would be relatively excluded (Fig. 2). Furthermore, many potent neutrophil enzymes, such as elastase, are preferentially located on the 'leading surface of the cell' and would need close apposition in order to cause effects. Finally, some of the most potent reactive oxygen intermediates are so labile that they are likely to have a very short distance of activity in tissues. This concept, of a restricted intercellular microenvironment necessary for neutrophil-mediated injury, is supported by experiments showing that matrix degradation occurs only in areas where stimulated neutrophils are tightly adherent and continues in the presence of the large molecular weight antiproteinase, a-1 proteinase inhibitor. The creation of such a microenvironment between neutrophils and endothelial cells in lung capillaries is likely to occur by a combination of adhesion mechanisms and a reduction in the ability of neutrophils to deform.

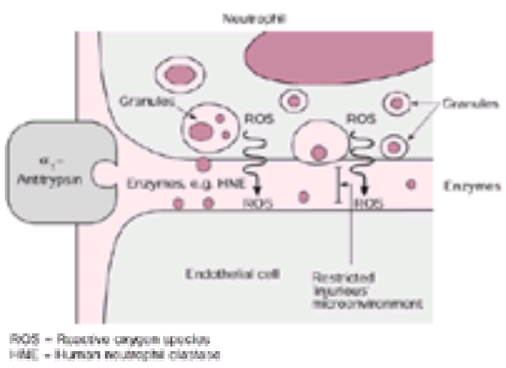

Fig. 2 The neutrophil and the injurious microenvironment in ARDS.

Neutrophil–endothelial surface adhesive molecules

Adhesion between neutrophils and endothelial cells *in vitro* is greatly enhanced within minutes of the addition of inflammatory mediators. Much of this enhanced adhesion can be abolished by monoclonal antibodies directed against the CD11/CD18 group of adhesive leucoproteins on the neutrophil surface. Similarly, endothelial cells that have been activated by LPS or cytokines express adhesion molecules on their surface, and others that are already expressed become activated. *In vivo*, it is likely that neutrophil adhesion to endothelial cells in microvessels occurs by a complex process that involves at least two phases. In the first transient phase of adhesion, which is nevertheless necessary for the second phase, interactions between molecules of the selectin family on neutrophils and endothelial cells are particularly important. In the second phase of 'tight' adhesion, which is necessary for the creation of an injurious microenvironment and also for capillary transmigration of neutrophils, integrin molecules play the central role.

Reduced neutrophil deformability

As described previously, neutrophils are normally required to 'squeeze' through the narrow lung capillaries. Hence, any factors that reduce neutrophil deformability would significantly increase their time of sequestration, and thereby increase the time of contact between activated neutrophils and the delicate gas-exchange membranes. Although it was generally believed that abnormal sequestration occurs mainly by upregulation of neutrophil and endothelial surface adhesive molecules, alteration in neutrophil deformability is also likely to play an important role in the pulmonary circulation. Neutrophils treated with relevant inflammatory mediators demonstrate markedly reduced deformability *in vitro*, and when injected intravenously have prolonged residence time in the pulmonary microcirculation. The molecular mechanisms controlling neutrophil deformability are much less well understood than those governing the expression of surface adhesion molecules.

Neutrophil priming, triggering, and secretion of injurious products

Even when neutrophils are tightly apposed to matrix proteins or 'target' endothelial cells *in vitro*, the induction of neutrophil-mediated injury is not an all-or-nothing phenomenon. When neutrophils are prepared by stringent methods that avoid their exposure to ubiquitous LPS or other agents that might influence their function, stimulation with secretagogues causes little or no release of reactive oxygen intermediates or enzymes unless they are previously exposed to low concentrations of priming agents such as LPS. These priming and triggering phenomena have a number of implications for tissue injury. First, the presence *per se* of neutrophils in tissue does not equate with injury—it is likely that they need to be primed and triggered to achieve a maximal secretory state. Second, when examined in this context, many of the mediators implicated in ARDS pathogenesis exert different effects: for instance, LPS, TNF-a, and PAF are poor secretagogues but highly effective priming agents, whereas C5a, IL-8, and leukotriene-4 (**LTB_4**), together with other neutrophil chemotaxins, are potent secretagogues for primed cells. Therefore, rather than seeking a 'single common mediator' it is perhaps more important to define how certain key mediators act together to influence neutrophil secretion and other critical mechanistic events.

The vast array of potentially injurious neutrophil products represents another example of the remarkable redundancy of the inflammatory response. Most of these products have probably evolved to assist the neutrophil in its rapid passage to the inflamed/infected site, and in its effective killing of bacteria, but in neutrophil-mediated tissue injury and disease processes the difficulty of identifying centrally important toxic agents cannot be exaggerated. Over the years, much circumstantial evidence has accrued to support a role for neutrophil-generated reactive oxygen intermediates in ARDS. However, studies in the early risk period for ARDS suggest that neutrophil elastase is also an important agent.

Lung scarring in ARDS

Whether or not there has been a critical level of epithelial injury in the primary inflammatory damage to the lung seems to be a key factor in determining whether excessive scarring occurs. Most pathologists now believe that the lung can tolerate a certain degree and extent of injury to type I alveolar epithelial cells without the necessity for excessive scarring. In these circumstances it is thought that gaps in the epithelium are repaired by the division of type II epithelial pneumocytes to form a new monolayer of type I cells. However, if there is extensive disruption of the epithelium, and particularly if the basement membrane is severely damaged and loses its architectural integrity, it appears that a scarring response is more likely to result. The inflammatory response can impinge at two levels on the scarring process (Fig. 3). First, on the degree of epithelial injury caused by the inflammatory process; second, by inflammatory cells producing agents that can induce fibroblasts to proliferate and deposit scar-tissue matrix proteins.

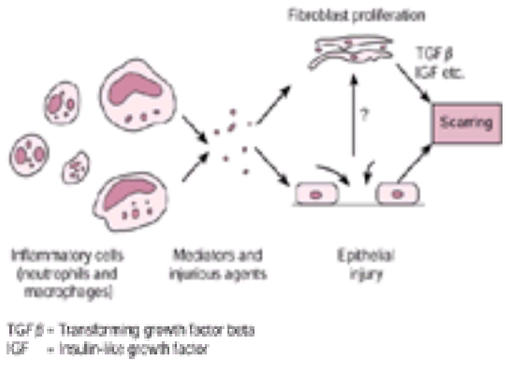

Fig. 3 Inflammation and scarring in ARDS.

Granulation tissue (the precursor of scar tissue) is a very cellular and dynamic tissue, particularly in the lung. It is composed of proliferating fibroblasts that lay down scar-tissue matrix proteins such as collagen. Collagen production by fibroblasts is normally a highly regulated process, with controls being exerted at several levels. All but 30 per cent of the extracellularly secreted collagen is normally degraded, mainly by the effect of fibroblast-derived collagenase. The effect of collagenase is under a further internal control mechanism whereby it is kept in check by inhibitors, for example by tissue inhibitors of metalloproteinases (**TIMPs**). Fibroblast activity is also under the control of external factors including cytokines and growth factors, many of which can be secreted in large quantities by local cells, particularly inflammatory macrophages. Most of these factors, including PDGF, TGF-b, FGF, and insulin-like growth factor (**IGF**), have been shown to exert permissive or stimulatory effects on fibroblast growth and secretion. External factors exerting negative influences must also exist. Although these have received less attention, prostaglandin E_2 represents a good example of a factor with mainly inhibitory effects on fibroblast function.

16.5.2The management of respiratory failure

Christopher S. Garrard

Acute respiratory failure: intensive care

Respiration is a complex process involving ventilation, pulmonary gas exchange, oxygen delivery by the circulation, and oxygen utilization by the tissues for the production of cellular high-energy phosphate. By convention, respiratory failure is used in a clinical context to mean failure of ventilation and/or pulmonary gas exchange. Accordingly, the treatment of acute respiratory failure is directed at:

1. establishing and maintaining the airway;
2. administering oxygen;
3. maintaining adequate ventilation, using mechanical ventilation if necessary;
4. enhancing oxygen 'on-loading' by the lungs, that is, improving the efficiency of getting oxygen into the blood for any given concentration of inspired oxygen;
5. identifying and treating the underlying cause (not the subject of this chapter);
6. monitoring SaO_2 (the oxygen saturation of arterial blood—pulse oximetry), ECG, and vital signs; and
7. staged withdrawal of respiratory support (weaning) as the underlying disease process resolves.

Establishing and maintaining the airway

Simple manoeuvres to re-establish and clear the airway must always be followed. These include positioning and maintaining the head and neck in the 'sniff position', inspection of the oropharynx, suctioning, and if necessary, the insertion of an oral or pharyngeal airway.

Endotracheal intubation

If a reliable or adequate airway cannot be established by the above means, endotracheal intubation must be performed. Orotracheal intubation is particularly suited to the emergency situation. Nasotracheal intubation requires a little extra time and should be avoided in those with coagulation defects or thrombocytopenia because of the risk of serious haemorrhage. Whatever technique is selected, intubation should be performed in a safe and expeditious manner by the most experienced clinician available. Neuromuscular relaxant drugs to facilitate intubation should only be used by experienced personnel.

The complications of endotracheal intubation are due to occlusion or displacement of the tube, and airway trauma. The appropriate endotracheal tube size for most adult men is 8 to 9 mm in internal diameter, and for women 7 to 8 mm. For children, a rough calculation using the child's age in years divided by 4, plus 4.0 will provide the tube internal diameter in millimetres.

It is essential that the endotracheal tube be securely anchored and the cuff inflation pressure restricted to less than 30 cmH_2O. High-volume, low-pressure cuffed tubes are generally recommended and cuff inflation pressures should be checked periodically using an aneroid manometer and adjusted accordingly. Using higher cuff pressures does not improve airway protection against aspiration but may damage the tracheal mucosa and risk later subglottic stenosis. Smaller tubes, as used for children, are typically uncuffed.

Difficulties with endotracheal intubation can be encountered in those with a short 'bull' neck or receding lower jaw. Any patient with restricted neck and jaw movements (rheumatoid arthritis or cervical spine injury) or who has abnormal oropharyngeal anatomy (tumour or trauma) should also be regarded as a potential problem. Several options can be considered in these situations. Inhalational anaesthesia by face mask can facilitate intubation, but under no circumstances must muscle relaxants be given unless satisfactory airway access can be ensured. Awake intubation can be performed with topical anaesthesia. Blind nasal intubation or intubation using a fibreoptic bronchoscope or laryngoscope requires considerable skill and training but may be the safest option.

Tracheostomy

Tracheostomy should only replace endotracheal intubation for specific indications and not merely after the elapse of a predefined time interval. Using modern endotracheal tubes and techniques, endotracheal intubation can be tolerated without permanent harm to the airway for months if necessary: the greater part of mucosal damage is done in the first week of intubation with little additional change thereafter.

The common indications for replacement of endotracheal intubation by tracheostomy include the need for chronic or permanent ventilation, to help weaning after previously failed attempts at extubation, to facilitate oral nutrition, or the presence of upper airway complications of endotracheal intubation.

Most tracheostomies for patients in intensive care units are now performed by a percutaneous Seldinger technique: this can be done at the bedside, avoiding the need for moving the patient to the operating theatre. Although percutaneous tracheostomy 'kits' have made the procedure rapid and safe, the clinician needs to be

aware of serious complications such as the formation of false tracks and perforation of structures adjacent to the trachea.

The same principles of cuff pressure management apply to tracheostomy tubes as to endotracheal tubes. Tracheostomy is associated with fewer but more serious complications than endotracheal intubation. These include tube displacement, pneumothorax, severe haemorrhage, and wound infection.

Minitracheostomy

Some patients with an ineffective cough or neurological impairment require continued suctioning of airway secretions without the need for formal endotracheal intubation or tracheostomy. In such cases a 3.5- to 4.0-mm diameter, cuffless minitracheostomy tube can be inserted percutaneously, under local anaesthesia, through the cricothyroid membrane. These tubes cannot be used for conventional ventilation, may result in local haemorrhagic complications, and can be the source of infection.

Cricothyroidotomy

A cricothyroidotomy may be needed in life-threatening, upper airway obstruction where endotracheal intubation is not feasible and there is insufficient time to perform tracheostomy. A full-sized tracheostomy tube (6 to 8 mm internal diameter) can be inserted under local anaesthesia to allow mechanical ventilation.

The administration of oxygen

Hypoxia should never be tolerated through a concern over oxygen toxicity; although this is a recognized complication of prolonged administration of a high concentration of oxygen, the use of 50 or 100 per cent oxygen for less than 24 h is usually considered acceptable. Oxygen can be delivered by a variety of means depending upon the concentration desired and the patient's minute ventilation (Table 1).

Oxygen should be given in such concentrations as to prevent hypoxia with the caveat that controlled (limited) oxygen concentrations should be administered, usually by a 'Venturi type' of face mask, to patients with chronic obstructive lung disease. The response to oxygen therapy can best be measured continuously by pulse oximetry (SaO_2) or by intermittent gas sampling of arterial blood. Once oxygen therapy has been initiated, sudden or abrupt removal of oxygen supplementation runs the risk of severe hypoxia, with the risk of neurological impairment, arrhythmias, or even cardiac arrest.

Mechanical ventilation

Indications for intubation and mechanical ventilation

Failure to intervene promptly can clearly have catastrophic consequences for the patient, but mechanical ventilation is not to be undertaken lightly since it is associated with much morbidity and some mortality.

The indications for mechanical ventilation fall into two broad categories: (i) inadequate alveolar ventilation with increasing PCO_2 and (ii) inadequate gas exchange with increasing $D(A\text{-}a)O_2$ and arterial hypoxaemia. Guidelines for mechanical ventilation in acute respiratory failure are shown in Table 2: the physician should exercise clinical judgement in the interpretation of these and anticipate problems before they arise. For example, one of the simplest criteria for mechanical ventilation is a respiratory rate of 35 breaths/min or more. If, with a respiratory rate of 30 breaths/min a patient is clearly fatiguing, then early elective intubation is clearly preferable to an emergency procedure an hour or so later. Similarly, a progressive fall in vital capacity in a patient with myasthenia gravis receiving full medication may need ventilatory support although the critical value of less than 15 ml/kg is not reached.

The treatment of hypoventilatory respiratory failure consists of assisting ventilatory function, usually by mechanical external means. Figure 1 shows a flow diagram outlining the decision process involved in the assessment of patients who may require mechanical ventilation.

Fig. 1 Respiratory failure algorithm.

Features and applications of a mechanical ventilator

The principles of mechanical ventilation using simple mechanical ventilators need to be understood before moving on to consideration of the complex and sophisticated mechanical ventilators that offer a bewildering range of features. Those not familiar with the field run the risk of being overwhelmed by an overabundance of studies claiming superiority of certain techniques over others. Fortunately, the application of common sense and sound physiological principles will serve better than devotion to attractive technical innovation.

Most adult patients are supported on volume/time-cycled, pressure-limited ventilators (volume ventilator or flow generator). These deliver preset tidal volumes regardless of changes in lung compliance or impedance. The price paid for this desirable characteristic is that the inflation pressure will rise to overcome any mechanical load. A limit must be set to protect the patient from inappropriately high pressure: when this limit is reached the ventilator terminates inspiration regardless of the volume delivered and triggers an alarm.

Neonates and infants can be satisfactorily ventilated using time-cycled, pressure-limited devices (pressure ventilator or pressure generator). The pressure-limited paediatric ventilator offers simplicity and reliable ventilation, although the delivered tidal volume is difficult to measure. In the premature neonate this is not a serious limitation and pressure-limited ventilation is the preferred technique.

Specifically designed, compact, lightweight ventilators, driven by cylinder oxygen and utilizing fluid logic circuits are available for transporting ventilator-dependent patients. These are pressure generators and can be used for both adults and children. By entraining air, a choice of either 60 or 100 per cent oxygen is available.

Modes of ventilation

Depending upon the underlying pathophysiology, the clinician must select the mode of ventilation, choose the ventilation parameters, and set the ventilator alarms. The most commonly available ventilator modes include:

1. control mechanical ventilation (**CMV**);
2. assist control (triggered ventilation, volume cycled);
3. pressure support (triggered ventilation, pressure cycled);

4. intermittent mandatory ventilation (**IMV**, or if synchronized, **SIMV**)—volume or pressure controlled;
5. bi-level positive airway pressure (**BiPAP**); and
6. others.

Control mechanical ventilation (CMV)

This provides time- and volume-cycled, pressure-limited breaths at a preset rate, but does not allow the patient to breathe spontaneously. This mode is suitable for the paralysed or heavily sedated patient.

Assist control

Assist control or triggered ventilation synchronizes the ventilator to the patient's own respiratory rhythm, delivering a volume-preset, pressure-limited tidal volume. A trigger sensitivity is selected, usually –0.5 to –2.0 cmH_2O, by which the patient can initiate volume-preset breaths. As a safety requirement, a high respiratory rate alarm is needed and a 'back-up' ventilation rate must be set in the event of apnoea. Assist control is better tolerated than CMV and the patient requires less sedation, but does have a tendency to hyperventilate.

Pressure support

Pressure support uses a triggering facility to deliver, not a volume-preset breath as in assist control, but a pressure-limited breath (i.e. as with paediatric pressure ventilation). The inspiratory flow rate is usually high so as to minimize phase lag and the work of breathing. Pressure support may be used alone or in conjunction with SIMV when it assists spontaneous breaths. Pressure support provides an efficient maintenance and weaning mode that is well tolerated by the patient. The trigger mechanism is usually a negative pressure threshold, but some ventilators trigger on changes in circuit gas flow that potentially could be more sensitive and reduce the work of breathing.

Intermittent mandatory ventilation (IMV)

This was originally devised for weaning but is now widely adopted as a maintenance mode. It provides the opportunity for the patient to breathe spontaneously and supplement the positive-pressure minute ventilation. In the standard IMV mode there is a theoretical risk of stacking a ventilator breath on top of a spontaneous breath. More modern ventilators utilize the triggering or assist facility to synchronize the IMV breaths with the patient's own spontaneous breathing pattern (synchronized IMV, SIMV). The IMV mode can provide complete or partial ventilation support and, with the patient taking spontaneous breaths, IMV is better tolerated than CMV. Compared with CMV, SIMV results in lower mean airway pressures, has less effect on the cardiovascular system, and allows patients to regulate their own PCO_2 to at least some degree.

Bi-level positive airway pressure (BiPAP)

This is a form of pressure-controlled ventilation based upon raising airway pressure from a lower setting (equivalent to constant positive airway pressure/positive end-expiratory pressure, **CPAP/PEEP**) to a higher setting (equivalent to the peak airway pressure). The lower pressure level should be set at a point above the inflection point in the respiratory pressure–volume curve. A potential advantage of this mode is that it allows spontaneous ventilation to occur at both the lower and higher positive airway pressures, which may be better tolerated by the patient. BiPAP has been successfully adopted as a method of delivering non-invasive positive-pressure ventilation via a nasal or full face mask.

High frequency ventilation

This may have potential advantages in supporting patients with acute respiratory distress syndrome. In randomized studies, peak airway pressures are lower but mean airway pressure and mortality are unchanged. High frequency ventilation can be delivered by several techniques including 'jet' ventilation and high frequency oscillation: both are capable of sustaining adequate oxygenation and carbon dioxide clearance. These techniques have been promoted by enthusiasts for over three decades and yet have failed to establish themselves in routine management of respiratory failure. However, high frequency ventilation may be useful following reconstructive laryngeal, tracheal, or bronchial surgery, or for patients with bronchopleural or bronchocutaneous fistulas, but even in these applications the advantage, if any, over conventional modes of ventilation seems marginal.

Mandatory minute ventilation (MMV)

This is an innovative mode whereby the combined spontaneous and mechanical ventilation must reach a minimum preset level. As the patient's spontaneous ventilation increases the mechanically assisted breaths become fewer. Individual ventilators vary in their ability to achieve successful MMV.

Setting ventilator parameters

Once a ventilation mode has been selected (at least temporarily), ventilatory parameters must be set before attaching the patient to the ventilator. The ventilator parameters include:

1. tidal volume;
2. ventilation rate;
3. inspiratory/expiratory (**I:E**) ratio;
4. flow waveform;
5. inspired oxygen concentration (FiO_2, 0.21 to 1.0);
6. pressure limit (if using volume cycling);
7. trigger threshold (if triggered mode selected)—-pressure trigger (–0.5 to –5 cmH_2O) or flow trigger (3 to 5 l/min); and
8. positive end-expiratory pressure (PEEP) or constant positive airway pressure (CPAP) (0 to 20 cmH_2O).

Tidal volume and respiratory rate

The delivered, inspiratory tidal volume may be set at 10 to 12 ml/kg body weight. This should be reduced if the patient has restrictive lung disease or has undergone lobectomy or pneumonectomy. Using respiratory rates of more than 10 breaths/min with such tidal volumes will provide full ventilatory support. If the patient is breathing spontaneously, an IMV mode will be preferred at rates of between 4 and 8 breaths/min. If assist control or pressure support is chosen, the respiratory rate will be the patient's spontaneous rate.

Respiratory rate, I:E ratio, inspiratory flow rate

These variables are linked and often affect one another. The ratio of inspiratory to expiratory time (I:E ratio) generally ranges from 1:2 to 1:4, allowing sufficient time for full passive exhalation. The higher the set respiratory rate the shorter expiration becomes and the I:E ratio falls. In patients with obstructive lung disease, failing to allow adequate time for exhalation results in air-trapping and hyperinflation, the extra pressure remaining in the alveoli at end-expiration being referred to as auto- or intrinsic-PEEP. This can lead to the paradoxical situation in the patient with chronic obstructive pulmonary disease where the PCO_2 rises as the ventilator rate is increased (usually at rates higher than 20 breaths/min).

The I:E ratio can be adjusted is several ways depending upon the make of ventilator: in some a ratio can be selected directly, whilst in others the inspiratory flow rate determines the duration of inspiration. An acceptable range for inspiratory flow rates is between 30 and 60 litre/min (0.5 to 1.0 litre/s)

Minute ventilation

Some ventilators require the minute ventilation to be set as a primary variable (e.g. Servo 900C). Setting the respiratory rate then effectively determines the tidal volume.

Inspiratory waveforms

Many volume- and time-cycled (flow generator) ventilators allow the choice of several waveforms. Although there is little evidence to favour one over another, a square waveform delivers the tidal volume in the least time and with higher peak pressures. A decelerating flow pattern results in lower peak pressures, longer inspiratory intervals, and lower I:E ratios.

Inspired oxygen concentration (F_iO_2)

This should be constantly adjusted to provide adequate arterial oxygenation without hyperoxia. Too high a F_iO_2 may risk oxygen toxicity and is frequently the cause of failure to wean patients with chronic obstructive pulmonary disease from a mechanical ventilator (by depressing 'hypoxic respiratory drive').

Pressure limit

In volume-cycled modes**,** a pressure limit about 10 cmH_2O above the peak pressure reached during each ventilator cycle protects the patients against inadvertently high pressures experienced during coughing or straining. Hitting the pressure limit terminates inspiration and triggers an audible alarm.

PEEP/CPAP

Maintaining airway pressure above barometric pressure in a spontaneously breathing patient is called constant positive airway pressure (CPAP, Fig. 2). The same pressure applied to a patient on intermittent positive-pressure ventilation is called positive end-expiratory pressure (PEEP). PEEP/CPAP is used to increase lung volume (functional residual capacity) in conditions where this is reduced, for example acute respiratory distress syndrome or cardiogenic pulmonary oedema. It may also be beneficial in patients with flail chest segments by splinting the chest wall. The terms PEEP and CPAP can be used interchangeably provided that the differences regarding spontaneous and assisted ventilation are recognized.

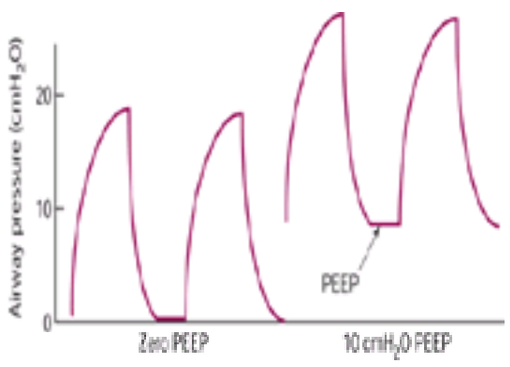

Fig. 2 Schematic of airway pressure measured without PEEP and following the addition of 10 cmH_2O PEEP. By preventing end-expiratory pressure from falling to zero, reinflation and recruitment of alveolar units is encouraged.

PEEP/CPAP is achieved by the inclusion of a resistance at the expiratory end of the breathing circuit. Ideally this resistance should be as close to a threshold resistor as possible, such as an underwater column. In practice most of the valves produce some flow-dependent retardation of expiration that increases the work of breathing in spontaneously breathing patients.

Sighs

Before the advent of high tidal-volume ventilation and PEEP/CPAP, sighs were added to ventilation protocols to prevent progressive atelectasis. Each sigh was delivered 2 to 6 times/h and was equivalent to about twice the conventional tidal volume. The risks of barotrauma probably outweigh the theoretical benefits.

Ventilator-induced lung injury and permissive hypercapnia

Animal and human studies indicate inhomogeneous reinflation of the lung in patients ventilated for acute respiratory distress syndrome. Some parts of the lung are therefore exposed to excessive shear stresses, resulting in a process known as 'volutrauma' that may lead to permanent fibrocystic changes. In the early 1990s evidence from randomized studies suggested that survival from acute respiratory distress syndrome could be improved if inflation pressures were kept below 40 mmHg. As a consequence there was an inevitable degree of hypoventilation and CO_2 retention (P_aCO_2 8 to 12 kPa). This technique of 'permissive hypercapnia' has been widely adopted and may reduce the incidence of ventilator-induced lung injury.

Ventilator monitors and alarms

The ventilation monitors and high/low alarms that must be set and maintained include the following:

- exhaled tidal volume (V_T)
- exhaled minute ventilation
- spontaneous respiratory rate
- airway pressure and circuit disconnect
- peak airway pressure
- inspired oxygen concentration (F_iO_2)
- inhaled gas temperature

The importance of ventilator alarms cannot be overemphasized. The modern, microprocessor-based ventilator is not only more efficient but is significantly safer than its predecessors. An audible alarm alerts the nurse or doctor to an adverse event, while an alarm section of the ventilator control panel indicates the exact event. Some ventilators have progressive alarms that change in character, sounding more urgent, until the alarm is cancelled or the alarm condition rectified.

Clinical monitoring of mechanical ventilation

An essential aspect of monitoring is regular clinical examination of the patient, and inspection of the ventilator and ventilator circuit. Expansion of the chest should be symmetrical with each ventilator-cycled breath (CMV, SIMV), assisted breath (assist control or pressure support), or unassisted spontaneous breath (SIMV). Auscultation should confirm air entry and detect any added sounds. The patient should be sat up or rolled side to side to allow inspection of the whole of the chest. The endotracheal tube should be secure and as comfortable as possible for the patient, and the endotracheal cuff pressure should be adjusted to less than 30 mmHg or so that a small air leak becomes audible with a stethoscope on the side of the neck with each ventilator cycle. The ventilator circuit should feel warm but be free of significant amounts of condensed water. The humidifier temperature and water level should be checked.

The pulse oximeter has contributed significantly to the monitoring and safety of patients on mechanical ventilation. Not only does it provide a continuous measurement

of oxygenation but it also reduces the need for arterial blood gas sampling.

Much can be appreciated from watching the ventilator pressure gauge with each cycle. In addition to evaluating peak inspiratory pressure the clinician will be able to judge whether the patient is 'fighting' the ventilator. Comparing inspiratory and expiratory tidal volumes may indicate a leak in the circuit, either at circuit connections or at the endotracheal tube cuff. When peak pressures are high, the internal compliance of the ventilator and circuit (about 2 to 2.5 ml/cmH_20) may account for much of the volume loss. An assessment of the compliance of the respiratory system can be made from the peak inflation pressures and the resulting exhaled tidal volume during SIMV-delivered breaths. Normal values approximate 50 to 60 ml/cmH_2O, while in severe acute respiratory distress syndrome, effective static respiratory system compliance may fall to 10 ml/cmH_2O.

Methods of enhancing oxygen on-loading

Positive end-expiratory pressure/constant positive airway pressure (PEEP/CPAP)

PEEP/CPAP is the most commonly adopted method of enhancing oxygen on-loading (other than oxygen administration) and is often used in the presence of refractory hypoxaemia due to acute lung injury. Trends in the application of PEEP/CPAP in patients with respiratory failure have changed over the years. The use of maximum tolerated levels of PEEP ('super-PEEP') and 'best' PEEP have generally been replaced by the employment of 'least' or 'enough' PEEP to allow adequate arterial oxygenation with an FiO_2 less than 0.6. However, it is still not uncommon to have to consider levels of PEEP greater than 10 or 15 cmH_2O, particularly in patients with acute respiratory distress syndrome.

An indication of the optimal PEEP level can be determined from the pressure–volume curve during lung inflation. An inflection point at the lower end of the curve suggests that areas of the lung are being allowed to collapse and therefore require higher pressures for their re-expansion. PEEP should be set above the inflection point to prevent collapse/re-expansion stresses.

Care must be exercised to ensure that oxygen delivery is not impaired in the unbridled pursuit of a higher level of arterial oxygenation. Monitoring continuous cardiac output or SvO_2 using a specially developed pulmonary artery catheter is particularly useful in detecting adverse effects of PEEP. If oxygenation is considered inadequate or the FiO_2 is greater than 0.6, increases in PEEP above 10 cmH_2O can be attempted in increments of 2.5 to 5 cmH_2O. If there are adverse effects, such as hypotension or reduced cardiac output (or SvO_2), then intravenous volume loading or circulatory support with an inotrope or pressor agent such as adrenaline may stabilize the patient.

Mask CPAP

CPAP can be applied without resorting to endotracheal intubation in the treatment of selected patients with acute respiratory failure. Close-fitting CPAP masks, which are very similar to standard anaesthetic masks, are widely available together with disposable circuitry and gas supply/pressure regulator mechanisms to ensure the safe delivery of air/oxygen mixtures.

The patient must be fully alert and co-operative since there is a major risk of aspiration should vomiting occur. Mask CPAP is particularly suited to patients with diffuse, reversible, interstitial processes such as cardiogenic pulmonary oedema or interstitial pneumonia (e.g. *Pneumocystis carinii* pneumonia). Recovery should be expected within 1 or 2 days since it is difficult for the patient to tolerate a tight-fitting CPAP mask for much longer periods, and CPAP levels above 10 to 15 cmH_20 should not be employed. In general, patients with established acute respiratory distress syndrome are unsuitable if a long or protracted period of treatment is envisaged.

Suitable patients must be carefully selected and managed in a clinical area where appropriate observation and monitoring can be assured, usually an intensive care, high dependency, or respiratory unit. Continuous assessment by the clinical team is essential so that endotracheal intubation can be substituted for the mask system if necessary.

PEEP/CPAP in unilateral lung disease

The use of PEEP/CPAP in patients with unilateral or irregularly distributed lung disease may not result in improved oxygenation. Indeed, paradoxical falls in oxygenation may occur as a result of the shunting of blood from areas of well matched V/Q to parts of the lung that are poorly ventilated. Unilateral lung consolidation, lung collapse, massive pleural effusion, and pulmonary infarction may therefore not benefit from PEEP/CPAP. Treatment should be directed at correction of the specific lung pathology whenever possible.

Weaning of PEEP

Reduction or weaning of PEEP/CPAP should be conducted carefully and gradually once the underlying pathology (e.g. sepsis) has resolved. Ideally, the FiO_2 should have been reduced to 0.4 or less to maintain a PaO_2 of 10 kPa (80 mmHg) and the PEEP/CPAP level should not have changed for at least 12 h. Even when these criteria are satisfied, a significant proportion of patients will require the return of PEEP/CPAP to previous or even higher levels. Reduction of PEEP/CPAP in 2.5 or 5.0 cmH_2O decrements should be carried out at 10- to 15-min intervals after clinical, pulse oximeter, and blood gas assessment. Even after resolution of lung pathology the retention of low levels of PEEP/CPAP of 3 to 5 cmH_2O ('physiological PEEP') up to the time of extubation may help maintain normal lung volumes and improve gas exchange.

Prone positioning

A feature of the patient with acute respiratory distress syndrome is the extensive gravity-dependent lung collapse that is best visualized by CT scan. To a large degree this is a consequence of nursing the patient for prolonged periods in the supine position. Sitting the patient as upright as possible minimizes the volume of dependent lung. In recognition that dependent regions of the lung exhibit severe atelectasis and loss of volume, it is logical to alternate the patient between prone and supine positions every 8 to 12 h. Up to half of patients with severe acute respiratory distress syndrome show improved oxygenation with such manoeuvres. The major drawback is that vascular access sites and airway access can be dislodged during the process of turning the patient over. However, of all the methods of enhancing oxygen on-loading, only prone positioning actively addresses the issue of dependent lung atelectasis.

Nitric oxide therapy

The addition of low concentrations of nitric oxide (2 to 10 parts per million NO) to the inspired gas mixture will improve oxygenation in about 50 per cent of patients with acute respiratory distress syndrome, but there is no evidence from randomized studies that survival is better. Care must be exercised with delivery systems to ensure correct doses and avoid excessive production of toxic metabolites (nitrogen dioxide and methaemoglobin).

Extracorporeal membrane oxygenation

Extracorporeal membrane oxygenation in premature infants with persistent respiratory distress significantly improves survival. Its use for respiratory failure in adults was largely abandoned over two decades ago following controlled, randomized investigation. With the availability of improved oxygenators there has been renewed interest in combining extracorporeal partial CO_2 removal and low frequency conventional ventilation. Whether this approach offers significant advantages over techniques of permissive hypercapnia remains unproven, although there are enthusiasts who promote the use of extracorporeal membrane oxygenation in adults. Both techniques are aimed at reducing the deleterious effect of positive pressure upon the alveolar epithelium and may therefore hasten recovery from acute respiratory distress syndrome.

Surfactant

Following the dramatic benefit from the use of surfactant in neonatal respiratory distress, attempts to achieve similar effects in adults have been explored. Despite

encouraging anecdotal reports, surfactant has not produced consistent improvement in acute respiratory distress syndrome, particularly when resulting from sepsis syndrome. This failure may stem in part from uncertainty regarding the type of surfactant (synthetic or animal derived) and the dose of surfactant required.

Liquid ventilation

Alveolar instability and collapse in acute respiratory distress syndrome stems, in part, from the high surface tensions at the alveolar air/liquid interface. Von Neerguard demonstrated in the 1920s that a liquid to liquid interface in the lung would remove surface tension effects. Application of this observation can be found in liquid lung ventilation, using a liquid with a high carrying capacity for both oxygen and carbon dioxide instead of air/oxygen mixtures. Perfluorocarbons (carbohydrate molecules with the hydrogen elements replaced by fluorine) are inert liquids that are capable of sustaining gas exchange when instilled into the lung. By partially filling the lungs with perfluorocarbon a conventional ventilator can be used to oxygenate the liquid, which in turn transfers the oxygen to the alveolar membrane (partial liquid ventilation). Most experience has been gained in infants initially sustained by extracorporeal membrane oxygenation. Much greater experience with this technique is required before more widespread use can be justified.

Weaning of mechanical ventilation

More than 80 per cent of patients who are ventilated postoperatively can be weaned simply by clinically evaluating their spontaneous ventilation on a 'T-piece' or similar circuit. The remainder require a progressive reduction in ventilatory support until measurement of ventilation parameters can be made, including the negative inspiratory force and vital capacity. A negative inspiratory force greater than –25 cmH_2O or a vital capacity greater than 10 ml/kg usually indicates sufficient ventilatory reserve for spontaneous ventilation. However, these parameters cannot be applied reliably to patients with severe chronic obstructive pulmonary disease, when blood gases have to be followed with each reduction in ventilation support. Modes of ventilation such as SIMV, IMV, BiPAP, and pressure support are very suitable for weaning since they allow gradual and progressive reduction in support. Regular clinical and physiological assessment after each reduction in ventilation support is essential. Failure to wean a patient successfully from mechanical ventilation should prompt the questions addressed in Table 3.

Complications of mechanical ventilation

Several complications of mechanical ventilation can be attributed to the local effects of the endotracheal tube upon the airway. These include airway obstruction due to tube displacement and pressure necrosis leading to vocal cord injury and subglottic stenosis. The risk of nosocomial pneumonia is increased in the intubated patient.

Many complications are the direct consequence of positive-pressure ventilation. Haemodynamic effects such as reduced cardiac output, reduced renal perfusion, salt and water retention are primarily the result of mechanical, neuroreflex, and humoral factors. The greatest concern relates to the risk of pneumothorax, pneumomediastinum, pneumopericardium, or subcutaneous emphysema (barotrauma). Pneumothorax is the most feared of these because it is associated with rapid deterioration unless dealt with quickly. Signs of tension pneumothorax include arterial desaturation (pulse oximeter), sudden rise in peak airway pressure, asymmetry of chest wall movement, hypotension and tachycardia, and finally circulatory collapse.

Tube thoracostomy is mandatory for pneumothorax in the ventilated patient since progression to a tension pneumothorax is very likely. However, prophylactic thoracostomy tubes are not recommended, even in the presence of pneumomediastinum. Emergency decompression with a 14-gauge cannula is essential in tension pneumothorax, can produce temporary relief of a pneumothorax not under tension, and may have a diagnostic role, but tube thoracostomy should be performed without delay and without radiographic confirmation if necessary. Blunt dissection through the parietal pleura with forceps and digital exploration of the pleural space prior to insertion of the thoracostomy tube is essential if lung damage is to be avoided. Thoracostomy tubes with rigid metal stylets must not be used under any circumstances.

Non-invasive methods of ventilation support

Positive pressure non-invasive ventilation

Non-invasive assisted ventilation may offer an alternative to endotracheal intubation in selected patients with acute respiratory failure. Current evidence suggests that positive pressure non-invasive techniques support the respiratory muscles and avoid upper airway obstruction better than negative pressure techniques. Non-invasive positive pressure ventilation can be applied with volume cycled ventilation, bi-level positive airway pressure (BiPAP), and pressure support modes delivered via face and nasal masks.

Although the principle of the treatment is straightforward, with the application of positive pressure being used to assist ventilation, the practice can sometimes be difficult. Masks must fit tightly or else leakage prevents the generation of adequate positive pressure, and they can be uncomfortable, particularly if not expertly fitted. Indeed, failure to tolerate the mask, sometimes with the development of pressure damage to the face or nose (up to and including necrosis), often prevents effective treatment. If patients are going to respond well to non-invasive ventilation, benefit is apparent within the first 60 min. The maximal duration of successful ventilatory support using non-invasive positive pressure ventilation is usually less than 7 days. A specialist unit with expertly trained nursing care is essential for best results.

Although suitable for those with a variety of causes of respiratory failure, the main use of non-invasive ventilation is in the management of patients with acute exacerbation of chronic obstructive pulmonary disease, and an increasing number of studies testify to its efficacy in this disorder. A prospective randomized study compared non-invasive pressure support ventilation delivered through a face mask with standard treatment in selected patients with acute exacerbation of chronic obstructive pulmonary disease admitted to five intensive care units. This found that non-invasive ventilation reduced the need for endotracheal intubation (11 of 43 (26 per cent) versus 31 of 42 (74 per cent)), the frequency of complications (16 versus 48 per cent), the mean hospital stay (23 days versus 35 days), and the in-hospital mortality rate (9 versus 29 per cent). In a similar population non-invasive ventilation has also been shown to be better than continued invasive pressure support ventilation by an endotracheal tube in a randomized study of weaning from mechanical ventilation, both reducing the duration of mechanical ventilation (from 17 to 10 days) and the time spent in the intensive care unit (15 versus 24 days), and improving survival at 60 days (92 versus 72 per cent).

The use of non-invasive ventilation has also been examined in a general respiratory ward setting. A prospective randomized controlled study in 14 United Kingdom hospitals compared this treatment with standard therapy in patients with acute exacerbation of chronic obstructive pulmonary disease and mild to moderate acidosis. The use of non-invasive ventilation reduced the need for intubation as defined by objective criteria from 27 per cent (32/118) to 15 per cent (18/118) and reduced in-hospital mortality from 20 per cent to 10 per cent.

Negative-pressure ventilation (NPV)

Negative-pressure ventilation is achieved by applying subatmospheric pressures to the surface of the thorax during inspiration and provides an alternative means of assisting ventilation without intubation. Expiration is usually accomplished passively by the elastic recoil pressure of the lungs and chest wall. Negative pressures at predetermined frequencies and depths can be applied to the whole body (iron lung), chest wall, or chest and abdominal wall (cuirass). Some devices can maintain a negative pressure at end-expiration to maintain lung recruitment in a negative-pressure equivalent of PEEP. The haemodynamic effects of NPV are variable and depend on whether negative pressure is applied to the whole body or only to the thorax.

NPV using 'iron lungs' has been used mostly in patients with neuromuscular disorders, such as poliomyelitis or muscular dystrophy, and in those with chronic obstructive pulmonary disease. NPV with negative end-expiratory pressure (NEEP) has been used in patients during hypoxaemic respiratory failure due to acute respiratory distress syndrome and *Pneumocystis carinii* pneumonia.

The negative intratracheal pressures generated during NPV may adduct the vocal cords producing laryngeal obstruction. As a result NPV is not ideal for diseases that may be complicated by upper airway obstruction, such as Guillain–Barré syndrome and myasthenia gravis. For similar reasons, NPV may be ineffective in patients with sleep apnoea. By contrast, the application of nasal CPAP (positive pressure) to such patients is recognized as reliably preventing upper airway obstruction (see Chapter 17.8.1).

Recent developments of the cuirass type of negative-pressure ventilator (Hayek®) permit high frequency oscillations to be used, resulting in enhanced gas exchange.

Specific strategies in ventilator management

Restrictive lung disease

Patients with restrictive lung diseases such as sarcoidosis or fibrosing alveolitis should be ventilated with small tidal volumes of between 5 to 8 ml/kg at rates of 15 to 20 breaths/min. Oxygen need not be restricted in the manner recommended for patients with chronic obstructive pulmonary disease.

Chronic obstructive pulmonary disease

Low rate SIMV (6 to 8 breaths/min) or low pressure levels of pressure support are ideal for patients suffering from chronic obstructive pulmonary disease with acute or chronic respiratory failure. The $PaCO_2$ should be reduced very slowly towards—but not to—normal levels. The FiO_2 rarely needs to be higher than 0.35. High ventilator rates (more than 16/min) are associated with incomplete expiration and air trapping, and the $PaCO_2$ may rise paradoxically if ventilator rates are increased in an attempt to increase minute ventilation. To avoid this, the I:E ratio should be maintained at 1:2 or more.

Weaning can begin as soon as the precipitating cause of respiratory failure has been corrected. Weaning will be unsuccessful if there is any underlying metabolic alkalosis or the patient receives sedative or analgesic agents. The $PaCO_2$ can be allowed to rise slowly to above normal levels provided sufficient time is given for the blood pH to correct and the FiO_2 is kept below 0.35. Carbon dioxide production can be minimized by providing balanced nutrition with calories from both lipid and carbohydrate.

Asthma

Probably less than 1 per cent of acute severe asthma attacks require mechanical ventilation. However, some patients suffer cardiac arrest and die every year because intubation and mechanical ventilation was not performed in time. Hypercarbia alone is generally insufficient as an indication for ventilation, but a combination of a rising $PaCO_2$, fatigue, failure of conservative measures, or arrhythmias does call for elective intubation and mechanical ventilation. Adequate oxygenation must be ensured by the administration of unrestricted and high concentrations of oxygen, in contrast to the patient with CO_2-retaining chronic obstructive pulmonary disease for whom controlled oxygen (24 to 28 per cent) is generally indicated.

Patients with asthma may be difficult to ventilate initially and often require high inflation pressures. Hypoxia may persist despite the use of high concentrations of oxygen and is probably the result of mucus plugging of the airways. A philosophy of 'permissive hypercapnia' or 'controlled hypoventilation' should be adopted with the $PaCO_2$ remaining at elevated levels (7 to 8 kPa, 50 to 60 mmHg). This allows lower tidal volumes and respiratory rates; lower inspiratory flow rates result in lower peak pressures and reduced risk of barotrauma. Deaths in ventilated asthmatic patients are rare but are usually the result of barotrauma, hypotension in volume-depleted patients, arrhythmias, or lung infection.

Maximal bronchodilator therapy including corticosteroids should be continued throughout the period of mechanical ventilation, supplemented if necessary with inhalational anaesthetics such as isoflurane or the intravenous anaesthetic ketamine. Both of these agents are potent bronchodilators. Rehydration and adequate humidification of inspired gases will ordinarily mobilize secretions and mucous plugs; if not, bronchoalveolar lavage may be indicated.

The use of extracorporeal membrane oxygenation and CO_2 removal has been reported in acute asthma. These must be considered exceptional cases and such techniques cannot be generally recommended.

16.6.1 Sedation and analgesia in the critically ill

G. R. Park and B. Ward

Sedation and analgesia are used to increase patient comfort by minimizing the pain and anxiety produced by illness and its treatment. Factors contributing to patient discomfort are shown in Fig. 1.

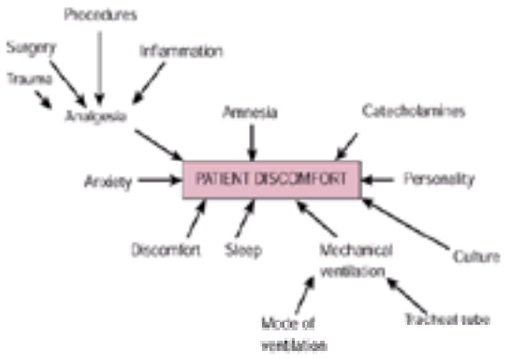

Fig. 1 Factors contributing to patient discomfort.

The relief of pain is an obvious part of being comfortable, but the role of sedation is more complex. The term sedation covers a broad range of conscious states, from almost wide awake to deeply unresponsive. The 'ideal' level of sedation for most patients is at ease, without signs of anxiety or agitation and easily rousable from light sleep. Sedation is needed for a variety of reasons, including:

1. reduction of anxiety caused by fear, inability to communicate, loss of control, or unfamiliar environment;
2. allowing patients to tolerate treatment—e.g. stops them pulling out the tracheal tube;
3. allowing patterns of ventilation to be imposed which do not synchronize with a normal breathing pattern;
4. prevention of awareness when neuromuscular paralysis is used;
5. minimizing distress during uncomfortable procedures;
6. allowing sleep; and
7. control of fits.

Patients will usually tolerate a tracheal tube without the need for paralysis if the ventilator is properly set and they are properly sedated. The indications for neuromuscular relaxation in the critically ill are listed below: the use of muscle relaxants is otherwise avoided.

1. Acute respiratory distress syndrome (ARDS)—paralysis allows the patient to tolerate unusual ventilatory modes, e.g. reverse ratio ventilation;
2. raised intracranial pressure—paralysis prevents coughing and straining; and
3. status asthmaticus—paralysis can reduce risks of barotrauma to lungs.

The intravenous route is used almost exclusively for the administration of analgesia and sedation in the critically ill, as it is faster and more reliable than other routes. Drugs can be given either as repeated bolus doses, or as a continuous infusion. Although a continuous infusion has the advantage of avoiding peaks and troughs associated with bolus doses, there is also an increased risk of inadvertent overdose or accumulation.

The analgesic needs of most patients can best be met with regular bolus doses of analgesic titrated against repeated assessment of the pain. A patient- or nurse-controlled syringe pump driver will deliver a bolus of a predetermined amount of drug when triggered to do so. There is usually a predetermined 'lockout' safety period during which further requests for bolus doses will be ignored. Morphine is the drug most commonly given in this manner, but diamorphine, pethidine, and fentanyl can also be used. A loading dose may be needed before starting.

Hazards of sedation and analgesia

The use of drugs for sedation and analgesia involves risks to the patient. These include:

1. over-sedation or a prolonged sedative effect caused by poor elimination in the critically ill;
2. hypotension/myocardial depression;
3. antitussive effects leading to failure to clear pulmonary secretions;
4. hypoventilation, delaying weaning;
5. toxic effects due to accumulation of sedative/analgesic agents or their metabolites; and
6. expense, both of the drugs and their adverse effects.

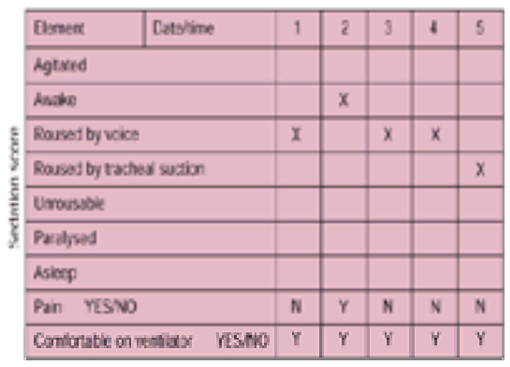
There are many reasons why the behaviour of drugs administered to the critically ill patient may be abnormal. These include:

1. hepatic failure leading to poor metabolism or biliary excretion of the drug;
2. renal failure leading to decreased excretion of the drug or its metabolites;
3. haemofiltration/dialysis may have unpredictable effects on clearance of the drug or its metabolites;
4. reduced plasma protein levels (e.g. albumin) may lead to increased free (active) drug levels;
5. volume of distribution may be affected by oedema, ascites, or hyper/hypovolaemia;
6. interactions between drugs; and
7. solvent toxicity.

The risks of using drugs can me minimized by a knowledge of their routes of breakdown and excretion. Agents that are unlikely to accumulate should be chosen when possible. Drugs with more than one site of metabolism, or those which can undergo non-organ-based breakdown are preferred. The risk of accumulation of a sedative drug can be reduced by stopping it every 24 h whenever possible and letting the patient recover from its effects. If the patient wakes or becomes restless, the drug can be restarted knowing that accumulation has not occurred.

To avoid under- or over-sedation, drugs need some assessment of their effects. Because of the many components which are involved in sedation, no simple method

exists. Although work is progressing on physical methods of assessing the level of sedation (e.g. spectral analysis of electroencephalogram waveforms), the most commonly used methods rely on bedside observations. We use a scoring system comprising several different elements (Fig. 2) (see below). The key to avoiding under- or over-sedation is regular assessment of the patient and adjustment of the sedation regimen accordingly.



Sedation score	Element	Date/time	1	2	3	4	5
	Agitated						
	Awake			X			
	Roused by voice		X		X	X	
	Roused by tracheal suction						X
	Unrousable						
	Paralysed						
	Asleep						
	Pain YES/NO		N	Y	N	N	N
	Comfortable on ventilator YES/NO		Y	Y	Y	Y	Y

Fig. 2 The Addenbrooke's Sedation Score.

Psychological disturbances

Severe illness, the intensive care environment, and drugs usually prevent patients from sleeping normally. Deprivation of sleep, especially if prolonged, combined with the fear of dying may make some patients psychotic. Close attention to environment (e.g. normal day/night light levels, noise etc.) may help. Drugs may be of some benefit, but can cause prolonged sedation. If the patient has a prolonged recovery phase then depression is common. Antidepressants are rarely of value and can have toxic effects.

Drug treatment

Before using drugs, causes of pain and agitation such as a full bladder or rectum should be excluded.

Sedative drugs

There are two main types of drugs, those principally sedative and those mostly analgesic. The agents most commonly used for sedation are the benzodiazepine midazolam and the anaesthetic agent propofol. These, and other agents commonly used for sedation in the intensive care unit, are described below.

Midazolam

Midazolam is a water-soluble benzodiazepine, which can be given peripherally without causing thrombophlebitis or pain. Like all benzodiazepines it has sedative, amnesic, anxiolytic, and anticonvulsive properties. It has a rapid onset, short half-life (approximately 2 h), and is commonly used in combination with morphine in order to achieve both analgesia and sedation. Midazolam is primarily metabolized by the liver, and accumulation occurs in liver failure. The (phase I) metabolic product, l-hydroxymidazolam has around 10 per cent of the activity of the parent drug. In renal failure, accumulation of l-hydroxymidazolam glucuronide (the phase II metabolic product) can cause prolonged sedation or coma.

Lorazepam

This has been used as an alternative to midazolam. It undergoes metabolism only by glucuronidation to render it water soluble. This makes it less likely for the parent drug to accumulate. It is dissolved in propylene glycol.

Diazepam

Diazepam is rarely used in the critically ill, having been replaced by midazolam. It has a much longer duration of action and has many metabolites with significant activity of their own. This increases the risk of accumulation.

Propofol

Propofol (2,6-di-isopropylphenol) was introduced as an anaesthetic agent but is widely used for sedation in the critically ill as a continuous infusion. Emergence from sedation is rapid and without hangover effect. Propofol is a respiratory depressant, and prolonged apnoea can occur after bolus doses. Hypotension associated with propofol use is common in the critically ill and is dose related. Although metabolized primarily in the liver, extrahepatic breakdown does occur. There are no active metabolites and propofol does not accumulate in hepatic or renal failure to a significant extent. However, because it is formulated in soya bean extract, prolonged infusion (more than 48 h) can lead to hyperlipidaemia. Propofol is expensive, and its use is often limited to those patients who require short-term sedation only.

Dexmedetomidine

Dexmedetomidine is a potent, highly selective, a_2-adrenoceptor agonist. It has sedative, anxiolytic, amnesic, and sympatholytic effects. In addition, dexmedetomidine appears to reduce requirements for opioid analgesia. These effects are mediated centrally at post-synaptic a_2-receptors. In contrast to the agents already discussed, dexmedetomidine does not seem to cause respiratory depression, and exhibits remarkable cardiovascular stability. Because of these features, there is currently great interest in the use of this agent.

Thiopentone

The intravenous anaesthetic agent thiopentone retains certain specialized indications, for example use in status epilepticus or to reduce raised intracerebral pressure. Thiopentone has a half-life of 11 h, and prolonged infusion (i.e. > 24 h) is usually associated with extremely prolonged action.

Combinations of agents

Sedative drugs often act via differing mechanisms and so have slightly different actions. This difference can be used to advantage. For example propofol is mostly an hypnotic, whilst midazolam is a good anxiolytic and amnesic agent as well as producing hypnosis. In combination they are synergistic.

Analgesic drugs

Opioid drugs remain the mainstay of analgesic treatment in the critically ill, and morphine is the most common choice. Some properties of the opioid drugs used in the critically ill are listed in Table 1.

Morphine

Morphine is a cheap and effective analgesic agent and is the opioid against which others are judged. It has both analgesic and sedative effects, although an excessive dose would be required to produce adequate sedation by its use alone. It is often given with a benzodiazepine, such as midazolam, to achieve analgesia

and sedation. It is the standard agent for use in patient- and nurse-controlled syringe pumps. Morphine is metabolized in the liver, forming two major metabolites—morphine 3-glucuronide (**M3G**) and morphine 6-glucuronide (**M6G**), both of which are active. M6G is a potent analgesic, whilst M3G is thought to be antianalgesic.

Pethidine

Pethidine is a synthetic compound and was originally developed as an anticholinergic agent. It does tend to cause anticholinergic effects, such as dry mouth, blurred vision, and tachycardia. It is claimed that pethidine induces less constriction of the biliary sphincter than morphine, and perhaps the only indication for its use is in patients with biliary pathology. It is metabolized in the liver to form norpethidine, pethidinic acid, and pethidine- *N*-oxide. These metabolites are excreted by the kidneys, and in renal failure significant amounts of norpethidine may accumulate, leading to grand mal convulsions.

Fentanyl

Fentanyl is approximately 100 times as potent as morphine, and has a rapid onset of action (3 min). In low doses the analgesic effect of fentanyl ends after about 20 min by its rapid redistribution around the body. With larger doses, tissues may become saturated and drug action is prolonged, termination depending on the slow process of *N*-demethylation in the liver. The major metabolite, norfentanyl, is excreted by the kidneys, and its accumulation may cause toxic delirium in patients with renal failure. Accumulation of fentanyl itself may occur in hepatic failure, causing prolonged effect. Fentanyl has a potent apnoeic effect, and in large doses, fentanyl can produce muscle rigidity, particularly of the chest wall.

Alfentanil

Alfentanil is approximately 10 to 20 times as potent as morphine, and has a very fast onset time (1 min). The effects of alfentanil are short lived (approximately 10 to 15 min), ending by redistribution to tissues. Because of this, alfentanil is unsuitable for use in patient-controlled syringe pumps, and it is administered by continuous infusion. Elimination takes place almost exclusively in the liver, and alfentanil is the current drug of choice in severe renal impairment. It can accumulate in hepatic failure, cirrhosis, or when hepatic enzyme inhibitors such as cimetidine are used.

Remifentanil

Remifentanil is a relatively new agent which may prove to have pharmacological properties useful in critically ill patients. It has a fast onset of action and a very short half-life (10 to 21 min). Remifentanil has an ester linkage within its structure, which is broken down by a non-specific, non-saturable enzyme system present in plasma. This breakdown pathway means that accumulation does not occur, and the drug wears off rapidly even after prolonged infusions and in renal or hepatic failure. Remifentanil must be given by constant infusion, indeed the effects wear off so rapidly that even small delays, such as the time taken to make up a new syringe, can leave the patient without analgesia.

Sedative and analgesic antagonists

When accumulation of a drug or its metabolite is suspected as the cause of prolonged sedation, the diagnosis can be confirmed with the use of antagonists. Naloxone will quickly (but temporarily) reverse the effects of opiates, whilst flumazenil is a benzodiazepine antagonist. Their use is not recommended in patients suffering from head injury. Large doses of either antagonist given quickly can produce sudden arousal, causing agitation. When using naloxone, the sudden reversal of analgesia can cause a massive outpouring of catecholamines and precipitate arrhythmias.

Regional and epidural anaesthesia

For analgesia after certain surgical procedures or trauma, regional and epidural techniques can be extremely effective. Lumbar or thoracic epidurals can prevent hypoventilation and diaphragmatic splinting caused by pain after abdominal or thoracic procedures and fractured ribs, whilst avoiding the side-effects of high-dose opioids. The problem of correct placement of regional blocks in critically ill patients is a considerable one, and complications (such as pneumothorax following intercostal block) must be carefully considered. Epidural analgesia, although desirable, may be contraindicated in the critically ill patient because of coagulopathy or sepsis.

16.6.2 Management of raised intracranial pressure

David K. Menon

Introduction

The normal intracranial pressure (**ICP**), measured at the level of the foramen of Monro, is between 5 and 15 mmHg in supine subjects. Intracranial hypertension (ICP >20 mmHg) is a common accompaniment of many central nervous system (**CNS**) diseases, when it is often the most important cause of symptoms and modulator of outcome, and—in fatal cases—frequently the immediate cause of death.

Pathophysiology

The cranial cavity contains brain (80 per cent), blood (10 per cent), and cerebrospinal fluid (10 per cent). These incompressible contents are contained in a rigid skull with a fixed capacity, hence an increase in volume of any of these contents, or the presence of any space-occupying pathology, results in an increase in ICP unless one of the other constituents can be displaced or its volume decreased (Fig. 1). This principle is referred to as the Monroe–Kelley doctrine. Increases in intracranial volume may be caused by:

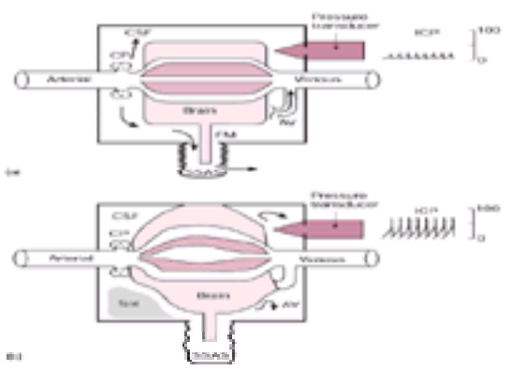

Fig. 1 Schematic diagram showing intracranial contents in the normal brain (a) and with elevated intracranial pressure (b). Note that cerebrospinal fluid (CSF) produced by the choroids plexus (CP), circulates freely, passing through the foramen magnum (FM) into the spinal subarachnoid space (SSAS), before absorption by arachnoid villi (AV) in the cerebral venous sinuses. Increases in ICP may be due to brain oedema, vascular engorgement, space-occupying lesions (SOL), or impaired CSF circulation or absorption. Compensatory mechanisms include translocation of CSF to the SSAS, and compression of cerebral vascular beds. The ICP trace shows a higher mean value, and the inability of the non-compliant brain to cope with increased blood during each systole results in an increased pulsatility of the ICP waveform.

1. *Brain oedema*, which may have different pathogenic mechanisms:
   - cytotoxic oedema occurs as a result of cell swelling, most commonly due to ischaemic energy depletion and rises in intracellular sodium and water;
   - vasogenic oedema results from an increased permeability of the blood–brain barrier with an expansion of the extracellular fluid compartment;
   - interstitial oedema occurs in the context of hydrocephalus, where increased intraventricular cerebrospinal fluid (**CSF**) pressures result in permeation of CSF into adjacent brain, typically in the frontal periventricular regions.
2. *Vascular engorgement*, which results from an increased cerebral blood volume. This may be due to the vasodilatation that accompanies normal or abnormal (for example, epileptiform) neuronal activity. In other situations vasodilatation may be due to the loss of vasoregulation, either due to disease (vasoparalysis), or to the effect of potent physiological (carbon dioxide) or pharmacological (nitrates and other nitric oxide donors) cerebral vasodilators.
3. *Hydrocephalus*, which may be non-communicating (where an obstruction prevents the ventricular system communicating with the subarachnoid space), or communicating (where there is a defect in CSF reabsorption).
4. *Space-occupying lesions* (**SOLs**), which may be chronic (for example, intracranial tumours) or acute (for example, intracranial haematomas associated with trauma).

Temporal patterns of ICP change

Initial increases in intracranial volume are buffered by the displacement or reduction in volume of other contents. Thus, cerebral oedema may result in compression of the ventricles, with translocation of CSF to the spinal subarachnoid space, and compression of cerebral vasculature. Over longer periods, normal brain may be compressed and CSF production diminished. The relationship between intracranial volume (**ICV**) and ICP is commonly depicted as a hyperbolic curve, with an initial flat part during which compensatory mechanisms are effective, moving after their progressive exhaustion to a steep phase when even small increases in intracranial volume produce large increases in ICP. However, the extent and efficiency with which these mechanisms buffer increases in volume depend on the speed of disease progression, and given these considerations it is more appropriate to depict the evolution of pathophysiology as a family of curves, with variable rates of progression (Fig. 2). It is important to make three further points in this context:

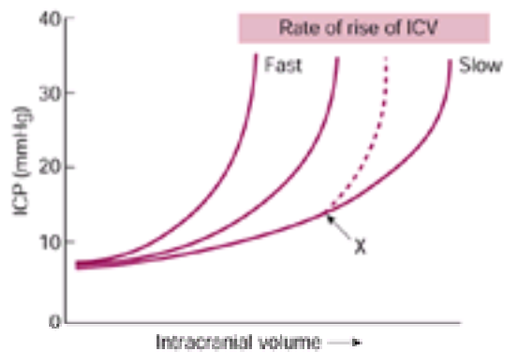

Fig. 2 Intracranial volume/pressure curves. Increases in intracranial volume (ICV) are initially buffered by compensatory mechanisms, but eventually result in elevation of intracranial pressure (ICP). The ability to buffer increases in ICV depends on the speed at which pathology develops. Gradually progressive ICV increases (such as those produced by a slow growing tumour) may be well compensated, until a precipitating factor (e.g. the development of hydrocephalus, denoted by X in the diagram) shifts the relationship to a steeper curve.

1. A precipitating factor may suddenly increase the speed of progression of a relatively slow pathophysiological process, and be the proximate cause of symptomatic decompensation.
2. Acute changes in cerebrovascular physiology are an important cause of such deterioration. Both hypoxia and hypercarbia can cause cerebral vasodilatation and elevate ICP, and whilst *severe* hypertension may result in cerebral oedema, it is far more common to find that relatively minor reductions in mean arterial pressure compromise cerebral perfusion and trigger reflex vasodilatation and a secondary increase in ICP. Such haemodynamic instability may be the underlying cause of phasic increases in ICP (Fig. 3).

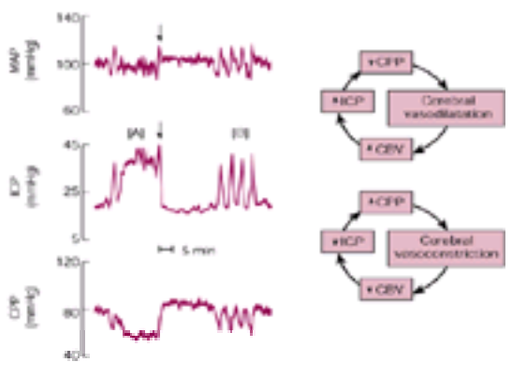

Fig. 3 Intracranial pressure (ICP) traces show phasic variations that may last several minutes (Lundberg A waves (A)) or be more transient (Lundberg B waves (B)). Elevations of ICP are often initiated by reductions in mean arterial pressure (MAP), which reduce cerebral perfusion pressure (CPP) and thereby trigger compensatory vasodilatation and increase cerebral blood volume (CBV) and ICP. This vicious cycle may be terminated by spontaneous hypertension associated with a Cushing response (arrow in MAP and ICP traces), or by therapeutic elevation of MAP, which triggers compensatory cerebral vasoconstriction and reductions in ICP. Note that a period of stable MAP greater than 100 mmHg is associated with a low, stable ICP. (Figure modified with permission from Rosner MJ (1993). Pathophysiology and management of increased intracranial pressure. In: Andrews BT, ed. *Neurosurgical intensive care*, p 75. McGraw-Hill, New York.)

3. Finally, since patients with significant intracranial hypertension operate on the steep part of the ICV/ICP curve, even small decreases in intracranial volume (for example, a 5-ml decrease in cerebral blood volume produced by mild hyperventilation) can have a gratifyingly large effect on ICP.

Why treat intracranial hypertension?

Brain perfusion depends on the difference between mean arterial pressure (**MAP**) and ICP, termed 'cerebral perfusion pressure' (**CPP**). While the normal brain autoregulates cerebral blood flow across a large range of CPP values, the lower limit of such autoregulation is about 50 mmHg in healthy subjects, but may be significantly higher (60–70 mmHg) in disease. CPP reductions below the lower limit of autoregulation result in cerebral ischaemia, and even minor reductions in CPP may trigger reflex vasodilatation and increase ICP in a non-compliant intracranial cavity.

An expanding focal mass can generate pressure gradients within the intracranial cavity. Moreover, the resulting displacement of brain against rigid structures and protrusion (herniation) of brain through narrow openings between intracranial compartments can press on vital structures and result in death (Fig. 4).

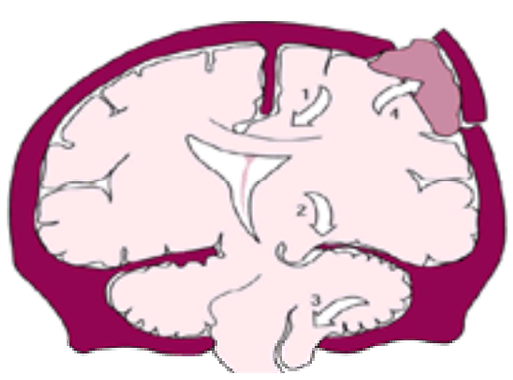

Fig. 4 Cerebral herniation may be: (1) subfalcine (beneath the falx cerebri); (2) transtentorial (through the tentorial hiatus with compression of the midbrain and posterior cerebral artery); (3) tonsillar (where the cerebellar tonsils herniate through the foramen magnum and compress the lower brainstem upper and cervical cord); or (4) transcalvarial (through a traumatic or surgical defect in the roof of the cranial cavity). (Modified with permission from Fishman RA (1975). *New England Journal of Medicine* **293**, 706.)

Prolonged intracranial hypertension may result in permanent damage to critical structures. Thus, benign intracranial hypertension rarely results in herniation syndromes, but frequently causes optic atrophy if left untreated.

Diagnosis

Symptoms

The symptoms that accompany ICP elevation are non-specific and insensitive. The cardinal feature is headache, which may be described as severe ('worst ever') and explosive in its onset in the setting of intracranial haemorrhage. By contrast, the headache of an intracranial tumour is often progressive, worst on awakening (possibly due to ICP elevations associated with the supine position and $PaCO_2$ elevation during sleep), and exacerbated by coughing and straining. However, it may

be indistinguishable from a common tension headache, and dangerous intracranial hypertension may occur without headache. The headache is often accompanied by vomiting, which is classically described as projectile and not preceded by nausea. Visual disturbances are common and may be attributable to optic or ocular motor nerve compression, with accompanying visual failure or diplopia, respectively. There may be alterations in mental function or conscious state, ranging from impaired concentration, through increased irritability, impaired cognition and memory, and altered personality to increased somnolence and deep coma.

Signs

Papilloedema is the classical sign associated with ICP elevation, but is not seen with acute intracranial hypertension and may be absent even where there are large intracranial masses. Pressure on the cranial nerves may result in weakness of ocular movement. The abducens nerve is often involved in such a process due to its long intracranial course; the resultant diplopia provides the classical example of a false localizing sign. Lesions that irritate the meninges of the posterior fossa can produce neck stiffness.

Progressive rises in ICP result in bradycardia and hypertension, which constitute the Cushing response, and signify stimulation of brainstem autonomic nuclei. Worsening brainstem compression and/or ischaemia result progressively in Cheyne–Stokes respiration, central neurogenic hyperventilation, and irregular respiratory patterns ('ataxia of breathing'). Both neurogenic pulmonary oedema and the adult respiratory distress syndrome have been associated with intracranial hypertension.

Severe ICP elevation may result in herniation of the temporal lobe through the tentorial notch (Fig. 4). This produces clinical features due to pressure on the ipsilateral oculomotor nerve (ipsilateral pupillary dilatation), pyramidal tract (contralateral weakness), and brainstem (Cushing response and abnormal respiratory patterns followed by circulatory collapse and respiratory arrest). The posterior cerebral artery is frequently compressed by the herniating temporal lobe, and successful resuscitation from threatened or early transtentorial herniation may leave a patient with an ipsilateral occipital infarction and cortical blindness.

Imaging

Tomographic imaging now provides most diagnostic information in intracranial hypertension. Computed tomographic scanning may reveal subarachnoid or intracerebral blood, contusions, or a tumour. In addition, cerebral oedema may be manifest by a loss of sulci, compression of the third and lateral ventricles, and effacement of the perimesencephalic and suprasellar cisterns. Unilateral lesions may result in a midline shift, compression of the ipsilateral lateral ventricle, and, in some cases, dilatation of the contralateral ventricle due to obstruction of the foramen of Monro. It is important to recognize that overt ventricular dilatation may be absent when hydrocephalus coexists with cerebral oedema. Indeed, the presence of normal-sized ventricles in the context of intracranial hypertension should suggest the possibility of coexisting hydrocephalus and trigger the consideration of CSF drainage as a means of therapy.

Magnetic resonance imaging may provide better definition of underlying pathology, particularly in the posterior fossa, and its multiplanar capability may allow a better appreciation of the extent of space-occupying lesions. Modern imaging methods can also detect patients who may have relatively normal ICP but are at high risk of severe intracranial hypertension, for example a patient with a middle cerebral artery territory infarction is at high risk of severe brain swelling if more than 50 per cent of the middle cerebral artery territory is hypodense.

Lumbar puncture

A lumbar puncture offers the opportunity to directly measure CSF pressure, and can be the defining investigation in meningitis, subarachnoid haemorrhage, or benign intracranial hypertension. However, in the context of clinical features that suggest intracranial hypertension, a lumbar puncture **must be preceded** by CT scanning, and **avoided** if the basal cisterns are effaced by cerebral oedema. Removal of CSF from the lumbar subarachnoid space under these circumstances can markedly increase the pressure differential in the supratentorial compartment, and precipitate transtentorial herniation.

Monitoring intracranial pressure

The clinical evaluation of intracranial hypertension is difficult due to its non-specific clinical picture and phasic variations. Management may therefore be greatly facilitated by direct monitoring of ICP using intraparenchymal or ventricular monitoring devices. Such monitoring is mandatory in patients with severe intracranial hypertension and in those who are sedated or deeply unconscious, in whom changes in clinical signs do not provide an alternative means of assessing progress and response to therapy.

Management

Management focuses on four areas.

Monitoring disease progression and response to therapy

The approach to monitoring will depend on the clinical context. Repeated clinical examination with regular charting of the Glasgow Coma Scale may suffice in many cases. Patients with benign intracranial hypertension may require a regular visual field assessment, whilst those with head injury, intracranial haemorrhage, or severe cerebral oedema may benefit from direct ICP monitoring. The value of ICP monitoring may be substantially enhanced by the use of other monitoring modalities such as jugular bulb oximetry.

Maintenance of stable physiology and removal of precipitating factors

Hyponatraemia and low plasma osmolality will tend to worsen cerebral oedema by favouring water entry into the brain: they should be corrected vigorously. Maintenance of cerebral perfusion pressure with fluid resuscitation and vasoactive agents will prevent cerebral ischaemia. Comatose patients should have their arterial blood gas levels measured, with intubation and ventilatory support provided if airway protection is required or gas exchange is impaired. Whilst hyperventilation has been widely used to control ICP in the past, there is increasing concern regarding the induction of critical cerebral ischaemia by hypocapnic vasoconstriction. Current recommendations suggest that near-normal $PaCO_2$ levels (4.5–5 kPa) should be maintained, with moderate hyperventilation ($PaCO_2$ 4.0–4.5 kPa) guided by jugular bulb oximetry, and reserved for the control of acute episodes of severe intracranial hypertension. Attention should also be paid to treating epilepsy and significant pyrexia, both of which can precipitate rises in ICP, and to discontinuing or reversing the action of drugs such as opiates, which may be responsible for physiological derangements that precipitate ICP elevation.

Treatment of the underlying condition

Early neurosurgical evaluation and operative therapy may be lifesaving if a patient has an acute intracranial haematoma, a large tumour, or established hydrocephalus. Specific antimicrobial therapy may be required for meningitis, encephalitis, or a brain abscess. Systemic arterial hypertension commonly accompanies intracranial hypertension: it should generally not be treated since it may be needed to preserve cerebral perfusion. It is best to avoid nitric oxide donors such as nitrates if therapy is needed for extreme hypertension or for hypertensive encephalopathy: these can cause cerebral vasodilatation and further increase ICP.

Specific treatment of intracranial hypertension

Several therapies can be used to reduce intracranial pressure: their application will depend on the cause and severity of ICP elevation. Commonly used interventions and their indications are outlined in Table 1, but it must be pointed out that few of these have been assessed by good-quality outcome studies.

Treatment pathways for the emergency management of an unconscious patient with suspected intracranial hypertension are outlined in Table 2.

16.6.3 Brainstem death and organ donation

M. J. Lindop

Introduction

The statement by the Conference of Royal Medical Colleges and their Faculties in 1976 led to the establishment of the concept of brainstem death in British practice. Similar procedures took place in many other countries, such as The President's Guidelines in the United States in 1981. Although the motive was to clarify the practice of organ donation for transplantation, the concept has proved useful in determining appropriate care for many patients in intensive care who are certainly not suitable as organ donors.

The concept of brainstem death

Brain death in the United States is defined as the 'irreversible cessation of all functions of the entire brain, including the brainstem... that are clinically ascertainable'. In the United Kingdom the focus has been on brainstem function since it is argued that, in the absence of brainstem function, there will be no activity of the reticular formation and the capacity for consciousness is lost. Deep unconsciousness results from damage bilaterally to a circumscribed area in the tegmentum of the mesencephalon and the rostral pons. In the determination of brainstem death, there is no testing of the function of other areas of the brain, such as electroencephalography of the cerebral cortex. The diagnosis can be made on clinical signs alone, and half of those who fulfil the necessary clinical criteria will have a cardiac arrest despite intensive treatment within 24 h, and this happens to almost all within 72 h.

Managing the patient who is potentially brainstem dead (Fig. 1)

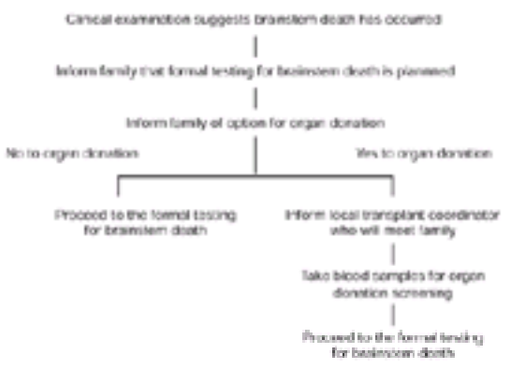

Fig. 1 Management of brainstem death diagnosis.

The patient with severe brain damage will be unconscious and on a ventilator. There will have been testing to chart progress showing that it is likely that the clinical signs of brainstem death will be present. The admitting consultant or the intensive care consultant should see the family to discuss the severity of the brain damage. They are told that there will be formal clinical testing of brainstem reflexes that will determine whether there is any prospect of recovering consciousness. A timetable for this testing is proposed. This interview is an opportunity to discuss the option for organ donation with the family. Organ donation when brainstem death occurs is now well known to the public, and often the family will be the first to raise the matter. In the United Kingdom there is no legal obligation for the doctor to raise the subject, but many families will feel cheated if they have had no chance to offer organ donation: they feel comfort when donation is seen as the only good that can come out of the disaster of an unexpected death. A transplant co-ordinator will be available to meet the family and discuss the process of organ donation. This is the time to check whether the patient fulfils the criteria for acting as an organ donor. The family may decide which organs should be available for donation, but they may not influence or make conditions regarding the choice of recipient.

Diagnosis of brainstem death

Planning the tests (Fig. 2)

Fig. 2 Organization of brainstem death testing after first family interviews.

The diagnosis must be confirmed by two medical practitioners that are competent in neurological examination and have been registered with the General Medical Council for more than 5 years. At least one should be a consultant, and neither can be a member of the transplant team. They can conduct the tests either separately or jointly. A second testing is done at a later time to remove the risk of observer error. The interval between the tests is not fixed, but usually between 1 and 6 h: it should be based on clinical judgement that will reassure all those concerned with the care of the patient that there has been a measured assessment. The legal time of death is the completion of the first set of tests that reveals no brainstem function. The declaration of death and, if organs will not be donated, the stopping of the

ventilator take place after the second testing. Most intensive care units now have a proforma which guides the process of testing.

Performance of the tests

There are three essential components to the clinical testing of brainstem function prior to the declaration of brainstem death—preconditions, exclusions, and clinical criteria.

Preconditions

1. The diagnosis must give an aetiology that confirms that the damage is irreversible.
2. The patient must be in unresponsive coma, though spinal reflexes do not exclude the diagnosis.

Exclusions

Reversible causes of coma must be excluded with certainty.

1. Drug activity, such as narcotics, muscle relaxants, or hypnotics. Due attention must be made to the possibility of prolonged action from previous overdosage, or from metabolism that could be impaired by hepatic or renal failure.
2. Metabolic or endocrine causes of coma—such as hypoglycaemia, hyperglycaemia, hyponatraemia, hepatic failure, uraemia, myxoedema, or Reye's syndrome.
3. Hypothermia—there is no fixed recommendation, but testing should be done at higher than 35°C.

Clinical criteria

These tests show absence of brainstem reflexes, and absence of spontaneous respiration. It is helpful to remember them by relating them to the relevant cranial nerves.

1. No pupillary response to light (II, III).
2. Absent corneal reflexes (V, VII).
3. Absent vestibulo-ocular reflex (VIII)—no nystagmus with installation of 20 ml of cold fluid into the unblocked ears.
4. No motor response within cranial nerve distribution with pain stimulus to face, trunk, or limbs. No limb response to painful pressure over supraorbital notch (V, VII).
5. Absent gag reflex (IX).
6. Absent cough reflex (X).
7. Absence of spontaneous respiration—the apnoea test. At the beginning of reflex testing, the ventilator should be set to deliver 100 per cent oxygen to denitrogenate the lungs (for more than 10 min). A blood gas may be taken. The patient is disconnected from the ventilator and oxygen is insufflated via a catheter into the tracheal tube. Although less than 1 litre/min is absorbed, a flow of 6 litre/min is usually recommended. In apnoea the $PaCO_2$ rises at between only 0.5 and 1 kPa/min. Careful observation of the patient for respiratory movements during the disconnection continues until a blood gas shows that the $PaCO_2$ has risen to more than 7 kPa (just over 50 mmHg). Oxygenation is usually well maintained. An alternative arrangement is to connect the patient to an anaesthetic breathing circuit with a reservoir bag. Respiratory movements may be seen more easily, but small cardiac pulsations can be transmitted and these can be mistaken for breathing activity by inexperienced staff. The patient is usually reconnected to the ventilator once the target $PaCO_2$ is reached if this is the first testing, or if organ donation is planned.

The patient who is brainstem dead and will not become an organ donor

After the completion of the apnoea test in the second testing, the oxygen catheter is removed from the tracheal tube, the patient is not reconnected to the ventilator and death is pronounced. The heart will stop over the next 15 min.

The patient who is brainstem dead and will become an organ donor

Acceptability as an organ donor

Transplant co-ordinators will ensure that the criteria in Table 1 are met.

Clinical management of the organ donor on the intensive care unit

The management of the patient now changes dramatically. Previously all therapy has been directed at maintaining cerebral perfusion to preserve brain function. Now the emphasis changes to care of the potential donor organs. The transplant co-ordinator is informed that the tests have now been completed and have confirmed brainstem death, and the donor operation is arranged as soon as possible.

The common problems of the organ donor are hypotension, cardiac arrhythmias, diabetes insipidus, pulmonary oedema, and disseminated intravascular coagulation.

Cardiovascular problems

Cardiovascular instability is the commonest problem in the organ donor. Brainstem death leads to high catecholamine levels that may increase heart rate, blood pressure, cardiac output, and systemic vascular resistance. Widespread myocardial ischaemic damage can occur associated with defective oxidative metabolism. These changes in autonomic tone, combined with myocardial ischaemia and metabolic and electrolyte instability, all lead to a high incidence of cardiac rhythm disturbance. The ECG may show atrial and ventricular arrhythmias, atrioventricular conduction blocks, and widespread ST-segment and T-wave changes.

An initial hypertensive phase is followed by hypotension in 80 per cent of patients, the common causes of which are shown in Table 2.

Cardiovascular management

Instability is so common that direct arterial and central venous pressure monitoring are essential. A pulmonary artery catheter often proves useful. Targets for management are:

1. mean arterial pressure at least 70 mmHg;
2. central venous pressure about 10 mmHg; and
3. urine output at least 1 ml/kg per hour.

Fluid replacement should be with blood or colloid, though urinary losses should be replaced with electrolyte solutions (nasogastric water or intravenous 5 per cent dextrose in uncontrolled diabetes insipidus). Likely electrolyte imbalance such as hypokalaemia must be sought by regular blood electrolyte measurements. Anti-arrhythmic drugs, inotropic agents, and vasopressors may be required. Inotropes and vasopressors are used as sparingly as possible since the direct action of large doses will threaten perfusion and function of the donor organs. Their use should only be considered when cardiac output studies confirm an indication; for example, when a profound fall in systemic vascular resistance with high cardiac output may justify use of noradrenaline in a minimal dose of 0.02 µg/kg per min. Some protocols use dopamine at 2 µg/kg per min routinely to improve renal, mesenteric, and coronary blood flow. Dopexamine at 1 µg/kg per min may give similar benefit. Use of a hormone replacement regimen may improve cardiovascular stability (see below).

Tight control of fluid balance is important as overload can impair organ function, particularly in lung transplantation.

Endocrine problems

Pituitary damage leads to failure of endocrine homeostasis. Tri-iodothyronine (T_3) and thyroxine (T_4) levels fall. Loss of antidiuretic hormone (ADH) leads to diabetes insipidus in up to 65 per cent of donors: Table 3 shows the characteristics of this condition. Cortisol production may fall, though this does not seem to correlate with cardiovascular changes. Blood sugar control is often defective and an insulin infusion is commonly required.

Endocrine management

The routine use of endocrine supplements is not established. Animal studies show no correlation between hormone deficiencies and cardiovascular instability, but endocrine supplements should be used where there is significant cardiovascular instability with substantial inotrope requirements. A suitable regimen is:

1. tri-iodothryonine as a 4 µg bolus with infusion of 3 mµg/h;
2. desmopressin or vasopressin (see Table 3);
3. insulin at 1 unit/ml, with continuous infusion of 1 to 10 ml/h titrated to keep blood sugar at 6–8 mmol/l; and
4. hydrocortisone supplements at 100 mg every 2 h (there is no risk of toxicity during the short period prior to donation).

Respiratory problems

The organ donor commonly has some pulmonary dysfunction. Possible causes are pneumonia, aspiration of gastric contents, neurogenic pulmonary oedema, and direct contusion.

Respiratory management

Controlled ventilation is used to achieve $PaCO_2$ in the normal range (4.5 to 5.5 kPa) to avoid hypocapnic reduction of peripheral oxygenation and disruption of regional blood flows. Sufficient oxygen is given to achieve a PaO_2 of 11 to 13 kPa. A large tidal volume (12 to 15 ml/kg) delivered at a low ventilatory rate promotes gas exchange and reduces atelectasis. Modest positive end-expired pressure (**PEEP**), about 5 cmH_2O, is useful, but higher levels may impair cardiac output, and hepatic and renal blood flow.

'Neurogenic' pulmonary oedema occurs in about 20 per cent of donors. The causes of this are not known and there is no specific therapy. The usual approach is to monitor the circulation closely and endeavour to optimize left ventricular function. PEEP often helps, but even at high levels (up to 15 or 20 cmH_2O) is not always effective.

Unless there is pulmonary oedema, regular tracheal toilet to prevent accumulation of secretions and atelectasis is important. Strict asepsis must be maintained as the lungs may be implanted into a recipient prone to infection. If PEEP is being used, then tracheal suction should be used sparingly and via a closed system.

Coagulation abnormalities

Disseminated intravascular coagulation can be precipitated in 30 per cent of donors by release of tissue thromboplastin, fibrinolytic substances, and plasminogen activators in severe head injury. Characteristic changes are thrombocytopenia with fall in fibrinogen levels and the appearance of D-dimer fibrin degradation products. Effective haemostasis is needed during the donor operation to reduce blood loss and maintain cardiovascular stability. Fresh frozen plasma and platelets should be given to correct the deficiencies. Antifibrinolytics such as epsilon aminocaproic acid must be avoided in case they provoke microvascular thrombosis in donor organs.

Temperature control

Temperature regulation is impaired. Heat production falls with low metabolic rate and muscle inactivity. Vasodilatation promotes heat loss. Cooling can lead to impaired oxygen delivery to tissues, aggravation of cardiac arrhythmias, increased diuresis, and impaired platelet function. There should be active warming (higher than 35°C) by use of limitation of exposure to the environment, warming blankets, fluid warming, and proper humidification of inspired gases.

Clinical management of the organ donor operation

The operation lasts 3 to 6 h. Four units of blood should be cross-matched to compensate for blood loss. Although anaesthesia is not required, an anaesthetist will be required to supervise cardiovascular monitoring and maintenance of a stable circulation. Reflex hypertension can be a problem and small doses of vasodilating isoflurane or intravenous vasodilators are often required.

16.6.4 The patient without hope

M. J. Lindop

The nature of the problem

A long-standing dilemma for doctors has been to judge the appropriateness of further treatment for patients who are already gravely ill. There has commonly been a reluctance to embark on major treatment, such as mechanical ventilation, for fear that it will be more difficult to withdraw this treatment than to avoid its introduction in the first place. Decisions are made on a constantly changing background—the views of society on the ethics of medical management, and the efficacy of new medical techniques are two prime factors.

Who is the patient without hope?

The public finds increasing difficulty with the concept that death is inevitable. There can be a pressure to prolong life for its own sake. Most people would cite as abilities that were important features for an adequate quality of life:

1. an ability to interact with others;
2. an awareness of his or her own existence with a pleasure in the fact of that existence; and
3. an ability to achieve some purposeful or self-directed action, or some self-set goal.

Where it is possible to know the patient's own wishes and values, it may be possible to infer whether he or she would consider life-prolonging treatment to be beneficial.

How certain is the outcome of a medical treatment?

Many treatments in intensive care will prolong life (mechanical ventilation or haemofiltration) but may not have a high likelihood of allowing complete recovery. Scoring systems, such as **APACHE** (Acute Physiology And Chronic Health Evaluation), and later APACHE II and III, have been developed to describe the severity of initial illness and have had some success in predicting hospital mortality. However, they have proved of little value in making decisions on individual patients.

Is the decision to withdraw treatment different from the decision not to institute therapy?

Although it is emotionally easier for the doctor to avoid embarking on treatment than to withdraw it once started, there are no legal or moral differences between these options. The patient will never have the chance of benefit if the treatment is untried. Precedent is not useful in determining the appropriateness of treatment. A treatment is reviewed by looking forward to whether the patient will gain benefit from it. Prolongation of life itself is not necessarily a benefit unless it is associated with the aforementioned qualities. If no benefit can be argued, a treatment should be withdrawn. Knowing that it is possible to withdraw a treatment can give the confidence to embark on that treatment where its outcome is uncertain.

Ways of tackling the problem

How is the decision to withhold or to withdraw treatment made?

The patient

Some patients, such as those with particular types of advanced neurological disease, will be able to participate in decision making. This may be in the form of an advance directive made before the moment of decision about life-prolonging treatment. In this situation the patient's view is paramount and limits the need for further discussion, but it is important that a full account of treatment options and their implications is given and that the patient is judged to understand the issues involved. The challenge for the physician is to embark on these discussions: they must not be avoided, but must take place at a time that has been chosen with the advice of family and nursing staff.

The family

Much time may need to be spent with the family to gain information about the quality of previous lifestyle, and the likelihood that the patient will see life-prolonging treatment as a benefit. They should understand and support any discontinuation of treatment, but should not be asked to make the decision to stop treatment, or be put in a position where they think that they are being asked to do so. This is rarely a problem if full discussions have taken place throughout the course of the illness. In rare instances, families can have complex structures and it will be clear that they are not able to put the interest of the patient first. In this situation further discussions may be required and the help of social workers and religious advisers can be useful in orchestrating dialogue. Neither the next of kin nor those with enduring power of attorney have any legal right to determine treatment. This responsibility remains with the doctor assisted by the health-care team, and, very rarely, by the courts of law.

The medical, nursing, and paramedical team

Much important information can be gained by talking to the patient's own doctor (general practitioner). The nurses caring for a patient over a prolonged period will be able to provide much useful information and should be consulted. Several physicians may have cared for patients with complex problems. In an intensive care unit there will be a team of consultants, and a formal arrangement should be made to consult all these doctors in the process of making the decision. Their opinions should be carefully documented. Their help will be needed to answer the essential questions:

1. Is the diagnosis secure? Are further investigations required before a decision can be made?
2. Is the benefit of further treatment to the patient clear?
3. Is the invasiveness of any treatment justified in the circumstances?

How can treatment be withdrawn?

Once a decision is made a drug or a feeding regimen can simply be stopped. An intermittent therapy such as haemofiltration can be omitted. However, patients who are mechanically ventilated need more careful management. Despite the discussions about terminal weaning of patients in the 1980s, a survey of critical care physicians in 1994 revealed widespread disparity of practice.

Terminal weaning is a protocol that allows death with dignity as mechanical ventilation is discontinued without causing distress to the patient or his family and carers. This is conducted as follows:

1. Stop vasoactive and antibiotic drugs.
2. Stop any paralysing drugs.
3. Continue sedatives and analgesics to avoid distress.
4. Continue physiological monitoring and recording of observations and medical actions.
5. Change the mode of ventilation to synchronized intermittent mandatory ventilation (**SIMV**), which allows the patient to breathe but superimposes a defined number of breaths per minute.
6. Halve the SIMV rate every 30 min until less than 6. Then discontinue SIMV.
7. Use morphine to control dyspnoea and benzodiazepines to control restlessness.
8. If breathing has become stable, allow the patient to breathe spontaneously, and consider lying the patient on the side for extubation.
9. Usually the patient will have died by this stage, but it may be necessary to transfer them to a general ward area for basic care. This can be very disruptive for the family and should be avoided if possible.

Decisions not to escalate treatment, and not to resuscitate a patient

Careful discussions as described above, which should be clearly documented in the medical notes, are a prerequisite of making decisions not to escalate treatment, or not to resuscitate a patient. The decisions must be reviewed each day by the consultant in charge of the patient to ensure their continuing relevance.

Do not escalate

If further complications supervene it can be decided that new treatment is unlikely to give the patient real benefit. A 'do not escalate' order is made so that no therapies will be added. Typically it may be decided not to increase the inotrope dose, not to use haemofiltration, not to transfuse blood or blood products, or not to implement or to increase ventilatory support. In summary, treatment continues only whilst the patient continues to show a beneficial response.

Do not resuscitate

In similar circumstances it may be appropriate to decide that in the event of unexpected circulatory arrest no resuscitation will be attempted. If the documentation is not clear, a resuscitation attempt will be necessary and this can be very distressing to the family at the bedside if it seems inappropriate. Where circulatory arrest has occurred as a result of a drug administration error, a tension pneumothorax, or a complication of therapy, it may be appropriate that a limited (5 min) attempt at resuscitation is made despite the existence of a 'do not resuscitate' order.

Does basic care include provision of fluids and nutrition?

Basic care provides warmth, shelter, hygiene, and comfort to the patient by relieving pain and distress. It includes the regular offer of oral fluid and nutrition. Fluid and nutrition provided 'artificially' by intravenous infusion, or by tube (whether nasogastric or percutaneous endoscopic gastrostomy—PEG), is considered a form of treatment and as such can be withdrawn (although in the specific instance of the persistent vegetative state in England and Wales, review by a court of law is needed).

Summary

Key points in the management of patients who are severely ill and in whom escalation of treatment may not be kind or sensible are:

1. early anticipation of possible outcomes;
2. continuing review of whether treatments remain beneficial;
3. establishment of local guidelines for limiting or withdrawing treatment;
4. good communication skills within the health team;
5. good communication skills with the patient and the family; and
6. clear documentation of decisions.

Case report

An 80-year-old patient with many severe chronic health problems is admitted shocked with acute abdominal pain. A laparotomy is required to establish the diagnosis. The patient may be admitted to an intensive care unit for stabilization prior to surgery.

1. The bowel is extensively infarcted with no hope of survival. The patient is extubated at the end of surgery, and is allowed to die peacefully with appropriate analgesia and sedation, perhaps in the post-anaesthesia care unit or the general ward.
2. There is extensive peritoneal sepsis that could respond to definitive surgery and antibiotic therapy. The patient is admitted to an intensive care unit where monitoring and initial treatment is aggressive. Limits are set beyond which treatment will not escalate. These may be a maximum dose of adrenaline of, say, 0.25 µg/kg per min, no haemofiltration in the event of renal failure, and no resuscitation and no continuing mechanical ventilation after 48 h if there has been no improvement.

17.1.1 The upper respiratory tract

J. R. Stradling

The upper respiratory tract extends from the anterior nares to the larynx. This part of the respiratory tract has to cope with specific problems: it is exposed to incoming air and has to double as the entry to the digestive system. This has led to specific evolutionary adaptations which are not always perfect.

The nose

The anterior nares, which includes the nasal valve just inside the nose, is usually the narrowest part of the respiratory tract and accounts for about 40 to 50 per cent of the total respiratory resistance. In normal subjects the resistance in the lower airways is small (less than 25 per cent) compared with the larynx and nose. This anterior nasal resistance is actively controlled by the levator alae nasi and procerus muscles, which flare the nostrils, and the compressor naris muscle, which narrows the nasal valve further. During mild exercise these muscles (combined with sympathetic nasal mucosal vasoconstriction) can halve the nasal resistance and allow minute ventilations up to 30 litre/min before conversion to oral breathing is necessary. These muscles receive a phasic inspiratory signal, to brace open the nares with each breath, just in advance of diaphragmatic activity.

Occasionally, owing to deformity of the anterior nasal cartilages, the anterior nares are very narrow and limit inspiration, particularly during sleep when the dilator muscle activity is reduced. This is one of the rarer causes of snoring which is amenable to treatment.

The main function of the nose is as first-line defence against problems with the incoming air. In this respect it acts as a coarse particle filter and a conditioner (temperature and humidity) of the air, and with the sense of smell helping to detect noxious substances that are best avoided. The turbinates in the nose present a surface on to which large inhaled particles, such as pollen grains and house dust mite faecal particles, will be retained, with the potential for an allergic response producing allergic rhinitis. Debris arriving on the mucosal surfaces is wafted backwards to be swallowed eventually. Without this so-called 'mucociliary carpet' there is decreased resistance to infections (usually a generalized respiratory problem and not just in the nose) with pooling of mucopurulent material, and recurrent sinus infections. This mucociliary function can be tested by placing a saccharine tablet on the anterior floor of the nasal cavity and timing the period that elapses before it can be tasted in the oral cavity. The normal interval is about 15 to 20 min, but when ciliary defects exist this can extend to an hour or more.

The turbinates fill such a large proportion of the nasal cavity that minor swelling produces large changes in nasal airflow resistance (Fig. 1). There are several rich vascular beds at different depths in the nasal mucosa, providing a large surface area to warm and humidify incoming air. These are supplied by the sphenopalatine branch of the maxillary artery, with venous drainage passing back into the cavernous sinus around the carotid artery. The volume of fluid in these vascular beds is controlled via the vidian nerve (containing sympathetic vasoconstriction and parasympathetic vasodilation) acting on both arterioles and venules. The overall blood flow and total volume of blood in the sinusoids determines the degree of mucosal congestion, which undergoes a cyclical reciprocal change across the two sides of the nose over 2 to 4 h, that is, as the mucosa on one side is congesting, that on the other side is shrinking. This cycle, usually only obvious to individuals with already narrowed nasal passages (when blockage can occur intermittently), can be interrupted by a reflex mediated by pressure on the side of the thorax or in the axilla. Thus, in the decubitus position, the upper nostril becomes clearer and the lower more congested, with the two sides swapping within a minute or two of turning on to the other side. The purpose of this nasal cycle is not known, but using the upper rather than the lower nostril when lying on one's side may lessen the chance of inhaling particulate matter. In addition to this effect, there is a general increase in nasal congestion on lying down due to a hydrostatic rise in capillary pressure.

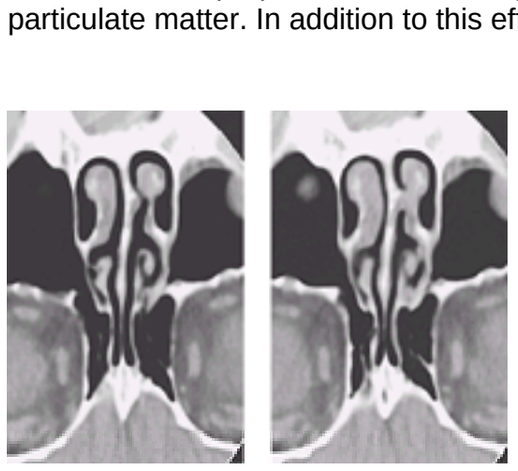

Fig. 1 Coronal sections of human maxillary sinuses and the turbinates in the nose. The view in the panel on the left is taken after ephedrine drops and shows mucosal shrinkage. The consequent small increase in the size of the lumina was attended by a large increase in maximum nasal airflow. (By courtesy of Dr F. Gleeson.)

The volume of fluid needed to humidify the incoming air is considerable, but is reduced by condensation of some of this moisture back on to the cooler nasal mucosa during exhalation. Of course, this conditioning is lost during oral breathing, which has important implications for exercise-induced asthma, which is due to cooling and drying of intrathoracic airways.

Nasal secretions come mainly from submucosal glands that are stimulated by parasympathetic (cholinergic) fibres. There is some evidence that sympathetic activity can also stimulate secretions, but of higher viscosity.

The sensory fibres from the nose travel in the maxillary nerve (mainly the ophthalmic branch) and are the afferent limb of some interesting reflexes. Airflow is sensed and can itself influence breathing pattern. Nerves containing substance P in the epithelium seem to be responsible for sensations leading to sneezing. Sneezing is like coughing in that an explosive expiration is generated in an attempt to expel foreign matter. Coughing involves closure of the larynx until pressure builds up, whereas sneezing involves closure of the pharynx. Unlike coughing, sneezing is never voluntary. Sensory fibres from much of the upper airway, nose, and face are also involved in the diving reflex. This reflex is of great importance to diving mammals when the combination of facial stimulation by cold water, apnoea, and hypoxaemia produce intense peripheral, splanchnic, renal, and muscular vasoconstriction. This diverts blood to the brain and conserves oxygen (producing a heart–lung–brain circulation that prolongs diving time), with the rise in blood pressure limited by a marked vagally induced bradycardia. This vestigial reflex in humans can be utilized in the control of some cardiac arrhythmias, when a brisk increase in vagal tone can be produced by applying ice-cold water to the face.

Nasal irritation can lead to either bronchoconstriction or bronchodilation. The bronchoconstriction can be prevented by atropine and is presumably vagally mediated. This reflex may be important in provoking bronchospasm in some asthmatics. Negative pressure in the nasal cavities can also be sensed, producing a reflex increase in upper airway dilator action (see the following section on the pharynx).

Olfaction depends on recognition of molecules by mucosal receptors at the very top of the nose. These olfactory cells have central axons that pass through multiple tiny holes in the skull (cribriform plate) to the brain. At this point they are very vulnerable to shearing forces during a blow to the head, leading to anosmia (loss of ability to smell).

The pharynx

The pharynx is divided into the nasopharynx, oropharynx, and laryngopharynx or hypopharynx—behind the soft palate, the back of the oral cavity down to the tip of

the epiglottis, and the tip of the epiglottis down to the cricoid cartilage, respectively. Thus the top end is level with the base of the skull and the bottom end is about level with the sixth cervical vertebrae, giving an overall length of about 12 cm. When being used to breathe through, the pharynx has to be a rigid tube (like the trachea), but during swallowing it has to be a collapsed tube capable of peristalsis (like the oesophagus). This combination of functions is achieved by having a muscular tube that can constrict to propel food, but also has external muscles whose function is to brace open the pharynx when required. Figure 2 shows the enormous complexity of the pharyngeal musculature, supplied mainly by the hypoglossal nerve (XII). The pharyngeal constrictors (superior, middle, and lower) are the main peristaltic muscles; the lower part of the inferior constrictor also functions as a sphincter to the top of the oesophagus, preventing air entry during inspiration. Most of the other pharyngeal muscles work in concert to hold open the pharynx. For example, the genioglossus pulls forward the tongue, the geniohyoid together with the strap muscles (sternothyroid, thyrohyoid, etc.) pulls forward the hyoid (enlarging the oropharynx), and the stylopharyngeus probably pulls sideways on the lateral pharyngeal walls. The palatopharyngeus will hold open the pharynx if supported by the levator palati, but will also pull forward the palate to open the nasopharynx. The upper pharyngeal muscles (tensor palati and levator palati) also close off the nasal cavity during swallowing to prevent regurgitation of fluids into the nose. To prevent aspiration, closure of the larynx and the false cords above is co-ordinated with swallowing. Some of these actions require sensory information about the exact location and consistency of any food being swallowed, carried via the glossopharyngeal and vagus nerves (IX and X). Sensory branches of these nerves also supply the ear, which explains why pharyngeal lesions may present with pain in the ear.

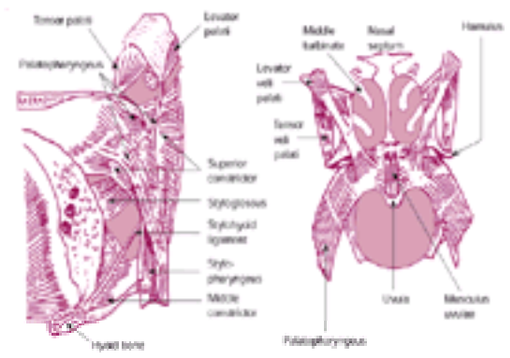

Fig. 2 Two views of the pharyngeal muscles: from inside the pharynx looking laterally, and from high up on the posterior pharyngeal wall looking anteriorly. These muscles act in concert and the physical effect of their contraction depends on which other muscles are simultaneously activated.

Given the complexities of pharyngeal function, it is not surprising that severe swallowing difficulties with aspiration of food and drink are often seen following cerebrovascular accidents in the brainstem involving the control of pharyngeal muscles and the sensory pathways.

Powerful mechanisms are available to maintain patency of the pharyngeal airway during breathing. As with the alae nasi, the pharyngeal dilator muscles receive a respiratory input in time with diaphragm activation. The diaphragm receives a gradually increasing level of phrenic activity to overcome elastic recoil as tidal volume increases, whereas the pharyngeal activation follows more of a 'square wave'. This makes teleogical sense, since the collapsing force is dependent on inspiratory flow and this is roughly constant throughout inspiration. In addition, if pharyngeal patency is threatened, the dilator activity increases. Figure 3 shows the increase in genioglossus tone in response to a fall in intrapharyngeal pressure. This negative pressure will pull in the pharyngeal walls, and there are thought to be 'distortion' receptors of some kind mediating this reflex. Snoring occurs when the pharynx narrows enough to vibrate, and there is some evidence that this vibration itself can also activate pharyngeal dilators, thus warding off full collapse. The factors predisposing to pharyngeal collapse during sleep are discussed in Chapter 17.8.2.

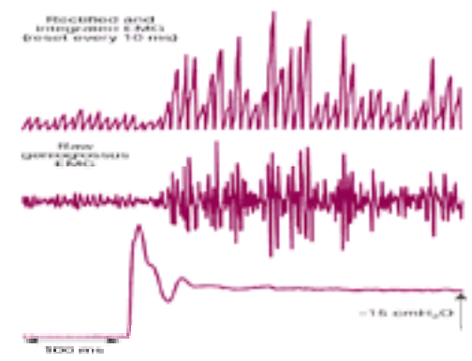

Fig. 3 Response of the genioglossus muscle in a conscious human to a sudden fall in intrapharyngeal pressure. The time delay (about 50 ms) is too short to be due to a cortical response and is presumably a spinal cord reflex. (Reproduced from Horner 1991, with permission.)

Sets of lymphoid tissue (Waldeyer's ring), comprising the adenoids, the palatine tonsils, and the lingual tonsils (back of tongue), are situated in the pharynx. These subepithelial collections of lymphoid tissue are ideally suited to process inhaled and swallowed antigens. Unfortunately, if they hypertrophy too much in response to recurrent infections, they are also positioned such that they obstruct the airway, particularly in small children. This is usually first apparent during sleep, but may become severe enough to provoke inspiratory stridor, even while awake. Adenoidal enlargement, by blocking nasal airflow, will force mouth breathing which, if it occurs early enough (perhaps under 18 months of age), retards development of the lower jaw (the so-called 'adenoidal facies'). This probably leads to overcrowding of the teeth and a narrower retroglossal space (this is further discussed in Chapter 17.8.2).

The larynx

The larynx (Fig. 4) has three important functions: communication, protection of the airway, and dynamic control of lung volume.

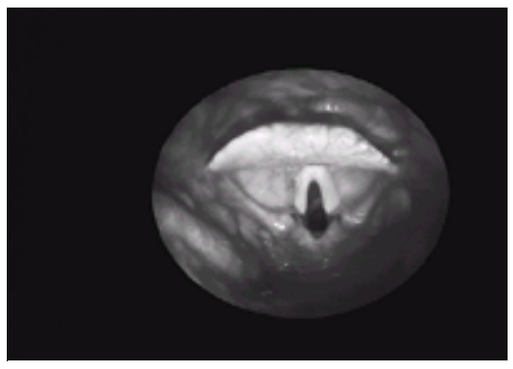

Fig. 4 Bronchoscopic view of the larynx from above. The top of the picture is the anterior. (By courtesy of Dr P. Stradling.)

A minority of the intrinsic and extrinsic muscles of the larynx (e.g. cricothyroid, posterior cricoarytenoid) open (abduct) or brace the vocal cords, whereas the majority (e.g. thyroarytenoid, transverse and oblique arytenoids) close (adduct) the cords. The recurrent laryngeal nerve (from the vagus) supplies all the muscles apart from

the cricothyroid (supplied from the superior laryngeal nerve, which is also a branch of the vagus). The left recurrent laryngeal nerve comes off the vagus and passes under the aortic arch before running up close to the thyroid gland to the larynx. This means that it can be damaged by a tumour at the left hilum and surgically during a thyroidectomy. The right recurrent laryngeal nerve passes under the right subclavian artery where it can be damaged by a right-sided apical lung tumour.

Complete paralysis of the recurrent laryngeal nerve gives permanent hoarseness of the voice, and the affected cord assumes a position midway between full abduction and adduction. The cord is floppy and can be moved passively very easily, being 'sucked' towards the mid-line during inspiration and blown open during expiration. The unparalysed cord may eventually compensate to some degree and move nearer the paralysed cord, improving the voice. If paralysis of the recurrent laryngeal nerve is incomplete, the affected cord may take up the adducted position, presumably because fibres running to the abductors are amaged first. When there is bilateral damage to the recurrent laryngeal nerves, loss of adequate abduction causes inspiratory stridor as the cords are passively drawn together.

As mentioned earlier, there are reflexes initiated by supralaryngeal sensory fibres (mainly via the internal branch of the superior laryngeal nerve) designed to protect the airway. Fluid or food landing on or near the vocal cords will provoke coughing and/or laryngeal closure. During sleep, irritation of the cords tends to produce apnoea and laryngeal adduction, and coughing occurs only when wakefulness supervenes.

One of the less well-known functions of the larynx is to brake expiratory flow and thereby control lung volume. In some species, and in neonates, laryngeal expiratory braking is very important, acting rather like positive end-expiratory pressure to maintain end-expiratory lung volume above the passive functional residual capacity, thus preventing atelectasis. In adults there is no good evidence that the rate of expiration is under active laryngeal control, but this mechanism may come into action during respiratory illnesses (such as pneumonia), especially if there is marked hypoxaemia. If the upper airway is bypassed, for instance by tracheostomy or intubation, then other mechanisms come into play to maintain end-expiratory lung volume, such as postinspiratory contraction of the diaphragm (thus delaying expiration) and shortening of expiratory time (thus starting inspiration again before lung volume has fallen too far). Figure 5 is from a tracheotomized dog with areas of atelectasis. This shows how once laryngeal braking is denied to the animal, expiration proceeds faster, lung volume falls, and expiratory time is shortened to produce tachypnoea. This reflex was not present when the areas of atelectasis had resolved. The clinical correlate of this is sometimes seen as an expiratory grunt in babies who have a respiratory illness. Intubation may worsen gas exchange in this situation unless positive end-expiratory pressure is also applied.

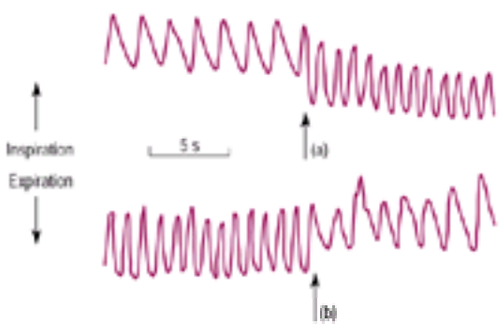

Fig. 5 Recorder tracings in a dog with atelectasis showing the effect of switching from upper airway to tracheostomy breathing (arrow at (a)) and from tracheostomy to upper airway breathing (arrow at (b)). The signal is from an inductive plethysmograph measuring movement of both the rib cage and abdomen which represents lung expansion and contraction.

17.1.2 Structure and function of the airways and alveoli

Peter D. Wagner

The organ of gas exchange

The lung is the organ of gas exchange, providing the means of transferring oxygen (O_2) from the air to the blood for subsequent distribution to the tissues. At the same time it enables removal of metabolically produced carbon dioxide (CO_2) from the blood, which is then exhaled to the atmosphere. Not just in health, but also in lung disease, the volumes of O_2 taken up and CO_2 removed by the lung per minute must equal the rate of O_2 consumption and CO_2 production by the aggregate tissues of the body.

The lung will also exchange any other gas that is presented to it, but the principles involved—passive diffusion—mirror those for O_2 and CO_2. Quantitative but not qualitative differences occur in how such gases (e.g. anaesthetic agents, carbon monoxide, toxic gases inhaled by accident) are handled by the lung. These differences stem from the means by which any particular gas is transported in the blood; whether in simple physical solution alone, or also in some chemical combination with molecules such as haemoglobin.

The principles are similar for gas uptake into blood and elimination from the blood. In fact, because gas exchange occurs by passive diffusion, whether a gas is taken up from the air into the blood or eliminated from the blood into the air depends simply on the partial pressures of the gas on each side of the blood–gas barrier, the 0.3-µm thick tissue layer separating alveolar gas from pulmonary capillary blood.

For transfer of a gas from the environment to the blood to occur, the gas in question must first be brought to the alveolar blood–gas barrier by the process of ventilation. Diffusion across this barrier then occurs at a rate proportional to: (i) the alveolar surface area available, (ii) the partial pressure difference between alveoli and blood, and inversely proportional to the thickness of the barrier, in concordance with the rules of simple passive diffusion. The gas molecules, now present dissolved physically in plasma, also distribute into the red cells. Depending on the gas, chemical associations may occur—with haemoglobin in the case of O_2, CO_2, carbon monoxide (CO) and nitric oxide (NO), and through transformation to bicarbonate ion for CO_2. The last element of the exchange process now occurs—the transport of the gas in blood pumped by the heart through the systemic circulation to the tissues of the body.

This chapter focuses on the first two of these three steps in gas exchange—ventilation and diffusion. A separate chapter deals with the third step—the pulmonary circulation (see Chapter 15.15.1). The structural basis of ventilation and diffusion, and the associated functional consequences, will be presented with particular emphasis on implications for disease. Lung diseases of many types commonly affect each of the steps involved in gas exchange, and the clinical consequences can usually be readily understood if the structure–function relationships are known.

Basic airway and alveolar design

In essence, the lung is a balloon undergoing cyclical inflation and deflation (ventilation, or tidal breathing) around some partially inflated state; the main anatomical elements are shown in Fig. 1. The gas-filled interior of the balloon corresponds to the alveolar gas spaces of the lung. The thin wall of the balloon may be likened to the blood–gas barrier, with the pulmonary capillary network imagined as covering the balloon's surface, separated from the interior gas by the elastic material making up the balloon's wall. The balloon is inflated through its neck (trachea) with each inspiration, thus bringing fresh air (21 per cent O_2, no CO_2) to the balloon's interior. This fresh gas is rapidly mixed with resident gas already present. This resident gas is partially depleted of O_2 by ongoing diffusion of O_2 into the capillaries, whilst at the same time, CO_2 is evolved into the gas from the capillary blood. Each inflation, by bringing fresh air into the alveoli, slightly increases alveolar P_{O_2} and decreases alveolar P_{CO_2}. Each deflation moves some of this alveolar gas back to the environment. This rids the lung of some CO_2, but also removes some O_2, albeit at lower concentrations than in room air. In normal quiet breathing, alveolar O_2 concentration averages about 16 per cent over a respiratory cycle, whilst that of CO_2 is about 5 per cent, and a long-term steady-state of gas exchange is achieved.

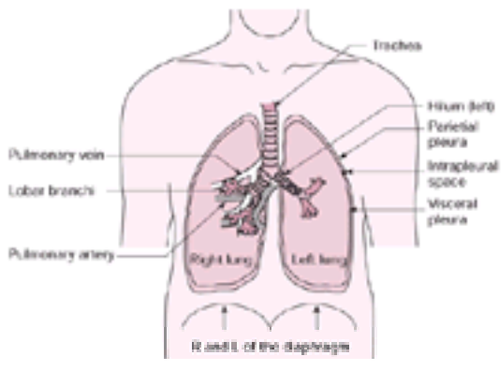

Fig. 1 The right and left lungs are separately encased within the thorax, and each is covered by a visceral pleural membrane. This is continuous with the parietal pleural membrane which lines the interior thoracic cavity, and the thin fluid-filled space between the visceral and parietal pleuras constitutes the intrapleural space. The hila of the two lungs contain the main stem bronchi, and accompanying pulmonary arteries and veins. The main stem bronchi join at the carina to form the trachea. The pulmonary arteries emanate from the right ventricle; the pulmonary veins empty into the left atrium. Within the lungs, the airways and blood vessels continue branching for approximately 20 generations. The major muscle of inspiration, the diaphragm, consists of two domes upon which the right and left lungs sit, and which separate the thoracic and abdominal contents.

Because the process of gas exchange depends on simple, passive diffusion, a large area of contact between alveolar gas and capillary blood is required to ensure sufficient gas flux across the blood–gas barrier to meet metabolic demand. The balloon analogy, while useful as an initial concept, thus exhibits a major difference from how the real lung is configured. The real lung has its total gas volume constituted not as a single balloon-like gas chamber, but as a very large number (about 300 million) of very small (radius, r, about 150 µm) almost spherical balloons or alveoli. Since the volume (V) of a sphere is $V = (4/3) \times p \times r^3$, while its surface area (A) is $A = 4 \times p \times r^2$, dividing a lung of a given volume (given because the lung must fit within the thoracic cage no matter whether as one large alveolus or 300 million small alveoli) into many small alveoli allows a much larger total surface area than if the lung were indeed a single large chamber, as seen from dividing the expression

for surface area by that for volume: $A/V = 3/r$. Since total volume V is fixed by the thoracic cage, total surface area A increases as the number of alveoli is increased because radius of each alveolus must be reduced if volume is to remain constant. A typical value for V is 4000 ml. A single sphere of this volume would thus have a radius of about 10 cm, and a surface area of about 1200 cm^2, only slightly more than 1 square foot. By contrast, 300 million alveoli, each with a radius of 150 µm, would by the above formulae have the same total volume, thereby fitting equally as well inside the chest, but have a total surface area of about 800 000 cm^2. This approximates the area of a tennis court, and is about 650 times larger than the 1200 cm^2 area were the lung a single chamber. Since the laws of diffusion state that diffusive gas transport is proportional to surface area, and since the maximal rate of O_2 uptake in a normal man is about 4000 ml/min in heavy exercise, maximal pulmonary O_2 exchange would be insufficient for life were the lung a single chamber, at 4000/650 or 6 ml/min. Normal resting O_2 utilization by the tissues is about 300 ml/min. These calculations serve to highlight the critical importance of dividing the lung into a large number of small alveoli, and set the stage for discussing the structural configuration of a lung that must find a way to ventilate simultaneously 300 million separate, miniscule units of gas exchange.

The lungs inside the thoracic cavity

As with a balloon, the lung cannot inflate itself (although, as an elastic structure, once inflated it is capable of unassisted deflation just like a balloon). Inflation requires creation of a pressure difference between the outside and inside of the lung, pressure being higher inside. This may be accomplished in one of only two ways. One is by positive pressure inflation, typical of most clinical ventilators that are connected to the trachea and produce inflation by mechanically increasing intratracheal airway pressure. Spontaneous breathing throughout normal life does not happen in this way, and so the only possibility of normally achieving lung inflation is by the second option—that of decreasing the pressure around the lungs below that of the surrounding air. This is accomplished by encasing the lungs within the closed thoracic cavity, and having the muscles in the wall of this cavity (the intercostal muscles and the diaphragm) contract when inflation is desired. Contraction of these muscles moves the diaphragm caudally and expands the rib cage in both anteroposterior and lateral dimensions. As a result, the pressure inside the thoracic cavity but external to the lungs (that is, within the intrapleural space) is reduced to below that of the air. Since the alveolar tissue is extremely thin and easily deformable, the pressure within the alveolar gas spaces is also reduced to below that of the air, and thus inflation occurs as a result of a hydrostatic pressure gradient from the mouth to the alveoli.

Inflation in the course of normal tidal breathing usually commences from a state of partial lung inflation that reflects that particular volume of the lung at which its own elastic recoil tendency to collapse is exactly balanced by the opposite, natural tendency of the rib cage to expand outwards. This volume is known as the functional residual capacity (**FRC**) and because it reflects recoil balance between lung and chest wall, it is the only volume which can be maintained without muscular effort. Thus, to inhale above FRC or to exhale below FRC both require respiratory muscle contraction, but the return to FRC from either higher or lower volumes can be passive, stored elastic energy provided by respiratory muscle contraction from the preceding active volume change being used to reverse the transpulmonary pressure difference and enable gas flow from the alveoli to the mouth.

Clinical significance

Elastic properties and lung volume

If the elastic properties of either the lungs or the chest wall are altered by disease, FRC will change. Should the lungs become less elastic, typically seen in emphysema due to disorganization of the elastin and collagen fibres making up much of the alveolar wall structure, the tendency for the lung to collapse is less, and the lung/chest wall recoil balance shifts to a higher lung volume, thus increasing FRC. By contrast, diseases characterized by proliferation of alveolar wall elements, collagen in particular, render the lung more elastic and thus collapsible, shifting FRC to lower values. These changes in FRC may be used to aid in diagnosis and in following the natural history and response to treatment of such diseases, since FRC is readily measured in the pulmonary function laboratory by either plethysmography or helium dilution methods. Changes in FRC also have important implications for lung function, discussed later in this chapter.

Whilst FRC is a key volume upon which to focus, the lung can normally be inflated to well above FRC, and also deflated to considerably below FRC. At maximal inflation, lung volume is referred to as the total lung capacity (**TLC**), while at maximal deflation, lung volume is called the residual volume (**RV**). Of major significance, RV is well above zero volume. As will be apparent, if all alveoli could be fully emptied of gas, they would be very difficult to reinflate to allow resumption of gas exchange, due to surface tension. The difference between TLC and RV is called the vital capacity (**VC**). As with FRC, each of these volumes is readily measured during routine pulmonary function testing, and together they provide a simple yet informative profile useful in characterizing many lung diseases and their progress. Unlike some physiological variables such as arterial pH or haemoglobin concentration, all of the above volumes depend to a major extent on body size. They also depend to a lesser degree on gender (smaller in females), age (deterioration with ageing), bodily habitus (often smaller in the obese), and ethnicity. Many tables of normal values have been published, and interpretation must allow for all of the determinants mentioned above.

Trachea, main bronchi, and pleura

For all 300 million alveoli to participate in the gas exchange process, each must be connected to the environment by an air pathway. The analogy now changes from a balloon to a tree. Imagining an upside-down tree, the main trunk represents the trachea, the single common airway segment through which inhaled and exhaled gas from all alveoli must pass. The upper end of the trachea begins at the lower margin of the larynx. The trachea lies anteriorly in the neck and chest, passing caudally in the midline retrosternally to the level of about the sternal attachment of the second rib. There it divides into left and right mainstem bronchi, each smaller and shorter than the trachea. These two airways angle caudally and laterally within the upper mediastinum to enter the left and right lungs at the left and right hilar regions, respectively, and they divide into the lobar bronchi, three on the right to feed the right upper, middle, and lower lobes, and two on the left to feed the two left lobes, upper and lower.

Note that the two hilar regions are the only normal points of actual connection of the left and right lungs to any thoracic structures, and also contain the large pulmonary arteries and veins, lymphatics, and nerves. The entire remaining lungs, while opposed against the chest wall, are not connected to it and are able to slide easily over the inner chest wall surface. This inner surface is covered by the parietal pleural membrane, and the outer surface of the lungs is similarly covered by the visceral pleural membrane. These two pleural membranes are joined at the hilar regions to form a fully enclosed sac that separates the lung and chest wall. The left and right pleural sacs do not communicate with each other, and normally contain only a very thin layer of plasma-like fluid and no gas at all. This arrangement may be pictured by imagining a sealed, but empty, plastic sandwich bag from which all air has been expelled and which contains a very small volume of water. If one's right hand is balled into a fist and invaginates this bilayered bag against the cupped left hand, we have the analogy to the right (or left) lung and chest wall. The balled right fist is the lung; the right wrist and forearm represent the hilar structures. The cupped left hand is the chest wall, and the two layers of the closed sandwich bag form the pleural membranes.

Clinical significance

Mainstem bronchial branching angles

The mainstem bronchial branching from the trachea is not quite symmetrical. The right mainstem bronchus continues caudally a little more directly in line with the trachea above it than does the left, which angles laterally more sharply. As a result, accidentally inhaled foreign bodies more frequently lodge in the right than left lungs. For similar reasons, advancing an endotracheal tube too deeply may cause it to lodge in the right mainstem bronchus rather than where intended—the trachea. This will result in lack of ventilation of the left lung, and if not recognized, hypoxaemia from continued perfusion of this unventilated lung with venous blood, and ultimately left lung collapse (over minutes to hours).

The intrapleural space and pneumothorax

The pressure within the pleural space (i.e. between visceral and parietal pleural surfaces) is normally subatmospheric because of the above-mentioned counterbalancing inward lung and outward chest wall recoil forces. This prevents lung collapse. Disruption of either the visceral or parietal pleura (i.e. pneumothorax) allows air to enter the pleural space, increasing the intrapleural pressure back to atmospheric. This results in collapse of the lung, with abolition of ventilation even if chest wall muscle contraction continues. Gas exchange therefore ceases, with life threatened. In humans, since the right and left lungs are encased in separate pleural sacs, if one side suffers pneumothorax, gas exchange can usually be maintained by the other. Pneumothorax can occur from rupture of lung surface alveoli in predisposed individuals, or from chest wall trauma in anyone. Whether the source of the intrapleural air is alveolar gas as in the former case or room air in the latter makes no difference. However, depending on conditions, intrapleural air pressure may actually rise above that of room air. This situation, the tension pneumothorax, can arise whenever air enters the pleural space via a valve-like mechanism, when the patient's respiratory effort or that of a mechanical ventilator can lead to intrapleural pressure rising well above atmospheric. The lung collapses, but the (increasingly desperate) respiratory effort or mechanical ventilator keeps pumping air

into the pleural space via the torn lung surface. This is a true emergency requiring immediate needle puncture of the chest wall of the affected side to relieve the built-up pressure. If this is not done, the high intrathoracic pressure compresses and distorts the mediastinum and vena cavae, impeding venous return. Both pulmonary gas exchange and the circulation fail, and death follows rapidly.

Mediastinal shifts

The separation of the right from left pleural spaces provides for lateral movement of the mediastinum should there be a difference in mechanical properties of the right and left lungs or their associated pleural spaces or chest wall structures. For example, fibrosis of the right lung, or alternatively its collapse from complete airway obstruction, will reduce the volume of intrathoracic contents and therefore pressure on that side, and mediastinal contents will shift towards the right, visible on chest radiography. In fact, the trachea may also be shifted from its normal midline location in this direction, evident on clinical examination of tracheal position just above the suprasternal notch. Conversely, a pleural effusion on the right or a right pneumothorax (see below) may raise intrathoracic pressure above that on the left, and have the opposite effects on mediastinal and tracheal position.

The bronchi and bronchioles

After the mainstem bronchi have arisen from the trachea, the airways continue an essentially dichotomous branching pattern until the alveoli are reached. Thus, successive branching yields of the order of 50 000 to 100 000 airways (called terminal bronchioles) that constitute the 16th generation ($2^{16} = 65\,536$). The entire collection of airways from the trachea to these last bronchioles before alveoli begin forms a system of connected conducting pipes needed to deliver gas between the alveoli and the environment during ventilation (Fig. 2).

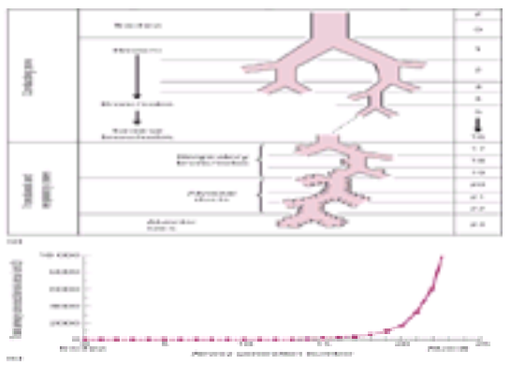

Fig. 2 (a) This shows a stylized model of the branching of the airways from trachea to alveoli encompassing some 23 generations of branching. The first 16 generations contain no alveoli and are purely conducting airways, but the next 7 generations contain progressively more alveoli in the airway walls and serve the dual -purpose of conducting air to the alveolar sacs and also providing gas exchange. (b) Total cross-sectional area of each generation shown in (a). This is obtained by multiplying the average cross-sectional area of a single airway by the number of airways in the particular generation. Cross-sectional area is small throughout the conducting zone (first 16 generations), but then increases exponentially in the respiratory zone. The implications are that the forward velocity of inspired gas falls dramatically in the respiratory zone such that diffusion becomes the faster mode of molecular movement. In addition, this diagram implies that during flow between the mouth and alveoli, most of the airways resistance resides in the first 15 generations. (Adapted from Weibel ER, 1984, with permission.)

As with the branching of a tree, both the diameter and the length of each successive branch falls. The trachea typically is 12 cm long and 2 cm in diameter. By contrast, the typical terminal bronchiole is just 1 to 2 mm long and 0.6 mm in diameter. Airflow is normally mostly laminar (except for that in the upper airways) and therefore is governed by Poiseuille's law of fluid dynamics. The essence of this law is that resistance to airflow depends inversely on the fourth power of the airway radius, but varies only in direct proportion to airway length. As airways become both narrower and shorter with increasing branching, it is evident that resistance of a single airway increases dramatically because of the dominating effect of the fourth power of the radius. However, if one asks how the entire system behaves by plotting how airway pressure must fall from trachea to generation 16 during, for example, steady inspiratory flow, one must allow for the fact that all airways of any single generation are arranged in parallel with one another. Because branching is essentially dichotomous, there are twice as many airways in any given generation as in the one before. Thus, total airway resistance of any one generation is diminished in proportion to the exponentially increasing number of airways as branching continues. This actually overcomes the fourth power disadvantage of Poiseuille's law, such that most of the pressure drop, or put another way, most of the system airway resistance, is associated with the first few generations despite their large individual airway size.

Another way to understand this somewhat counterintuitive result is to consider the sum total of the cross-sectional areas of all airways in a single generation. This is of course the area of a typical airway multiplied by the number of airways in that generation. That number is low for the first few generations, but then rises dramatically because of the exponentially increasing number of airways in each generation. Airway resistance of a generation therefore falls from the first few generations to the terminal bronchioles. The summed total volume of gas contained within all 16 generations of these conducting airways is only about 150 ml despite their prodigious number.

Clinical significance

Dead space

The interposition of airways between the mouth and the alveoli creates a volume of gas (about 150 ml as mentioned) called the anatomical dead space. The gas in this dead space simply passes back and forth during inspiration and expiration without contributing to gas exchange since the conducting airways contain no alveoli in their walls. It constitutes a penalty since it adds an obligatory 150 ml volume requirement to every breath taken. This is of no importance in health, but in patients with severe lung disease such as chronic obstructive lung disease or fibrosis, the energy cost of overcoming either high resistance in obstructed airways or low compliance of fibrotic lung tissue, and of thus mounting adequate ventilation, may be greatly increased. Then, the need to breathe some 150 ml more per breath than actually required for alveolar gas exchange can be clinically important as a factor contributing to respiratory failure. Recognition of this has led to the use of transtracheal insufflation of air, which permits the anatomical dead space of at least the upper airways to be circumvented and reduces the ventilation necessary for any given activity.

Particle deposition

Ventilation involves breathing some 6 to 10 litres of air every minute of our lives. Air contains much particulate matter of very small size. Depending on particle size, rate of gas flow in the airways, and airway geometry, such particles may move harmlessly in and out with the next breath or they may be deposited somewhere on the epithelial surface in the bronchial tree. To the extent that they do deposit and are chemically or physically harmful to tissue, they can be responsible for disease. Pneumoconioses, chronic obstructive pulmonary disease, bacterial and viral infections, asthma, and other diseases may all be initiated and/or afftected by such mechanisms. The dividing airway structure described above combines ever-diminishing individual airway diameter with ever-diminishing gas velocity (due to increasing summed cross-sectional airway area of all airways in a generation) as branching continues. As airways narrow and flow velocity falls, the chance of airborne particles being deposited on airway walls increases. It is for this reason that coal dust, for example, settles mostly in the terminal bronchiolar region deep within the branching system. Thus, the basic nature of gas exchange, demanding the branching network of airways described, leads to intrinsic vulnerability to disease from airborne particulate matter.

Mucociliary function

As seen commonly in evolutionary responses to deleterious phenomena, a protective system has been developed to mitigate the consequences of particle deposition in the airways. This is the mucociliary apparatus. It has several components. There are submucosal glands in the walls of the conducting airways that secrete mucus into the airway lumen when stimulated by irritant signals. These glands are supported by other secretory cells in the epithelium of the airways such as goblet cells. The epithelial cells that line the entire conducting airway system are ciliated, and they function in a co-ordinated manner, beating rhythmically to move the secreted

mucus upward from smaller to larger airways. The primary purpose of the mucus is to trap inhaled particulates before they can reach and damage the airway and lung tissues themselves. This upwardly transported mucus is clinically evident as sputum.

The volumes of sputum produced normally are so small as to be unnoticeable, and are usually swallowed. However, inhalation of toxic irritants, infectious agents, and other particles will rapidly increase the volume of sputum to noticeable levels, and chronic airway inflammation from, for example, cigarette smoking will produce chronically increased amounts of mucus that give rise to the syndrome of chronic bronchitis. It is especially noteworthy that in asthma, not only is the volume of mucus increased, probably from airway inflammation, but its composition is altered, rendering it much more tenacious and difficult to eliminate by the ciliary system. Mucus thus accumulates in the airway lumina, particularly those of the smaller conducting bronchioles, creating mucus plugs that cause obstruction to airflow and marked reduction in ventilation of alveoli lying distal to them. When this occurs, asthma is often refractory to usual pharmacological therapy, and patients dying from asthma universally exhibit widespread airway mucus plugging.

Dynamic airway compression

Another intrinsic physiological problem of the branching airway system within the chest is related to the mechanical nature of respiration—the need for inflating and deflating the lung by altering the pressure around it—combined with the fact that the airways are not rigid tubes. The airways are thus susceptible to expansion and compression (and therefore to collapse) on inspiration and expiration, respectively. The intrapleural pressure may be transmitted to the conducting airways, and while reduction in this pressure on inspiration will only distend the airways, allowing air to flow more freely, opposite effects during expiration may not be innocuous. Passive expiration, that is, expiration fuelled only by the elastic energy stored in the lung tissue from the previous inspiration, without active expiratory muscle effort, does not compress the airways because the intrapleural pressure remains subatmospheric. However, active expiratory muscle contraction as occurs during a forced expiratory manoeuvre and during heavy exercise leads to compression of the airways because intrapleural pressure is raised to above atmospheric. In fact, the greater the expiratory effort made, the greater the increase in intrapleural pressure and the degree of airway compression. Because of this, flow rates uring forced expiration cannot be increased by making a greater muscular effort: any greater driving pressure for expiratory flow is balanced by the increased resistance resulting from more compression. As a result, even in normal subjects, expiratory flow of air under these conditions is limited by this phenomenon, known as dynamic compression, which is illustrated in Fig. 3.

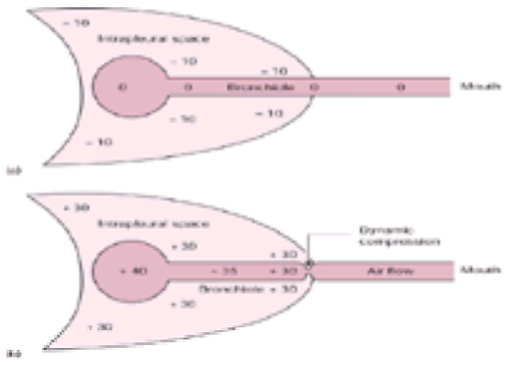

Fig. 3 Diagram to explain dynamic compression during expiration. (a) This depicts intrapleural, alveolar, and airway pressures while breath holding with an open glottis at total lung capacity. Due to lung elasticity, intrapleural pressure is negative (–10 cmH2O), but because of breath holding there is no flow, and pressure in the airways and alveoli equals that at the mouth, 0 cmH_2O. Immediately after commencing a forced expiration from total lung capacity (b), intrapleural pressure is high due to expiratory muscle contraction (+30 cmH_2O). Alveolar pressure is even higher due to 10 cmH_2O of lung elastic recoil pressure. However, due to flow resistance, pressure falls from +40 gradually to +30 as shown. At this point, intrapleural pressure equals intraluminal pressure and immediately downstream dynamic compression occurs as airway pressure falls even further and is now less than intrapleural pressure.

The loss of elastic recoil in emphysema, mentioned above in the context of its effects on FRC, also has a major influence on dynamic compression. The airways are much more susceptible to dynamic compression (discussed below), such that even breathing at rest with just small increases in intrapleural pressure from active expiratory muscle contraction may be subject to flow limitation by this mechanism. When this problem is compounded by the separate phenomenon of increased airway luminal mucus from chronic inflammation induced by cigarette smoking, it is easy to understand how chronic obstructive lung disease (emphysema and chronic bronchitis) has airway obstruction as its major disturbance.

In the consideration of dynamic compression it is important to note that the alveoli are not physically independent of one another or of the conducting airways, which run within the lung parenchyma from the lobar bronchi all the way out to the terminal bronchioles. The alveoli share walls in their mutual attachments, and the alveoli beside any intrapulmonary conducting airway are physically connected to the outside of that airway wall. A good analogy for how the alveolar parenchyma is configured comes from examining the cut surface of a sponge where the myriad air cells are surrounded by thin tissue walls. Every wall serves two adjacent air cells, and the overall structure is solid (rather than like the leaves of the tree which are physically independent of each other even while being connected to the same dividing network of branches). The net result of this matrix of alveolar and airway connections is that when the lung is inflated, the elastic tension in the parenchyma exerts radial traction on the conducting airways, increasingly so as the lung is further inflated. This stiffens the airway walls and acts to oppose dynamic compression during active expiration. That maximal expiratory flows are greater at high than low lung volumes is explained by the greater radial traction at high volumes as the alveoli are stretched more.

The walls of the larger conducting airways (the trachea and first few generations of bronchi) are reinforced with cartilage rings that further help to counter the forces favouring dynamic compression. However, the smaller conducting airways do not enjoy this protection, and it is in the smaller airways that dynamic compression usually has its major effects.

Airway smooth muscle

All generations of conducting airways contain smooth muscle cells. When stimulated to contract, their concentric arrangement leads to reduction in airway lumen size, and airway obstruction results. While not a significant effect in normal individuals, patients with asthma have hyperresponsive airway smooth muscle that contracts in response to the inflammatory reaction usually present in the asthmatic airway walls. This is a major mechanism of airway obstruction in asthma, and is the basis of the mainstay therapy in this disease—bronchodilators. For reasons that remain unclear, smooth muscle contraction does not occur to the same degree in all airways of the asthmatic lung: there are different degrees of obstruction both with respect to airway generation number and among airways of a given generation. Ventilation of alveoli is thus very uneven, with many alveoli being very poorly supplied with air, yet others well-supplied. Gas exchange becomes inefficient as a result, and arterial hypoxaemia is seen.

Airway smooth muscle also contracts when local CO_2 concentrations fall. This happens commonly in pulmonary thromboembolism, when vascular obstruction results in focal areas of hypoperfusion that remain relatively overventilated, such that their local alveolar CO_2 tension falls. This, possibly in concert with bronchoactive inflammatory mediators released in association with the embolic event, can produce local airway smooth muscle contraction and airway obstruction. This might tend to better matching of local ventilation with blood flow, but the benefit is generally small, and local bronchoconstriction can manifest as wheezing, which should not be mistaken for asthma.

Dynamic tests of airflow

All of the consequences of the branched structure of the airways and their interconnectedness need to be integrated if one is to understand common pulmonary function tests. How the 'static' lung volumes (FRC, TLC, VC, and RV) are affected by changes in elastic recoil are discussed above, but such measures form only a part of standard pulmonary function testing. Usually included are 'dynamic' tests that measure expiratory and inspiratory gas flow rates, conventionally during manoeuvres wherein the patient is asked to make a maximal inspiratory or expiratory muscle effort. These are discussed in Chapter 17.3.2.

Distribution of ventilation

The extremely large number of very small respiratory bronchioles creates an environment in which alveoli distal to each bronchiole become susceptible to impaired ventilation. Small intrinsic or pathological reductions in airway diameter of such bronchioles can impair distal ventilation substantially. When the effects of variation in mucus secretion, bronchial smooth muscle tone, and radial traction are added to this inherently vulnerable system, it is surprising that the distribution of ventilation to the 300 million alveoli is as uniform as it is. Were it not, there would probably be considerable hypoxaemia, even in health. This topic is discussed further below.

The parenchyma distal to the terminal bronchioles

The terminal bronchioles (16th generation airways) are the final divisions of the wholly conducting airways. They are completely lined with ciliated epithelium, and function primarily as simple conduits for gas, linking the air around us to the alveoli where gas exchange occurs. The next few divisions of the airways result in transitional airways called respiratory bronchioles, so named because they serve a dual role—as continued gas conduits and as the first locations for gas exchange. Respiratory bronchioles are partly lined with ciliated epithelium, but also have small alveolar outpouchings opening directly into the airway lumen. With continued branching of these bronchioles, more and more of the luminal surface is given to the alveolar outpouchings, and less and less to ciliated epithelium. After about three generations of respiratory bronchioles, the airways, whilst still essentially tubular in shape, are made up entirely of alveolar tissue capable of gas exchange, and are called alveolar ducts. These alveolar ducts branch even further into collections of alveoli whose distal end is blind, known as alveolar sacs, the end of the line of the airway branching system. A diagram of the functional lung unit is shown in Fig. 4. With some 7 orders (or division points) of branching between the terminal bronchioles and the final alveoli, together with 16 orders of branching in the conducting airway segment, the whole airway tree consists of about 23 orders or branch points. Because, after the final branch point, the alveolar sacs are blind, the process of ventilation must occur as a tidal (back and forth) event, alternately adding air to, and removing alveolar gas from, each alveolus with each breath.

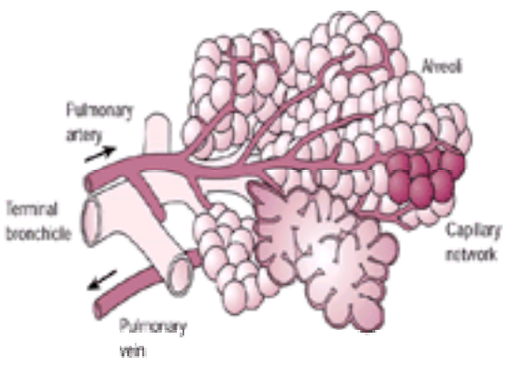

Fig. 4 Diagram of the functional lung unit. The collection of alveoli and associated pulmonary arteries and veins distal to the terminal bronchiole constitutes a functionally homogeneous unit of gas exchange. Mixing of gas amongst alveoli and of blood in the capillary networks of the alveoli in the unit is sufficiently rapid that gas concentrations are in effect uniform throughout. This unit, also called the acinus, corresponds approximately to generations 17 to 23 of Fig. 2(a).

The transport of gas in either direction between the trachea and the last conducting airway takes place principally by convective flow, much as water flowing in a pipe depends on the pressure difference between the two ends of the pipe and the flow resistance of the pipe. Since flow is mostly laminar, velocity profiles are largely parabolic, flow being highest in the centre of the lumen and lowest at the airway wall, just as is the velocity profile across a quietly flowing river. There are, however, minor additional influences of diffusive movement at the interface between the convective front of each inspiration and residual gas from the previous breath. These interactions, and eddies that develop at each branch point, may assist gas mixing, but their effects are physiologically small. Of much more significance is the fact that the total luminal cross-sectional area of each generation increases exponentially as the airways divide. Since total volumetric flow of gas is the same in each generation, average gas velocity falls reciprocally with the increase in area.

By the time inspired gas reaches the first alveoli, forward velocity has dropped to such a low level that random, thermally fuelled molecular motion (i.e. diffusion) becomes a more important mechanism of gas transport than convection. The small size of the alveoli, about 150 μm in radius, means that diffusive mixing of each new breath with gas resident in the alveoli from prior breaths is nearly instantaneous. Although careful physiological studies can show that low-molecular-weight gases mix slightly faster than those of high molecular weight, this turns out to be of essentially no quantitative significance to gas exchange. Even in emphysema, where many alveolar spaces are enlarged, there is evidence that diffusive mixing in alveolar gas is functionally complete and does not pose a gas exchange threat.

Of more concern for gas exchange is whether all alveoli receive a similar share of each breath. It was pointed out above that the intrinsic structure of the lungs makes it vulnerable to ventilatory inequality, and that this has the potential to disrupt gas exchange. Indeed, recent studies of the structural influence on gas distribution reveals that there are sometimes substantial differences in the ventilation of different alveoli. One property of the system that lessens the negative effects of such inhomogeneity on gas exchange is the finding that individual alveoli do not maintain gas exchange differences from closely adjacent alveoli. In fact, a fairly large number of connected alveoli are normally able to function as a single homogeneous unit of gas exchange. This is no doubt due partly to the rapid diffusive movement of molecules throughout the alveolar gas mentioned above, but it is also facilitated by the rich capillary network lying in the wall of each alveolus. The density of capillaries is so great that should flow fall in one, its neighbour can seamlessly take over its gas exchange role without any resultant inefficiency. It turns out that the functional unit of gas exchange, known as the acinus, corresponds approximately to all the alveoli distal to the last terminal bronchiole.

Clinical significance

The functional lung unit

Pathological events, in either the alveoli or the capillaries, occurring at a scale smaller than that of the functional lung unit will not *per se* have much impact on gas exchange. Thus, a large number of tiny pulmonary emboli each lodging in one capillary of different functional lung units will not impair gas exchange function, whilst a single large embolus of the same total mass obstructing one much larger vessel may. However, if enough microvessels within functional units become obstructed, their summed effects may become considerable.

Surface tension and mechanical instability of the lung

Another consequence of the branched nature of the lungs resulting in so many very small alveoli is inherent mechanical instability. The alveolar wall, where it interfaces with alveolar gas, forms a roughly spherical air–liquid interface. In this context, the alveoli may be likened to a mass of soap bubbles lying together. All air–liquid interfaces are subject to surface tension, which in this case will act to minimize the surface area of each bubble. For an enclosed bubble, this tension increases the pressure inside the bubble, with the relationship between the tension and the interior pressure given by the law of Laplace: pressure = 2 × surface tension/radius. Thus, pressure inside a small bubble exceeds that inside a larger bubble, and if two such unequal bubbles are in contact and their interiors become connected, the small bubble will collapse into the larger. This process of bubble accretion may continue until the many small soap bubbles have collapsed into a single large one. Based on the opening premise of this chapter, if small alveoli had this tendency to collapse into larger neighbours due to surface tension effects, the end result would be disaster for gas exchange. There would be massive alveolar collapse, and with loss of surface area, sufficient O_2 exchange to support metabolic needs would not be possible. Only if all alveoli were identical in both size and surface tension would this problem be avoided, but when 300 million alveoli exist, it is impossible to imagine them all being identical, and indeed they are not.

The lung avoids this dilemma through two quite separate but complementary mechanisms of stabilization. The first, already mentioned above in a different context, is the interconnected nature of the whole alveolar structure. Any tendency for one alveolus to collapse would have to increase the tension on all its immediately connected neighbours. This tension from surrounding alveoli will automatically serve to splint open the alveolus in question, thus opposing its tendency to collapse. This concept, termed alveolar interdependence, is felt to be of considerable importance in maintaining alveolar stability. The second mechanism is the presence of phospholipid molecules that reduce surface tension in the alveolar air–liquid interface. Termed surfactant, and produced in conjunction with proteins from alveolar

type II epithelial cells lying free in the alveolar spaces against alveolar walls, this material reduces surface tension severalfold (Fig. 5). Thus, whilst that of water is some 75 dyn/cm, surface tension of the alveolar lining fluid is only about 10 dyn/cm. Moreover, probably due to molecular realignment of surfactant molecules, surface tension is even lower when lung volume is reduced. Based on the law of Laplace given above, this can be seen to be even more advantageous for evening out surface tension differences among alveoli of different size.

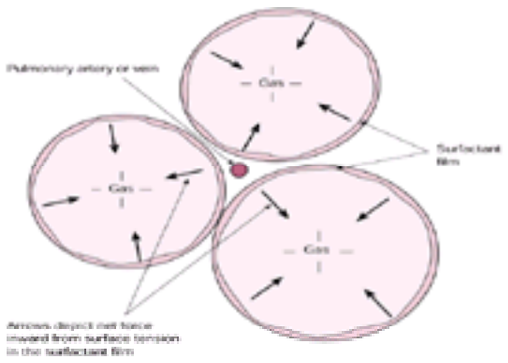

Fig. 5 Diagram to indicate potential effects of surface tension on lung structure and function. Three gas-filled alveoli are shown, each lined by a thin film of surfactant. A pulmonary artery or vein is shown in the corner formed where the three alveoli come together. Arrows show the net inward force produced by surface tension, tending to reduce alveolar gas volume and promote atelectasis. In addition, the pressure in the perivascular space around the corner vessel shown will be reduced by these inward surface forces, increasing the pressure difference from inside to outside the vessel lumen and thereby promoting fluid movement from plasma to interstitial space. The presence of surfactant reduces the magnitude of surface tension forces and therefore stabilizes the alveoli against atelectasis and reduces the transmural pressure difference, attenuating transvascular fluid movement.

Surfactant is thought to have another crucial role that promotes efficient gas exchange between alveolar gas and capillary blood. Given that adjacent alveoli share a common wall, the tendency for surface reduction in each alveolus will create a force that tends to reduce the interstitial tissue pressure around capillaries in the alveolar wall between the adjacent alveoli. From the Starling relationship that governs water escape out of capillaries in any tissue (based on the transcapillary differences in both hydrostatic and oncotic pressures), reducing pressure around the capillary will lead to increased water escape into the alveolar wall. This could have several deleterious consequences. First, the affected alveolar walls would become stiffer and harder to inflate, tending to reduce lung volume. Second, the tissue separating gas from capillary blood would become thicker, directly impairing diffusive transport between gas and blood. Third, this water would find its way into the pulmonary lymphatics, which begin in the alveolar interstitium and run along the large airways and vessels to the hilar regions, before exiting the lungs and emptying into the superior vena cava. Extra water frequently accumulates in the peribronchial and perivascular spaces and results in their partial compression, reducing distal ventilation and/or blood flow of subtended alveoli, causing maldistribution of either or both, and rendering gas exchange inefficient. The presence of surfactant is thought to reduce the rate of transcapillary water exchange, and therefore to contribute to efficient gas exchange.

Clinical significance

Impaired surfactant activity

When surfactant is not present, when its rate of renewal is insufficient, or when it is inactivated rapidly, pathological changes can be severe. Best known is the infant respiratory distress syndrome, occurring in otherwise normal premature infants born before the late-maturing surfactant system is functional. Without exogenous surfactant replacement therapy the condition may be fatal because of alveolar collapse and pulmonary oedema. Surfactant activity is also compromised in the adult respiratory distress syndrome and may compound the disturbances of pulmonary function arising from the primary cause of the pulmonary disease.

Gravity and lung function

Causes of potential unequal distribution of ventilation or blood flow to the alveoli extend beyond those associated with the intrinsic branching structure of the lungs discussed above. In particular, the presence of gravity influences lung function because key components of the lungs have significant weight. The weight of the parenchyma itself, plus the blood within the alveolar capillaries, feeding arteries and draining veins, together cause the lungs to sag toward the diaphragm in the upright lung sitting at FRC. The upper pole of the lungs is still applied to the parietal pleural surface of the chest wall—there is no pleural airspace created by this gravitational stress. Rather, the rest of the lung is displaced caudally, sagging much like a heavy sweater pegged to a clothes line. As expected, this creates stress in the alveolar walls, more in the uppermost than lowermost alveoli. A good analogy is the toy Slinky—a coiled spring that when hanging vertically under its own weight shows wider separation between adjacent coils at its top than at its bottom. Correspondingly, the uppermost alveoli in the upright lung are larger than the lowermost alveoli. The lowermost alveoli are thus more compliant—that is, able to be further inflated more per unit transpulmonary pressure—than the uppermost alveoli, because the latter are stretched almost to their limit. Accordingly, normal ventilation from FRC results in greater ventilation of the lung bases than of the lung apices. Much the same effect is seen for blood flow: apical blood flow is less than that at the base of the upright lung. In this case it is the weight of the blood itself that is responsible: perfusion depends on pulmonary arterial pressure, which falls linearly with height up the lung.

The apex to base differences in perfusion exceed those of ventilation, such that the ratio of ventilation to blood flow is higher at the apex than at the base. The local ventilation/perfusion ($\dot{V}_A/\dot{Q}$) ratio determines local alveolar P_{O_2} and P_{CO_2}, P_{O_2} increasing and P_{CO_2} falling as the $\dot{V}_A/\dot{Q}$ ratio increases. Thus, P_{O_2} at the apex is higher, and P_{CO_2} lower than at the base. If the $\dot{V}_A/\dot{Q}$ ratio everywhere was the same, so too would be P_{O_2} and P_{CO_2}, and the exchange of O_2 and CO_2 would be maximally efficient. However, the presence of a range of $\dot{V}_A/\dot{Q}$ ratios (no matter what its cause) results in gas exchange inefficiency and arterial hypoxaemia.

Clinical significance

Effects of gravity on lung function in disease

Although gravity creates $\dot{V}_A/\dot{Q}$ maldistribution, common disease processes are in large part randomly distributed in the lungs, and their effects on $\dot{V}_A/\dot{Q}$ matching generally much greater than those of gravity. Thus, whilst the effect of gravity on $\dot{V}_A/\dot{Q}$ mismatching in normal lungs is barely measurable, $\dot{V}_A/\dot{Q}$ mismatching based on non-gravitational influences in many diseases leads to profound gas exchange disturbances. However, the presence of gravity must not be discounted in several disease states.

Emphysema, and even the normal ageing process, often causes tissue breakdown in the apical lung regions because, as in the Slinky analogy, the alveolar wall stresses are largest there. When mechanical failure occurs, it is most likely to happen in the regions of greatest stress, and as a result the alveolar wall breakdown so typical of emphysema, and to a much lesser extent normal ageing, is often exaggerated in the apices. An important gravitational influence occurs in patients in intensive care with severe lung disease. In any body position, both blood flow and alveolar fluid collection tend to be concentrated in dependent regions (e.g. posteriorly in the supine patient). Those regions with high blood flow may also have little or no ventilation if their alveoli are filled with fluid and cell debris. The blood flowing through such regions can therefore pick up little or no O_2, and hypoxaemia may be severe. This has led some intensive care staff to rotate their patients from supine to lateral to prone and back. The argument being that the gravitational influences on blood flow are essentially instantaneous, whilst those on alveolar fluid collection may take hours to respond to body positional changes. Thus, for a time after rotating a patient, the dependent region may enjoy high flow but not yet be fluid filled and thus still be well ventilated. Gas exchange is therefore enhanced, and arterial hypoxaemia is mitigated. Such behaviour may also explain positional influences on gas exchange in patients with unilateral lung disease such as pneumonia, effusion, or atelectasis.

17.1.3 'First-line' defence mechanisms of the lung

C. Haslett

Introduction

In their critically important service as our central gas exchange organs the lungs are continuously exposed to more than 7000 litres of air per day, but their membranes are delicate and require to be kept moist and protected from the daily bombardment of particles including dust, pollen, and pollutants, together with viruses and bacteria. These agents have the potential to cause lung injury or to invade the lung and generate potentially life-threatening infections. That these problems rarely occur is because the lung possesses very effective local 'primary' protective mechanisms, which are the focus of this chapter. If an infectious agent is able to penetrate these defences and set up a 'bridge-head', highly effective and complex 'secondary' responses, including the inflammatory and classic immune responses, can be recruited rapidly. In the event that immune or inflammatory responses should be initiated, the lung also has mechanisms by which it can protect itself from their potentially detrimental local side-effects. The inflammatory and immune responses themselves will only briefly be alluded to; detailed treatment of these processes is beyond the scope of this chapter (see Chapter 16.5.1 for further discussion).

The respiratory tract is protected by different mechanisms at its various levels. In general terms, physical mechanisms, including cough, are particularly important in the large airways; the lower airways are protected by complex mucociliary clearance mechanisms; and the gas exchange units at the alveolar level are protected by surfactant and by 'patrolling' alveolar macrophages. The lung lining fluids (mucus in the airways and surfactant in the gas exchange units) contain a variety of proteins that are particularly important in host defence. In this section we will therefore consider physical defences, mucociliary clearance mechanisms, surfactant and important defensive proteins in the lining fluid of the lung, and how the 'second-line defences'—the classic inflammatory and immune responses—can be initiated in the lungs.

Physical defences

The nose makes an important contribution to the physical defences of the upper airway. It comprises a stack of fine aerodynamic filters of respiratory epithelium arranged over the turbinate bones. These remove most large particles from inspired air. Their filtering effect is greatly enhanced by fine hairs in the anterior nares and by mucociliary action that, apart from a small area anterior to the inferior turbinates, is directed posteriorly such that trapped particles are swallowed or expectorated. The larynx acts as a sphincter during cough and expectoration and is an essential protective mechanism for the lower airways during swallowing and vomiting.

Particles with a size greater than 0.5 µm that survive passage through the nose will be trapped by the lining fluid of the trachea and bronchi, to be cleared by the mucociliary clearance mechanism, which has been called the 'mucociliary escalator'.

Mucociliary clearance

Cilia

The mucociliary escalator works by a complex interaction between cilia, which are a series of projections on the bronchial epithelial cells, and mucus, forming a 'raft' on top of the cilia, which then sweep this raft in a cephalad direction. The combined effect of this interaction can readily be appreciated by scanning electron microscopy (Fig. 1). There are about 200 cilia on each of the pseudostratified columnar epithelial cells lining the bronchi and it has been calculated that these can carry weights of up to 10 g/cm without slowing, working with a ciliary beat frequency of 12 to 14 beats/s. Their motility depends upon the contraction of longitudinal fibrils that contain the contractile protein tubilin arranged as nine outer and two central microtubular pairs, and their effectiveness in sweeping mucus in the cephalic direction is enhanced by small 'claws' in their tips, which penetrate the overlying mucus sheet. The actual driving mechanism of the cilia is uncertain, but involves dynein, an ATPase protein that forms a major part of the cilium. This appears to derive energy from ATP along the cilium and convert it into the forces that are generated by the contractile proteins.

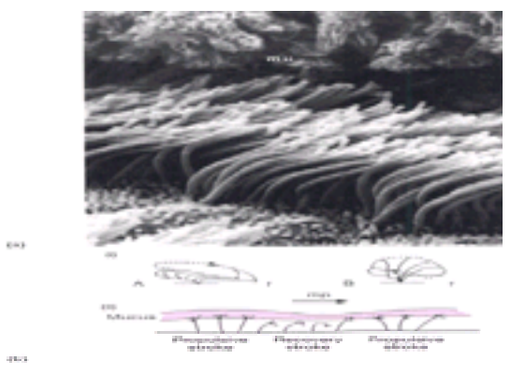

Fig. 1 (a) Scanning electron micrograph (× 14 000) of the 'mucociliary escalator' of the bronchial epithelium. The cilia and the overlying 'raft' of mucus (mu) are clearly seen. (By courtesy of Dr P.K. Jeffery.) (b) Beat cycle of a tracheal cilium seen from the side: (i) In a single cilium during the recovery stroke (A) the cilium starts from its rest position r and unrolls backwards; in the propulsive stroke it remains extended to reach its rest position (B). Mucus is propelled to the right (mp). (ii) Groups of cilia move in co-ordinated waves with clusters in their propulsive phase bordered by those in recovery. (Adapted from Sleigh MA, Blake JR, Liron N (1988). The propulsion of mucus by cilia. *American Review of Respiratory Disease* **137**, 726.)

It is generally believed that ciliary beating occurs by the microtubules, which provide the 'skeleton' of the cilia, sliding over each other, much like the sliding fibre theory of muscle contraction. Since not all microtubular pairs move at the same time, their co-ordinated shortening leads to reduction in length of some microtubules relative to those at the opposite side of the cilium, and with the skeletal rigidity that is provided by the radial pairs of the microcilial 'spokes' and their basal anchoring system, this causes the cilium to bend in the direction of shortening. The ciliary beat itself can be divided into two phases: the forward mucus-propulsive stroke, and a slower recovery stroke (much like the forward and recovery actions of a whip, Fig. 1(b)). Where this occurs in a co-ordinated fashion in the ciliated epithelium, the wave-like motion of numerous cilia effected through their terminal claws propels the mucus raft in a cephalad direction.

Ciliary function can be assessed in a number of ways, facilitated by the fact that cilia can survive freezing for up to a month and may beat for several hours after death

of the host. Thus, it is possible to assess their motility directly in cytological specimens from nasal and bronchial brushings and to perform detailed photometry and determine ciliary beat frequency in epithelial specimens sampled by biopsy. Cilial structure can also be assessed by electron microscopy. In a simple and practical clinical test, the time taken for saccharine placed in the anterior nares to cause a sweet taste in the mouth (around 11 min normally) can be used as a convenient clinical measure of ciliary function, which is informative because in most examples of ciliary disease the nasal cilia are also affected. Other more complex methods of assessing mucociliary clearance *in vivo* include cinebronchography and assessment of the rate of clearance of radio-aerosols.

Mucus

Mucus is secreted by the goblet cells and submucosal glands of the first few bronchial generations. Secretion is under the control of a variety of chemical mediators: neuropeptides including substance P, vasoactive intestinal polypeptide, and bombesin, in addition to vagal stimulation and acetylcholine, will cause discharge. In health, mucus is composed of 95 per cent water, the mucus glycoproteins or mucins, and a variety of other proteins (see below), which although present in low concentration, probably play an important part in defence of the bronchial tree. The function of mucus is to trap and clear particles, to dilute noxious influences, to lubricate the airways, and to humidify respired air. The viscoelastic or rheological properties of mucus are likely to be controlled by the concentration of different mucins and are probably critical in determining adequate mucociliary transport.

Factors that affect mucociliary clearance

A number of external factors may reduce mucociliary clearance by interfering with ciliary function or by causing direct ciliary damage. These include pollutants, cigarette smoke, local and general anaesthetic agents, bacterial products, and viral infection. In severe asthma it is thought that eosinophil products including major basic protein may have detrimental effects on ciliary function. Thus there are a number of diseases in which mucociliary clearance may be adversely affected in a secondary fashion. There is also an autosomal recessive condition (occurring with a frequency of about 1 in 30 000 population), called primary ciliary dyskinesia, in which defects in cilial dynein may be associated with male infertility and situs inversus (Kartagener's syndrome). Primary ciliary dyskinesia is associated with repeated sinusitis and respiratory infections that often progress to persistent lung suppuration and severe bronchiectasis, thus underlining the importance of cilia in antibacterial lung defences.

There is now a great deal of interest in abnormal properties of mucus and deranged mucociliary clearance in cystic fibrosis. In this condition, mucus is abnormally viscous with grossly altered rheological properties resulting in markedly retarded mucociliary clearance (see Chapter 17.10).

Surfactant and surfactant 'collectins'

As is discussed in more detail elsewhere (Chapter 17.1.2), surfactant is a complex surface-active material that lines the alveolar surface to reduce surface tension and prevent the lung from collapsing at resting transpulmonary pressures. It also provides a simple mechanism for alveolar clearance since, at end expiration, surface tension decreases and the surface film moves from the alveolus towards the bronchioles, thus carrying small particles and damaged cells towards the mucociliary transport system.

Surfactant is synthesized and secreted by the alveolar type II pneumocytes. It comprises phospholipids, neutral lipids, and at least four different specific proteins, termed surfactant proteins A, B, C, and D (**SP-A**, **SP-B**, **SP-C**, and **SP-D**). It is now recognized that in addition to promoting the surface-active properties of surfactant these proteins have important roles in host defence. SP-B and SP-C are likely to have the major surface-active roles, since both accelerate the adsorption of lipids to an air–liquid interface. Although SP-A can act co-operatively with SP-B in the formation of a surface film, there is no significant derangement of surfactant function or metabolism in SP-A gene-targeted ('knockout') mice, whereas genetically engineered SP-D deficient mice demonstrate abnormal accumulation of surfactant, suggesting a previously unsuspected role for SP-D in surfactant homeostasis.

While it has been recognized for decades that, in addition to its surface-active properties, surfactant can modulate host defence responses, interest in this area has recently intensified with the discovery that SP-A and SP-D, which are secreted by Clara cells in the epithelial lining of the lungs, are members of the collectin (collagen-like lectins) family of proteins. Members of this family in the serum are known to possess important bacterial binding and opsonization properties, and also to influence inflammatory cell function, including stimulation of chemotaxis and the production of reactive oxygen species and cytokines by immune cells. Moreover, mutations of the serum collectin mannose-binding lectin are linked to repeated infections in neonates and children. The collectin family now includes mannose-binding lectin, conglutinin, and CL-44 in blood, and SP-A and SP-D in lung secretions. The collectins are also known as the group II C-type lectins, since their binding to carbohydrate requires calcium.

SP-A and SP-D have been shown to bind to a wide variety of pathogenic microbes (Table 1) and *in vitro* will stimulate the uptake of many of these by macrophages. More recently SP-A, which has been better studied than SP-D, has been shown to possess a number of other properties to suggest that it represents an important component of the lungs armamentarium in the first line of defence against infection (Table 2). Gene-targeted mice deficient in SP-A show marked reduction in the ability to clear *Streptococcus pneumoniae*, *Pseudomonas aeruginosa*, and respiratory syncitial virus from their lungs. The relevance of these observations to human disease remains to be clearly defined.

It has long been recognized that surfactant lipids suppress a variety of immune cell functions, including lymphocyte proliferation, whereas SP-A (and probably SP-D) mainly enhance immune cell functions, suggesting the intriguing possibility of counter-regulatory effects of changes in lipid/protein ratios that might be important in regulating the immune status of the lung. Levels of SP-A (and SP-D) can vary greatly in human disease, with reduced concentrations in HIV-positive patients and markedly reduced concentrations in adult respriratory distress syndrome (**ARDS**) and severe pneumonias. While it is tempting to speculate that low levels of SP-A predispose to infection and immune dysfunction in these settings, it is not certain whether these changes are 'cause' or 'effect' (for example simply reflecting local consumption). There has been less study of SP-D, but it may well possess many of the immune modulatory functions as well as the bacterial-binding properties of SP-A; studies in SP-D ' knockout mice' suggest an important role in influenza neutralization *in vivo*.

Other protective proteins of the lining fluid of the respiratory tract

These may be derived from plasma (e.g. albumin, transferrin, a_2-antiplasmin, a_2-macrogrobulin), by secretion from local epithelial cells, macrophages, or inflammatory cells (e.g. lysozyme, lactoferrin, and defensins), or by selective epithelial transport (e.g. IgA). Clearly the local availability of plasma-derived proteins increases greatly during the exudative phase of any inflammatory process, thus adding more complement, antiproteinases, immunoglobulins, and proteins, including cytokines derived from inflammatory cell secretion.

Defensins and other antibacterial proteins and peptides

Some of the principal antimicrobial molecules isolated from human pulmonary secretions are outlined in Table 3.

Lactoferrin

Lactoferrin was first recognized as a high-affinity iron chelator in human milk, but in the 1960s it was found to possess bacteriostatic properties that were thought to be exerted by deprivation of iron, which is essential for bacterial growth. It occurs in the primary granules of neutrophils and mammalian exocrine secretions, including lung fluids. More recently it has been shown to exert direct membrane effects on some bacteria and to have important modulatory effects on the inflammatory process. Some of these effects may be mediated by its high-affinity binding to bacterial lipopolysaccharide and include the inhibition of cytokine release from cells of the monocyte/macrophage series and modulation of the proliferation and differentiation of immune cells.

Lysozyme

Lysozyme is a 1,4-b-N-acetylmuraminidase that enzymatically degrades a glycosidic linkage of bacterial membrane peptidoglycan. Acting alone, human lysozyme can lyse and kill a variety of Gram-positive micro-organisms, but most Gram-negative organisms are resistant to its direct effects. Like lactoferrin, lysozyme is a major component of the specific granules of neutrophils and is found in the mucosal secretions of the respiratory tract; it has recently been suggested that they may collaborate in killing Gram-negative bacteria such as *Escherichia coli* by disrupting the cell membrane.

Defensins

Defensins are small-molecular-weight, cationic, cysteine-rich peptides that are able to kill a wide range of micro-organisms. They are membrane active and are believed to aggregate in order to 'punch' pores or channels in microbial cell membranes. The a-defensins are major constituents of the neutrophil a granule and are also found in airway secretions. In humans, the a-defensins HNP 1 to 4 account for about 5 per cent of the total cellular protein of neutrophils and are active against staphylococci, *E. coli*, *Pseudomonas aeruginosa*, *Cryptococcus neoformans*, and some enveloped viruses such as herpes simplex virus 1 and vesicular stomatitis virus. The b-defensins are derived from the epithelial lining and were first discovered in cattle as antimicrobial peptides of airway cells, for instance tracheal antimicrobial peptide. At least three human b-defensins have been identified. HBD-1 and HBD-2 are expressed in airway epithelial cells from patients with and without cystic fibrosis. HBD-2 protein is found in lung secretions from patients with cystic fibrosis, patients with inflammatory lung disease, and also from healthy volunteers, whereas HBD-1 protein is not detected in healthy controls but is found in lung secretions from patients with cystic fibrosis and inflammatory lung diseases. Together with the observation that the pro-inflammatory mediator interleukin 1b stimulates epithelial generation of HBD-2 but not HBD-1 *in vitro*, these observations suggest that in the lung HBD-2 is induced by inflammation whereas HBD-1 may serve as a lung defence in the absence of lung inflammation. HBD-1 has also recently been implicated in the athogenesis of cystic fibrosis where it appears to be inactivated by the high salt milieu.

Cathelicidins

Cathelicidin peptides contain a highly conserved signal sequence ('cathelin') but show substantial heterogeneity in the C-terminal domain. The first human cathelicidin to be characterized—LL-37/hCAP-18—is expressed in airway epithelium and displays antibiotic activity against a range of Gram-negative and -positive organisms.

Small-molecular-weight antiproteinases

Agents such as secretory leukoproteinase inhibitor and elafin, previously thought to exist in lung secretions solely as part of the 'antiproteinase protective shield', have now been shown to possess important additional antibacterial properties. Both secretory leukoproteinase inhibitor and elafin display major activity against *Pseudomonas aeruginosa* and *Staphylococcus aureus*, which resides in a molecular position distinct from their powerful antineutrophil elastase activities.

In summary, a growing number of antibiotic peptides are now shown to demonstrate a marked selectivity for prokaryotic and eukaryotic micro-organisms, thus providing an effective but simple method whereby diverse classes of micro-organisms can be recognized and destroyed as 'non-self'. Many more peptides and proteins like these are likely to emerge, displaying properties that combine antibacterial actions with important roles in modulating the key cells responsible for our host defences, perhaps providing important links between primary 'innate' defence mechanism and the generation of secondary inflammatory and immune responses. Some of these agents may be of value in future therapeutic regimes, particularly in situations where the lungs are injured and at risk of secondary infection, such as cystic fibrosis and the adult respiratory distress syndrome.

Immunoglobulins

Normal lung secretions contain all the immunoglobulins present in plasma, but in different proportions. In the absence of disease, immunoglobulins are produced locally, with IgA greatly in excess and only small contributions from IgG and IgM. It is thought that B lymphocytes and plasma cells are particularly important in producing secretory IgA in the upper airways by a collaborative mechanism involving the epithelial cells as follows. Dimeric IgA is assembled in the plasma cells from two monomeric IgA molecules and joined by another protein, the J chain. Dimeric IgA then binds to the secretory component on the surface of epithelial cells, forming a dimeric IgA–secretory component complex that is pinocytosed, transported through the epithelial cell, and released from its luminal surface into the airways. The secretory component appears to protect IgA from enzymic attack during bacterial infection and inflammation in the host. IgA is produced in very high concentrations in the upper airways and is therefore likely to serve a number of important roles, but these are not fully understood. IgA deficiency is associated with local defects in immunity.

IgG concentrations in lung secretions are quantitatively similar to plasma IgG concentrations and may be particularly important in the lower airways where IgG may act as a very effective opsonin and activator of complement. IgG deficiency is associated with recurrent respiratory tract infection, suggesting that it provides an important local defence mechanism.

Complement proteins, proteinase inhibitors, etc.

Most of the proteins involved in the complement system have been identified in lung secretions. Most are probably derived by plasma exudation during inflammation, and C3a, C3b, and C5a may be secreted by alveolar macrophages. Patients with C3 deficiency have recurrent upper and lower respiratory tract infections, particularly with *Streptococcus pneumoniae* and *Haemophilus influenzae*. C3 is likely to play a key role in opsonization (via C3bi) of bacteria.

Lung secretions also contain a variety of antiproteinases, including the large molecules a $_2$-macroglobulin and a$_1$-proteinase inhibitor as well as moieties of lower molecular weight, such as secretory leukoproteinase inhibitor and elafin. Antiproteinases are probably secreted in higher concentrations by local epithelial cells and alveolar macrophages during inflammatory and injurious processes, at which time there will be additional contribution to local defences from leakage of plasma protein-derived antiproteinases. It is likely that these antiproteinases play an important part in the antiproteinase 'shield' which is necessary to protect the healthy local tissues against damage from the release of proteinases by inflammatory cells.

The alveolar macrophage and other alveolar cells

Alveolar macrophages are highly differentiated cells that have matured in the lung from bloodborne, bone marrow-derived monocytes. They normally 'patrol' the alveoli (Fig. 2), where they exist with a half-life of several weeks. The technique of bronchoalveolar lavage, whereby fluid is instilled into the small airways via a fibreoptic bronchoscope and fluid and harvested cells (normally greater than 95 per cent alveolar macrophages in healthy individuals) are returned by suction, has greatly facilitated the *ex vivo* study of the various functions of these versatile cells. It was quickly recognized that alveolar macrophages possessed marked phagocytic ability, with the capacity to ingest and destroy pathogenic bacteria, but only recently has their capacity to generate mediators of central importance in the initiation of inflammation and to present antigen in the initiation of the immune response been fully recognized. The alveolar macrophage could therefore be considered as a 'microcomputer', sampling and sensing via a vast array of receptors (Table 4) the external environment in the alveolar spaces and subsequently determining whether inflammatory or immune responses should be generated. It is also likely to assist the inflammatory monocyte-derived macrophages in the scavenging roles required during the aftermath of infections and the resolution of inflammation, and may play a further important role in the processes whereby inflammatory tissue injury is repaired, since it can produce a number of proteins involved in tissue repair processes and can generate a variety of cytokines that influence fibroblast function (Table 5).

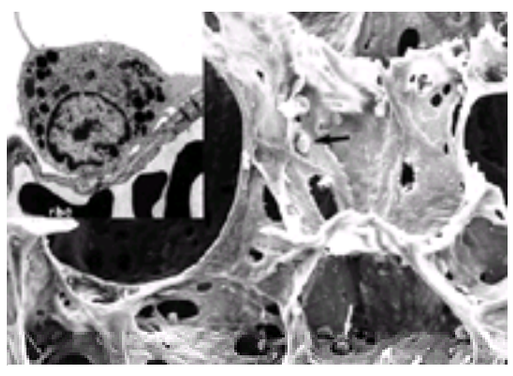

Fig. 2 Scanning electron micrograph (× 350) showing alveolar macrophages (arrows) 'patrolling' the alveolar airspaces. A high power view of a single alveolar macrophage adhering to the alveolar lining (arrows illustrate points of adhesion) is shown in section on the inserted (top left) transmission electron micrograph. (By courtesy of Dr P.K. Jeffery.)

Phagocytosis and bacterial killing

Macrophages can recognize and ingest opsonized (via their surface CR3 or FcR) or non-opsonized particles by a variety of receptors (Table 4). Within the phagolysosome, ingested particles are subjected to the combined destructive forces of reactive oxygen intermediates generated via the metabolic burst and a wide range of degradative enzymes that have the capacity to digest proteins, lipids, and carbohydrates. It appears that the local generation of nitric oxide is an important defence mechanism against a variety of micro-organisms. Activated macrophages form nitrite (NO_2), nitrate (NO_3), and nitric oxide (NO). *In vitro* experiments suggest that these products, particularly NO and the peroxynitrite anion, contribute to antifungal, antiparasitic, and tumoricidal activity of macrophages. Macrophages may 'call in antibacterial reinforcements' of other phagocytic cells including neutrophils, monocytes (which mature into inflammatory macrophages), and eosinophils by the generation of specific chemotaxins (see below). They may also generate a local immune response by presenting antigen and producing a variety of lymphokines.

Despite the availability of such powerful mechanisms, it is clear that not all phagocytosed particles are effectively destroyed. For example, asbestos, silica, and a number of micro-organisms including tuberculosis, some strains of *H. influenzae*, and trypanosomes at various stages of their lifecycle are able to resist destruction within macrophages.

Generation of the inflammatory response

Macrophages can secrete a number of chemotactic proteins in the chemokine family as well as mediators in the 5-lipoxygenase and cyclo-oxygenase pathways, all of which can exert profound pro-inflammatory effects. Neutrophil chemotaxins include interleukin 8, leukotriene B_4, and NAP-2. Peptides chemotactic for monocytes include MCP-1 and MIP-1. Other macrophage-derived cytokines may have important secondary pro-inflammatory effects through their influences on other cells. For example, tumour necrosis factor and interleukin 1 act not only on endothelium to stimulate the expression of adhesion molecules necessary for inflammatory cell emigration, but may also act on local fibroblasts to produce interleukin 8 that exerts neutrophil chemotactic effects. Thus, macrophages not only generate chemoattractants for inflammatory cells, but they can also recruit other local cells such as fibroblasts to help in the initiation of inflammation, thereby governing graded levels of amplification of the inflammatory response.

Generation of the immune response

Alveolar macrophages are effective antigen-presenting cells and can display partially degraded antigens on their surface to interact with recirculating T and B cells, generating clonal expansion and initiating the immune response.

Tissue remodelling and repair

Alveolar macrophages can secrete proteins, including fibronectin, vitronectin, and laminin, which are important in tissue repair. Macrophages can also produce a number of cytokines including PDGF, TGF-b, and interleukin-1 that can influence the behaviour of other cells, particularly fibroblasts that are critically involved in the repair process (see Chapter 16.5.1).

The pulmonary marginated pool of neutrophils

The neutrophil is the archetypal acute inflammatory cell, equipped with a variety of mechanisms that make it a very effective agent in host defences against bacteria such as streptococci. After release from the bone marrow, mature neutrophils exist in the vascular compartment with a half-life of about 6 h. Unlike red blood cells, up to half of the neutrophils in the vascular compartment do not circulate at any given time, but form a 'marginated pool', which is in dynamic equilibrium with the 'circulating pool' of vascular neutrophils. The marginated pool can be released into the circulating pool by exercise or adrenaline. The vascular beds of the lung and spleen appear to make the most important contribution to the marginated pool, which may serve as a source of rapidly releasable neutrophils in times of stress or injury. The presence of large numbers of neutrophils in the pulmonary microvascular bed is likely to increase the mobilization and effectiveness of local lung defences in response to their inevitable exposure to inhaled micro-organisms or toxins. The mechanisms underlying the formation of the lung marginated pool are uncertain. It could be formed as the result of low-grade adhesive interactions between neutrophils and lung capillary endothelial cells, but it is likely that the rheological properties of neutrophils in pulmonary capillaries are more important in the physiological margination of neutrophils in the lung. The mean diameter of the pulmonary capillary is 5.5 µm, whereas that of the neutrophil is 7.5 µm, hence neutrophils are normally required to squeeze through the pulmonary capillaries and minor changes in their deformability or alterations in the fluid pressure gradient across the lung capillary bed would be expected to influence markedly the size of the pulmonary marginated pool. The presence of this pool of neutrophils in the lung may have advantages for host defence, but, paradoxically, it could also partly explain why the lung appears to be such an important target in conditions such as the adult respiratory distress syndrome, which may result from systemic or distant insults, such as Gram-negative septicaemia, multiple trauma, or pancreatitis (see Chapter 16.5.1).

17.2 The clinical presentation of chest diseases

D. J. Lane

The presenting symptoms of chest diseases are few, but the structural and functional disturbances that these symptoms reflect are numerous and the underlying disease entities are many. The symptoms of lower respiratory tract disease can be grouped under just three headings: cough, breathlessness, and chest pain.

Cough may or may not produce sputum. Patients occasionally report the expectoration of sputum while denying they have a cough. This seems to be a socially determined separation of the act of 'clearing the throat' to expel sputum, from a non-productive cough which, perhaps because it appears to have no purpose, is regarded as more sinister. Breathlessness itself is a complex symptom. Wheezing and stridor, which are audible accompaniments to the act of breathing, are rarely reported without breathlessness and so they will all be considered together. Discussion of chest pain will include mention of chest tightness.

In the analysis of symptoms it is important to recognize and differentiate between the pathology or disordered physiology likely to be responsible for the symptoms, and the clinical diagnoses associated with that symptom. The investigation of mechanism, although superficially of little clinical relevance, can be the key to symptomatic treatment, creating opportunities for relief when the underlying condition is untreatable. Knowledge of the clinical significance of symptoms is largely empirical, but forms the essential diagnostic base of clinical medicine. Thus research into the mechanisms of breathlessness, for example, will continue to be a proper concern of clinicians as long as disabling and irreversible conditions such as chronic airways obstruction exist. By contrast, knowing the mechanism of dyspnoea in pleural effusion is unimportant compared with knowing how to relieve the symptom by draining the effusion, and being able to diagnose the underlying clinical condition.

Cough

Coughing is a defensive reflex designed to clear and protect the lower respiratory tract. The act of coughing is essentially a forced expiratory effort against a transitorily closed glottis, which then opens allowing a sudden expulsion of air from the lungs. Except when the cough arises from laryngeal irritation, there is an initial deep inspiration which allows the respiratory muscles to act to greater mechanical advantage, although this could draw any offending material deeper into the bronchial tree. The pressure that builds up behind the closed glottis can reach as much as 40 kPa and, if often repeated in a sequence of coughs, can seriously impede venous filling of the heart. The consequent drop in cardiac output is responsible for the well-described 'cough syncope'.

Mechanism

The cough reflex can be initiated by the stimulation of irritant receptors in the pharynx, larynx, trachea, and major bronchi. These receptors respond to mechanical irritation by mucus, dust, or foreign bodies, and to chemical irritation by fumes and toxic gases. Mechanical events within the thorax, such as sudden and large changes in airway calibre or lung collapse, can also stimulate cough receptors. The afferent fibres run in the branches of the superior laryngeal nerve and the vagus to the medulla, where the resultant efferent activity of virtually the whole of the respiratory musculature is co-ordinated. The explosive action of the respiratory muscles produces laryngeal air velocities that can approach the speed of sound and is accompanied by bronchial constriction, mucus secretion, and a transient systemic hypertension.

Causes of cough

An epidemiological analysis of cough would reveal an acute, viral, upper respiratory tract infection affecting the pharynx, larynx, or postnasal space as the most common cause of short-lived cough at all ages, with smoking being the main cause of chronic cough in adults. Half of those smoking 20 or more cigarettes a day can expect to have a persistent cough. Children exposed to passive smoking from their parents are twice as likely to cough as children in non-smoking families. Asthma is the next commonest cause at all ages, with chronic upper or lower respiratory tract infection also important. Tuberculosis heads the list in the developing world. Of the more sinister causes, carcinoma of the lung is the most important. It remains the commonest neoplasm in men and is second only to carcinoma of the breast in women, and must feature high in the differential diagnosis of a new presentation of cough or a change in the character of cough in a middle-aged smoker. Less usual causes are endobronchial sarcoidosis and pulmonary fibrotic conditions. Both beta-blockers and angiotensin-converting enzyme (**ACE**) inhibitors can cause an irritating and persistent cough. Although rare, an inhaled foreign body must not be forgotten.

Clinical features

The clinical description of cough relies on its sound, its timing, and whether or not there is expectoration. A dry cough with an irritative barking quality, short and often repeated, is heard in pharyngitis, tracheobronchitis, and early pneumonia. With laryngitis the sound is harsh and hoarse ('croup'). The long inspiratory sound that gives whooping cough its name is also produced by tracheal and laryngeal inflammation. Abductor paralysis of the vocal cords creates a cough that is prolonged and lowing like the sound of cattle, and hence is described as 'bovine'. The usual cause is pressure on the left recurrent laryngeal nerve by lesions in the thorax: carcinoma of the bronchus or oesophagus, enlarged (usually neoplastic) hilar nodes, or (now very rarely) aortic aneurysm. If similar lesions press on the trachea but spare the nerve, the cough has a hard metallic quality described as 'brassy'. Unilateral abductor palsy of the larynx does not affect the voice, and even with additional abductor palsy the voice often remains good. Complete paralysis of both cords gives aphonia and a weak ineffectual cough. Weakness of the thoracic muscles, as in polyneuritis or the muscular dystrophies, will lessen the expulsive force in coughing, as will the general weakness of prostration, toxaemia, or the deeper states of unconsciousness. Cough may be suppressed when there is severe thoracic or upper abdominal pain.

Certain aspects of the timing of coughing may give useful diagnostic clues. A cough that awakens the patient in the small hours of the night suggests asthma; wheezing need not be evident. Cough with expectoration on rising in the morning is characteristic of chronic bronchitis, although it may also be reported by

asthmatics. A bout of coughing with food or when lying down after a meal points to oesophageal, pharyngeal, or neuromuscular disease, causing aspiration into the lungs. Changes of posture can also set off coughing in the bronchiectatic; and free expectoration of sputum at any time of day is common in these patients. A dry cough that persists over many weeks can signify a neoplasm, but a non-productive barking cough that has lasted for years is more likely to be a nervous habit often perpetuated by psychogenic factors.

A cough may fail to produce expectoration because there is nothing to produce, because secretions are swallowed (as is almost universal in children), because there is severe airways obstruction, because of weakness (as outlined above), or because the secretions are too viscid. In the last four instances the sound quality of the cough differs from that of a dry cough, in the sense that secretions can be heard moving in the major airways. This type of cough and the cough productive of sputum can be described as 'moist' or 'loose'.

Phlegm and sputum

Phlegm, the secretions of the lower respiratory tract, is admixed with nasal and pharyngeal secretions as well as saliva to give expectorated sputum. It has been very difficult to study the natural secretions of the healthy tracheobronchial tree in man, for only about 100 ml is produced daily and most of this is swallowed. In disease the quantity of secretions is often sufficient to swamp contamination from the upper respiratory tract, so that valid observations can be made, but it may be necessary to obtain lung secretions by induced coughing or by bronchoscopy.

Mucus is viscoelastic. Its viscosity or stickiness influences the effect of forces applied to it in coughing. Initially it resists flow, but then as increasing force is applied it becomes more and more liquid, returning to its original state when the flow stops. The elasticity of sputum appears to alter with the rate of application of stress to it, and this may be important in relation to the rate of beating of the bronchial epithelial cilia. Intrabronchial mucus exists in two layers: one of low viscosity and high elasticity touching the cilia, and above this a more viscous layer which, in disease, carries globules of mucus.

Airway mucus is 95 per cent water and derives its distinctive physical characteristics from the glycoprotein content. Two components of these glycoproteins, sialic acid and sulphate, enable airway mucus to be chemically analysed and identified *in situ* in histological sections. At least four glycoproteins have been identified in human bronchial mucus, produced in various combinations by different mucous-cell types. Serous fluid is produced from other cells in the bronchial glands, and with water, lipids, and proteins makes up a transudate component. Although bronchial secretions do not show diagnostically distinctive changes in disease, there is, for example, a shift towards greater glycoprotein production in chronic bronchitis and greater transudate formation in asthma. In infection both components increase, and the breakdown of leucocytes and of bronchial mucus increases the DNA content of sputum, making it less viscid. The accumulated debris of cells and micro-organisms imparts a yellow colour to infected sputum, and the subsequent action of verdoperoxidase derived from leucocytes gives a green colour.
